

Kelley's Textbook of Internal Medicine 4th edition (August 15, 2000): by H. David Humes (Editor), Herbert L. Dupont (Editor) By Lippincott Williams & Wilkins Publishers

By OkDoKeY

Kelley's Textbook of Internal Medicine

Table of Contents

[Editors](#)

[Contributors](#)

[Preface](#)

[List of Clinical Decision Guides](#)

RAPID ACCESS GUIDE

Paul L. Fink

[How to Use the Rapid Access Guide to Internal Medicine](#)

[Cardiology](#)

[Gastroenterology](#)

[Nephrology](#)

[Rheumatology](#)

[Oncology and Hematology](#)

[Infectious Diseases](#)

[Pulmonary Medicine](#)

[Endocrinology](#)

[Neurology](#)

PART 1: PRINCIPLES OF MEDICAL PRACTICE

SECTION I: HUMANISM AND ETHICS

[Chapter 1: Introduction to Internal Medicine as a Discipline](#)

William N. Kelley and Joel D. Howell

[Chapter 2: Clinical Medicine, Clinical Ethics and Physicians' Professionalism](#)

Mark Siegler, Arthur L. Caplan, and Peter A. Singer

SECTION II: BASIC MECHANISMS OF HEALTH AND DISEASE

[Chapter 3: The Genome Project and Molecular Diagnosis](#)

Leslie G. Biesecker, Barbara B. Biesecker, and Francis S. Collins

[Chapter 4: Cell Growth, Differentiation, and Death](#)

Max Wicha

[Chapter 5: Principles of the Immune Response](#)

Robert Winchester

[Chapter 6: Inflammation: Cells, Cytokines, and Other Mediators](#)

Zoltan Szekanecz and Alisa E. Koch

[Chapter 7: Mechanisms of Hormone Action](#)

Daryl K. Granner

[Chapter 8: Principles of Nutrition](#)

David H. Alpers

[Chapter 9: Principles of the Renal Regulation of Fluid and Electrolytes](#)

L. B. Gardner and H. David Humes

[Chapter 10: Pulmonary Gas Exchange](#)

John J. Marini and David R. Dantzker

[Chapter 11: Vascular Biology](#)

Elizabeth G. Nabel

[Chapter 12: Disorders of Lipid Metabolism](#)

Daniel J. Rader

[Chapter 13: Pathogenesis of Atherosclerosis](#)

Alan M. Fogelman, Franklin L. Murphy and Peter A. Edwards

[Chapter 14: Some Functional Pathways in the Central Nervous System](#)

John A. Kiernan

[Chapter 15: Biology and Genetics of Aging and Longevity](#)

Richard A. Miller

[Chapter 16: Clinical Physiology of Aging](#)

Lewis A. Lipsitz

[Chapter 17: Healthcare Implications of an Aging Society](#)

Joan Weinryb, Dennis Hsieh, Risa Lavizzo-Mourey

[Chapter 18: Host-Microbe Interaction](#)

Herbert L. DuPont and Liliana Rodriguez

[Chapter 19: Etiology of Malignant Disease](#)

William A. Blattner

[Chapter 20: Molecular and Cell Biology of Neoplasia](#)

Peter C. Nowell

[Chapter 21: Epidemiology of Malignant Disease](#)

David Schottenfeld

[Chapter 22: Prevention of Neoplasia](#)

Peter Greenwald

[Chapter 23: Transplantation Immunology](#)

Judith A. Shizuru

SECTION III: APPROACH TO COMMON PRIMARY CARE ISSUES

[Chapter 24: Periodic Health Evaluation](#)

Albert G. Mulley, Jr.

[Chapter 25: Preoperative Medical Evaluation](#)

Judi M. Woolger

[Chapter 26: Immunizations](#)

Theodore C. Eickhoff

[Chapter 27: Infectious Disease Prevention in the International Traveler](#)
David O. Freedman

[Chapter 28: Cancer Screening and Early Detection](#)
Jhon K. Gohagan, Barnett S. Kramer, and William C. Black

[Chapter 29: Epidemiology and Prevention of Cardiovascular Disease](#)
Lori Mosca

[Chapter 30: Systemic Hypertension](#)
Myron H. Weinberger

[Chapter 31: Approaches to Hypercholesterolemia and Other Abnormal Lipid Profiles](#)
Daniel J. Rader

[Chapter 32: Approach to the Patient With Chest Pain \(Cardiac and Non-Cardiac\)](#)
Alberto A. Mitrani and Mark Multach

[Chapter 33: Smoking and Smoking Cessation](#)
Alfred Munzer

[Chapter 34: Approach to the Problem of Alcohol Abuse and Dependence](#)
Charles P. O'Brien

[Chapter 35: Approach to the Problem of Substance Abuse](#)
Charles P. O'Brien

[Chapter 36: Obesity](#)
Albert J. Stunkard and Thomas A. Wadden

[Chapter 37: Anorexia Nervosa and Eating Disorders](#)
Paul M. Copeland

[Chapter 38: Approach to the Patient With Unintentional Weight Loss](#)
Daniel M. Lichtstein and Robert L. Hernandez

[Chapter 39: Depression, Anxiety, and Other Psychiatric Disorders](#)
Maria D. Llorente

[Chapter 40: Care of the Dying Patient](#)
Joanne Lynn and Betty Ferrell

SECTION IV: PRINCIPLES OF CLINICAL EVALUATION

[Chapter 41: The Clinical Approach to the Patient](#)
James O. Woolliscroft

[Chapter 42: Principles of Clinical Epidemiology](#)
Jay M. Sosenko

[Chapter 43: Evidence-Based Medicine](#)
Mark T. O'Connell

[Chapter 44: Computers in Support of Clinical Decision Making](#)
Edward H. Shortliffe

[Chapter 45: Quality Improvement and Clinical Outcomes Assessment](#)
David Shulkin

[Chapter 46: Assessment of Physician Performance in the New Century Health Care Environment](#)
Roberta Parillo, Mark Rivo, and Laurence B. Gardner

[Chapter 47: Medical Malpractice and Risk Management](#)
Kimberly A. Cook and Juan D. Reyes

SECTION V: RELATED MEDICAL DISCIPLINES

[Chapter 48: Adolescent Medicine](#)
Gail B. Slap

[Chapter 49: Principles of Occupational Medicine](#)
Mark R. Cullen and Linda Rosenstock

[Chapter 50: Medical Ophthalmology](#)
Michele R. Piccone and Stuart L. Fine

[Chapter 51: Medical Otolaryngology](#)
Erica R. Thaler and David W. Kennedy

[Chapter 52: Principles of Women's Medicine](#)
Erin N. Marcus

[Chapter 53: Principles of Sports Medicine](#)
Paul McCaffrey Ford and Gordon O. Matheson

[Chapter 54: Principles of Rehabilitation Medicine](#)
Kresimir Banovac, Debbie Fertel and Joseph Bauerlein

[Chapter 55: Principles of Clinical Pharmacology](#)
D. Craig Brater

[Chapter 56: Alternative Medicine: Prevalence, Cost, and Usefulness](#)
Mark Multach

SECTION VI: SELECTED MEDICAL EMERGENCIES

[Chapter 57: General Principles in the Approach to the Patient with an Acute Emergency](#)
Sheldon Jacobson

[Chapter 58: Animal Bites and Stings](#)
Faith T. Fitzgerald

[Chapter 59: Near Drowning](#)
Leonard D. Hudson and Kenneth P. Steinberg

[Chapter 60: Treatment of Anaphylaxis](#)
Marc S. McMorris

[Chapter 61: Cardiopulmonary Resuscitation](#)

Kathleen S. Schrank

[Chapter 62: Hyperthermia and Hypothermia](#)
Faith T. Fitzgerald

[Chapter 63: Ionizing Radiation Injuries](#)
Brahm Shapiro

PART 2: CARDIOLOGY

SECTION I: APPROACH TO THE PATIENT WITH CARDIOVASCULAR DISORDERS

[Chapter 64: Essential Features of the Cardiac History and Physical Examination](#)
Elizabeth G. Nabel

[Chapter 65: Approach to the Patient With Chest Pain](#)
Elizabeth G. Nabel

[Chapter 66: Approach to the Patient With Heart Failure](#)
Robert J. Cody

[Chapter 67: Approach to the Patient With Cardiac Arrhythmias](#)
S. Adam Strickberger, Douglas P. Zipes and Fred Morady

[Chapter 68: Approach to the Patient With Heart Murmurs](#)
Jonathan Abrams

[Chapter 69: Approach to the Patient With Syncope](#)
Patrick T. O'Gara and Kristin Ellison

[Chapter 70: Approach to the Pregnant Patient With Heart Disease](#)
G. Michael Felker and Kenneth L. Baughman

[Chapter 71: Approach to the Patient With Hypotension and Shock](#)
Todd M. Koelling and Robert J. Cody

SECTION II: DISORDERS OF THE CARDIOVASCULAR SYSTEM

[Chapter 72: Coronary Artery Disease](#)
Mihai Gheorghide and Robert O. Bonow

[Chapter 73: Acute Myocardial Infarction](#)
Robert Roberts

[Chapter 74: Myocardial Diseases](#)
Michael R. Bristow, John B. O'Connell and Louisa Mestroni

[Chapter 75: Tumors of the Heart](#)
Joel S. Raichlen and Martin G. St. John Sutton

[Chapter 76: Cardiac Arrhythmias](#)
Bradley P. Knight, Douglas P. Zipes, and Fred Morady

[Chapter 77: Valvular Heart Disease](#)
David Bach and Kim A. Eagle

[Chapter 78: Congenital Heart Disease in the Adult](#)
Thomas J. Ryan and J. Kevin Harrison

[Chapter 79: Pericardial Diseases](#)
E. William Hancock

[Chapter 80: Pulmonary Hypertension and Cor Pulmonale](#)
Lewis J. Rubin

[Chapter 81: Vascular Medicine](#)
Mark A. Creager and Marie Gerhard-Herman

[Chapter 82: Genetics of the Cardiovascular System](#)
Craig T. Basson and Carl J. Vaughan

SECTION III: DIAGNOSTIC AND THERAPEUTIC MODALITIES IN CARDIOVASCULAR DISEASES

[Chapter 83: Cardiovascular Radiology](#)
Robert D. Tarver, Dewey J. Conces, Jr., and Lynn S. Broderick

[Chapter 84: Electrocardiography, Exercise Stress Testing, and Ambulatory Monitoring](#)
Charles Fisch

[Chapter 85: Echocardiography](#)
William F. Armstrong

[Chapter 86: Radionuclide and Magnetic Resonance Techniques](#)
Mark A. Lawson and Gerald M. Pohost

[Chapter 87: Diagnostic and Therapeutic Catheterization](#)
Richard A. Lange and L. David Hillis

[Chapter 88: Electrophysiologic Testing](#)
Fred Morady

[Chapter 89: Principles of Cardiac Conditioning and Rehabilitation](#)
Victor F. Froelicher and Jonathan N. Myers

[Chapter 90: Clinical Pharmacology of Cardiovascular Drugs](#)
D. Craig Brater

[Chapter 91: Use of Anticoagulant Drugs](#)
Michael D. Ezekowitz

[Chapter 92: Principles and Applications of Cardiac Surgery](#)
John G. Byrne, Raymond H. Chen, and David H. Adams

[Chapter 93: Medical Management of the Cardiac Transplant Patient](#)
Keith Aaronson and Robert Cody

PART 3: GASTROENTEROLOGY

SECTION I: APPROACH TO THE PATIENT WITH DIGESTIVE AND HEPATOBILIARY DISORDERS

[Chapter 94: Approach to the Patient With Dysphagia](#)
Joel E. Richter

[Chapter 95: Approach to the Patient With Noncardiac Chest Pain](#)
Henry P. Parkman

[Chapter 96: Approach to the Patient With Abdominal Pain](#)
Robert B. Stein and Gary R. Lichtenstein

[Chapter 97: Approach to the Patient With Acute Abdomen](#)
Stewart C. Wang and Michael W. Mulholland

[Chapter 98: Approach to the Patient With Nausea and Vomiting](#)
William L. Hasler

[Chapter 99: Approach to the Patient With Diarrhea](#)
Carol E. Semrad and Eugene B. Chang

[Chapter 100: Approach to the Patient With Constipation, Fecal Incontinence, and Gas](#)
Jeffrey L. Barnett

[Chapter 101: Approach to the Patient With an Abdominal or Rectal Mass](#)
Ilias Scotiniotis and Michael L. Kochman

[Chapter 102: Approach to the Patient With Gastrointestinal Bleeding](#)
Grace H. Elta

[Chapter 103: Approach to the Patient With Jaundice](#)
Richard H. Moseley

[Chapter 104: Approach to the Patient With Abnormal Liver Chemistries](#)
Richard H. Moseley

[Chapter 105: Approach to the Patient With Complications of Chronic Liver Disease and Fulminant Hepatic Failure](#)
Charmaine A. Stewart and Michael R. Lucey

SECTION IIA: DISORDERS OF THE ALIMENTARY TRACT

[Chapter 106: Diseases of the Esophagus](#)
Joel E. Richter

[Chapter 107: Gastroduodenal Ulcer Disease and Gastritis](#)
David C. Metz and John H. Walsh

[Chapter 108: Motor Disorders of the Gastrointestinal Tract](#)
Chung Owyang

[Chapter 109: Irritable Bowel Syndrome](#)
Yehuda Ringel and Douglas A. Drossman

[Chapter 110: Disorders of Digestion and Absorption](#)
Dennis J. Ahnen

[Chapter 111: Inflammatory Bowel Disease](#)
Lawrence S. Friedman and Daniel K. Podolsky

[Chapter 112: Mesenteric Vascular Diseases](#)
James C. Stanley

[Chapter 113: Gastrointestinal Infections](#)
C. M. Thorpe and Andrew G. Plaut

[Chapter 114: Gastrointestinal Diseases With an Immune Basis](#)
Charles O. Elson

[Chapter 115: Upper Gastrointestinal Neoplasms](#)
Anil K. Rustgi

[Chapter 116: Colorectal Neoplasia](#)
C. Richard Boland

SECTION IIB: DISORDERS OF THE PANCREAS, LIVER, AND BILIARY TRACT

[Chapter 117: Pancreatitis](#)
James H. Grendell

[Chapter 118: Pancreatic Cancer and Gut Neuroendocrine Tumors](#)
Daniel G. Haller

[Chapter 119: Viral Hepatitis](#)
Frederick Nunes

[Chapter 120: Autoimmune Hepatitis and Primary Biliary Cirrhosis](#)
Gillian Ann Zeldin and Albert J. Czaja

[Chapter 121: Alcoholic Liver Diseases](#)
David W. Crabb and Lawrence Lumeng

[Chapter 122: Drug-Induced Hepatic Injury](#)
Shelly C. Lu and Lawrence S. Maldonado

[Chapter 123: Metabolic, Granulomatous, and Infiltrative Disorders of the Liver](#)
Bruce R. Bacon

[Chapter 124: Gallstones and Cholecystitis](#)
John H. Sekijima and Sum P. Lee

[Chapter 125: Biliary Tract Disease](#)
Jenny Heathcote

[Chapter 126: Hepatobiliary Neoplasms](#)
Andrew Stolz

SECTION III: DIAGNOSTIC AND THERAPEUTIC MODALITIES IN DIGESTIVE AND HEPATOBILIARY DISORDERS

[Chapter 127: Endoscopic Diagnosis and Therapy](#)
Gregory G. Ginsberg

[Chapter 128: Abdominal and Alimentary Tract Imaging and Interventional Radiology](#)

Stephen W. Trenker

[Chapter 129: Diagnostic Tests in Gastrointestinal Motility and Physiology](#)
William L. Hasler

[Chapter 130: Parenteral and Enteral Nutrition](#)
William F. Stenson and Patti Eisenberg

[Chapter 131: Laparoscopic Surgery for Gastrointestinal Disorders](#)
C. Daniel Smith and Timothy M. Farrell

[Chapter 132: Liver Transplantation](#)
Christopher F. Schultz and Michael R. Lucey

PART 4: NEPHROLOGY

SECTION I: APPROACH TO THE PATIENT WITH RENAL AND ELECTROLYTE DISORDERS

[Chapter 133: Approach to the Patient With Renal Disease](#)
H. David Humes

[Chapter 134: Approach to the Patient With Hematuria](#)
John H. Galla

[Chapter 135: Approach to the Patient With Proteinuria and Nephrotic Syndrome](#)
Jeffrey R. Schelling and John R. Sedor

[Chapter 136: Approach to the Patient With Dysuria and Pyuria](#)
Eric W. Young

[Chapter 137: Approach to the Patient With Polyuria or Nocturia](#)
Robert M. A. Richardson and Sheldon Tobe

[Chapter 138: Approach to the Patient With Urinary Retention and Obstruction](#)
Nelson Leung, Amit K. Ghosh, and Karl A. Nath

[Chapter 139: Approach to the Patient With Nephrolithiasis](#)
Rebecca D. Monk and David A. Bushinsky

[Chapter 140: Approach to the Patient With Oliguria and Acute Renal Failure](#)
H. David Humes

[Chapter 141: Approach to the Patient With Chronic Renal Failure](#)
Fuad N. Ziyadeh

[Chapter 142: Approach to the Patient With Volume Depletion and Dehydration](#)
James A. Shayman

[Chapter 143: Approach to the Patient With Edema](#)
James A. Shayman

[Chapter 144: Approach to the Patient With Hyponatremia](#)
Lawrence S. Weisberg and Malcolm Cox

[Chapter 145: Approach to the Patient With Hypernatremia](#)
Harold M. Szerlip and Malcolm Cox

[Chapter 146: Approach to the Patient With Hypokalemia](#)
Manuel Martinez-Maldonado

[Chapter 147: Approach to the Patient With Hyperkalemia](#)
Manuel Martinez-Maldonado

[Chapter 148: Approach to the Patient With Altered Magnesium Concentration](#)
Anton C. Schoolwerth, George M. Feldman, and R. Michael Culpepper

[Chapter 149: Approach to the Patient With Acid-Base Abnormalities](#)
Thomas D. DuBose, Jr.

SECTION II: DISORDERS OF THE KIDNEY

[Chapter 150: Immune-Mediated Glomerulopathies](#)
Ian R. Rifkin and David J. Salant

[Chapter 151: Tubulointerstitial Diseases](#)
Carolyn J. Kelly and Eric G. Neilson

[Chapter 152: Vascular Diseases of the Kidney](#)
William L. Henrich

[Chapter 153: Diabetes and the Kidney](#)
Frank C. Brosius III and Charles W. Heilig

[Chapter 154: Dysproteinemias and the Kidney](#)
Paul W. Sanders

[Chapter 155: Renal Tubular Acidosis and Fanconi Syndrome](#)
Peter C. Brazy

[Chapter 156: Renal Cysts and Cystic Diseases](#)
William D. Kaehny

[Chapter 157: Hereditary Nephropathies](#)
Martin C. Gregory

[Chapter 158: Obstructive Nephropathy](#)
Nelson Leung, Amit K. Ghosh and Karl A. Nath

[Chapter 159: Renal Lithiasis](#)
David A. Bushinsky

[Chapter 160: Tumors of the Kidney, Ureter, and Bladder](#)
Jia Bi and Derek Raghavan

[Chapter 161: Congenital Anomalies of the Kidney, Ureter, and Bladder](#)
Patrick Brophy and Jean E. Robillard

[Chapter 162: Pregnancy, the Kidney, and Hypertension](#)
Marshall D. Lindheimer and Adrian I. Katz

SECTION III: DIAGNOSTIC AND THERAPEUTIC MODALITIES IN RENAL AND ELECTROLYTE DISEASES

[Chapter 163: Laboratory Evaluation of Renal Disorders](#)
Majd I. Jaradat and Bruce A. Molitoris

[Chapter 164: Renal Biopsy and Treatment of Glomerular Disease](#)
Ronald J. Falk

[Chapter 165: Renal Substitution Treatment in Acute and Chronic Renal Failure](#)
Paul Sakiewicz and Emil Paganini

[Chapter 166: Renal Transplantation](#)
Christopher Y. Lu, Miguel A. Vazquez, Mariusz Kielar, D. Rohan Jeyarajah, and Xin J. Zhou

[Chapter 167: Adjustment of Drug Dosage in Patients With Renal Insufficiency](#)
Suzanne K. Swan

PART 5: RHEUMATOLOGIC, ALLERGIC, AND DERMATOLOGIC DISEASES

Rheumatology and Allergy

SECTION I: APPROACH TO THE PATIENT WITH RHEUMATOLOGIC AND ALLERGIC DISORDERS

[Chapter 168: Approach to the Patient With Musculoskeletal Complaints](#)
Eric L. Radin

[Chapter 169: Approach to the Patient With Pain in One or a Few Joints](#)
Alisa E. Koch

[Chapter 170: Approach to the Patient With Polyarthritits or Generalized Musculoskeletal Pain](#)
Theodore Pincus

[Chapter 171: Approach to the Patient With Back Pain](#)
Glen S. O'Sullivan

[Chapter 172: Approach to the Patient With Anergy](#)
Abba I. Terr

[Chapter 173: Approach to the Patient With Allergy](#)
Abba I. Terr

SECTION II: DISORDERS OF THE RHEUMATOLOGIC AND ALLERGIC SYSTEMS

[Chapter 174: Rheumatoid Arthritis](#)
Gary S. Firestein

[Chapter 175: Osteoarthritis and Polychondritis](#)
Marc C. Hochberg

[Chapter 176: Spondyloarthropathies](#)
Frank C. Arnett

[Chapter 177: Crystal-Induced Synovitis](#)
Michael M. Ward

[Chapter 178: Systemic Lupus Erythematosus and Overlap Syndromes](#)
Ronald F. van Vollenhoven

[Chapter 179: Scleroderma and Raynaud's Syndrome](#)
James R. Seibold

[Chapter 180: Idiopathic Inflammatory Myopathies](#)
Robert L. Wortmann

[Chapter 181: Vasculitis: Its Many Forms](#)
Gary S. Hoffman, Brian Mandell

[Chapter 182: Infectious Arthritis](#)
Mary M. Stimmier

[Chapter 183: Lyme Disease](#)
Leonard H. Sigal

[Chapter 184: Infiltrative, Neoplastic, and Endocrinologic Causes of Musculoskeletal Complaints](#)
Juan J. Canoso

[Chapter 185: Fibromyalgia \(Fibrositis\), Chronic Fatigue Syndrome, Bursitis, and Other Nonarticular Rheumatic Complaints](#)
Juan J. Canoso

[Chapter 186: Heritable Disorders of Connective Tissue](#)
Uta Francke

[Chapter 187: Inherited Deficiencies of Complement and Immunoglobulins](#)
George F. Moxley

SECTION III: DIAGNOSTIC AND THERAPEUTIC MODALITIES IN RHEUMATOLOGIC AND ALLERGIC DISEASES

[Chapter 188: Use of Laboratory Tests in Rheumatic and Immunologic Diseases](#)
John A. Hardin

[Chapter 189: Arthroscopy](#)
William J. Arnold

[Chapter 190: Imaging Techniques for Rheumatologic Diagnosis](#)
Curtis W. Hayes and Avinash A. Balkissoon

Dermatology

SECTION I: APPROACH TO THE PATIENT WITH DERMATOLOGIC DISEASES

[Chapter 191: Approach to the Patient With Skin Lesions](#)
Christopher M. Barnard

[Chapter 192: Approach to the Patient With Alopecia or Balding](#)
Susan M. Swetter

SECTION II: DISORDERS OF THE DERMATOLOGIC SYSTEMS

[Chapter 193: Psoriasis, Lichen Planus, and Pityriasis Rosea](#)
Christopher M. Barnard

[Chapter 194: Infections of Skin](#)
Gary L. Darmstadt

[Chapter 195: Bullous Diseases of Skin and Mucous Membranes](#)
Mark C. Udey

[Chapter 196: Atopic and Contact Dermatitis](#)
Teresa A. Borkowski and Mark C. Udey

[Chapter 197: Allergic Urticaria and Erythema Multiforme](#)
Christopher M. Barnard

[Chapter 198: Approach to the Management of Skin Cancer](#)
Susan M. Swetter

[Chapter 199: Cutaneous Reactions to Drugs](#)
Martin Vazquez

SECTION III: DIAGNOSTIC AND THERAPEUTIC MODALITIES IN DERMATOLOGIC DISEASES

[Chapter 200: Dermatologic Diagnosis: Fundamentals for the Internist](#)
Julie Anne Winfield

PART 6: ONCOLOGY AND HEMATOLOGY

SECTION I: APPROACH TO THE PATIENT WITH ONCOLOGIC AND HEMATOLOGIC DISORDERS

[Chapter 201: Approach to the Patient With Lymphadenopathy](#)
David J. Vaughn

[Chapter 202: Approach to the Patient With Splenomegaly](#)
Lynn M. Schuchter

[Chapter 203: Approach to the Patient With a Mediastinal Mass](#)
Kevin R. Fox

[Chapter 204: Approach to the Patient With Superior Vena Cava Syndrome](#)
Janice P. Dutcher

[Chapter 205: Approach to the Patient With a Palpable Breast Mass and/or An Abnormal Mammogram](#)
Helen Pass, Mark Helvie and Sofia D. Merajver

[Chapter 206: Approach to the Patient With a Testicular Mass](#)
Stephen D. Williams

[Chapter 207: Approach to the Patient With a Prostate Nodule or Elevated Prostate-Specific Antigen Level](#)
David C. Smith and James E. Montie

[Chapter 208: Approach to the Patient With an Adnexal Mass](#)
Ivor Benjamin and Stephen C. Rubin

[Chapter 209: Approach to the Patient With an Abnormal Papanicolaou Smear](#)
Andrew W. Menzin and Stephen C. Rubin

[Chapter 210: Approach to the Patient With a Pathologic Fracture](#)
Janice P. Dutcher

[Chapter 211: Approach to the Patient With Anemia](#)
Thomas P. Duffy

[Chapter 212: Approach to the Patient With Leukopenia](#)
Laurence A. Boxer

[Chapter 213: Approach to the Patient With Thrombocytopenia](#)
Douglas B. Cines

[Chapter 214: Approach to the Patient With Pancytopenia](#)
Joel M. Rapoport

[Chapter 215: Approach to the Patient With an Elevated Hemoglobin Level](#)
Eugene P. Frenkel

[Chapter 216: Approach to the Patient With Leukocytosis](#)
Stephen G. Emerson

[Chapter 217: Approach to the Patient With Thrombocytosis](#)
Alan M. Gewirtz

[Chapter 218: Approach to the Patient With Bleeding](#)
Keith R. McCrae

[Chapter 219: Approach to the Patient With Thrombosis](#)
Joel S. Bennett

SECTION II: DISORDERS OF ONCOLOGY AND HEMATOLOGY

[Chapter 220: Breast Cancer](#)
Teresa Gilewski and Larry Norton

[Chapter 221: Gynecologic Malignancies](#)
Mark A. Morgan and Stephen C. Rubin

[Chapter 222: Germ Cell Malignancies in Men](#)
Stephen D. Williams

[Chapter 223: Prostate Cancer](#)
Kenneth J. Pienta and David C. Smith

[Chapter 224: Sarcomas of Soft Tissue and Bone](#)
J. Sybil Biermann and Laurence H. Baker

[Chapter 225: Epithelial Malignancies of the Head and Neck](#)
George J. Bosl and David G. Pfister

[Chapter 226: Cancer of Unknown Primary Origin](#)

John D. Hainsworth and F. Anthony Greco

[Chapter 227: Acute Leukemias](#)

Peter H. Wiernik

[Chapter 228: Chronic Leukemias](#)

George P. Canellos

[Chapter 229: Myelodysplastic Syndrome](#)

Frederick R. Appelbaum

[Chapter 230: Aplastic Anemia and Bone Marrow Failure Syndromes](#)

Joel M. Rappaport

[Chapter 231: Myeloproliferative Disorders: Polycythemia Vera, Thrombocythemia, and Myelofibrosis](#)

Eugene P. Frenkel

[Chapter 232: Hodgkin's Disease](#)

Sandra J. Horning

[Chapter 233: Non-Hodgkin's Lymphomas](#)

R. Gregory Bociek, Julie M. Vose, and James O. Armitage

[Chapter 234: Plasma Cell Disorders](#)

Phillip R. Greipp

[Chapter 235: Amyloidosis](#)

Robert A. Kyle

[Chapter 236: Waldenström's Macroglobulinemia](#)

Robert A. Kyle

[Chapter 237: Inherited Disorders of Blood Coagulation](#)

David Ginsburg

[Chapter 238: Acquired Disorders of Blood Coagulation](#)

Alvin H. Schmaier

[Chapter 239: Disorders of Platelet Function](#)

Keith R. McCrae and Sanford J. Shattil

[Chapter 240: Thrombotic Disorders](#)

Joel S. Bennett

[Chapter 241: Hemoglobinopathies](#)

George F. Atweh and Edward J. Benz, Jr.

[Chapter 242: Iron Deficiency and Iron Loading Anemias](#)

Kenneth R. Bridges

[Chapter 243: Megaloblastic Anemias](#)

Ralph Carmel

[Chapter 244: Hemolytic Anemias](#)

Joseph P. Catlett

[Chapter 245: Sickle Cell Anemia](#)

Bertram H. Lubin

[Chapter 246: Anemia of Chronic Disease](#)

Robert T. Means, Jr.

[Chapter 247: Paraneoplastic Syndromes](#)

Gregory P. Kalemkerian

SECTION III: DIAGNOSTIC AND THERAPEUTIC MODALITIES IN ONCOLOGIC AND HEMATOLOGIC DISORDERS

[Chapter 248: Imaging in Oncology](#)

Stephen I. Marglin and Ronald A. Castellino

[Chapter 249: Pathology and Cytology](#)

Virginia A. LiVolsi and John E. Tomaszewski

[Chapter 250: Tumor Markers](#)

Daniel F. Hayes

[Chapter 251: Molecular Diagnosis of Cancer](#)

Jeffrey Sklar and Neal Lindeman

[Chapter 252: Principles of Surgical Oncology](#)

John M. Daly and Michael D. Lieberman

[Chapter 253: Principles of Radiation Oncology](#)

Allen S. Lichter

[Chapter 254: Principles of Chemotherapy and Hormonal Therapy](#)

Bruce A. Chabner, Michael Seiden, and Jeffrey Clark

[Chapter 255: Principles of Biologic Therapy](#)

John W. Smith II and Walter J. Urba

[Chapter 256: Hematopoietic Growth Factors](#)

Malcolm A.S. Moore

[Chapter 257: Blood Types, Tissue Typing, and Transfusion of Blood Products](#)

Frank T. Hsieh, Steven A. Mechanic, Edward Snyder, and Albert Deisseroth

[Chapter 258: Hematopoietic Stem Cell Transplantation](#)

Stephanie J. Lee and Joseph H. Antin

[Chapter 259: Anticoagulant and Fibrinolytic Therapy](#)

Bruce Furie

[Chapter 260: Cancer Pain Management](#)

Janet L. Abrahm

[Chapter 261: Antiemetic Treatment](#)

Richard J. Gralla

[Chapter 262: Design and Conduct of Cancer Clinical Trials](#)

Michael A. Friedman and Richard Simon

PART 7: INFECTIOUS DISEASES AND AIDS

Infectious Diseases

SECTION I: APPROACH TO THE PATIENT WITH INFECTIOUS DISEASES

[Chapter 263: Approach to the Patient With Cellulitis and Other Soft-Tissue Infections](#)
Ronald T. Lewis

[Chapter 264: Intra-Abdominal Abscess: Diagnosis and Management](#)
Marianne Cinat and Samuel E. Wilson

[Chapter 265: Approach to the Patient With Osteomyelitis](#)
Layne O. Gentry

[Chapter 266: Approach to the Febrile Patient](#)
Philip A. Mackowiak

[Chapter 267: Approach Infection in the Immunocompromised Host](#)
Kenneth V. I. Rolston and Gerald P. Bodey

[Chapter 268: Approach to the Patient With Bacteremia and Sepsis](#)
Gary A. Noskin and John P. Phair

[Chapter 269: Approach to the Patient With Recurrent Infections](#)
Burke A. Cunha

SECTION II: INFECTIOUS DISEASES

[Chapter 270: Endocarditis, Intravascular Infections, Pericarditis, and Myocarditis](#)
C. Glenn Cobbs and Michael Saccente

[Chapter 271: Approach to Infections of the Genitourinary Tract, Including Perinephric Abscess and Prostatitis](#)
Baldwin Toye and Allan R. Ronald

[Chapter 272: Sexually Transmitted Diseases and Genital Tract Infections](#)
William C. Levine

[Chapter 273: Surgical Infections, including Burns and Postoperative Infections](#)
E. Patchen Dellinger

Bacterial Infections

[Chapter 274: Staphylococcal Infections](#)
Dennis R. Schaberg

[Chapter 275: Streptococcal Infections](#)
Monica M. Farley and Benjamin Schwartz

[Chapter 276: Anthrax](#)
Raymond A. Smego, Jr.

[Chapter 277: Listeria and Erysipeloid Infections](#)
Barry Zeluff, Marcia Kielhofner and Susan J. Burgert

[Chapter 278: Corynebacterial Infections](#)
Robert T. Chen and Charles R. Vitek

[Chapter 279: Meningococcal Infections](#)
Peter Densen

[Chapter 280: Gonococcal Infections](#)
Geo F. Brooks

[Chapter 281: Salmonellosis](#)
Sonja J. Olsen and Robert V. Tauxe

[Chapter 282: Shigellosis](#)
Karen Kotloff and Myron M. Levine

[Chapter 283: Infections Caused by *Vibrio* and *Campylobacter* Species](#)
J. Glenn Morris, Jr. and Martin J. Blaser

[Chapter 284: Infection Caused by *Helicobacter pylori*](#)
David Y. Graham

[Chapter 285: Brucellosis, Tularemia, Pasteurellosis, and Yersiniosis](#)
Edward J. Young

[Chapter 286: Infections Caused by *Hemophilus* and *Bordetella* Species](#)
Charles J. Schleupner and Kenneth M. Sosnowski

[Chapter 287: Legionellosis](#)
Emanuel N. Vergis and Robert R. Muder

[Chapter 288: Chancroid and Granuloma Inguinale](#)
George P. Schmid

[Chapter 289: Bartonellosis](#)
Norbert J. Roberts, Jr.

[Chapter 290: Clostridial Infections](#)
W. Lance George

[Chapter 291: Infections Caused by Nonclostridial Anaerobes](#)
Sydney M. Finegold and W. Lance George

[Chapter 292: Cat-Scratch Disease, Bacillary Angioinomatosis, and Peliosis Hepatitis](#)
Thomas H. Belhorn

[Chapter 293: Rat-Bite Fever](#)
Ronald G. Washburn

Mycobacterial Infections

[Chapter 294: Tuberculosis](#)
Lisa K. Fitzpatrick and Christopher Braden

[Chapter 295: Nontuberculous Mycobacterial Diseases](#)
David E. Griffith and Richard J. Wallace, Jr.

Robert A. Salata

[Chapter 333: Cestode Infections](#)
Robert Blanton

[Chapter 334: Trematode Infections](#)
Charles H. King

SECTION III: DIAGNOSTIC AND THERAPEUTIC MODALITIES IN INFECTIOUS DISEASES

[Chapter 335: Antimicrobial Therapeutic Agents](#)
William A. Craig

[Chapter 336: Approach to the Treatment of Systemic Fungal Infections](#)
John H. Rex

[Chapter 337: Antimicrobial Chemoprophylaxis](#)
F. Marc LaForce

[Chapter 338: Hospital Epidemiology and Infection Control](#)
Jan Evans Patterson

HIV & AIDS

SECTION I: APPROACH TO THE PATIENT WITH HIV INFECTION

[Chapter 339: Approach to the Patient With HIV Exposure](#)
Elise M. Jochimsen and Denise M. Cardo

[Chapter 340: Approach to the Patient With Asymptomatic HIV Infection \(and Counseling\)](#)
Abraham Verghese

[Chapter 341: Approach to the Symptomatic Patient With HIV Infection](#)
Henry Masur

[Chapter 342: HIV/AIDS: Approach to the Patient With Pulmonary Disease](#)
Philip C. Hopewell

[Chapter 343: HIV/AIDS: Approach to the Patient With Diarrhea and/or Wasting](#)
Roberto C. Arduino

[Chapter 344: HIV/AIDS: Approach to the Patient With Neurologic Symptoms](#)
Richard W. Price

[Chapter 345: Pathogenesis of HIV Infection](#)
Sharon Lewin and Martin Markowitz

SECTION II: DISORDERS OF HIV INFECTION

[Chapter 346: HIV/AIDS: Clinical Considerations](#)
Stephen B. Greenberg and Christopher J. Lahart

[Chapter 347: Neoplasms in AIDS](#)
David M. Abouafia and Ronald T. Mitsuyasu

SECTION III: MANAGEMENT, PREVENTION, AND CONTROL

[Chapter 348: Principles of Antiretroviral Treatment and Vaccines](#)
Christopher J. Lahart

[Chapter 349: HIV/AIDS: Epidemiology, Prevention and Control](#)
Subhash K. Hira

PART 8: PULMONARY AND CRITICAL CARE MEDICINE

SECTION I: APPROACH TO THE PATIENT WITH RESPIRATORY DISEASE OR CRITICAL ILLNESS

[Chapter 350: Approach to the Patient With Hypoxemia](#)
David H. Ingbar

[Chapter 351: Approach to the Patient With Dyspnea](#)
Kathy E. Sietsema

[Chapter 352: Approach to the Patient With Cough](#)
K. F. Chung

[Chapter 353: Approach to the Patient With Hemoptysis](#)
Edward F. Haponik

[Chapter 354: Approach to the Critically Ill Patient](#)
Leonard D. Hudson and Kenneth P. Steinberg

[Chapter 355: Management of the Critically Ill Patient With Multiple Organ Dysfunction](#)
Paul M. Dorinsky and Michael A. Matthay

[Chapter 356: Approach to the Patient With Acute Respiratory Failure](#)
Thomas Corbridge

[Chapter 357: Approach to the Management of the Patient With Acute Respiratory Distress Syndrome](#)
Kenneth P. Steinberg and Leonard D. Hudson

[Chapter 358: Approach to the Patient With Pleural Disease](#)
Steven A. Sahn and John E. Heffner

[Chapter 359: Approach to the Patient With a Solitary Pulmonary Nodule](#)
Joseph P. Lynch, III and Ella A. Kazerooni

[Chapter 360: Approach to the Patient With Interstitial Lung Disease](#)

Kevin K. Brown

[Chapter 361: Approach to the Patient With Suspected Pneumonia](#)
Galen B. Toews

[Chapter 362: Evaluation of Pulmonary Disease in the Immunocompromised Host](#)
Phillip C. Hopewell

SECTION II: DISORDERS OF THE RESPIRATORY SYSTEM

[Chapter 363: Asthma](#)
Sally E. Wenzel

[Chapter 364: Chronic Obstructive Pulmonary Disease \(COPD\)](#)
Andrew L. Ries

[Chapter 365: Bronchiectasis](#)
John M. Luce and Robert M. Jasmer

[Chapter 366: Diseases of the Upper Airway](#)
Michael G. Glenn and Ernest A. Weymuller Jr.

[Chapter 367: Lung Abscess](#)
Hugh A. Cassiere and Michael S. Niederman

[Chapter 368: Pulmonary Tuberculosis](#)
Charles L. Daley

[Chapter 369: Bronchopulmonary Aspergillosis](#)
Alan F. Barker

[Chapter 370: Cystic Fibrosis](#)
Maira L. Aitken

[Chapter 371: Idiopathic Interstitial Pneumonias](#)
Talmadge E. King, Jr.

[Chapter 372: Hypersensitivity Pneumonitis](#)
William W. Merrill

[Chapter 373: Sarcoidosis](#)
Lee S. Newman and Cecile S. Rose

[Chapter 374: The Granulomatous Vasculitides](#)
Ulrich Specks

[Chapter 375: Occupational Lung Diseases](#)
Patrick G. Hartley and David A. Schwartz

[Chapter 376: Miscellaneous Pulmonary Disease](#)
Leslie Zimmerman

[Chapter 377: Lung Cancer](#)
Eric J. Olsen and James R. Jett

[Chapter 378: Pulmonary Thromboembolism](#)
Thomas M. Hyers

[Chapter 379: Diseases of the Mediastinum and Chest Wall](#)
Cameron D. Wright

[Chapter 380: Diseases of Respiratory Muscles](#)
Thomas K. Aldrich

[Chapter 381: Diseases of Ventilatory Control](#)
Clifford W. Zwillich and Sogol Nowbar

[Chapter 382: Sleep Apnea Syndrome, Hypersomnolence, and Other Sleep Disorders](#)
David P. White

[Chapter 383: Inhalation and Aspiration Syndromes](#)
Norman E. Adair and Edward F. Haponik

[Chapter 384: Diseases of High Altitude](#)
Robert B. Schoene

SECTION III: DIAGNOSTIC AND THERAPEUTIC MODALITIES

[Chapter 385: Essential Points of the Pulmonary History and Physical Examination](#)
Michael E. Hanley

[Chapter 386: Approach to Imaging of the Chest](#)
David A. Lynch

[Chapter 387: Pulmonary Function Testing](#)
Jack L. Clausen

[Chapter 388: Hemodynamic and Respiratory Monitoring in Critical Care](#)
Barbara A. Cockrill

[Chapter 389: Diagnostic Procedures in Pulmonary and Critical Care Medicine](#)
Suzette Garofano and Diane E. Stover

[Chapter 390: Respiratory Therapy Techniques](#)
Carolyn H. Welsh

[Chapter 391: Lung Transplantation](#)
Robert M. Kotloff

PART 9: ENDOCRINOLOGY, METABOLISM, AND GENETICS

SECTION I: APPROACH TO THE PATIENT WITH ENDOCRINOLOGIC, METABOLIC, AND GENETIC DISORDERS

[Chapter 392: Approach to the Patient With a Thyroid Nodule](#)
James A. Fagin

[Chapter 393: Approach to Menstrual Disorders and Galactorrhea](#)
Robert L. Barbieri

[Chapter 394: Approach to the Patient With Virilization](#)

Richard S. Legro

[Chapter 395: Approach to the Patient With Gynecomastia](#)
Glenn D. Braunstein

[Chapter 396: Approach to the Infertile Male](#)
Frances J. Hayes

[Chapter 397: Approach to Sexual Dysfunction in the Female](#)
Robert L. Barbieri

[Chapter 398: Approach to Sexual Dysfunction in the Male](#)
Max Hirshkowitz and Glenn R. Cunningham

[Chapter 399: Approach to the Patient With Hyperglycemia](#)
Jay S. Skyler

[Chapter 400: Approach to the Patient With Hypoglycemia](#)
John F. Service

[Chapter 401: Approach to the Patient With Flushing](#)
Jerome M. Feldman

[Chapter 402: Approach to Hypercalcemia and Hypocalcemia](#)
Bruce Lobaugh and Marc K. Drezner

SECTION II: DISORDERS OF ENDOCRINOLOGY, METABOLISM, AND GENETICS

[Chapter 403: Disorders of the Hypothalamic and Anterior Pituitary Gland](#)
John C. Marshall and Ariel L. Barkan

[Chapter 404: Disorders of Posterior Pituitary Function](#)
Alan G. Robinson

[Chapter 405: Disorders of the Pineal Gland](#)
Warner Burch

[Chapter 406: Disorders of the Thyroid Gland](#)
Leonard Wartofsky

[Chapter 407: Adrenal Cortical Disorders](#)
David E. Schteingart

[Chapter 408: Adrenal Medullary Disorders](#)
Brahm Shapiro and Milton D. Gross

[Chapter 409: Endocrinology of the Female](#)
Robert L. Barbieri

[Chapter 410: Disorders of Gonadal Function in Men](#)
Peter J. Snyder

[Chapter 411: Diabetes Mellitus, Types I and II](#)
Jay S. Skyler

[Chapter 412: Metabolic Bone Disease](#)
Dolores Shoback and Coleman Gross

[Chapter 413: Disorders of Carbohydrate Metabolism \(Excluding Diabetes\)](#)
Stanton Segal

[Chapter 414: Disorders of Amino Acid Metabolism](#)
Robert J. Smith

[Chapter 415: Multiple Endocrine Neoplasia](#)
Stephen J. Marx

[Chapter 416: Genetic Disorders](#)
Richard W. Erbe

SECTION III: DIAGNOSTIC AND THERAPEUTIC MODALITIES IN ENDOCRINOLOGIC, METABOLIC, AND GENETIC DISORDERS

[Chapter 417: Testing and Evaluation of Pituitary End-Organ Function](#)
Ariel L. Barkan and John C. Marshall

[Chapter 418: Evaluation of Thyroid Function Tests](#)
Rasa Kazlauskaitė, Bruce Weintraub, and Kenneth Burman

[Chapter 419: Human Gene therapy](#)
James M. Wilson

PART 10: NEUROLOGY

SECTION I: APPROACH TO THE PATIENT WITH NEUROLOGIC DISEASES

[Chapter 420: Approach to the Patient With Neurologic Complaints](#)
Vincent P. Sweeney and Donald W. Paty

[Chapter 421: Approach to the Patient With Headache](#)
James W. Lance

[Chapter 422: Approach to the Patient With Dizziness and Vertigo](#)
Mark F. Walker and David S. Zee

[Chapter 423: Approach to the Patient With Tumors of the Central Nervous System](#)
Lisa M. DeAngelis and J. Gregory Cairncross

[Chapter 424: Approach to the Patient With Impairment of Consciousness](#)
John J. Caronna

[Chapter 425: Approach to the Patient With a Sleep Disorder](#)
Roger J. Broughton

[Chapter 426: Approach to the Patient With Seizures](#)
Antonio V. Delgado-Escueta

[Chapter 427: Approach to the Patient With Visual Complaints](#)
Preston C. Calvert

[Chapter 428: Approach to the Patient With a Gait Disorder](#)

Stephen G. Reich

[Chapter 429: Approach to the Patient With Abnormal Movements and Tremors](#)
Stephen G. Reich

[Chapter 430: Approach to the Patient With Disorders of Sensation](#)
John W. Griffin

[Chapter 431: Approach to the Patient With Suspected Infection of the Central Nervous System](#)
Anthony W. Chow and Donald W. Paty

SECTION II: DISORDERS OF THE NERVOUS SYSTEM

[Chapter 432: Cerebrovascular Diseases](#)
John J. Caronna

[Chapter 433: Demyelinating Diseases](#)
John J. Richert

[Chapter 434: Parkinson's Disease and Related Disorders](#)
Stephen G. Reich

[Chapter 435: Chronic Dementing Conditions](#)
Bruce L. Miller

[Chapter 436: Cerebellar Degeneration](#)
Ging-Yuek Robin Hsiung and Oksana Suchowersky

[Chapter 437: Amyotrophic Lateral Sclerosis](#)
Andrea M. Corse

[Chapter 438: Huntington's Disease](#)
Michael R. Hayden and Blair R. Leavitt

[Chapter 439: Central Nervous System Poisoning](#)
J. William Langston, Ian Irwin, Sarah A. Jewell

[Chapter 440: The Neurologic Complications and Consequences of Ethanol Use and Abuse](#)
Stanley A. Hashimoto and Donald W. Paty

[Chapter 441: Bacterial Infections of the Nervous System](#)
Anthony W. Chow and Donald W. Paty

[Chapter 442: Viral Infections of the Nervous System](#)
Jorge T. Gonzalez

[Chapter 443: Slow Virus Infections in the Nervous System, Including AIDS](#)
Jerry S. Wolinsky and Justin C. McArthur

[Chapter 444: Seizures and Epilepsies](#)
Antonio V. Delgado-Escueta

[Chapter 445: Structural Disorders of the Spinal Column](#)
John Dean Ryboch

[Chapter 446: Disorders of the Peripheral Nervous System](#)
Ahmet Höke and Thomas E. Feasby

[Chapter 447: Mononeuropathies and Entrapment Neuropathies](#)
Andrew A. Eisen

[Chapter 448: Muscle Disease](#)
Andrew A. Eisen and Kenneth Berry

SECTION III: DIAGNOSTIC AND THERAPEUTIC MODALITIES IN NEUROLOGIC DISEASES

[Chapter 449: Lumbar Puncture and Cerebrospinal Fluid Analysis](#)
George C. Ebers

[Chapter 450: Electroencephalography and Evoked Potentials](#)
David B. Macdonald

[Chapter 451: Neurophysiology: Nerve Conduction and Electromyography](#)
Andrew A. Eisen

[Chapter 452: Neuroimaging](#)
Jack O. Greenberg

[Chapter 453: Serologic and Molecular Genetic Diagnoses](#)
Russell Margolis and Christopher Ross

PART 11: GERIATRICS

SECTION I: APPROACH TO ASSESSMENT AND MANAGEMENT OF THE ELDERLY PATIENT WITH A MAJOR GERIATRIC PROBLEM COMPLEX

[Chapter 454: Diagnosis and Management of the Elderly Patient](#)
Michele F. Bellantoni

[Chapter 455: Approach to the Elderly Patient With Hypertension](#)
William B. Applegate

[Chapter 456: Approach to the Elderly Patient With Diabetes](#)
Jeffrey B. Halter

[Chapter 457: Approach to the Elderly Patient With Dyslipidemia](#)
Walter H. Ettinger, Jr. and William R. Hazzard

[Chapter 458: Approach to the Elderly Patient With Incontinence](#)
Joseph G. Ouslander and Theodore M. Johnson, II

[Chapter 459: Approach to the Elderly Patient With Altered Mental Status](#)
Sharon K. Inouye

[Chapter 460: Approach to the Elderly Patient With Depression](#)
Dan G. Blazer

[Chapter 461: Approach to the Elderly Patient With Disorders of Fluid and Osmolality Regulations](#)
Jo Wiggins

[Chapter 462: Approach to the Elderly Patient With Falls and Impaired Mobility](#)

Mary E. Tinetti

[Chapter 463: Approach to the Patient With Pressure Ulcers](#)
Richard M. Allman

[Chapter 464: Approach to the Frail Elderly Patient](#)
Linda P. Fried and Jeremy Walston

SECTION II: DISORDERS PROMINENT IN GERIATRIC MEDICAL PRACTICE

[Chapter 465: Diagnosis and Management of Osteoporosis in Older Adults](#)
Karen Prestwood

[Chapter 466: Dementia, Including Alzheimer's Disease](#)
Christopher M. Clark

[Chapter 467: Benign Prostatic Hyperplasia/Urinary Obstruction](#)
J. Lisa Tenover

SECTION III: DIAGNOSTIC AND THERAPEUTIC MODALITIES IN THE ELDERLY: SPECIAL ASPECTS AND CONSIDERATIONS

[Chapter 468: Geriatric Assessment](#)
David B. Reuben

[Chapter 469: Geriatric Clinical Pharmacology](#)
Janice B. Schwartz

[Chapter 470: Geriatric Clinical Nutrition, Including Malnutrition, Obesity, and Weight Loss](#)
Jeffrey I. Wallace, Robert S. Schwartz

[Chapter 471: Exercise in the Elderly](#)
Alice S. Ryan and Andrew P. Goldberg

[Chapter 472: Geriatric Rehabilitation](#)
Kenneth Brummel-Smith

[Chapter 473: Philosophical and Ethical Issues in Geriatrics](#)
Christine K. Cassel

Thomas Butler, MD Professor of Internal Medicine, Chief of Infectious Diseases, Texas Tech University Health Sciences Center, Chief of Infectious Diseases, University Medical Center, Lubbock, Texas

John G. Byrne, MD Assistant Professor of Surgery, Harvard School of Medicine, Brigham and Women's Hospital, Boston, Massachusetts

J. Gregory Cairncross, MD CEO, London Regional Cancer Center, Chair, Division of Neurosciences, University of Western Ontario, London, Ontario, Canada

Preston Calvert, MD Assistant Professor of Neurology and Ophthalmology, Johns Hopkins University School of Medicine, Director, Neurology Outpatient Consultation Center, Johns Hopkins Outpatient Center, Baltimore, Maryland

George P. Canellos, MD, FACP, FRCP William Rosenberg Professor of Medicine, Harvard Medical School, Dana-Farber Cancer Institute, Boston, Massachusetts

Juan J. Canoso, MD Adjunct Professor of Medicine, Tufts University School of Medicine, Lomas de Chapultepec, Mexico

Arthur L. Caplan, PhD Director, Center for Bioethics, University of Pennsylvania, Philadelphia, Pennsylvania

Denise M. Cardo, MD HIV Infections Branch, Hospital Infections Program, National Center for Infectious Disease, Centers for Disease Control and Prevention, Atlanta, Georgia

Ralph Carmel, MD Director of Research, Department of Medicine, New York Methodist Hospital, Professor of Medicine, Cornell University Medical College, New York, New York

John J. Caronna, MD Professor of Clinical Neurology, Department of Neurology and Neuroscience, Weill Medical College of Cornell University, Attending Neurologist, The New York-Presbyterian Hospital, New York, New York

Christine K. Cassel, MD Professor and Chairman, The Henry L. Schwartz Department of Geriatrics and Adult Development, Professor, Department of Geriatrics and Internal Medicine, Mount Sinai/NYU Health, New York, New York

Ronald A. Castellino, MD Professor of Radiology, Cornell University Medical School, Chairman, Department of Radiology, Memorial Sloan Kettering Cancer Center, New York, New York

Joseph P. Catlett, MD, FACP Attending Physician, Section of Hematology/Oncology, Washington Hospital Center, Assistant Professor of Medicine, Uniformed Services University, of the Health Sciences, Washington, DC

Bruce A. Chabner, MD Professor of Medicine, Harvard Medical School, Clinical Director, MGH Cancer Center, Massachusetts General Hospital, Boston, Massachusetts

Eugene B. Chang, MD Department of Medicine, University of Chicago, Chicago, Illinois

Cynthia L. Chappell, PhD Associate Professor, Center for Infectious Diseases, University of Texas School of Public Health, Houston, Texas

Sarah H. Cheeseman, MD Professor of Medicine, Pediatrics, Molecular Genetics and Microbiology, University of Massachusetts Medical School, Worcester, Massachusetts

Robert T. Chen, MD, MA Chief, Vaccine Safety and Development Branch, National Immunization Program, Centers for Disease Control and Prevention, Atlanta, Georgia

Raymond H. Chen, MD, PhD Clinical Fellow in Surgery, Harvard School of Medicine, Brigham and Women's Hospital, Boston, Massachusetts

Anthony W. Chow, MD, FRCP, FACP Professor of Medicine, Division of Infectious Diseases, Department of Medicine, Director MD/PhD Program, University of British Columbia, Vancouver, British Columbia

Kian Fan Chung, MD, FRCP Professor of Respiratory Medicine, National Heart and Lung Institute, Imperial College School of Medicine, Consultant Physician, Royal Brompton Hospital, London, England

Marianne Cinat, MD Assistant Professor of Surgery UCI Medical Center, Orange, California

Douglas B. Cines, MD Professor, Department of Pathology and Laboratory Medicine, Director, Hematology and Coagulation Laboratories and Medicine, Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania

Christopher M. Clark, MD Associate Professor of Neurology, Director, Memory Disorders Program, Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania

Jack L. Clausen, MD Clinical Professor of Medicine, School of Medicine, University of California, San Diego, San Diego, California

C. Glenn Cobbs, MD Professor Emeritus and Vice Chairman for VA Affairs, UAB, Chief, Medical Service, VAMC, Birmingham, Alabama

Barbara A. Cockrill, MD Assistant Physician, Pulmonary and Critical Care, Director, Partners Asthma Center, Massachusetts General Hospital, Boston, Massachusetts

Robert J. Cody, MD Professor of Medicine, Associate Chief, Division of Cardiology, Director, Heart Failure and Transplant Management, University of Michigan Medical Center, Ann Arbor, Michigan

Peter Cole, MD Host Defense Unit/Thoracic Medicine, National Heart & Institute, London, England

Francis S. Collins, MD, PhD Director, National Human Genome Research Institute, Bethesda, Maryland

Robert E. Condon, MD Department of Surgery, Medical College of Wisconsin, Milwaukee, Wisconsin

Kimberly A. Cook, Esq. Fowler-White, Miami, Florida

Paul Michael Copeland, MD Assistant Clinical Professor of Medicine, Harvard Medical School, Endocrine Unit, Massachusetts General Hospital, Boston, Massachusetts, Co-Director, Eating Disorders Program, Salem Hospital, Salem, Massachusetts

Tom Corbridge, MD Director, Medical Intensive Care Unit, Northwestern Memorial Hospital, Chicago, Illinois

Andrea M. Corse, MD Assistant Professor of Neurology, Johns Hopkins University School of Medicine, Attending Neurologist, Johns Hopkins Hospital, Baltimore, Maryland

Malcolm Cox, MD Professor of Medicine, Associate Dean, Network and Primary Care Education, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania

David W. Crabb, MD Professor and Vice Chair for Research, Department of Medicine, Indiana University, Indianapolis, Indiana

William A. Craig, MD Professor of Medicine, University of Wisconsin, Madison, Wisconsin

Mark A. Creager, MD Associate Professor of Medicine, Cardiovascular Division, Brigham & Women's Hospital, Boston, Massachusetts

William F. Crowley, Jr., MD Professor of Medicine, Harvard School of Medicine, Boston, Massachusetts

Mark R. Cullen, MD Professor of Medicine and Public Health, Yale University School of Medicine, Occupational and Environmental Medicine Program, New Haven, Connecticut

Burke A. Cunha, MD, FACP Chief, Infectious Disease Division, Winthrop-University Hospital, Mineola, New York, Professor of Medicine, State University of New York at Stony Brook, Stony Brook, New York

Glenn R. Cunningham, MD Professor of Medicine and Cell Biology, Vice Chairman for Research, Baylor College of Medicine, ACOS, Research & Development, Veterans Affairs Medical Center, Houston, Texas

Albert J. Czaja, MD Professor of Medicine, Mayo Medical School, Consultant, Gastroenterology and Hepatology, Mayo Clinic, Rochester, Minnesota

Charles L. Daley, MD Assistant Professor of Medicine, University of California, San Francisco, Chief, Chest Clinic, San Francisco General Hospital, Medical Director, Training Center, F.J. Curry National Tuberculosis Center, San Francisco, California

John M. Daly, MD, FACS Lewis Atterbury Stimson Professor and Chairman, Department of Surgery, Weill Medical College of Cornell University, Surgeon-in-Chief, New York Presbyterian Hospital- Cornell Campus, New York, New York

Gary L. Darmstadt, MD Assistant Professor, Divisions of Dermatology and Infectious Diseases, Departments of Pediatrics and Medicine, University of Washington School of Medicine, Seattle, Washington; Adjunct Assistant Professor, Department of International Health, School of Hygiene and Public Health, The Johns Hopkins Medical Institutions, Baltimore, Maryland

Lisa M. DeAngelis, MD Chairman, Department of Neurology, Memorial Sloan Kettering Cancer Center, Professor of Clinical Neurology, Weill Medical College of Cornell University, New York, New York

Albert B. Deisseroth, MD, PhD Ensign Professor of Medicine, Chief, Section of Medical Oncology, Department of Internal Medicine, Yale University School of Medicine, New Haven, Connecticut

Antonio V. Delgado-Escueta, MD Professor of Neurology, West Los Angeles Healthcare Center, Los Angeles, California

E. Patchen Dellinger, MD Professor and Vice-Chairman, Department of Surgery, University of Washington School of Medicine, Associate Medical Director, University of Washington Medical Center, Seattle, Washington

Peter Densen, MD Professor of Internal Medicine, University of Iowa, Iowa City, Iowa

Paul M. Dorinsky, MD Clinical Associate Professor of Medicine, University of North Carolina, Chapel Hill, North Carolina

Marc K. Drezner, MD Professor of Medicine, Head, Section of Endocrinology, Diabetes and Metabolism, University of Wisconsin Medical School, Madison, Wisconsin

Douglas A. Drossman, MD Professor of Medicine and Psychiatry, Division of Digestive Diseases, Co-Director, UNC Functional Gastrointestinal Disorder Center, University of North Carolina, Chapel Hill, North Carolina

Thomas D. DuBose, Jr., MD Peter T. Bohan Professor and Chairman, Department of Internal Medicine, Kansas University Medical Center, Kansas City, Kansas

Thomas P. Duffy, MD Professor of Medicine, Yale University School of Medicine, Attending Physician, Yale-New Haven Hospital, New Haven, Connecticut

Richard J. Duma, MD, PhD Director of Infectious Diseases, Halifax Medical Center, Daytona Beach, Florida

Janice P. Dutcher, MD Professor, New York Medical College, Associate Director for Clinical, Affairs, Our Lady of Mercy Cancer Center, New York, New York

Kim A. Eagle, MD Albion Walter Hewlett Professor of Internal Medicine, Senior Associate Chair, Department of Internal Medicine, Chief, Clinical Cardiology, University of Michigan Medical Center, Ann Arbor, Michigan

George C. Ebers, MD University Department of Clinical Neurology, Radcliffe Infirmary, Oxford, United Kingdom

John E. Edwards, Jr., MD Chief, Division of Infectious Diseases, Harbor-UCLA Medical Center, Professor of Medicine, UCLA School of Medicine, Torrance, California

Theodore C. Eickhoff, MD Professor of Medicine, Division of Infectious Disease, University of Colorado Health Sciences Center, Denver, Colorado

Andrew A. Eisen, MD Neuromuscular Diseases Unit, Vancouver Hospital, Vancouver, British Columbia, Canada

Wafaa El-Sadr, MD, MPH Director, Infectious Diseases, Columbia University, New York, New York

Charles O. Elson, MD Basil I. Hirschowitz Chair in Gastroenterology, Professor of Medicine, University of Alabama at Birmingham, Birmingham, Alabama

Grace H. Elta, MD Professor of Medicine, University of Michigan School of Medicine, Ann Arbor, Michigan

Stephen G. Emerson, MD, PhD Professor of Medicine, University of Pennsylvania School of Medicine, Chief, Hematology-Oncology Division, Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania

Richard W. Erbe, MD Chief, Division of Genetics, Children's Hospital of Buffalo, Professor of Pediatrics and Medicine, School of Medicine and Biomedical Sciences, State University of New York at Buffalo

Walter H. Ettinger, Jr., MD, MBA Executive Vice-President for Physicians' Services, Virtua Health, Marlton, New Jersey

Michael D. Ezekowitz, MB, ChB Professor of Medicine, Yale University School of Medicine, New Haven, Connecticut

James A. Fagin, MD Heady Professor of Medicine, Director, Division of Endocrinology and Metabolism, University of Cincinnati Medical Center, Cincinnati, Ohio

Ronald J. Falk, MD Professor of Medicine, University of North Carolina at Chapel Hill, Department of Medicine, Division of Nephrology and Hypertension, Chapel Hill, North Carolina

Monica M. Farley, MD Veterans Affairs Medical Center, Decatur, Georgia

Timothy M. Farrell, MD Department of Surgery, Emory University school of Medicine, Atlanta, Georgia

Thomas E. Feasby, MD Department of Clinical Neurosciences, University of Calgary, Calgary, Alberta, CANADA

Jerome M. Feldman, MD Professor of Medicine, Division of Endocrinology and Metabolism, Duke University Medical Center, Durham, North Carolina

G. Michael Felker, MD Fellow, Division of Cardiology, The Johns Hopkins University School of Medicine, Baltimore, Maryland

Debbie Fertel, MD Department of Medicine, University of Miami School of Medicine, Miami, Florida

Stuart L. Fine, MD William F. Norris and George E. de Schweinitz Professor of Ophthalmology, Chairman, Department of Ophthalmology, Director, Scheie Eye Institute, University of Pennsylvania, Philadelphia, Pennsylvania

Sydney M. Finegold, MD Staff Physician, Infectious Disease Section, Wadsworth Veterans Medical Center, Los Angeles, California

Gary S. Firestein, MD Division of Rheumatology, University of California, San Diego School of Medicine, La Jolla, California

Charles Fisch, MD Distinguished Professor Emeritus of Medicine, Indiana University School of Medicine, Krannert Institute of Cardiology, Indianapolis, Indiana

Daniel B. Fishbein, MD Senior Medical Epidemiologist, Division of International Health, Epidemiology Program Office, Centers for Disease Control and Prevention, Atlanta, Georgia

Faith T. Fitzgerald, MD Professor of Internal Medicine, University of California, Davis Medical Center, Sacramento, California

Lisa Fitzpatrick, MD Centers for Disease Control and Prevention, National Center for HIV, STD, TB Prevention, Division of TB Elimination, Atlanta, Georgia

Alan M. Fogelman, MD Professor, Executive Chairman of Medicine, UCLA School of Medicine, Los Angeles, California

Kevin R. Fox, MD Associate Professor of Medicine, Attending Physician, Hematology/Oncology Division, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania

Uta Francke, MD Professor of Genetics, Stanford University School of Medicine, Stanford, California

David O. Freedman, MD Director, UAB Travelers Health Clinic, Associate Professor of Medicine and Epidemiology/International Health, Division of Geographic Medicine, University of Alabama at Birmingham, Birmingham, Alabama

Eugene P. Frenkel, MD Professor of Internal Medicine and Radiology, Patsy R and Raymond D. Nasher, Distinguished Chair in Cancer Research, A. Kenneth Pye Professorship in Cancer Research, University of Texas Southwestern Medical Center at Dallas, Dallas, Texas

Linda P. Fried, MD, MPH Professor, Medicine and Epidemiology, Director, Center on Aging and Health, Deputy Director, Department of Medicine, for Clinical Epidemiology and Health Services Research, The Johns Hopkins Medical Institutions, Baltimore, Maryland

Michael A. Friedman, MD Deputy Commissioner for Operations, Food and Drug Administration, Rockville, Maryland

Lawrence S. Friedman, MD Associate Professor of Medicine, Harvard Medical School, Physician, Gastrointestinal Unit and Chief, Walter Bauer Firm (Medical Services), Massachusetts General Hospital, Boston, Massachusetts

Victor F. Froelicher, MD Professor of Medicine, Stanford University, Director, ECG/Cardiology Laboratory, PAVAHCS, Palo Alto, California

Bruce Furie, MD Professor of Medicine, Harvard Medical School, Director, Beth Israel Deaconess Cancer Center, Boston, Massachusetts

John H. Galla, MD Professor of Medicine, Director, Division of Nephrology and Hypertension, University of Cincinnati College of Medicine, Cincinnati, Ohio

Suzette Garofano, MD, FCCP Clinical Assistant Professor, Department of Medicine, NYU School of Medicine, Assistant Attending, Tisch Hospital, New York, New York

York

Layne O. Gentry, MD Infectious Diseases, St. Luke's Episcopal Hospital, Houston, Texas

W. Lance George, MD Professor of Medicine, UCLA School of Medicine, Los Angeles, California

Anne A. Gershon, MD Professor of Pediatrics, Attending Physician, Babies and Childrens Hospital, New York, New York

Alan M. Gewirtz, MD Professor of Medicine and Pathology, Leader, Stem Cell Biology/Transplantation Program, University of Pennsylvania Cancer Center, University of Pennsylvania Medical Center, Philadelphia, Pennsylvania

Mihai Gheorghiade, MD Professor of Medicine, Associate Chief, Division of Cardiology, Northwestern University Medical School, Chicago, Illinois

Amit K. Ghos Professor, Materials Science & Engineering, College of Engineering, University of Michigan, Ann Arbor, Michigan

Teresa Gilewski, MD Memorial-Sloan Kettering Cancer Center, New York, New York

Gregory G. Ginsberg, MD Associate Professor of Medicine, Gastroenterology Division, Director of Endoscopic Services, University of Pennsylvania Health System, Philadelphia, Pennsylvania

David Ginsburg, MD Professor of Internal Medicine and Human Genetics, Chief, Division of Medical Genetics, University of Michigan Medical School, Ann Arbor, Michigan

Roger I. Glass, MD, PhD Chief, Viral Gastroenteritis Section, Centers for Disease Control and Prevention, Atlanta, Georgia

Michael G. Glenn, MD Clinical Associate Professor of Otolaryngology- Head and Neck Surgery, University of Washington, Seattle, Washington

John K. Gohagan, PhD, FACE Chief, Early Detection Research Group, Division of Cancer Prevention, National Cancer Institute, Rockville, Maryland

Andrew P. Goldberg, MD Chief, Division of Gerontology and GRECC Director, University of Maryland, Baltimore, Baltimore VA Maryland Health Care System, Baltimore, Maryland

Jorge T. Gonzalez, MD Neurology, Alpena General Hospital, Alpena, Michigan

David Y. Graham, MD Professor of Medicine and Molecular Virology, Chief, Gastroenterology, Department of Medicine, Baylor College of Medicine and Veterans Medical Center, Houston, Texas

Richard J. Gralla, MD Director, Oshner Cancer Institute, New Orleans, Louisiana

Daryl K. Granner, MD Director, Vanderbilt Diabetes Center, Vanderbilt University Medical Center, Nashville, Tennessee

Frank Anthony Greco, MD Medical Director, Sarah Cannon-Minnie Pearl Cancer Center, Centennial Medical Center, Nashville, Tennessee

Stephen B. Greenberg, MD Professor of Medicine, Baylor College of Medicine, Houston, Texas

Jack O. Greenberg, MD Clinical Professor of Neurology, MCP-Hahneman, School of Medicine, Philadelphia, Pennsylvania

Peter Greenwald, MD, DrPH Director, Division of Cancer Prevention, National Cancer Institute, Bethesda, Maryland

Martin C. Gregory, BM, D. Phil Professor of Medicine, Divisions of General Internal Medicine and Nephrology, Department of Medicine, University of Utah Health Sciences Center, Salt Lake City, Utah

James H. Grendell, MD Professor of Medicine, Weill Medical College of Cornell University, Attending Physician, New York Presbyterian Hospital, New York, New York

Phillip R. Griep, MD Professor of Medicine, Professor of Laboratory Medicine and Pathology, Department of Internal Medicine, Division of Hematology, Mayo Clinic, Rochester, Minnesota

David E. Griffith, MD Professor of Medicine, Director of Tuberculosis Services, Director of Medical Affairs, Center for Pulmonary, Infectious Disease Control, The University of Texas Health Center at Tyler, Tyler, Texas

Coleman Gross, MD Assistant Professor of Medicine, Department of Medicine, University of California, San Francisco, Staff Physician, Department of Veterans Affairs Medical Center, San Francisco, California

John D. Hainsworth, MD Director, Clinical Research, Sarah Cannon Cancer Center, Centennial Medical Center, Nashville, Tennessee

Daniel G. Haller, MD Professor of Medicine, Hematology/Oncology Division, University of Pennsylvania, Philadelphia, Pennsylvania

Jeffrey B. Halter, MD Professor of Internal Medicine, Chief, Division of Geriatric Medicine, Director, Geriatrics Center, University of Michigan, Research Scientist, GRECC, Ann Arbor VAMC, Ann Arbor, Michigan

E. William Hancock, MD Professor of Medicine (Cardiovascular) (Emeritus), Stanford University School of Medicine, Stanford University Hospital, Stanford, California

Michael E. Hanley, MD Associate Professor of Medicine, University of Colorado School of Medicine, Denver, Colorado

Edward F. Haponik, MD Clinical Director, Pulmonary and Critical Care Medicine, Department of Medicine, Johns Hopkins Medical Institutions, Baltimore, Maryland

John A. Hardin, MD Chair, Department of Medicine, Medical College of Georgia, Augusta, Georgia

Stanley Hashimoto, MD, FRCPC Clinical Professor of Medicine, Division Neurology, University of British Columbia, Vancouver, British Columbia, Canada

William L. Hasler, MD Associate Professor of Internal Medicine, University of Michigan Medical Center, Ann Arbor, Michigan

Michael R. Hayden, MB, ChB, DCh, PhD, FRCPC, FRSC Centre for Molecular Medicine & Therapeutic, University of British Columbia, Vancouver, British Columbia

Frances J. Hayes, MB, MRCPI Instructor in Medicine at, Harvard Medical School, Assistant in Medicine at Massachusetts General Hospital, Boston, Massachusetts

Curtis W. Hayes, MD Professor, Radiology Department, University of Michigan Medical Center, Ann Arbor, Michigan

Daniel F. Hayes, MD Associate Professor of Medicine, Georgetown University Medical Center, Clinical Director, Breast Cancer Program, Lombardi Cancer Center, Washington, DC

William R. Hazzard, MD Professor of Internal Medicine, Senior Adviser, J. Paul Sticht Center on Aging, Wake Forest University School of Medicine, Winston-Salem, North Carolina

E. Jenny Heathcote, MD, FRCP Professor of Medicine, University of Toronto, University Health Network, Toronto Western Hospital, Toronto, Ontario, Canada

John E. Heffner, MD Professor and Vice Chair, Department of Medicine, Medical University of South Carolina, Charleston, South Carolina

Charles M. Helms, MD, PhD Professor of Medicine, Department of Internal Medicine, The University of Iowa College of Medicine, Iowa City, Iowa

Mark A. Helvie, MD Associate Professor of Radiology, Director, Division of Breast Imaging, University of Michigan Health System, Ann Arbor, Michigan

William L. Henrich, MD Professor and Chairman, Department of Medicine, University of Maryland School of Medicine, Baltimore, Maryland

Robert Hernandez, MD University of Miami School of Medicine, Division of General Medicine, Miami, Florida

L. David Hillis, MD Vice Chair, Department of Medicine, University of Texas Southwestern Medical Center, Dallas, Texas

Subhash K. Hira, MD, MPH Professor of Infectious Diseases, The University of Texas-Houston, Director, AIDS Research and Control Centre, Mumbai, Technical Advisor, Ministry of Health, Government of India, Mumbai, India

Max Hirshkowitz, PhD Associate Professor, Department of Psychiatry, Baylor College of Medicine, Director, Sleep Research Center, Veterans Affairs Medical Center, Houston, Texas

Marc C. Hochberg, MD, MPH Professor of Medicine, Head, Division of Rheumatology, University of Maryland, Baltimore, Maryland

Gary S. Hoffman, MD, PhD Chairman, Rheumatic and Immunologic Diseases, Cleveland Clinic Foundation, Professor of Medicine, Ohio State University

Ahmet Hoke, MD, PhD, FRCP (C) Assistant Professor, Department of Neurology, Johns Hopkins University School of Medicine, Baltimore, Maryland

Philip C. Hopewell, MD Professor of Medicine, University of California, San Francisco, Associate Dean, San Francisco General Hospital, San Francisco, California

Leslie H. Zimmerman, MD Associate Professor of Clinical Medicine, University of California at San Francisco, Medical Director, ICU at the San Francisco Veterans Administration Medical Center, San Francisco, California

Fuad N. Ziyadeh, MD Professor of Medicine, Renal-Electrolyte and Hypertension Division, Penn Center for Molecular Studies of Kidney Diseases, Philadelphia, Pennsylvania

Clifford W. Zwillich, MD Professor of Medicine, University of Colorado School of Medicine, Department of Medicine, Vice Chairman, Chief Medical Services, Denver VA Medical Center, Denver, Colorado

COLOR IMAGES

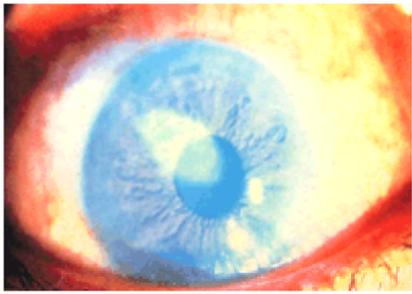

FIGURE 50.2. Neovascularization of the disc and retina.

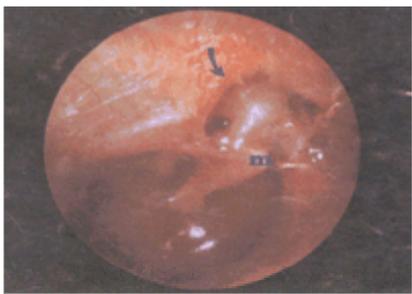

FIGURE 51.1. Otoscopic photograph of right tympanic membrane with large attic retraction pocket causing erosion of the bony external auditory canal. A serous effusion is also present. *m*, malleus short process.

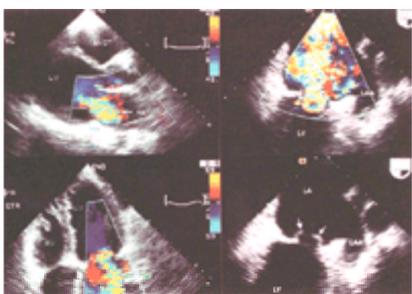

FIGURE 85.5. Four-panel view of patients with mitral regurgitation. The two panels on the left are transthoracic echocardiograms. The upper panel was recorded in a parasternal long-axis view and reveals moderate mitral regurgitation filling approximately 50% of the left atrium. The lower panel reveals a more eccentric mitral regurgitation jet along the lateral wall of the left atrium. The upper right panel is a transesophageal echocardiogram revealing severe mitral regurgitation and the lower panel the same view with the color signal suppressed. In this view, a flail anterior and posterior mitral valve leaflets (*arrows*) can be visualized as the mechanism for severe mitral regurgitation. LAA, left atrial appendage.

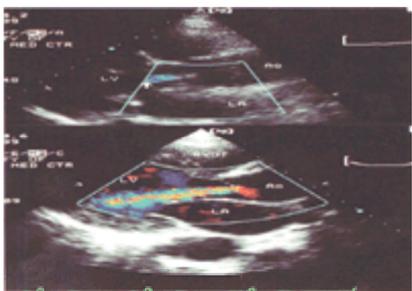

FIGURE 85.7. Parasternal long-axis views of two patients with aortic insufficiency. In each case the images were recorded in diastole. In the upper panel mild aortic insufficiency with a relatively small, narrow jet is seen (*arrow*). The lower panel demonstrates a greater degree of aortic insufficiency with a wide jet that penetrates down past the tips of the mitral valve leaflets.

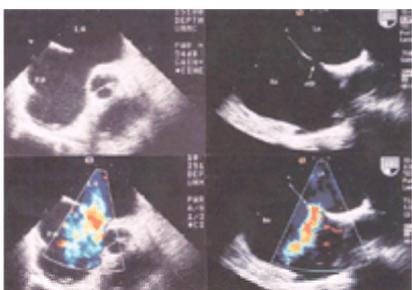

FIGURE 85.8. Transesophageal echocardiograms recorded in two patients with ASDs. On the left is a large ASD seen as echo dropout in the atrial septum on the two-dimensional image. The lower left panel shows the color flow image representing flow from the left atrium to the right atrium. The two right panels represent

standard two-dimensional imaging and color flow imaging of a patient with a smaller ASD and predominant left-to-right shunting. ASD, atrial septal defect.

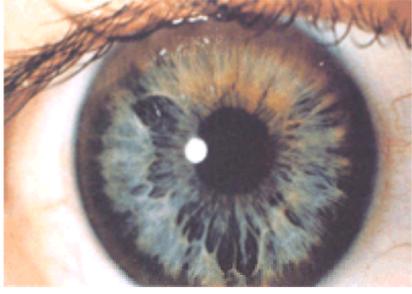

FIGURE 105.4. Kayser–Fleischer ring.

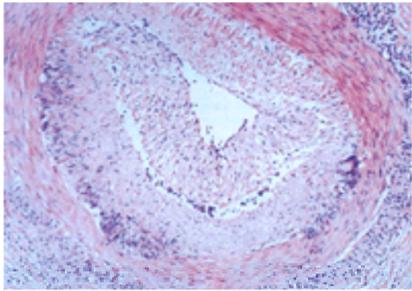

FIGURE 181.2. Temporal artery biopsy in a 64-year-old woman with new onset severe headaches, scalp tenderness, and polymyalgia rheumatica. Note the intense inflammatory changes in the adventitia and media, where giant cells are present. Intimal proliferation has caused luminal narrowing.

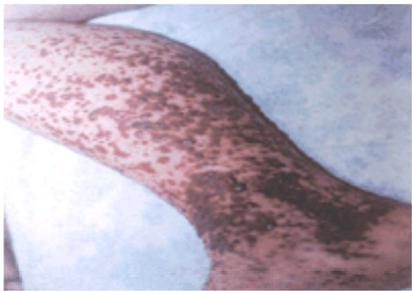

FIGURE 181.5. Henoch–Schönlein purpura. Skin lesions in this 14-year-old girl are particularly striking. Fever, polyarthralgias, and purpura cleared without glucocorticoid therapy. However, several recurrences followed a period of wellness.

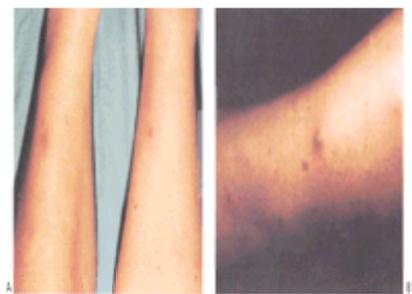

FIGURE 182.1. Disseminated gonococcal infection. **A:** Multiple skin lesions on lower extremities. **B:** Papule on hemorrhagic base. (Courtesy of Thomas H. Rae, MD.)

LIST OF CLINICAL DECISION GUIDES

The Clinical Decision Guides are denoted by category grades appearing below the legends or captions of key decision algorithms and/or tables that are particularly directed at common medical problems. Using these algorithms as guides, a practitioner can quickly sort through a differential diagnosis and/or treatment and formulate options in an evidence-based fashion.

The Clinical Decision Guides have been selected from literally scores of decision algorithms and tables included in the *Textbook*. Each Guide has been graded based on the level of scientific evidence underlying the material so that the user has an appropriate level of confidence surrounding the scientific information. Category "A" tables and figures are based upon national guidelines and/or highly robust clinical trials. Category "B" refers to material which is based upon a limited amount of trial information or large observational studies. Category "C" decision aids are based primarily upon expert consensus. The Category indication appears just below the legend or caption of the Guide.

The Clinical Decision Guides are intended to be used at the patient's bedside. Providers can use this information in real time as they try to create the most appropriate and evidenced-based care possible for their patients.

PREFACE

In just over ten years, the *Textbook of Internal Medicine* has become widely regarded as a classic medical text, both for its breadth of coverage and ease of use by busy students and practitioners. Hundreds of talented individuals contributed to the success of the first three editions. These include the many leading scientists and scholars who served as editors and authors, and the dozens of supporting staff who met the organizational and logistical challenges associated with so large a publishing endeavor.

In this new 4th edition, the present editorial board has strived to maintain the high standards of excellence set forth by its predecessors. Seven of the eleven section editors are new to this project and have demonstrated the highest degree of professionalism and commitment in their new roles. The new Editors include Laurence B. Gardner, Principles of Medical Practice; Elizabeth G. Nabel, Cardiology; Peter G. Traber, Gastroenterology; Robert F. Todd, III, Oncology and Hematology; Talmadge E. King, Jr., Pulmonary and Critical Care Medicine; Lynn D. Loriaux, Endocrinology; Metabolism, and Genetics; and John W. Griffin, Neurology. With the addition of these new Editors, several sections have been substantially reorganized to improve content and accessibility.

We are proud to add many more new contributors representing a wide range of specialties—their expertise has immensely enriched the *Textbook*. We are greatly indebted to their efforts and to the fine work of the many authors of the present edition who were repeat contributors.

The organization of the *Textbook* continues to emphasize the quick reference needs of the student and clinician seeking cogent solutions to real world medical problems everyday.

Each major section includes a series of “Approach to the Patient” chapters focusing on evaluation and work-up of major presenting problems and clinical syndromes—the problems most often seen by the student or physician on the ward or by the “front-line” physician in a primary care practice.

The descriptions of specific disease entities are complete, to the point, and eminently practical, with “Indications for Referral” and “Indications for Hospitalization” cited wherever relevant for quick reference to these key decision points in pressing situations.

Each major section also includes chapters discussing diagnostic and therapeutic modalities. These technique-oriented chapters focus particularly on cost-effective use of the technology of medicine today.

The *Textbook* is the flagship of a series of products published by Lippincott, Williams & Wilkins designed to be responsive to the changing needs of medical students and practitioners. Related products include the *Rapid Access Guide*, a distillation of the key facts about diseases or conditions commonly encountered in the clinical setting. Conspicuously located at the front of the main volume and indexed on the inside covers, the *Guide* permits the quick retrieval of basic presentation, diagnosis, and other information. It is also separately available in a handy pocket-size format. The new edition, superbly edited by Dr. Paul Fine, contains more comprehensive discussions and many more figures and tables.

A major new feature for the 4th edition is a series of evidence-based “clinical decision guides,” which concisely outline the work-up or management protocols for major problems indicated by the most authoritative data available. With these clinical decision guides the *Textbook* brings evidence-based medicine from academic study to direct utility for the student or clinician at the point of care. The clinical decision guides are also separately available as a pocket-sized *Clinical Decision Manual* edited by Dr. Kim A. Eagle.

The *Textbook* is again supported by a companion board review book, *Review of Internal Medicine*, again ably edited in its 2nd edition by Dr. David Schlossberg.

We are pleased to announce that preparations are under-way to launch an up-to-date web version of the *Textbook*. This new format will feature ongoing content updates to help keep pace with the latest clinical breakthroughs as well as a highly user-friendly interface designed for clinical efficiency and utility, and links to other key sites. Finally, the 2nd edition of the *Textbook*'s condensed version, the *Essentials of Internal Medicine*, will be published in 2001. The *Textbook of Internal Medicine* and its related training and reference tools provide a wealth of information in a variety of formats, improving accessibility and responding to the need for greater flexibility.

Like prior editions, this edition of the *Textbook* would not have been possible without the editorial and production assistance of numerous individuals. The work of the Editors has been greatly facilitated by the excellent editorial and organizational skills of Tom Cichonski. The Editors were fortunate to receive the assistance of many staff members, including Virginia Benen, Jean Dorean-Matua, Nancy Esajian, Kathryn Eslinger-Lutz, Marianne Incmikoski, Anne Mraunac, Mark Multach, MD, Rene Tesdal, Teri Tyrrell and Nancy Woolard.

Successful completion of the present edition could not have been accomplished without the commitment of Lippincott Williams & Wilkins to publish the most authoritative and the best-formatted textbook of medicine currently available. The Editors give special thanks to our colleagues at Lippincott Williams & Wilkins for their unswerving dedication, professionalism, and organizational talents. Although they are numerous, we especially wish to recognize the tireless efforts of Richard Winters and Mary Beth Murphy.

The person most responsible for the *Textbook*'s enthusiastic welcome by the medical community, however, is its founding Editor-in-Chief, Dr. William N. Kelley. Keenly aware of the increasing rate of scientific, technical, economic, and social change faced by the internal medicine practitioner, and of the many difficulties and opportunities this change presents, Dr. Kelley saw the need for a “fresh and pragmatic” approach to the teaching of internal medicine. Training and reference resources, he asserted, must adapt to the vastly expanding body of knowledge and the demands to reduce costs and improve efficiency that characterize today's dynamic health care environment. Thanks to his vision, dedication, and fine stewardship, the *Textbook* is acclaimed for both its encyclopedic depth and its utility in the clinical setting.

H. David Humes
Editor-in-Chief

CHAPTER 1: INTRODUCTION TO INTERNAL MEDICINE AS A DISCIPLINE

WILLIAM N. KELLEY AND JOEL D. HOWELL

[History](#)
[The Practice of Internal Medicine and its Subspecialties](#)
[Roles of the Textbook of Internal Medicine](#)

Internal medicine is a scientific discipline encompassing the study, diagnosis, and treatment of nonsurgical diseases of adolescent and adult patients. Intrinsic to the discipline are the tenets of professionalism and humanistic values. Mastery of internal medicine requires not only comprehensive knowledge of the pathophysiology, epidemiology, and natural history of disease processes but also acquisition of skills in medical interviewing, physical examination, humanistic relations with patients, and procedural competency.

HISTORY

Throughout the 19th century, the idea of specialization was tinged with suspicion, if not outright hostility. Some thought the specialist was a “rattlebrained person, who, having tried general practice for a year or two and miserably failed, immediately takes up some sub-department of medicine which his inclination may point out as alluring, and becomes a specialist” (Van Zant, 1887).

Against the background of such attitudes, those who advocated specialization in the early 20th century attempted to define a method for identifying medical specialists. The structure of undergraduate medical training was becoming standardized and presented an unlikely place to train specialists. Although 70% of graduating medical students elected a 1-year rotating internship, it was not until 1914 that Pennsylvania became the first state to require postgraduate training for licensure. Few physicians pursued formal training beyond that single year of internship.

During World War I, the Surgeon General divided U.S. Army physicians into specialist sections. How those sections were defined illustrates the arbitrary definition of internal medicine. The Army considered cardiovascular disease, tuberculosis, dermatology, neurology, and psychologic disorders to be subspecialties of internal medicine. (The latter three divisions are no longer considered part of internal medicine.) After World War I, various groups debated how to define a specialist. Each definition might well have succeeded, and every alternative would have produced very different results. The definition of internal medicine might have been different, depending on who defined it and when.

Through the early 20th century one point remained clear: American medicine needed a system for defining specialists. The public needed to know whom to trust, physicians needed to be able to identify appropriate colleagues for consultations, and hospital administrators wanted assurance of a physician's ability to perform specialized procedures. As the prestigious Commission on Medical Education reported in 1932, “many specialists are self-named; many are not fully trained even in their limited field and still less well equipped in the broad fundamentals of medicine.” The Commission further advised that “a particular identification for those who profess to be specialists should be created” (Wilson, 1940).

That identification came to be certification by a specialty board. In 1917, the American Board of Ophthalmology was the first to offer board certification, and by 1936, 10 specialty boards had been created. During the next 2 years, internal medicine (in 1936) and surgery (in 1937) incorporated their specialty boards.

The founders of the American Board of Internal Medicine (ABIM) did not want every practitioner of internal medicine to be board-certified. Rather they saw the ABIM as a national group designed to recognize only a few outstanding internists. The board examination was designed to test whether the candidate had superb knowledge of the practice of medicine. As originally envisioned, the board-certified internist would be part of a special breed and function as an outstanding consultant. Most of the ABIM's founders thought that a small, highly qualified group of specialists would practice within clearly defined areas, and the rest of medical practice, accounting for 85% of all care, would remain the realm of general physicians. This vision depended on the continued existence of general practitioners who could refer patients to the consulting internists.

The ABIM was formed just in time to include some nascent subspecialists under the larger umbrella of internal medicine. In 1940, soon after its formation, the ABIM decided to certify candidates as subspecialists in four fields—cardiology, gastroenterology, tuberculosis (later called pulmonary medicine), and allergy—but only if the candidates were first board-certified in general internal medicine.

By 1940, 16 specialty boards had been formed and more than 14,000 physicians had earned the right to call themselves board-certified specialists. However, medicine was soon confronted with World War II, whose impact persisted far longer than the 5 years the United States spent at war. The war changed the shape of American medicine by emphasizing the importance of specialization and by enabling the federal government to become the primary source of support for scientific research. These new conditions transformed the ABIM from the original vision of its founders—that the ABIM should recognize a few exceptional consulting physicians—into an organization more consistent with the large, successful, subspecialized discipline that internal medicine has become.

Additional subspecialties of internal medicine were formally recognized through the ABIM in 1972 with the development of subspecialty examinations in endocrinology and metabolism, hematology, infectious diseases, nephrology, and rheumatology. “Tuberculosis” was changed to “pulmonary medicine.” In subsequent years, additional specialties and areas of special competence were added, including oncology, geriatrics, sports medicine, electrophysiology, and others.

THE PRACTICE OF INTERNAL MEDICINE AND ITS SUBSPECIALTIES

The changing nature of internal medicine and its subspecialties can be expected to continue. The internist has been a case manager, a consultant, and a primary care physician. Today there is intensified interest in the role of the general internist as a primary care physician. The essential role of the generalist physician has become apparent to other providers of health care and to payers for health care. The primary care physician sees each patient with a focus on prevention and on management of the patient's health, hoping to minimize the development of disease, and, when disease does occur, to detect it early and manage it effectively.

Other professionals have entered the realm of primary care. The family practitioner has established a major role as a primary care physician, and nurse practitioners are commonly involved in providing primary care in collaboration with primary care physicians and through more independent roles. Occasionally, primary care is provided by subspecialists, and this role may become increasingly common as fewer physicians need to function entirely as subspecialists. One of the major unanswered policy questions is who is best able to provide primary care most efficiently: the subspecialist, the general internist, the family practitioner, or the nurse practitioner?

A second major role of the general internist has been to function as a case manager. Case management may range from appropriate placement of the patient after hospitalization to the management of social issues or management of home care to allow the patient to remain independent and continue to receive good follow-up care at a reasonable cost. As more people need more long-term care for chronic illnesses, case management may become increasingly important. The case manager role commonly is supplemented by others, such as nurse case managers, who focus their efforts on the ancillary aspects of managing the patient in collaboration with the physician, who manages the medical aspects of the patient's illness.

Case management often is critical to achieving good outcomes, particularly with the 5% of the patient population who require 50% of health care dollars. The potential cost savings of this approach has led to aggressive implementation of programs for case management by payer and provider organizations that take full financial risk for patient care. For many years, general internists, particularly those in major academic health centers, served as case managers for patients with complex illnesses requiring the participation of many different specialists. In that setting, it is productive to have one physician who is able to manage the vast array of consultant recommendations. This function is a requirement of some health maintenance organizations (HMOs).

The creators of the ABIM envisioned that the internist could serve as consultant to the generalist physician. The breadth of the internist's role led to important differences between internal medicine and family medicine, which excluded the role of consultant. At a time when virtually all physicians were general practitioners, the role of the consultant internist was quite different from the situation today. However, this function continues to be important in rural settings, where most care is still provided by nurse practitioners or family practitioners and where few subspecialists are available. Furthermore, the generalist as consultant to the surgical practitioner has grown in importance.

With the continued development of integrated delivery systems, a new division of labor is likely to occur among general internists. In urban areas that have heavy market penetration of managed care, the general internist can spend virtually all of his or her time in the ambulatory setting, providing continuity of care as a primary care physician. It becomes extremely inefficient for those physicians also to care for patients who may require hospitalization, and it becomes more practical for another population of general internists, "hospitalists," to care for patients admitted to the hospital. In this capacity, they may serve as the physicians responsible for the patients' overall care, prioritizing the advice and recommendations of the various subspecialty consultants. This function is likely to remain less common in rural areas.

In response to the dramatic and ongoing evolution of specialties within internal medicine, the ABIM has recognized three types of subspecialists. The first is the basic scientist. This individual has training in internal medicine, has clinical training in her or his subspecialty, has spent substantial time in the basic research laboratory, and is able to carry out fundamental research, collaborating and competing with other basic scientists who have no clinical expertise. These individuals can envision the importance of basic research findings in improving human health—a valuable skill in this era of rapidly advancing biomedical research. These individuals often have some continued clinical practice in their subspecialty, and they teach in that subspecialty, but they spend most of their time in the laboratory doing basic research.

The second type of subspecialist is the clinical investigator. This individual has extensive training in internal medicine and in a clinical subspecialty, and has considerable research training involving human subjects. These subspecialists are able to transfer the advances in the laboratory to human subjects. This is perhaps best exemplified in an area such as gene therapy, which requires critical initial studies using selected human subjects before application to larger groups of patients can be carried out.

The third group contains those who serve as subspecialty clinicians. This is the largest group of subspecialists in internal medicine and is perhaps the group in greatest oversupply. This group can be further subdivided. The first subtype encompasses those providing principal care, which is long-term continuity of care for patients with chronic disease; most care is provided by the subspecialist, with some care provided by other members of the team, such as a general internist or nurse practitioner. The second subtype of the subspecialty clinician is the individual who is highly procedure-oriented and spends most of his or her time conducting procedures. An example is the invasive cardiologist who spends a substantial portion of his or her time in the cardiac catheterization laboratory doing coronary angiograms and angioplasties. A continuum of subspecialty practice exists between these two extremes.

All subspecialists in internal medicine must have received full training as general internists before their specialization. In this way, they differ from most other subspecialists in organized medicine because they can function as generalist physicians when that role is appropriate. In an era of an apparent oversupply of subspecialists, this additional training is immensely valuable because it allows these physicians to provide principal or primary care. This is especially valuable in the management of chronic, complex disease.

ROLES OF THE TEXTBOOK OF INTERNAL MEDICINE

Kelley's Textbook of Internal Medicine is designed for the medical student, for the postgraduate trainee, for the practitioner in general internal medicine, and for the subspecialist. Certain sections of the book may appeal more to some individuals than others, but it has been our commitment to make this book useful across this broad range of training. For example, the "Approach to the Patient" sections are probably most useful to the medical student or beginning resident in internal medicine. The sections on the "Approach to Common Primary Care Issues" and "Diagnostic and Therapeutic Modalities" might also be of considerable interest to students and residents. The sections on "Basic Mechanisms of Health and Disease" and on "Disorders" should interest students, residents, and physicians who have been practicing medicine or one of its subspecialties for many years. In this context, *Kelley's Textbook of Internal Medicine* serves as an important device for continuing medical education.

CHAPTER 2: CLINICAL MEDICINE, CLINICAL ETHICS, AND PHYSICIANS' PROFESSIONALISM

MARK SIEGLER, ARTHUR CAPLAN AND PETER SINGER

[Three Central Professional Values](#)
[Quality End-of-Life Care](#)
[Informed Consent and Shared Decision Making](#)
[The Doctor-Patient Relationship in the Age of Managed Care](#)
[Conclusion](#)

To practice medicine competently, physicians require both scientific–technical proficiency and knowledge of clinical ethics. They need to manage issues in the areas of informed consent, truth telling, confidentiality, do-not-resuscitate orders, end-of-life decisions, palliative care, proxy decision making, and patient rights. A working knowledge of practical clinical ethics is an addition to, not a substitute for, the traditional standards of character and virtue expected of the good physician: competency, integrity, honesty, compassion, and respect for patients and colleagues. During the past 15 years, the discipline of clinical ethics has emerged as a new and useful component of medical practice and has assisted physicians and patients to reach ethically acceptable decisions.

Clinical ethical issues now occur more frequently in medical practice for a variety of reasons. Scientific advances and new technologies have raised unprecedented ethical problems, e.g., when should efforts to prolong life with ventilators or dialysis machines be stopped and under what circumstances is it permissible to forgo life-prolonging interventions such as artificial hydration? Changes in molecular medicine, genetics, and the neurosciences are generating new and different ethical problems in such traditional areas as informed consent and confidentiality. Changes in the relationship between patients and physicians to a more equal relationship of shared decision making require attention to ethical issues such as honest disclosure, effective communication, and informed consent. Managed care has given rise to new ethical issues such as limitations on decisional freedom for patients and physicians, the need to accurately explain what is available for patients with respect to diagnostic services and treatments, and potential financial conflicts of interest associated with limiting the use of health resources.

Sound ethical analysis in clinical settings rests on a foundation of trust between the patient and physician. Crucial components in the analysis of any ethical issue include an understanding by both parties of the medical and scientific facts; the preferences, values, and goals of both patient and physician; and the external constraints such as cost, limited resources, and legal duties that shape or restrict choices. By communicating clearly with patients about the prognosis and treatment goals, physicians can cement trust and reduce the chances of conflict arising with respect to care decisions, including end-of-life decisions.

The doctor–patient relationship (DPR) is the central and organizing theme in clinical ethics. Most of the routine ethical problems that arise in patient care present in the context of the DPR and most are resolved within this relationship. The field of clinical ethics focuses on how patients and physicians work within existing administrative, economic, and political structures to reach mutual agreement on clinical decisions that affect the patient. In the United States, the DPR has undergone two major changes in the past generation. Initially, in the 1970s and 1980s, the relationship changed from a paternalistic one, in which physicians make choices for patients based on professional values, to a more equal relationship of shared decision making, in which physicians advise patients but patients ultimately make their own health care choices. The second major change in the DPR, which occurred in the 1990s, relates to cost containment and managed care. Private and government payers for health care are effectively limiting the decisional freedom of both patients and physicians, and such actions have given rise to new and recurring ethical concerns within the DPR. This latter change in the DPR has seen a new emphasis on populations rather than individual patients and on attempts to eliminate variations in health care decisions by emphasizing practice guidelines derived from evidence-based medicine, outcomes studies, and clinical trials. These shifts, while laudable in many ways, put new pressures on the traditional patient advocacy that has been at the core of the DPR.

In this chapter, we examine three of the central professional values of physicians: clinical competence, respect for patients, and efforts to minimize conflicts of interest by placing the patient's welfare above other considerations. These three values are then related to three clinical–ethical issues that physicians frequently encounter: (a) providing quality end-of-life care (an application of clinical competence); (b) negotiating informed consent (an application of respect for persons); and (c) working within managed care organizations (an application of minimizing conflicts of interest).

THREE CENTRAL PROFESSIONAL VALUES

In considering three of the central professional values of medicine, we realize that despite scientific developments of the past century the role of the medical profession in human societies has changed surprisingly little since the time of Hippocrates. The DPR has also changed very little, and the encounter of healer and patient has remained the principal means by which medicine achieves its goals. Several reasons explain the extraordinary continuity of the DPR over time: (a) medicine serves a universal and unchanging human need by responding to a patient's sense of illness or "dis-ease"; (b) medicine has an unchanging central goal, which is to help patients; and (c) most medical help is delivered in the direct encounter of patient and physician, that is, in the DPR. In this context, we examine three core professional values: competence, respect for patients, and minimizing of conflicts of interest.

CLINICAL COMPETENCE

Excellent clinical practice has always blended technical proficiency with ethical sensitivity. The physician's relationship to the patient is based on specific technical training and competency and on respect for medicine's ethical standards. This specialized knowledge and proficiency is used to assist patients, sometimes by curing or managing their illness and disease, and sometimes by helping them overcome the fear, pain, and suffering that are often associated with illness. Once sought out by the patient, the physician becomes involved in the patient's problem and never again is a mere observer. Physicians are responsible and personally accountable to their patients if they fail to perform their task adequately because of lack of skill, knowledge, dedication, or clinical judgment, or if, for any other reason, they fail to act in the patient's behalf.

RESPECT FOR PATIENTS

In 1983, a report of the American Board of Internal Medicine defined "respect" as the personal commitment to honor the preferences, choices, and rights of others regarding their medical care and to recognize the dignity and freedom of the patient. Patient preferences are the ethical and legal nucleus of the DPR. In addition, respect for patients and their preferences is a clinical obligation because patients who reach a shared health care decision have greater trust and loyalty in the DPR, cooperate more fully to implement the shared decision, express greater satisfaction with their health care, and, most important, have been shown to have better clinical outcomes in several chronic diseases.

MINIMIZING CONFLICTS OF INTEREST

Conflicts of interest are inevitable. A minimum requirement for a conflict of interest is two human beings, especially when they are involved in a relationship that provides care in return for a fee. Such conflicts have always existed in medicine: in Hippocratic times, under fee-for-service systems of payment, and today, in managed health systems. The central issue is not the existence of conflicts of interest but rather how these conflicts are addressed and minimized within the professional relationships of doctors and patients. Two basic rules offer guidance to physicians: (a) Place the patient's interest first by subordinating financial matters and other self-interests to achieve the central goal of medicine, i.e., helping patients. The American Medical Association's 1994 guidelines on this point are clear: "Under no circumstances may physicians place their own financial interests above the welfare of their patients. If a conflict develops between the physician's financial interest and the physician's responsibilities to the patient, the conflict must be resolved to the patient's benefit." (b) Inform the patient when there are substantial conflicts of interest, such as financial or similar incentives that could influence the physician's recommendations to the patient. The three central professional values will now be related to three specific clinical-ethical issues.

QUALITY END-OF-LIFE CARE

Good-quality care at the end of life, an example of clinical competence, is something that the public is demanding and medicine is committed to deliver. Although media reports on end-of-life care frequently highlight euthanasia or assisted suicide, most of the care provided by internists to dying patients focuses on the control of pain, symptom management, decisions about life-sustaining treatments, and the provision of support to patients and families. While there is increasing expertise among physicians, nurses, and others specializing in palliative care medicine, most end-of-life care is delivered by internists. The training and education available in

this area have not always been adequate.

There are some simple steps that physicians can take to ensure the ethical management of terminally ill patients. In approaching patients at the end of life, internists should ask themselves three questions: Have I relieved the patient's pain and other symptoms? Have I addressed the use of life-sustaining treatment? Am I doing what I can to support the patient and family?

HAVE I RELIEVED THE PATIENT'S PAIN AND SYMPTOMS?

Adequate pain and symptom management is the *sine qua non* of ethical end-of-life care. Although most pain can be controlled, unfortunately, many patients still die with uncontrolled pain. Other symptoms experienced by dying patients such as dyspnea, fatigue, depression, and nausea are also often inadequately addressed. The reasons for suboptimal control of pain and other symptoms are complex, but two principal reasons are inadequate education about pain and symptom control in medical school and residency, and physician concerns about the ethics of hastening death. Physicians must seek sources of continuing education on treatment of pain and symptom management in dying patients. If the primary physician cannot control a dying patient's pain or other symptoms, the physician should seek assistance from a palliative care specialist (see [Chapter 40](#)).

Physicians sometimes feel that by administering adequate analgesia or sedation they are hastening death. This concern is understandable in light of the opinions advanced in professional codes of ethics such as those of the American Medical Association and the American College of Physicians opposing any form of active euthanasia. There are also serious legal consequences facing anyone participating in euthanasia.

It is important, however, to distinguish appropriate analgesia and sedation of dying patients from euthanasia. Physicians are morally bound to manage pain and suffering aggressively. Legal authorities must be made to understand this duty. For instance, according to guidelines developed by the Chief Coroner of Ontario, an act is considered palliative care, and not euthanasia, if (a) it is intended solely to relieve the person's suffering, (b) it is administered in response to symptoms or signs of the patient's suffering and is commensurate with that suffering, and (c) it is not the deliberate infliction of death. The Supreme Court of the United States and many state courts have endorsed similar considerations in allowing physicians the discretion to pursue aggressive pain control even to the point of terminal sedation.

HAVE I ADEQUATELY ADDRESSED THE USE OF LIFE-SUSTAINING TREATMENTS?

The basic principles applying to use of life-sustaining treatment are those of consent. Patients have the ethical and legal right to decide to not start (withhold) or to stop (withdraw) treatment, including life-sustaining treatment such as cardiopulmonary resuscitation and renal dialysis, even if this refusal results in their death. Valid consent requires adequate disclosure of information and voluntary decision making by a competent patient. If the patient is incompetent, his or her right to accept or refuse treatment is exercised through a process known as substitute decision making, which asks two key questions: (a) Who should make the decision on behalf of the patient? and (b) How should the decision be made? The specific detailed answers to these questions will vary from jurisdiction to jurisdiction. In general, the most appropriate decision maker is (a) someone named by the patient in advance, (b) a family member or loved one, and (c) for those with no other substitute decision maker, a public official such as a public guardian or trustee. The most appropriate basis for the decision is (a) the person's previously expressed wish (either verbal or through a written advanced directive), (b) their known values and beliefs, and (c) their best interests.

Patients and their families may plan in advance for decisions about life-sustaining treatment using a process called *advance care planning*. An advanced directive is a written document in which the patient states who should make the treatment decisions (a durable power of attorney for health care) and what decisions the patient wants made (a living will) if he or she becomes incompetent and can no longer make decisions. The Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatments (known as the SUPPORT study) showed that an advanced care planning intervention had no effect on clinical and administrative outcomes. However, Singer's recent qualitative research suggests that the primary goal of advanced care planning is to help patients prepare for death, which entails facing death, achieving a sense of control, and strengthening relationships.

In contrast to cases in which patients and families refuse life-sustaining treatment proposed by health care providers, a "new" type of case, in which patients and families request treatment that health care providers believe is inappropriate, is becoming increasingly prevalent. These so-called "futility" cases lead to great distress on the part of patients, families, and health care providers since there are few policies and almost no legislation governing this issue. On the one side, some patients and families insist that the decision about treatment is one of values and therefore they have the right to make it. On the other side, health care providers sometimes argue that they should not be forced to provide treatment that will not prolong life or will lead only to prolonged unconsciousness and debility and dependence on medical technology. In such cases, it is important to negotiate a treatment plan based on realistic prognosis and in this way to avoid such conflicts by not raising false hopes of patients and families. It is also important that decisions to end treatment on the grounds of futility not be made individually but rather be undertaken with guidance and consultation from hospital ethics committees and if necessary appropriate administrative and legal bodies.

HAVE I DONE WHAT I CAN TO SUPPORT THE PATIENT AND FAMILY?

Many psychological, social, cultural, and religious issues surface at the end of life. Psychologically, individuals might want to maintain a sense of control over their dying. Socially, individuals might want to strengthen relationships with, or relieve burdens of, their family members. Culturally, death and dying have different meanings and rituals for different cultural groups. People often seek meaning at the end of life through their spiritual beliefs.

Physicians who care for dying patients must help patients and families address these issues. Every death is different, and there is no specific "formula" for assisting patients and families. Nevertheless, the simple, open-ended question "Is there anything else I can do to help you or your family?" might evoke useful clues for physician action. Physicians must be aware of, and offer to dying patients, spiritual, religious, and emotional resources such as chaplaincy, social services, and hospice care.

INFORMED CONSENT AND SHARED DECISION MAKING

The process by which physicians and patients make decisions together is often summarized in the phrase *informed consent*. This doctrine, which reflects respect for patients, is at the heart of the DPR and is based on the ethical principles of respect for individual autonomy, dignity, and self-determination. Informed consent has three key components: disclosure, competency, and voluntariness.

Disclosure means that physicians tell patients about the medical diagnosis, prognosis, and risks and benefits associated with possible treatment options. Patients are entitled to enough information to permit them to ask reasonable questions about the diagnosis and the options that are available. *Competency* means that patients are capable of understanding relevant information, appreciate their own needs and values, manipulate information rationally, and communicate a treatment choice. *Voluntariness* means that a patient chooses freely, ideally without coercion from the physician or anyone else.

Informed consent is not an event, nor does it refer to a patient's signature on a consent form. It is a process of continuous communication and dialogue between doctor and patient. In this process, physicians empower patients to act in an autonomous manner by educating them about the nature of their medical problems and reasonable medical alternatives to resolve or cope with them. Patients are then in a position to choose treatment based on personal preferences, values, and goals.

The outcome of care may be improved by the informed consent process. Empowering patients to participate in decision making has been associated with beneficial outcomes for several chronic diseases. In patients with diabetes, hypertension, and peptic ulcer disease, pilot programs aimed at increasing patient participation in medical care result in improved functional and health outcomes. Compliance is improved by informing patients about their options and maintaining open and full communication with them. And the prospects for conflict around highly charged decisions, such as end-of-life decisions, are minimized when informed consent is managed effectively.

THE DOCTOR–PATIENT RELATIONSHIP IN THE AGE OF MANAGED CARE

Efforts at cost containment, which raise the specter of physician conflict of interest, often involve some of the following approaches: using clinical guidelines to standardize care; restricting services seen to be of marginal benefit; rationing some potentially beneficial services; and restricting both patient and physician freedom of choice to make individual clinical decisions. These strategies for achieving cost containment and health reform already have placed enormous stress on the DPR. A recent study of managed care physicians highlights the ways in which physician-respondents believe that financial conflicts of interest interfere with the DPR and with

the doctors' ethical obligations to patients.

In order to maintain ethical integrity in clinical practice, particularly in dealing with end-of-life care decisions, physicians must adopt and maintain a patient-centered perspective that makes patients understand that the physician is their advocate, seeking, within the financial and practice limits that exist, to permit patients to make their own health care decisions. Physicians must also insist on patients' rights in developing clinical guidelines and appeal mechanisms for the large number of clinical decisions that, despite research on medical outcomes, will continue to be made in the face of considerable clinical uncertainty.

CONCLUSION

In the face of unprecedented changes in the doctor–patient relationship, the question has sometimes been raised regarding whether the relationship will survive in modern medicine and whether it is really necessary. Is there a residual role for the physician within a DPR when practice guidelines and expert consensus statements exist? We believe there is. A vigorous defense of the role of the physician was offered almost a generation ago by Dr. Philip Tumulty: “A clinician is defined as one whose prime function is to manage a sick person with a purpose of alleviating most effectively the total impact of the illness upon that person. ... Managing a sick person is entirely different from diagnosing an illness and prescribing therapy for it. ... Management means that the physician comprehends and is sensitive to the total effects of an illness on the total person.” In Tumulty's view, the DPR is essential for determining the diagnosis, communicating effectively with the patient, reaching a joint decision on how to treat the problem, and then proceeding to the management of the disease process with the goal of alleviating most effectively the total impact of the illness on the patient. In our view, the clinical encounter between the patient who seeks help and the physician who is trained to provide help is the *unchanging event in medicine* and has remained relatively constant despite the scientific, social, economic, and political changes that have occurred in medicine during the past 3,000 years. Furthermore, the goals of the encounter have not changed much as physicians have always attempted to help those who ask for help and to improve patients' length and quality of life. Finally, the DPR, with its emphasis on the primary clinical skills of communication, history taking, and physical diagnosis—skills that internists are trained to provide—probably remains the most cost-effective way to provide health care to individuals and populations.

CHAPTER 3: THE GENOME PROJECT AND MOLECULAR DIAGNOSIS

LESLIE G. BIESECKER, BARBARA B. BIESECKER AND FRANCIS S. COLLINS

[Genetic Testing in Medical Practice](#)
[Complex Genetic Disorders](#)
[Treatment](#)

Advances in molecular biology have begun to transform the practice of clinical medicine in many specialties and subspecialties. The genetic and molecular dissection of pathogenic mechanisms will fundamentally alter medical practice, comparable in scale to the alterations caused by the advent of antibiotics. Adult medical practice that involves genetic testing and counseling will require melding the disciplines of internal medicine and clinical genetics. Primary care internists and subspecialists will need to become familiar with advances in molecular genetics and genetic counseling to effect these changes in their practices.

To understand the magnitude of these advances, it is necessary to consider some of the research sources. The Human Genome Project is an organized effort to create a biologically and medically useful database of genome structure, sequence, and function in humans and experimental animal model systems. Initiated in 1990, the genome project provides resources that allow investigators to rapidly locate and clone disease or susceptibility genes—efforts that previously required years of work. By the year 2003, the entire human DNA sequence encoding 80,000 to 100,000 genes will be determined. In addition to the genome project, medical genetics research is performed in independent laboratories around the world. The melding of information from the large-scale project and the independent research efforts will produce an enormous dataset that will profoundly alter medical practice.

The successes in gene discovery thus far have primarily included single-gene disorders that cause symptoms in a large proportion of persons who have abnormal genotypes (highly penetrant mutations). These include disorders such as cystic fibrosis, neurofibromatosis, muscular dystrophy, Huntington's disease, and many others. These disorders can have variable severities because different mutations lead to various degrees of dysfunction. Although we consider these to be single-gene disorders, the severity of the phenotype also depends on other gene products in a molecular pathway.

In contrast, many diseases result from the interaction of multiple genes with the environment. Because these diseases involve many genes and potentially many possible mutations, an enormous number of combinations of genotypes are possible. These combinations lead to a range of susceptibility and a distribution of phenotypic severity. In addition to causing or predisposing to a disease, genetic variation might also affect a drug's efficacy or its ability to induce side effects. These concepts of disease have the potential to radically alter not only how medicine is practiced but also how medical research trials are designed and conducted. In addition, pharmacogenomics will profoundly alter our approach to therapeutics. Research studies will divine variations in drug efficacy and metabolism among the population and assist in the definition of distinct subject cohorts. Drugs that have significant pharmacogenetic variation will spawn clinical pharmacogenetic tests that will be used before the selection of a drug for a given patient. Such testing will have two profound effects: the ability to maximize drug efficacy and to minimize adverse effects by determining the pharmacogenetic variables of the individual patient.

Determining the molecular pathophysiology of human disease and pharmacogenomics will provide opportunities for diagnosis, prevention, and treatment ([Fig. 3.1](#)). However, genetic tests differ from other medical tests in that they have important implications for family members and for reproductive decision making. They often raise issues of privacy, autonomy, voluntariness, and discrimination, and the test results may have significant emotional consequences. Genetic counseling is the process that combines the provision of genetic information with psychosocial counseling. It is generally nondirective in that patients are not advised as to whether to undergo genetic testing. The voluntary and personal nature of decisions about genetic tests, most importantly tests that impact reproductive decisions, are respected.

FIGURE 3.1. Flow chart of the course of gene discovery and its implications for clinical medicine.

Genetic counseling should accompany the offer of any genetic test to facilitate informed decision making. This process of genetic counseling includes an explanation of risk, and an exploration of the patient's perceptions of the meaning of the condition and implications of the potential results of testing. In this context, the outcomes of test decisions are anticipated in a manner that supports decision making. While genetic testing is increasingly used as a tool of medicine, the choice to pursue it remains personal. People may or may not prefer to learn predictive or diagnostic genetic information about their own health. Their interest in the information depends primarily on their perception of what they can do with the information to protect their future health. Furthermore, state-of-the-art genetic testing may produce ambiguous molecular results associated with uncertainty about the susceptibility to, and severity of, the disorder. These technical complexities speak to the importance of providing genetic counseling in follow-up to testing for help with interpretation and risk communication.

Before genetic testing can be offered, the state of the art for the specific disorder must be evaluated. The number and distribution of different mutations are major determinants of the practicality of genetic testing. Disorders that are caused by one or a few mutations (e.g., sickle cell anemia, Huntington's disease) are amenable to the design of simple, sensitive, and reliable molecular diagnostic tests that rarely have false-positive or false-negative results. Disorders with multiple mutations may have none of these desirable features. Along with the technical challenges of designing a genetic test, there are other issues that must be addressed before a test is ready for clinical use. Issues of genotype–phenotype correlation, sensitivity and specificity, proper informed consent, access to genetic counseling, and other concerns must be addressed before test release. For all types of genetic testing, it is important for the medical practitioner to be familiar with the methodologies, strengths, and limitations of all tests that will likely be used in clinical practice.

GENETIC TESTING IN MEDICAL PRACTICE

In addition to common tests that have genetic implications (e.g., cholesterol levels for familial hypercholesterolemia, echocardiograms for Marfan's syndrome), there are a host of DNA and cytogenetic diagnostic tests that may be used in a clinical genetics encounter.

DIRECT MUTATION ANALYSIS

It is possible to design a test that can directly detect the causative mutations for a disorder if several conditions are satisfied. The gene must be cloned, and there must be a specific and sensitive method to detect most mutations. The severity of the phenotype associated with the specific mutations must also be determined through analysis of the patient's family or by studies of many other affected individuals. Although the analysis of mutations by the direct method is technically straightforward, the interpretation of results can be challenging. For genes that have multiple alleles, it might be difficult to predict the severity of the disorder from the mutation, especially when the mutation causes amino acid substitutions. Such “mutations” must be carefully analyzed to ensure that they do not represent polymorphisms and are, in effect, false positives. The BRCA1 breast cancer susceptibility gene provides an example of this problem. Mutation detection by

whole-gene sequencing has led to the description of more than 600 mutations. The penetrance and severity of some of the mutations are well delineated (e.g., del185AG); however, others are so rare (and some are even unique to single families) that it is difficult or impossible to assess the consequences of having such a mutation. This is an example of a test that has the potential to assist greatly in the management of a patient, yet it also has a significant probability of generating an uninterpretable result.

The complexities of predicting phenotype from genotype suggest that physicians should be skeptical about ordering such tests. Before ordering a test, one should be clear about the prior probability of finding a mutation (a screening study versus a person at 50% risk of inheriting a mutation), the state of knowledge concerning the penetrance of various mutations in the gene under consideration, and how a normal or abnormal result will affect the care of the patient. These considerations are overlaid by many of the factors described above including insurability and employability, self-esteem, anxiety about risks to the offspring of the patient, and so forth. All of these factors must be taken into account before ordering such a test, and they conspire to make such a decision complex and multifaceted.

LINKAGE ANALYSIS

Linkage analysis may be used for a mendelian disorder when mutation detection is impractical because the gene has not yet been cloned or because the mutations are too heterogeneous to be readily identified. This test takes advantage of the fact that markers that are located near certain genes are likely to be inherited together with those genes and can be used to assess the probability that a mutant allele was inherited. The advantages of linkage analysis are that it can be performed before the responsible mutations are discovered and that it can be used on families in whom the responsible mutation is unknown or is undetectable. The disadvantages of linkage analysis are that it requires blood samples on multiple family members and that the results are often limited to maximum confidences of 95% to 98%. This reduced confidence is related to the distance between the marker and the mutation on the chromosome. The uncertainty of a linkage test is in addition to the variables described above for direct mutation analysis because the linkage is being used as a proxy for the actual mutation.

COMPLEX GENETIC DISORDERS

One current major challenge for medical genetics is the elucidation of the molecular etiology of disorders that are caused by alterations in several genes and that have significant variability attributable to environmental influences. Examples of this class of disorders include adult-onset diabetes mellitus, essential hypertension, and schizophrenia, among others. The complexity of identifying each of these genetic and environmental components of disease liability is much greater than that involved in the isolation of a single-gene disorder. It is anticipated that such research will reveal an array of genes, some of which have more than one allele contributing to disease liability. Within that array of genes, some will pose particular susceptibilities to environmental influences. The determination of the cumulative liabilities and susceptibilities of each of these allelic variants will require detailed analyses of large cohorts of subjects.

As of this writing, no significant diseases in this category have been fully or even partially elucidated, though it is expected that some of these will be unraveled in the near future. Beyond the challenges of isolating the genes that predispose to these disorders, the implementation of testing for such disorders will pose a number of technical, logistical, and clinical practice challenges. The technical challenges of such testing will require developing tools to assay one or more alleles of several genes. These technologies, such as microarrays, mass spectroscopy, and gene chips, are already under development and may be mature before the genetic research to find and determine the effects of the genes is complete. It is reasonable to anticipate that such testing will require the input of a small blood sample and entry of a number of clinical parameters (age, sex, weight, etc.) into a computerized testing apparatus. The apparatus will output an assessment not only of the overall risk of the disease but of particular environmental susceptibilities. The melding of this approach with that of pharmacogenomics, described above, will allow prediction of therapeutic options that maximize efficacy and minimize side effects. It should be noted that such testing is not dependent on the presence of any disease symptom, nor is treatment limited to those with symptoms. The ability to diagnose a high susceptibility to adult-onset diabetes mellitus, for example, may allow presymptomatic pharmacologic treatment of insulin resistance and dietary advice about weight control that might delay or even prevent the onset of frank disease.

TREATMENT

Clinical genetics has been historically characterized as a diagnostic specialty because it has traditionally focused on diagnosis, prognosis, and counseling but provided few treatment options. This perception was never entirely correct, and the specialty is changing rapidly in this regard. The dissection of the molecular pathophysiology of disease, the ability to assess individual disease susceptibility, and pharmacogenomics will provide opportunities for treatment of many common and rare genetic disorders. Thus, the molecular dissection of human disease will provide a plethora of therapeutic targets and the design of novel classes of agents to be applied to the treatment and prevention of disease. All of these advances will require internists to expand their current understanding of genetic diagnosis and treatment.

CHAPTER 4: CELL GROWTH, DIFFERENTIATION, AND DEATH

MAX WICHA

[Extracellular Signals](#)
[Cell Growth, Differentiation, and Death](#)

In multicellular organisms, the function and fate of cells is tightly regulated. These cells must respond to environmental factors and to each other in a manner that promotes survival and reproduction of the entire organism. The basic mechanisms involved in this complex organization and cellular interdependence have been conserved throughout evolution and are remarkably similar in organisms as diverse as the roundworm, the fruit fly, mice, and humans.

As indicated in [Figure 4.1](#), cell function can be conceptualized as occurring along three pathways: cell growth (division), cell differentiation, and cell death (apoptosis). Although these are depicted as distinct pathways, in actuality they are highly interconnected. The extracellular signals that regulate these cellular behaviors fall into three main classes: soluble signals (hormones and growth factors), extracellular matrix (ECM) signals (e.g., basement membrane), and cell–cell interactions (gap junctions). These extracellular signals act on the cell through specific receptors that transmit this information to the interior cellular machinery through signal transduction pathways. The cell must in turn integrate these complex signals and respond by initiating programs of cell growth, differentiation, or cell death. Our knowledge of the molecular details of these pathways has been greatly expanded in recent years. It has also become clear that dysregulation of these pathways results in a variety of pathologic conditions, including cancer formation ([Figure 4.1](#)). Aspects of these pathways are summarized below and discussed in more detail in references.

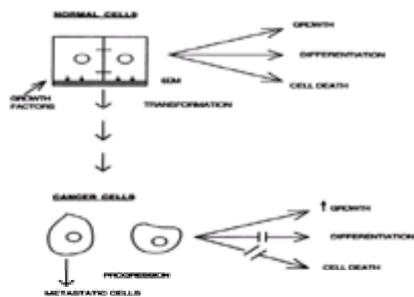

FIGURE 4.1. Regulation of cell growth, differentiation, and death. In normal cells, cell growth, differentiation, and death are regulated by extracellular signals from soluble signals (hormones and growth factors), extracellular matrix components, and cell–cell communication. Defects in these pathways result in neoplastic transformation.

EXTRACELLULAR SIGNALS

GROWTH FACTORS, HORMONES, AND THEIR RECEPTORS

Growth factors and hormones serve to facilitate intercellular communication to coordinate cellular functions in complex multicellular organisms. Hormones produced in one organ act at distant sites, whereas growth factors and cytokines usually act locally, facilitating interactions between tissues. This interaction manifests itself in such phenomena as stromal epithelial interactions regulating cellular differentiation. Such locally acting factors are said to function in a paracrine fashion.

Both hormones and growth factors act by binding to specific cellular receptors, either on the plasma membrane or in the intracellular compartment. These receptors in turn initiate signal transduction pathways that ultimately regulate gene expression, controlling growth, differentiation, and cell death states. There has been a tremendous increase in our understanding of receptor function. This information has provided important new insights for pharmacologic development. In general, cell receptors can be divided into two classes. “Cargo receptors” (such as the low-density lipoprotein receptor) deliver nutrients, minerals, and other components directly to cells. Such receptors themselves do not initiate signal transduction pathways. The other major class of receptors are capable of interacting with and triggering intracellular signal transduction molecules. For example, one class of these receptors has intrinsic activity, such as that of tyrosine kinase, and are activated by growth factors. Receptors in this class with tyrosine kinase activity include those for epidermal growth factor and platelet-derived growth factor. Another class of receptors of which several hundred have been described is coupled to large G proteins.

EXTRACELLULAR MATRIX AND INTEGRINS

Extracellular matrix molecules provide a scaffolding to which most cells are anchored. The composition of the ECM differs from tissue to tissue. Epithelial and endothelial cells are anchored to a basement membrane containing mostly type IV collagen, laminin, and heparan sulfate proteoglycans, whereas stromal cells are anchored to an ECM consisting largely of type I and type III collagens and fibronectin. It is now clear that these ECMs are far more than an inert scaffolding; rather, they provide important positional information and cooperate closely with growth factors and hormones to regulate cellular functions. For example, the basement membrane attachment of epithelial cells regulates their decisions to undergo growth, differentiation, or cell death.

The ECM molecules interact with cells through specific receptors, the most important of which are the integrin receptors. These heterodimeric molecules mediate cellular attachment to ECM and are linked to signal transduction pathways. There are important interactions between these ECM-regulated pathways and those for growth factors, allowing cells to integrate complex information from the cell's environment. Furthermore, the interaction between ECM and integrin receptors is bidirectional. The ECM components regulate integrin expression and activation, and integrins function in turn in ECM assembly. Abnormalities in these pathways may contribute to a number of disease states, such as cardiovascular disease and psoriasis.

CELL–CELL INTERACTIONS AND GAP JUNCTION PROTEINS

Cells may communicate directly with each other through proteins that form small channels, termed *gap junctions*, which link cells within tissues. Gap junctions are composed of a family of proteins known as connexins. Most normal cells utilize these channels to transport nutrients and small molecules. At least 13 connexins have been described, and recently, the three-dimensional structure of a recombinant gap junction channel was solved. Mutations in connexin molecules have been described and are believed to play an important role in the etiology of a number of human disease states such as the X-linked form of Charcot–Marie–Tooth syndrome and autosomal recessive deafness, as well as abnormalities in the development of the cardiovascular system. In addition, it has been shown that many if not most cancers show defects in gap junctional communication, which might contribute to their cellular autonomy.

CELL GROWTH, DIFFERENTIATION, AND DEATH

As summarized above, cells receive diverse cues from their environment through interconnecting signal transduction pathways. In turn, cells regulate the expression of genes that determine whether a quiescent cell will enter the cell cycle, differentiate, or die.

CELL CYCLE

Growth factors engaging specific cellular receptors trigger signal transduction pathways that in turn cause quiescent cells in the G₀ phase of the cell cycle to enter the

cell cycle G_1 at which time specific protein synthesis begins. In late G_1 the cell reaches a point termed the restriction point R in which the cell makes a commitment to undergo DNA replication and complete the cell cycle. DNA is replicated during the S phase. Following the G_2 phase, the cell divides in the M or mitotic phase. At each stage in the cell cycle, cells must traverse checkpoints that ensure the integrity of the process. Abnormalities in cell cycle control contribute to such disease states as arteriosclerosis and cancer. An understanding of these pathways might lead to new interventions for these diseases.

DIFFERENTIATION

Most cells in tissues and organs are capable of exiting the cell cycle and initiating a program of gene expression specific to these tissues. It is this process, termed *terminal differentiation*, that distinguishes cells in different organs such as those in the liver, brain, or breast. Deregulation of these differentiation pathways might contribute to cancer formation.

CELL SENESCENCE AND DEATH

In 1961, Hayflick showed that normal somatic cells have a limited replicated potential of approximately 50 cell divisions. Furthermore, fibroblasts from younger individuals underwent more cell divisions than those from older individuals, suggesting that a finite number of cell divisions characterizes both in vivo and in vitro growth. Although the mechanisms responsible for this phenomenon have yet to be fully elucidated, there is increasing evidence that shortening of the telomeric ends of chromosomes during each cell division plays an important role in determining cellular age and in triggering cellular senescence. In support of this, expression of the enzyme telomerase, which can block telomere shortening, results in increased replicative life span of cells. The contribution of telomerase to human aging and related diseases remains to be determined; however, many tumor cells express telomerase, thus overcoming replicative senescence.

APOPTOSIS

Another process that limits growth of cells is programmed cell death, or "apoptosis." This process plays a pivotal role in such normal processes as lymphocyte and nervous system development. In addition, it provides a means for multicellular organisms to eliminate cells damaged beyond repair. There has been a tremendous increase in our knowledge of the intracellular pathways that mediate apoptosis. There is substantial evidence that growth factors, hormones, and ECM, regulate apoptotic pathways, ensuring that a cell in an inappropriate environment will "self-destruct." The apoptotic "threshold" of a cell is regulated by the bcl-2 family of proteins, which act by regulating cytochrome *c* release. These pathways might have evolved as a protection against neoplastic transformation. Indeed, most if not all cancers have defects in cellular apoptotic pathways. In contrast, inappropriate activation of caspases may be important in a variety of neurodegenerative diseases such as Alzheimer's disease.

Apoptotic pathways have been highly conserved in organisms as diverse as worms, flies, mice, and humans. Indeed, valuable insights into these pathways have come from elucidation of apoptosis pathways in the roundworm, *Caenorhabditis elegans*. Apoptotic signals result in cell death through activation of a specific set of proteases, termed caspases, which cleave at aspartic acid residues, and ultimately result in cellular destruction. These caspases may be activated through specific cellular receptors, such as *fas*, or through the sensing of cellular damage. This results in mitochondrial release of cytochrome *c*, which together with the protein Apaf-1 and dATP initiates caspase activation and triggers cell death.

INTER-RELATIONSHIP OF SIGNAL TRANSDUCTION PATHWAYS

Although signaling mechanisms and signal transduction pathways have been described as distinct pathways, in actuality they are highly interconnected. For instance, appropriate hormones, ECM, and cell-cell contact are necessary for cells to initiate differentiation programs. In addition, both growth factors and ECM closely cooperate in regulating cell growth and apoptosis. Removal of either the appropriate growth factor or ECM molecule triggers a normal cell to undergo apoptosis. In addition, there is evidence that cell growth and death are closely related. This interconnection might have evolved as a mechanism to prevent against cancer formation. The recent development of new DNA array technologies that can simultaneously examine the expression of thousands of genes promises to lead to a better understanding of how these signal transduction pathways interact. Indeed, the picture that is emerging from such technologies is that these pathways are not linear but rather branched networks with numerous interconnections. These new technologies might facilitate our understanding of how defects in these pathways contribute to human diseases. Furthermore, elucidation of these pathways provides a multitude of new targets for therapeutic development.

CHAPTER 5: PRINCIPLES OF THE IMMUNE RESPONSE

ROBERT WINCHESTER

[Integration of the Systems Mediating Inflammation, Wound Healing, and Immunity](#)
[Components of the Innate Immune System](#)
[The Adaptive Immune System](#)

INTEGRATION OF THE SYSTEMS MEDIATING INFLAMMATION, WOUND HEALING, AND IMMUNITY

The integrated and closely regulated group of diverse processes responsible for the homeostatic maintenance of tissue integrity includes wound healing, inflammation, and the immune response. Two fundamentally distinct systems contribute to the immune response. The first is the adaptive immune system proper, based on recognition of specific antigenic structures by different clones of lymphocytes. The function of the adaptive system depends on expansion of particular lymphocyte clones and their subsequent differentiation into effector cells, each separately specific for unique structures. These phenomena account for the acquisition of specific immune recognition and for immune memory. The second is the innate immune system. It is triggered by stereotyped receptors that recognize evolutionarily conserved features of microorganisms or by receptors that recognize cytokines elaborated by activated or injured cells. The innate immune system includes the mononuclear and polymorphonuclear, leukocyte phagocytes, natural killer (NK) cells, and the complement, clotting, and fibrinolysis systems of the plasma. A large number of diseases or pathophysiologic processes may be classified as the direct or indirect result of either the failure of one of these homeostatic mechanisms to maintain tissue integrity or an inappropriately excessive activation of a response system that suggests improper function of a regulatory element (Table 5.1).

Disease of immune deficiency (i.e., failure to perform one or more surveillance and elimination functions)
Disorders of immune recognition and response
Allergic diseases (i.e., misidentification of environmental antigens molecules as suitable targets for an IgE or cellular immune response)
Autoimmune diseases (i.e., misidentification of endogenous self antigens as targets of an immune response)
Attack of self by T cells; release of cytokines
Attack by antibody and immune complex disease
Persistent infections
Disease may result from viral infection of cells, such as measles without effective class I surveillance mechanism, by suppression of surveillance mechanisms, or lack of ability of an individual's immune system to recognize appropriate regions of the viral sequence.
Effector mechanisms of injury may merge with those of autoimmune disease.
Disorders of inappropriate activation of elements of the immune system, such as rhegnetogenic streptococcal infection that induces C3rd, superantigenic anaphylatoxin syndromes, including toxic shock syndrome, and possibly Kawasaki's disease and rheumatic fever
Unregulated proliferation of immune system cells, such as leukemia, lymphomas, and B-cell neoplasms (gammapathies), which each reflect altered expression of a lymphoid cell at a particular state of differentiation
Disorders of immune and fibroblast disorders of unknown cause in which wound healing, inflammation, and certain immune effector processes are implicated in the mechanisms of disease

TABLE 5.1. CLASSIFICATION OF DISEASES INVOLVING THE IMMUNE SYSTEM

The coordination of the immune and inflammatory responses involves the interaction of several cell lineages, including lymphocytes, monocytes, macrophages, dendritic cells, and vascular endothelium. The regulation of these interactions is through the release of cytokines and chemokines as well as cell–cell contact. However, these coordinating molecules have the potential to affect the structure and function of bystander cells that compose the organ in which the response is occurring.

COMPONENTS OF THE INNATE IMMUNE SYSTEM

THE NEUTROPHIL

The terminally differentiated circulating neutrophil has a half-life of 6 hours and is produced at a baseline rate of 10^{11} per day. Neutrophils have a series of innate immune defense functions initiated by engagement of stereotyped receptors typical of the innate immune system that are shared by neutrophil, macrophage, and monocyte lineage cells. There are receptors that stimulate phagocytosis, such as those binding the immunoglobulin constant region (FcR), and complement receptors that bind to particles opsonized with C3b or C3bi, products of the activated complement system. There are also receptors for stereotyped structures on microorganisms, such as CD14, the receptor that binds bacterial lipopolysaccharide (endotoxin) when complexed to the serum lipopolysaccharide-binding protein and formyl–methionine–leucine–phenylalanine receptors that are directly triggered by the N-terminally modified peptide characteristic of prokaryotes. Other receptors bind the chemotactic and activating anaphylatoxic fragments of certain complement components, such as C3a and C5a. Many of these receptors are G-protein-linked. The response of the neutrophil to engagement of these receptors is rapid activation characterized by multiple events, among which are up-regulation from preformed reserves and subsequent activation of molecules such as the C3bi receptors CR3 (CD11b/CD18) and CR4 (CD11c/CD18), integrin structures that have adhesive and phagocytic functions. The CR3 and CR4 receptors also function in aspects of leukocyte adhesion involving passage of these cells into sites of inflammation from the vasculature, but this depends on interaction with counter-receptors such as intercellular adhesion molecule (ICAM) and not with C3b. The disorder known as leukocyte adhesion deficiency involves a defect in production of the CD18 chain and illustrates the importance of this molecule to inflammation. Other consequences of neutrophil activation include production of reactive oxygen intermediates, discharge of proteolytic enzymes, activation of arachidonic acid cascades, and release of cytokines such as interleukin-1 (IL-1), IL-8, tumor necrosis factor α (TNF- α), and IL-12, which signal to both neutrophils and other cells in the innate and adaptive immune response.

Inappropriate triggering of neutrophil receptors by cytokines or other triggers results in the marked activation of adhesive receptors, especially the CD11b/CD18 integrin molecule. The overexpression of this molecule appears to be implicated in the induction of the pathologic states of homotypic neutrophil–neutrophil adhesion underlying a Schwartzmann response–like reaction in blood vessels and lungs. This response is seen in certain infections, in immune disorders such as systemic lupus erythematosus, and in vasculopathies.

MONONUCLEAR PHAGOCYTES

The mononuclear phagocyte, including monocytes and macrophages, is arguably the central cell lineage in inflammation and immunity, serving as a critical link between the innate and the adaptive immune systems. The relatively long life of this cell and its ability to respond to a variety of stimuli by sustained changes in patterns of gene expression result in its prolonged activation, modulation, or differentiation.

The engagement of one or more of the receptors on the mononuclear phagocytes that are shared with the neutrophil initiates the response of activation that includes the synthesis of a variety of cytokines, including IL-1, IL-6, IL-8, IL-12, and TNF- α . Interleukin-1 and TNF- α act on the vascular endothelium to increase its expression of adhesive receptors and foster an increase in permeability, allowing cells and plasma factors necessary for the inflammatory response to enter the tissue. In terleukins 1 and 6 foster lymphocyte activation. Interleukin-12 causes both activation of NK cells and differentiation of CD4 T cells to a T_H1 phenotype. Interleukin-8 is responsible for neutrophil chemotaxis and, in concert with TNF- α , for neutrophil activation. Interleukin-6 also orchestrates the systemic response of fever by acting on the hypothalamus and the hepatic synthesis of acute phase reactants.

The mononuclear phagocyte is the effector cell for two components of the adaptive immune system. First, it recognizes and phagocytizes targets that have been coated with specific antibody or opsonized with C3b. Second, it is specialized for an intricate interaction with CD4 T cells that involves serving not only as the effector cell of an antigen-activated CD4 T cell, but also as one of the cells capable of presentation of antigen to this T cell. Indeed, some monocytes differentiate into dendritic cells that are particularly specialized for the presentation of peptides to naive CD4 T cells. The activated CD4 T cell in turn elaborates a series of cytokines including IL-1 and interferon- γ (IFN- γ), which bind to receptors present on the monocyte. These cytokines, in concert with cell–cell interactions involving molecules such as CD40L, prompt the monocyte to become activated to a far more destructive functional stage, characterized by more effective phagocytosis and killing. The interaction of the CD4 T cell with the macrophage also influences the potential for the naive CD4 T cell to differentiate into either a T_H1 or a T_H2 effector T cell through

the phagocyte's elaboration of cytokines such as IL-12. Another pathway of IFN- γ production is via the NK cell, discussed below.

The tissue macrophage can remain in an activated state for several months, releasing additional cytokines and engaging cell–cell interactions that result in the accumulation and activation of fibroblasts. This process, if sustained, leads to a granulomatous and fibrotic reaction. Sustained release of cytokines such as IL-1 and TNF- α may alter the pattern of gene expression in the parenchymal cells of the involved organ. Thus, the inappropriately activated monocyte is a key mediator of pathogenic consequences in many diseases apart from those with a typical autoimmune etiology, and agents that block the effects of TNF- α are finding application in various diseases. The activated monocyte may also express tissue factor and plasminogen activator, which serve to initiate clotting and fibrinolysis, respectively. Inappropriate activation of the monocyte by autoantibodies occurs in the antiphospholipid syndrome, resulting in pathologic thrombosis.

NATURAL KILLER CELLS

The NK cell is an unusual member of the lymphocyte lineage that does not have a somatically rearranged T-cell antigen receptor (TCR), but contains several stimulatory and inhibitory receptors that regulate its ability to kill target cells. Different NK subpopulations exist with various combinations of stimulatory and inhibitory receptors. Among these is CD16, an Fc receptor that stimulates the NK cell to kill antibody-coated targets in the antibody-dependent cellular cytotoxicity (ADCC) pathway. The stimulated NK cell produces IL-4, a cytokine that deviated the adaptive CD4 T-cell response toward the production of T_{H2} cells. In addition, the NK cell has receptor for cytokines such as IL-12 and TNF- α , and the combination of these two cytokines produced by the macrophage or neutrophil elicits the production of IFN- γ by the NK cell. Interferon- γ acts to activate the macrophage and also causes the CD4 T-cell response to deviate to a T_{H1} phenotype.

In addition, the NK cell has several other types of important but less well-defined activating receptors. One of these is a lectin receptor that recognizes cell surface carbohydrate of intracellularly infected cells. Another receptor recognizes self antigens presented by the CD1d molecules. This recognition involves an unusual type of T-cell *ab* receptor that does not undergo somatic junctional diversity and often uses a single Va and Ja gene segment, Va24 and JaQ. These two receptors are involved in the recognition of tumor or infected cells. Key to the regulation of the function of these latter self-recognition receptors are two additional receptors with interesting recognition specificities that give an inhibitory signal to the NK cell and prevent its killing a normal cell. One receptor is a heterodimer of two molecules used to define the presence of a cell in the NK lineage (CD94 and NKG2). This molecule recognizes human leukocyte antigen E (HLA-E), a nonclassical major histocompatibility complex (MHC) class I molecule that can usually be expressed only if other typical class I molecules are expressed. Another receptor is the killer inhibitory receptor (KIR), which comes in several varieties that are separately specific for HLA-A, B, or C class I MHC molecules. Thus, normal class I molecules down-regulate a potentially always “on” killing function of NK cells. When class I gene expression is altered by certain intracellular infections with viruses and some other microorganisms, or by malignant transformation, the potential of the NK cell to kill the target cell is released.

COMPLEMENT SYSTEM

The complement system is a tightly regulated cascade of at least 24 interacting molecules found in serum and on cells. It participates in the inflammatory response in three ways. First, it coordinates several elements of the inflammatory response to microorganisms and tissue injury through the generation of potent, biologically active peptides, C3a and C5a, termed anaphylatoxins, derived from cleavage of C3 and C5 that initiate effects such as mononuclear phagocyte or neutrophil activation, chemotaxis, and adhesion. The anaphylatoxins also directly enhance endothelial permeability and cause mast cell degranulation. Second, the system participates in the immune response as a potent amplifier of phagocytosis. It facilitates this function by coating (opsonizing) the target particle with the C3b fragment derived from C3. Third, the complement system has a series of proenzymes and other molecules that form the membrane attack complex capable of lysing the cell membranes of certain bacteria such as *Neisseria* and human cells.

The central event in the complement system is the generation of C3 convertase, which cleaves C3 into C3a and C3b. Three different recognition events and associated pathways initiate the generation of C3 convertase. The classical complement pathway is activated by IgG or IgM immune complexes. The transducing molecule is C1q, a part of the trimolecular first component of the complement system. C1q circulates loosely bound to serum immunoglobulin molecules but, on encountering several immunoglobulin molecules fixed to an antigen, C1q undergoes a conformational change that initiates activation of the classic pathway. It then interacts with C2 and C4 to generate C3 convertase. The classical pathway can also be activated by the binding of C1q to the acute phase protein (C-reactive protein) when the latter has bound to certain bacterial and fungal lipopolysaccharides. A second pathway is initiated by bacterial mannose-containing carbohydrate. The transducing molecule is a plasma protein, mannan-binding lectin (MBL), a calcium-dependent lectin that shares overall structural features with C1q and, like it, activates C2 and C4. This activation occurs via binding of MBL to two proteases, the MBL-associated proteases (MASP-1 and MASP-2). The third, or alternative, pathway is triggered by C3b fragments bound to a substrate that have been generated through either of the preceding pathways and is in many respects an amplification loop. Factors B and D bind to C3b to generate the C3 convertase activity.

A set of circulating proteins and cell-associated molecules regulate the ability of the complement system to injure the individual's own cells. Most act to reduce the generation or effect of C3 convertase. C1 inhibitor, in contrast, acts to inhibit the serine esterase function of C1, and a deficiency of this molecule results in hereditary angioneurotic edema. CD59 acts to prevent the formation of the membrane attack complex on homologous cells. This GPI-anchored protein becomes deficient in some hemopoietic clones in paroxysmal nocturnal hemoglobinuria.

In addition to the complement receptors, CR3 and CR4, discussed previously, another complement receptor on phagocytic leukocytes capable of binding C3b is CR1 (CD21), a member of the immunoglobulin family. CR1 is also highly expressed on erythrocytes where it serves the protective function of binding soluble circulating immune complexes and transporting them to the liver for removal. Erythrocyte CR1 is markedly depleted in immune complex diseases.

THE INNATE IMMUNE SYSTEM IN THE RESPONSE TO EARLY INFECTION

The integration of these systems is seen in the early events of an infection. Almost immediately after entrance of microorganisms into the tissue, the foreign organisms are detected by binding and activation of complement components through the MBL pathway or by binding C-reactive protein. Wandering tissue neutrophils and monocytes initially interact with the microorganism through their stereotyped receptors that recognize characteristic features of microbial structure and are subsequently drawn to the microorganism by complement chemotactic fragments or the presence of bacterial products. The immediate response of the neutrophil is to release cytokines and chemokines that recruit additional neutrophils and monocytes, as well as lymphocytes, into the region through their effects on both the vasculature and the leukocytes. The monocyte reinforces the chemokine release initiated by the neutrophil, and together both phagocytes may interact with NK cells to initiate elaboration of IFN- γ to potentiate monocyte activation—functions also related to the adaptive immune response.

ENTRANCE OF CELLS INTO A SITE OF INFLAMMATION

As discussed above, the presence of inflammation in a region is reflected by alterations in the vascular endothelium that are induced by cytokines such as IL-1, IFN- γ , and TNF- α . These act on the vascular endothelium to increase the expression of adhesive receptors such as ICAM-1 and vascular addressins. At the same time, a gradient of immunoreactants is established. The immunoreactants include chemokines released by neutrophils or monocytes (macrophage inflammatory protein, IL-8) that have had chance encounters with the bacteria or that have been activated by other routes. Other potent chemokines, such as slow death factor-1 (SDF-1), are released by parenchymal cells. Anaphylatoxins such as C3a and C5a are elaborated locally if a microorganism activates the complement system. The intravascular leukocyte that enters this inflammatory environment is diverted from rapid laminar flow motion and begins to roll along the endothelium, interacting weakly with the addressins via its homing receptors. When the leukocyte encounters the gradient of immunoreactants it undergoes prompt activation via G-protein-coupled receptors that activate β_2 integrins such as lymphocyte function-associated antigen-1 (LFA-1, or CD11a) to an adhesive state. This arrests the leukocyte via an interaction with molecules such as ICAM-1. The chemokine receptors are rapidly inactivated, releasing the cell to diapedese through the endothelial junctions to enter the tissue. There it is attracted to the site of inflammation by the chemokinetic gradient of immuno-reactants.

THE ADAPTIVE IMMUNE SYSTEM

The adaptive immune system is characterized by the following: (a) the intricate diversity and specificity of the recognition structures employed in the immune response; (b) the somatic genetic processes underlying their development; (c) the clonal nature of the expression of these receptors; (d) the selection of an individually specific repertoire that is efficient and lacking potential for injurious self-recognition; and (e) the selective processes of clonal expansion and the differentiation to effector status that is induced by antigen. The adaptive immune system is closely interrelated to the innate immune system, making a highly antigen-specific way of intensively activating the innate immune system to a higher level of selective destruction that could not be obtained through the use of stereotyped receptors.

ADAPTIVE IMMUNE RESPONSE PROVIDES MULTIPLE TYPES OF IMMUNITY

The inaccurate older division of the adaptive immune system into humoral and cellular components has been replaced by grouping the main protective tasks facing the immune system into three categories that each involve a fundamentally different type of immunity.

CD4 T-CELL SYSTEM

This component of the adaptive immune system deals with recognizing the presence of microorganisms, such as bacteria (e.g., *Mycobacterium tuberculosis*), fungi, and parasites that seek to replicate within the environment of the body and that can be phagocytized by macrophages. The CD4 TCR is specialized to recognize small portions of the amino acid sequence of antigens that have been endocytized and degraded to peptides of 9 to 15 amino acids in the endocytic pathway following phagocytosis (Figure 5.1). The peptides are bound by the MHC class II molecules in a chaperone-like function. The class II molecules have previously trafficked to the endosome with the aid of a protein, the invariant chain, that both directs the MHC class II molecule to the endosomal compartment and blocks the peptide binding groove. The invariant chain is degraded in the endosome, freeing the MHC molecule to bind peptides derived from ingested proteins. The MHC molecule containing a peptide then travels to the cell surface where antigen presentation occurs. The complex of MHC class II molecule and peptide is recognized by specific TCRs found on CD4 T-cell clones. The CD4 molecule assists in this recognition process by specifically binding to MHC class II molecules.

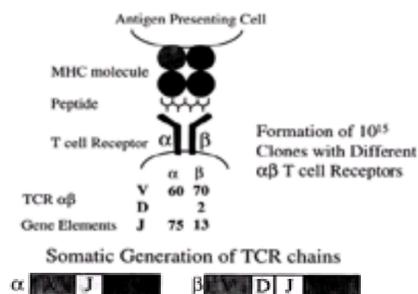

FIGURE 5.1. The molecular elements involved in the somatic generation of an $\alpha\beta$ T-cell receptor from germ line elements

B-CELL SYSTEM

The second parallel adaptive immune system detects largely the same group of organisms as the CD4 T-cell immune system, but it is able to recognize regions of molecules in their intact state or free in solution prior to phagocytosis and digestion. This system is centered on the properties of the specific B-cell antigen receptors present on the surface of B cells that are capable of recognizing molecular conformations with sufficient affinity such that there is no requirement for an antigen-presenting molecule. When a B-cell clone characterized by a specific BCR responds fully to recognition of a specific antigen, the B-cell terminally differentiates into a plasma cell and expresses the recognition portion of the specific B-cell antigen receptor in a soluble form that is the familiar antibody of humoral immunity. We can envision that the requirement to control organisms, such as *Streptococcus pneumoniae*, drove the evolution of this immune system. These organisms are optimally controlled by the formation of antibodies that coat the incoming organism, placing on it a set of recognition signals that activate neutrophil phagocytosis and other effector systems described in the section on innate immunity, leading to clearance and inactivation of the invader.

In the B-cell system, there is another extensive level of diversification of the receptor immunoglobulin molecule involving the constant regions and their potential to interface with various effector systems. IgM and IgD are two surface immunoglobulin isotypes, both expressing the same variable region sequences. Each has a transmembrane domain and sites for cytoplasmic signaling. As the B cell differentiates to an antibody-secreting form (the plasma cell), different exons are used to encode secreted forms of these molecules. With the help of the CD4 T cell, the immunoglobulin class may switch to IgG, IgA, or IgE. IgA-bearing cells often are found in mucosal membranes, and the IgA molecule may be secreted with a supplemental "chaperone" secretory piece that protects the IgA molecule from digestion. The COOH⁻ terminal portion of the IgE molecule binds to receptors found in high concentration on basophils and mast cells. This serves to passively arm these cells with receptors containing immunoglobulin detection molecules that are, in allergic individuals, directed to a variety of environmental allergens. The allergic symptoms result from the activation and discharge of the potent pathways of acute inflammation initiated by the molecules of these cells.

CD8 T-CELL SYSTEM

The third task is dealing with infection by a virus, whose own genome can commandeer the replicative machinery of a host cell. The recognition of a virally infected cell, especially early in the infectious cycle, is dependent on the presence of the surveillance functions of the MHC class I molecule and the cytotoxic function of the CD8 T cell. The class I molecule binds the cytoplasmically derived viral peptide and the complex is recognized by the specific CD8 TCR in a manner that is generally similar to that of the class II MHC molecule. However, subtle differences in the structure of the specific TCR render it specific for interacting with peptides presented in the context of class I MHC molecules. Moreover, the CD8 molecule on the T cell interacts with the MHC class I molecule on the infected cell to further increase the affinity of the interaction. Thus, the TCRs on CD8 or CD4 T cells are separately specific for peptide presented in the context of class I or class II MHC molecules, respectively. However, unlike the class II molecules, the class I MHCs are synthesized and assembled with β_2 -microglobulin in the endoplasmic reticulum and the Golgi apparatus. The peptides are derived from cytoplasmic molecules that are degraded by a complex of enzymes, the proteasome, and the resulting peptides transported to the endoplasmic reticulum compartment by an ATP-dependent transporter of antigenic peptides (TAP) that spans the endoplasmic reticulum membrane. The peptides enter the class I molecule peptide binding groove and stabilize its interaction with β_2 -microglobulin, resulting in the expression of the class I molecule on the cell surface with its bound peptide. The proteasome system degrades a fraction of all cytoplasmic proteins, especially those with anomalous structural features, a property that might increase the representation of virally encoded peptides in this surveillance system. In the case of an influenza virus-laden respiratory epithelial cell, the virally encoded peptides are degraded in the cell's cytoplasm and appear on the cell surface in the context of MHC class I molecules. Each of the 100,000 to 200,000 MHC class I molecules on the epithelial cell surface displays a single peptide, the large majority being from normal self-peptides, but among them a few contain virally encoded peptides. Each T cell sifts through this collection of presented peptides until it identifies a specific peptide. Recognition activates the cytotoxic mechanism of the peptide-specific CD8 T cell, which kills the infected epithelial cell.

The adaptive systems do not function in separate compartments, e.g., antibodies also play a role in virus infection by mediating viral neutralization or by binding to intact virions budding through the cell surface. Similarly, macrophages phagocytize infected cells if triggered by bound antibodies or by innate mechanisms.

CLONAL BASIS OF ADAPTIVE IMMUNE RECOGNITION AND ITS REGULATION

Engagement of the clonal antigen-specific receptor on the lymphocyte initiates a complex series of signaling events that induce the expression of new genes and initiate several developmental consequences. Included among these genes are those that induce the cell to divide and to sustain subsequent proliferation by an autocrine mechanism, which in the case of the T cells involves elaboration of IL-2 and receptors for this cytokine. Each lymphocyte involved in the recognition of a specific antigen is characterized by a single type of antigen-specific receptor. The descendants of a lymphocyte inherit the same receptor genes, making the same specific receptor and thus constituting a clone. The clones proliferate in response to specific antigenic stimulation. This expansion is one of the key elements that confers enhanced responsiveness to the inciting antigen, the fundamental element of adaptive immunity. The signaling events also include the acquisition of new functional properties as a result of the activation and differentiation mediated by this gene expression, the second key element in adaptive immunity. These may be specific effector functions, such as acquiring the mechanism to kill a target by the CD8 T cell, or the secretion of IFN- γ by a CD4 T cell. In the case of the B cell this includes differentiation to antibody-secreting plasma cells. The outcome of the signaling process is not stereotyped and in some instances a proportion of the expanded clone differentiates into long-lived memory cells that remain quiescent until exposed again to the stimulating antigen. This is the third key feature that the response of the lymphocyte provides to the clonal basis of adaptive immunity.

TWO SIGNALS REQUIRED FOR T-CELL ACTIVATION

It is evident that a multiplicity of regulatory steps exist to control this process. While the general process of clonal activation and expansion are common to all lymphocytes, the regulatory steps obviously must be specific to each of the three main lymphocyte lineages to effect their separate control. In the case of the CD4 or CD8 T cell, one or more second signals are required that are provided by the activated antigen-presenting cell. Without these second signals the T cell responds by entering an anergic or tolerized state, presumably to safeguard against stimulation by self-peptides. A dendritic cell, derived from a macrophage precursor, is specially constituted to effectively provide these costimulatory signals. Most CD4 T-cell responses are initiated by antigen presentation by a dendritic cell and then subsequently expanded by subsequent presentation of the same antigen by a macrophage or a B cell, both of which express class II MHC molecules and have the appropriate endocytic processing pathway. In the case of the B cell, internalization of the antigen is mediated by binding to the specific B-cell clonal receptor. The critical second signal is provided by engagement of the CD28 molecule on the T cell with its ligand molecule, B7 (CD80, CD86), that is selectively expressed on the surface of the activated antigen-presenting cell. Activation of the CD4 T cell by this two-signal mechanism also initiates a down-regulatory mechanism in the form of the initiation of synthesis of the molecule CTLA-4 (CD152). This molecule competes with higher affinity to bind to the B7 molecule, making it unavailable to the T cell. Furthermore, engagement of CTLA-4 by B7 activates an additional negative signaling pathway in the T cell.

The expression of several molecules on the surface of the activated T cell serves as clinically useful markers of the presence of T-cell activation. The most frequently measured activation markers are the appearance of MHC class II molecules (HLA-DR), CD69, and CD40 ligand, all of which are undetectable on resting T cells. As the cell continues its response to receptor engagement, the cell surface phenotype changes to reveal the appearance of new molecules such as integrins involved in cell–endothelial adhesion and additional molecules responsible for the trafficking of the cell to particular sites. The problem of getting the lymphocyte that has been activated in a lymph node to the site of inflammation where it is needed is solved by the presence of a variety of homing receptors that are expressed in a combinatorial pattern to give some vascular anatomic specificity. The cells undergo the same sequence of rolling, activation, arrest, and diapedesis discussed above in the section on innate immunity.

CENTRAL ROLE OF THE T_h1 OR T_h2 CD4 T CELL IN REGULATING B-CELL AND CD8T-CELL RESPONSE TO STIMULATION

The CD4 T cell occupies a central role in the regulation of the response of the B cell to antigen. While the B cell can be fully triggered to activation without involvement of the CD4 T cell, the differentiation of the B cell to a plasma cell, and especially the class switch from IgM to IgG, requires a signal provided by the CD4 T cell. Importantly, the somatic maturation of B-cell affinity, which depends on the induction of mutation in the B-cell receptor and selection of progeny containing the more avidly binding receptors, also requires CD4 T-cell help. The interaction is mediated by a regulatory cell–cell interaction that is somewhat similar to that between CD28 and B7. The B cell constitutively expresses CD40 molecules and stimulation through this molecule by an activated CD4 T cell bearing the CD40 ligand molecule is necessary for induction of these two features of B-cell differentiation. The CD40 ligand molecule is transiently expressed on the CD4 T cell for several hours following activation of the T cell. This requirement for cognate interaction between a B cell and a CD4 T cell responding to the same antigen is an essential mechanism to give specificity to the immune response. While T-cell cytokines such as IL-4 assist in this process, the cell–cell interaction is the biologically relevant control of B-cell differentiation. This interaction between B cell and T cell occurs in the germinal center of the lymph node. It appears that each germinal center is organized around the interaction of a particular clone of CD4 T cells and a clone of B cells undergoing class switching and somatic mutation.

One subset of CD4 T cells, designated the T_h2 T cell, appears particularly specialized to engage in this interaction. The T_h2 T cell is stimulated by peptides presented by MHC class II molecules on the B cell. In turn, it becomes activated, expresses CD40 ligand molecules, and secretes IL-4, IL-5, IL-10, and IL-13, fostering high-affinity IgG antibody production by the B cell. The decay of expression of CD40 ligand on the T_h2 T cell stops the provision of the cognate help activity.

A second subset of CD4 T cells, designated the T_h1 T cell, is primarily involved in either activating macrophages via secretion of IFN- γ or in inducing the differentiation of precursor CD8 T cells to cytolytic effector CD8 T cells. The most characteristic difference between T_h1 and T_h2 CD4 T cells is that T_h1 T cells secrete IFN- γ upon stimulation, while T_h2 T cells secrete IL-4 and related B-cell cytokines. Analogously to the interaction of the T_h2 cell, the T_h1 cell is capable of reacting to antigen presented by the macrophage by in turn fostering further specific activation of the presenting macrophage. T_h1 cells also secrete abundant IL-2. The second role of the CD4 T cell in inducing the differentiation of the CD8 T cell is, however, primarily carried out on the surface of dendritic cells, forming a three-cell complex. The CD40–CD40 ligand system also plays a critical role in these cognate interactions, with the activated CD4 T_h1 cell also transiently expressing the CD40 ligand molecule.

The development of a given CD4 T cell to acquire the T_h1 or T_h2 phenotype is a property of the cytokine milieu and is possibly influenced by the intensity of the signaling through the TCR. Members of a given CD4 T-cell clone can differentiate to either T_h1 or T_h2 status. The presence of IL-12 results in a naive T cell acquiring the T_h1 phenotype, while the presence of IL-4 fosters the development of the T_h2 phenotype. The activation status of the cells of the innate immune system plays a major role in this determination, with activated macrophages or dendritic cells a source of IL-12, whereas NK cells are a source of IL-4.

FORMATION OF THE ADAPTIVE IMMUNE SYSTEM LYMPHOCYTE REPERTOIRES

The enormous size of the initial repertoire of clones bearing different T- and B-cell antigen–specific receptors necessitates that they each be developed by a somatic mechanism in which a limited series of gene elements are joined in a diversification process that produces well in excess of 10^{15} different clones. Otherwise, there is insufficient germ line DNA in a cell to encode these repertoires. The Ig heavy chain and the T-cell β chain are each assembled from four different gene elements: V (variable), D (diversity), J (joining), and C (constant). The Ig light chain and the T-cell α chain are assembled from V, J, and C elements. One level of diversity comes from the selection of various combinations of elements to make up a given receptor chains as shown in [Figure 5.1](#). A second and much greater form of diversification, called junctional diversity, comes about because junctional events that bring together the V, D, and J elements involve nibbling back by exonucleases and addition of nucleotides not encoded in the germ line. This results in chains that differ in size from another by 10 or more amino acids. The somatically created junctional region in the T-cell receptor interacts specifically with the peptide in the MHC molecule.

The B-cell repertoire is formed initially in the bone marrow and subsequently refined to higher affinity interactions during the immune response in the germinal centers. The B-cell tolerance and repertoire formation is less clearly etched and appears far less stringent than T-cell repertoire formation. Indeed, a major form of B-cell clonal regulation is performed by the cognate interaction with CD4 T cells. A large proportion of the receptors of the B-cell repertoire are potentially reactive with self-molecules, as can be demonstrated by the production of autoantibodies by many B cells during infection of the B cell by Epstein–Barr virus. Presumably, this event does not generate a sustained autoimmune disease because T-cell help is not forthcoming.

The T-cell repertoire is generated and stringently selected in the thymus. Somatic mutation is not permitted. Precursor T cells, lacking CD4 and CD8 molecules, begin by rearranging their β chains. If this is successfully done in frame, the β chain pairs with a monomorphic precursor T α chain. This event shuts off the recombination process, excluding the rearrangement of a second β chains (allelic exclusion). The clone expands about 100-fold, at which time α -chain rearrangement is initiated in a successive wave of recombinase activity. At this time, if the rearrangement is successful, the T cell expresses a functional $\alpha\beta$ receptor in association with CD3. The CD4 and CD8 molecules are expressed (double positive) and the cell is subjected to the processes of selection to determine whether the receptor is better suited at recognizing peptides in the context of the individual's class I or class II MHC molecules. If the T cell recognizes a self-peptide in a class I MHC molecule, the cell is signaled to express only CD8 molecules; reciprocally, if it recognizes self-peptides in the context of class II MHC, it will then express only CD4. If the cell is not positively selected by either route, it undergoes apoptosis. Excessively self-reactive T cells are eliminated centrally by negative selection, but this negative selection does not eliminate the potential for all self-reactivity, since the remaining 10^{12} T cells have been selected with a self-peptide.

Subsequently, in the immune response to a microorganism or virus, a number of different T-cell clones are expanded, including ones drawn from different V-region families and characterized by variable junctional patterns. Certain microorganisms contain molecules that bind specific sequences on particular V regions. For example, the staphylococcal exotoxin TSST, which mediated the toxic shock syndrome, binds specifically to all T-cell receptors that have been derived from the V gene designated BV2 (Vb2). The clinical syndrome is produced by the massive release of a variety of cytokines by all BV2 CD4 and CD8 T cells. Repertoire analysis is proving to give valuable insight into the clonal immune recognition events in immunologic disorders.

AUTOIMMUNE DISEASE

Although the capacity to differentiate self from nonself is considered intrinsic to the formation of the immune system during early development, the phenomenon of positive selection on self-peptides lays the basis for the potential development of overtly autoreactive T cells. It is now clear that autoreactive T cells underlie the

development of autoimmune disease by providing help to the switch to IgG isotype and somatic maturation of autoantibody affinity. Thus, autoimmune disease is a reflection of the fact that all T cells used in any immune response have been originally selected on self-peptides. The still unanswered question is what events initiate sustained activation of these T cells in the events leading to the development of an autoimmune disease. The control stage of the two-signal activation requirement and other regulatory check points are bypassed. Two prominent possible mechanisms are activation of a T-cell clone by mimicry of a self-peptide by one in a microorganism and stimulation of a clone by a superantigen. It appears that in all respects the autoimmune response parallels the normal physiologic immune response. The regulatory mechanisms involving CD28 and CD40 ligand appear to be very attractive targets for returning the T cells to a self-tolerant state.

ROLE OF THE MAJOR HISTOCOMPATIBILITY COMPLEX ALLELES IN IMMUNE REGULATION

The alternative allelic forms of the MHC molecules make a critical contribution to diversifying the immune recognition capabilities of a species by endowing each individual with a nearly unique repertoire of T cells that recognizes different peptides. The evolutionary strategy used by the repertoires of immune recognition receptors on CD4 T cells, CD8 T cells, and B cells is to endow each individual with the ability to make any receptor, and before repertoire selection all persons are essentially equivalent. Then this repertoire is selected and edited by events that are dependent on the particular allelic MHC molecules of the individual. The MHC allele differ from one another primarily in a functional sense by the presence of different pockets that preferentially bind different amino acids and hence different peptides. The particular MHC molecules that a person inherits select the particular self-peptides to be bound. The complex of the individual's MHC molecules and self-peptides preferentially bound, in turn, selects the T-cell clones that comprise the CD4 and CD8 T-cell repertoires. [Figure 5.2](#) shows the organization of the class I and II genes of the MHC. The alleles, which are not shown, are numbered and grouped according to the major serologic specificity (e.g., DR1, DR2, B8, B27) that is encoded by the allele. The designation of the allele includes the locus, an asterisk followed by two digits describing the serologic specificity, and an additional two digits referring to the particular allele that reflects the order in which the allele was identified by gene sequencing, e.g., HLA-DRB1*0101 or HLA-B*2705.

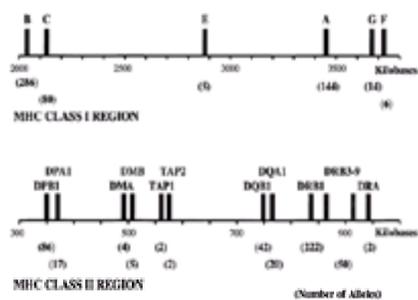

FIGURE 5.2. The organization of class I and II major histocompatibility complex genes. The class II region is centromeric to the class I region on the short arm of the sixth chromosome. The current number of alleles is indicated in parentheses. The genes of the class II region are not shown.

As an example, in the class I MHC molecule, the peptide is linearly splayed out, with its NH₂ terminus at the left and COOH terminus to the right. An important pocket in the MHC class I molecule is formed by the polymorphic amino acids that define the different class I alleles. This pocket is located at the upper left portion of the peptide binding groove, under the α -helical portion of the α chain. This pocket, termed the "B" pocket, binds the side chain of what is usually the second amino acid in the antigenic peptide, and it is the major determinant of the specificity of a class I allele for different peptides. For example, this pocket in an HLA-B35 molecule (HLAB*3501) has a narrow hydrophobic shape and preferentially binds peptide antigens with proline at this position. The HLA-B27 (HLAB*2705) molecule has a very hydrophilic pocket with a negative charge at its base, making it likely to bind a peptide with a positively charged lysine or arginine at this position. The universe of peptides seen by T cells in an HLA-B27 molecule nearly all have arginine at position 2, while the very different universe of peptides presented by an HLA-B35 molecule mainly have proline at this position. Other pockets define a second set of specificities for the side chains of the peptide COOH terminus. The positively selected T-cell repertoires of individuals with these two HLA types are, as a result, different. This is the basis of the phenomenon of MHC restriction, which means that the T-cell repertoire selected in an HLA-B27 person is incapable of recognizing a peptide presented in the context of an HLA-B35 molecule and vice versa.

The marked influence that class I or II MHC alleles have on the susceptibility to develop autoimmune disease is a reflection of the repertoire of self-peptides that can be bound and the recognition properties of the T-cell receptors selected by them in the positive selection phase of repertoire formation. For this reason, considerable insight can be gained into a distinctive and potentially pathogenic mechanism by measuring the HLA alleles shared by individuals with a particular disease. There are currently 222 HLA-DRB1 alleles, 286 HLA-B alleles, and 144 HLA-A alleles ([Figure 5.2](#)). In contrast with the situation in the MHC class I molecule, class II MHC molecules have their most important allele-associated binding pockets nearer to the center of the peptide. This point is emphasized by the "shared epitope" susceptibility motif in the region of the fourth amino acid side chain (P4) that confers susceptibility to rheumatoid arthritis. The several alleles (DRB1*0401, 0404, 0101, etc.) that encode positively charged residues in the rim of this pocket on the b chain appear to influence both the T-cell repertoire and the binding of a self-peptide with a negatively charged amino acid in position 4.

If there were no MHC alleles, the resulting state of immunity would be optimized against one set of foreign molecules or peptides. This, from the viewpoint of a microorganism, would be a Maginot line of static defense against which the bacterium or virus would employ its mutational diversity to find a point of vulnerability. For example, a microorganism could mutate to create a peptide sequence that was inefficiently bound or presented by the monomorphic MHC molecule, thus evading recognition and overwhelming the species. Indeed, this unfortunate event does occur in some individuals with chronic HIV infection who are not able to bind functionally critical parts of the virus, leading to the development of escape mutants that can no longer be recognized and controlled by the immune system.

In addition to the use of MHC alleles, another strategy used by the species is to increase the number of different kinds of MHC molecules on the cells of an individual through duplication of class I and II loci. This evolutionary strategy results in the presence on a typical somatic cell of three kinds of classic MHC class I and class II molecules: HLA-A, HLA-B, and HLA-C, and HLA-DR, HLA-DQ, and HLA-DP ([Figure 5.2](#)). The total of 12 to 14 different types of MHC molecules is near the point of diminishing returns for the repertoire. Further numerical increases in different MHC species in an individual would diminish the size of the T-cell receptor repertoire because autoreactivity must be avoided at the price of deleting an increasingly larger proportion of the repertoire.

pathogenesis of scleroderma, pulmonary fibrosis, and other fibrotic conditions.

INFLAMMATORY MEDIATORS

Cytokines are composed of a broad spectrum of soluble mediators. Apart from interleukins, interferons, and tumor necrosis factors (the first mediators described as cytokines), the discovery of numerous growth factors, colony-stimulating factors, and chemokines (chemotactic cytokines) led to the expansion of the cytokine family (Table 6.1). Mediators of inflammation also contain proteases, reactive oxygen and nitrogen intermediates, membrane lipid-derived mediators, coagulation factors, components and regulators of the complement cascade, and neuropeptides, among others.

INTERLEUKINS

At present, the interleukin family has at least 18 members. Most of them have been associated with inflammation. Interleukins 3, 4, 6, and 11 are involved in neutrophil and monocyte/macrophage development, whereas IL-1, IL-2, IL-4, IL-5, IL-6, IL-7, IL-11, and IL-13 are important for thymocyte/T-lymphocyte differentiation, as well as B- and plasma cell maturation. Interleukins 3 and 5 are also involved in mast cell and eosinophil development, respectively. The role of interleukins in various inflammatory processes will be described later. Briefly, IL-1 and IL-8 are major proinflammatory cytokines. Interleukin 1 exerts a variety of systemic and local proinflammatory effects as it is involved in matrix metabolism by stimulating MMP production, thereby stimulating angiogenesis and cell adhesion molecule expression. IL-8, also a C-X-C chemokine, is chemotactic for neutrophils. In contrast, IL-4, IL-10, and IL-13 inhibit most mechanisms underlying inflammation. Interleukins 6 and 11 have disparate, both pro- and anti-inflammatory effects in chronic inflammation. IL-2 plays a role in T-cell growth and activation. Interleukin 15 exerts IL-2-like activities. The recently described IL-16, IL-17, and IL-18 are involved in T-cell chemotaxis and function.

INTERFERONS

Interferon-g enhances cell adhesion and activates endothelial cells. Both IFN- α and IFN-g inhibit neovascularization and fibrosis.

TUMOR NECROSIS FACTOR α

Tumor necrosis factor α plays a central role in inflammation. Tumor necrosis factor α affects leukocyte extravasation, matrix degradation, and angiogenesis in a way similar to that of IL-1. Tumor necrosis factor α induces the production of a number of other proinflammatory cytokines and chemokines, thus up-regulating the inflammatory response.

COLONY-STIMULATING FACTORS

Granulocyte-macrophage colony-stimulating factor and granulocyte colony-stimulating factor (G-CSF) also exert proinflammatory effects. Apart from mediating leukocyte differentiation and growth, these mediators enhance intercellular adhesion and angiogenesis.

GROWTH FACTORS

A number of these mediators are involved in the inflammatory events, mesenchymal cell proliferation and synovial pannus formation. Yet their key functions in inflammation are stimulation of angiogenesis as well as tissue fibrosis and repair. The major angiogenic growth factors are basic and acidic fibroblast growth factors (bFGF and aFGF), as well as vascular endothelial (VEGF), platelet-derived (PDGF), hepatocyte (HGF), epidermal (EGF), insulin-like (IGF-I), and transforming growth factors (TGF- β). Transforming growth factor β , PDGF, IGF-I, FGFs, and EGF are also fibrogenic. These mediators are produced by macrophages and endothelia.

CHEMOKINES

Chemokines constitute the largest cytokine family, consisting of almost 40 members, which has been classified into at least four distinct supergene families based on their structural homology regarding the location of two of four conserved cysteine residues. Some C-X-C chemokines, such as IL-8, epithelial neutrophil-activating protein (ENA) 78, growth-related oncogene a (groa), grob, and connective tissue-activating protein (CTAP) III are chemotactic for neutrophils, exert proinflammatory effects, and mediate angiogenesis. In contrast, platelet factor 4 (PF4) and IFN-g-inducible protein-10 (IP-10), which belong to the same subfamily of chemokines, are anti-inflammatory and angiostatic mediators. The C-C chemokines, including monocyte chemoattractant protein-1 (MCP-1), macrophage inflammatory protein-1a (MIP-1a), MIP-1b, and the chemokine termed Regulated upon Activation Normally T cell Expressed and Secreted (RANTES) are monocyte chemoattractants, but they may also be chemotactic for T cells, natural killer cells, basophils, and eosinophils. The role of the recently described additional chemokine families termed C and C-X-C3 chemokines in inflammation is still under investigation.

PROTEOLYTIC ENZYMES

Matrix metalloproteinases, including collagenase, gelatinase, and stromelysin, are crucial mediators of tissue destruction. Proinflammatory cytokines, such as IL-1 and TNF- α , stimulate, whereas anti-inflammatory cytokines, such as IL-4, IL-10, and IL-13, inhibit MMP secretion. Other important enzymes include hyaluronidase, cathepsins, lysozyme, angiotensin convertase, and others.

OTHER INFLAMMATORY MEDIATORS

Reactive oxygen and nitrogen intermediates, such as O_2^- , H_2O_2 , OH, NO, NO_2 , and NO_3 , as well as membrane lipid-derived mediators, such as prostaglandins E_2 , F_{2a} , leukotrienes, prostacyclin, and PAFs, are produced by macrophages. The activation of the complement system results in the production of anaphylatoxins, such as C5a. Neuropeptides including substance P, somatostatin, vasoactive intestinal polypeptide, and nerve growth factor trigger mast cells to secrete histamine. All of these mediators play an important role in tissue destruction and immediate hypersensitivity reactions.

MAJOR BALANCE MECHANISMS IN INFLAMMATION

There is a balance of mediators in inflammation based on feedback mechanisms and the opposing effects of these soluble factors. The net outcome of the inflammatory response depends on the balance or imbalance between these mediators on the levels of cell adhesion, migration, angiogenesis, tissue destruction, and fibrosis (Table 6.1; Fig. 6.1).

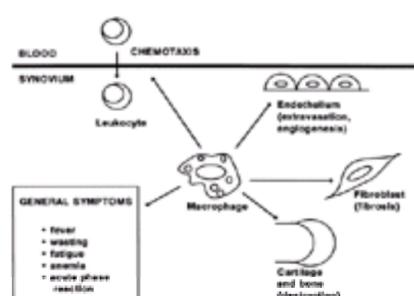

FIGURE 6.1. Interactions between inflammatory cells via mediators in inflammation. This figure represents an example of this intercellular communication existing in the inflamed synovial tissue in rheumatoid arthritis.

INTERCELLULAR ADHESION AND ADHESION MOLECULE EXPRESSION

Leukocyte extravasation into tissues occurs in four distinct steps. The initial, relatively weak adhesion to endothelium termed "rolling," which is mediated by selectins, triggers leukocyte activation due to the interactions between chemokine receptors on leukocytes and proteoglycans on endothelial cells. Then activation-dependent, firm adhesion occurs; this interaction is mediated by integrins. Finally, transendothelial migration or diapedesis occurs when secreted chemokines bind to endothelial proteoglycans. Chemokines attract endothelium-bound neutrophils and mononuclear leukocytes. Among cytokines, IL-1, TNF- α , IL-4, and IFN- γ stimulate the expression of most endothelial adhesion molecules and therefore leukocyte extravasation. Interleukins 12 and 15 have also been found to enhance T-cell recruitment under certain conditions. Cell contact itself may also up-regulate adhesion molecule expression, which is highly TNF- α -dependent. In contrast, anti-inflammatory cytokines, such as IL-10 and IL-13, may under various conditions stimulate or inhibit leukocyte-endothelial adhesion and endothelial adhesion molecule expression. Transforming growth factor β also exerts disparate effects on adhesion, as it locally induces integrin expression on leukocytes but may down-regulate adhesion molecule expression on endothelial cells.

PROINFLAMMATORY AND ANTI-INFLAMMATORY MEDIATORS

Interleukin 1, IL-8, and TNF- α have been termed major pro-inflammatory cytokines, as these mediators stimulate most mechanisms in inflammation including cell proliferation and activation, adhesion, chemotaxis, angiogenesis, as well as cartilage and bone destruction. Interleukin 6, the IL-6-like IL-11, and oncostatin M, as well as TGF- β , have both stimulatory and inhibitory effects in inflammation. The T_H2-type cytokines IL-4, IL-10, and IL-13 suppress the T_H1-type response, the production of proinflammatory cytokines, and inflammatory cell emigration. In addition, they increase the synthesis of IL-1Ra, and inhibit the release of proteolytic enzymes. As described above, certain chemokines, such as PF4 and IP-10, may also inhibit crucial events in inflammation.

ANGIOGENESIS

The formation of new vessels leads to the perpetuation of leukocyte emigration. Most growth factors, such as aFGF, bFGF, VEGF, HGF, PDGF, EGF, and IGF-I, the cytokines TNF- α , IL-1, IL-6, and IL-15, as well as some C-X-C chemokines containing the ELR amino acid sequence including IL-8, ENA-78, groa, grob, and CTAP-III are potent inducers of angiogenesis. In a dose-dependent fashion, TGF- β stimulates or inhibits neovascularization. The major angiostatic mediators are IFN- α , IFN- γ , IL-4, IL-12, and the chemokines PF4 and IP-10.

TISSUE DESTRUCTION

Interleukin 1 and TNF- α are the main proinflammatory and destructive cytokines. Both cytokines stimulate the production of MMPs. Tissue inhibitors of metalloproteinases (TIMPs) oppose the effects of the proteolytic enzymes. Thus, IL-4, IL-10, and IL-13, cytokines stimulating the synthesis of TIMPs, may also prevent tissue injury.

FIBROSIS AND REPAIR

A number of growth factors, such as TGF- β , PDGF, aFGF, bFGF, IGF, and EGF, stimulate fibroblast activation, the transcription of collagen mRNA, and extracellular matrix deposition. Among other "fibrogenic" cytokines, IL-1, IL-4, and TNF- α have been shown to activate fibroblasts, although they are less potent than growth factors. The C-X-C chemokine CTAP-III also stimulates connective tissue metabolism. Cytokines that may directly inhibit collagen production in vitro include EGF, IFN- α , and IFN- γ .

CLINICAL RELEVANCE

Therapeutic intervention targeting these balance mechanisms may influence the outcome of inflammation ([Fig. 6.1](#)). There are a number of ongoing trials using agents to suppress the effects of pro-inflammatory mediators or to enhance the anti-inflammatory response.

CHAPTER 7: MECHANISMS OF HORMONE ACTION

DARYL K. GRANNER

[Target Cell Concept](#)
[Hormone Receptors](#)
[Classification of Hormones](#)
[Mechanism of Action of Group I Hormones](#)
[Mechanism of Action of Group II Polypeptide Hormones](#)

Multicellular organisms employ intercellular communication mechanisms to coordinate the responses necessary for adjusting to a constantly changing external and internal environment, thereby ensuring their survival. Two convergent systems comprising several highly differentiated tissues have evolved to serve these functions. The nervous system conducts signals or messages through a fixed structural system, although the final mediator may be a neurotransmitter substance released from a nerve ending. The endocrine system uses mobile messages, called *hormones*, to alter cellular function. Neurotransmitters and hormones share certain structural similarities and often have common mechanisms of action; these two systems converge. This chapter briefly describes the concepts and principles necessary for understanding how hormones work.

TARGET CELL CONCEPT

There are approximately 200 types of differentiated cells in humans. Only a few of these produce hormones, but virtually all of the 75 trillion cells in each human being are targets of one or more of the 50 or so known hormones.

The concept of target cells is undergoing redefinition. It was originally thought that hormones affected a single cell type or a few different kinds of cells, and that a hormone elicited a unique biochemical or physiologic action. With the delineation of specific cell surface and intracellular hormone receptors, the definition of a target has been expanded to include any cell in which the hormone binds to its receptor, whether or not a biochemical or physiologic response has been determined. This definition also is imperfect, but it has heuristic merit because it assumes that not all actions of hormones have been elucidated.

The response of a target cell is determined by the differentiated state of the cell, and a cell can respond in several ways to a single hormone. Cells can also respond to a given hormone in an endocrine (i.e., distant regulation), paracrine (i.e., adjacent regulation), or autocrine (i.e., self-regulation) fashion. Several factors determine the overall response of a target cell to a hormone. The concentration of a hormone around the target cell depends on five factors: the rate of synthesis and secretion of the hormone; the proximity of target and source; the association–dissociation constants of the hormone with specific plasma carrier proteins, if the latter exist; the rate of conversion of an inactive or suboptimally active form of the hormone into the active form; and the rate of clearance of the hormone from blood by other tissues or from degradation or excretion. The actual response to the hormone depends on (a) the relative activity or state of occupancy, or both, of the specific hormone receptors on the plasma membrane or within the cytoplasm or nucleus, and (b) the rate of metabolism of the hormone in the target cell and postreceptor desensitization of the cell. Alterations of any of these processes can result in a change of the hormonal activity on a given target cell and must be considered in addition to the classic feedback loops.

HORMONE RECEPTORS

One of the major challenges in making the hormone-based communication system work is that these molecules are present at low concentrations in the extracellular fluid, generally in the range of 10^{-15} to 10^{-9} mol per L. This is much lower than that of the many structurally similar molecules (e.g., sterols, amino acids, peptides, proteins) and a variety of other molecules that circulate at concentrations in the range of 10^{-6} to 10^{-3} mol per L. Target cells must differentiate between different hormones present in small amounts and between a given hormone and the 10^6 - to 10^9 -fold excess of other molecules. This high degree of discrimination is provided by recognition molecules called *receptors*, which are protein molecules located in the plasma membrane or within the target cell. Hormones initiate their biologic effects by binding to specific receptors, and because any effective control system must also provide a means of stopping a response, hormone-induced actions begin to terminate when the effector dissociates from the receptor.

RECOGNITION AND COUPLING DOMAINS

All polypeptide and steroid receptors have at least two functional domains, and most have several more. A recognition domain binds the hormone, and a second region generates a signal that couples hormone recognition to some intracellular function. The binding of hormone by receptor implies that some region of the hormone molecule has a conformation that is complementary to a region of the receptor molecule. The degree of similarity, or fit, determines the tightness of the association; this is measured as the affinity of binding (K). If the native hormone has a relative K value of 1, other natural molecules range between 0 and 1. In absolute terms, this actually spans a binding affinity range of more than a trillion.

Coupling (i.e., signal transduction) occurs in two general ways. Polypeptide hormones, protein hormones, and catecholamines bind to receptors located in the plasma membrane, and binding generates a signal that regulates various intracellular functions. Steroid, sterol, and thyroid hormones interact with intracellular receptors, and this complex provides the signal. The recognition and coupling functions generally reside in a single molecule, and these dual functions ultimately define a receptor. It is the coupling of hormone binding to signal transduction, the *receptor–effector coupling*, that provides the first step in the amplification of the hormonal response. This dual purpose also differentiates the target cell receptor from the plasma carrier proteins that bind hormone but generally do not generate a signal.

RELATION BETWEEN RECEPTOR OCCUPANCY AND BIOLOGIC EFFECT

The concentrations of hormone required for occupancy of the receptor and for elicitation of a specific biologic response often are similar (Fig. 7.1A), such as steroid hormone induction of enzymes. This is especially true for steroid hormones, but some polypeptide hormones also exhibit this characteristic. This tight coupling is remarkable, considering the many steps that must occur between hormone binding and complex responses such as transport, enzyme induction, cell lysis, or cell replication. When receptor occupancy and biologic effect are tightly coupled, significant changes in the latter occur if receptor occupancy changes. This happens when fewer receptors are available or when the affinity of the receptor changes but the hormone concentration remains constant. In other instances, there is a marked dissociation of binding and effect, producing a maximal biologic effect despite the fact that only a small percentage of the receptors are occupied (Fig. 7.1B, effect 2), as is the case for most aspects of insulin action. Different responses within the same cell can require various degrees of receptor occupancy. For example, successively greater degrees of occupancy of the adipose cell insulin receptor increase, in sequence, lipolysis, glucose oxidation, amino acid transport, and protein synthesis.

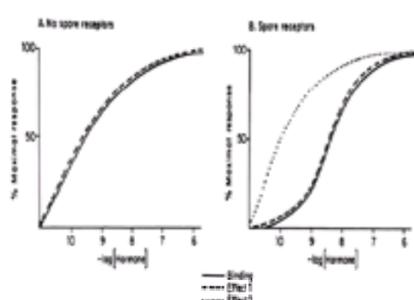

FIGURE 7.1. Hormone binding and biologic effects are compared in the absence (A) and presence (B) of spare receptors. Some biologic effects in a tissue may be tightly coupled to binding; another effect shows the spare receptor phenomenon (compare effects 1 and 2 in B). (Adapted from Murray RK, Granner DK, Mayes PA, et

Receptors not involved in eliciting a response are said to be *spare receptors*. Spare receptors are observed in the response of several polypeptide hormones and are thought to provide a means of increasing the sensitivity of a target cell to activation by low concentrations of hormone and to provide a reservoir of receptors. The concept of spare receptors is operational, and it might depend on which aspect of the response is examined and which tissue is involved. For example, there is excellent agreement between luteinizing hormone binding and cAMP production in rat testis and ovarian granulosa cells (there are generally no spare receptors when any hormone activates adenylate cyclase), but steroidogenesis in these tissues, which is cAMP-dependent, occurs when fewer than 1% of the receptors are occupied (compare effect 1 with effect 2 in [Fig. 7.1](#)).

AGONIST-ANTAGONIST CONCEPT

Molecules can be divided into four groups with respect to their ability to elicit a given hormone receptor-mediated response: agonists, partial agonists, antagonists, and inactive agents. *Agonists* elicit the maximal response, although different concentrations may be required ([Fig. 7.2](#), line A). *Partial agonists* evoke an incomplete response, even when large concentrations of the hormone are employed (see [Fig. 7.2](#), line B). *Antagonists* generally have no effect themselves, but they competitively inhibit the action of agonists or partial agonists (see [Fig. 7.2](#), line A + C and line B + C). A large group of structurally similar compounds elicit no effect at all and have no effect on the action of the agonists or antagonists. These are classified as *inactive agents* and are represented in [Figure 7.2](#), line D.

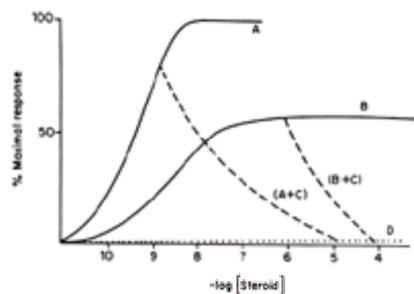

FIGURE 7.2. Classification of hormones according to their biologic activity. Steroids, for example, can be classified as agonists (*line A*), partial agonists (*line B*), antagonists (*C in A + C or B + C*), or inactive agents (*dotted line D*). (Adapted from Murray RK, Granner DK, Mayes PA, et al. *Harper's biochemistry*, twenty-second ed. East Norwalk, CT: Appleton & Lange, 1990.)

Partial agonists also compete with agonists for binding to and activation of the receptor, in which case they become partial antagonists. The extent of the inhibition of agonist activity caused by partial or complete antagonists depends on the relative concentration of the various steroids. Generally, much higher concentrations of the antagonist are required to inhibit an agonist than are necessary for the agonist to exert its maximal effect. Because such concentrations are rarely achieved *in vivo*, this phenomenon usually is employed for studies of the mechanism of action of glucocorticoid hormones *in vitro*.

REGULATION OF RECEPTORS

Receptors are in a dynamic state. They can be regulated physiologically, or they can be influenced by diseases or therapeutic measures. Receptor concentration and the affinity of hormone binding can be regulated. These changes can be acute and can significantly affect hormone responsiveness of the cell. For instance, cells exposed to β -adrenergic agonists for minutes to hours no longer activate adenylate cyclase in response to the addition of agonist, and the biologic response is lost. This particular desensitization occurs by the loss of receptors from the plasma membrane and by covalent modification, with corresponding inactivation, of these receptors by phosphorylation. Other examples of physiologic adaptation that is accomplished through *down-regulation* of receptor number by the homologous hormone include insulin, glucagon, thyrotropin-releasing hormone, growth hormone, luteinizing hormone, follicle-stimulating hormone, and catecholamines. A few hormones, such as angiotensin II and prolactin, *up-regulate* their receptors. These changes in receptor number can occur rapidly (minutes to hours) and are probably an important means of regulating biologic responses.

How the loss of receptors affects the biologic response elicited at a given hormone concentration depends on whether there are spare receptors. This can be illustrated by describing the effect a fivefold loss of receptor has on the concentration-response curve in both conditions. With no spare receptors, the maximal response obtained is 20% that of control; the effect is on the V_{max} . With spare receptors, the maximal response is obtained, but at five times the originally effective hormone concentration, analogous to a K_m effect.

RECEPTOR MOVEMENT IN TARGET CELLS

There is little evidence to suggest that peptide hormone-receptor complexes must enter the cell to act. Receptor-mediated endocytosis, analogous to the process used to get low-density lipoprotein particles into cells, occurs with hormones. For example, intact insulin is found within the cell, often in association with lysosomes and other organelles, although this probably represents a degradative or down-regulation pathway. The cytoplasmic and nuclear receptors for steroids and thyroid hormones are a different case because they move between compartments within the cell, probably in response to changes in the intracellular concentration of the hormone.

CLASSIFICATION OF HORMONES

Hormones can be classified according to chemical composition, solubility properties, the location of receptors, or the nature of the signal used to mediate their action within the cell. A classification based on the last two properties is illustrated in [Table 7.1](#), and general features of each group are illustrated in [Table 7.2](#).

(Table content is illegible due to low resolution)

TABLE 7.1. CLASSIFICATION OF HORMONES BY MECHANISM OF ACTION

Feature	Class I	Class II
Types	Steroids Iodothyronines Calcitriol	Polypeptides Proteins Glycoproteins Catecholamines
Solubility	Lipophilic	Hydrophilic
Transport proteins	Yes	No
Plasma half-life	Long (hours to days)	Short (min)
Receptor	Intracellular	Plasma membrane
Mediators	Receptor hormone complex	cAMP, Ca ²⁺ , phosphatidylinositides, diacylglycerol, cGMP, protein kinase cascade

TABLE 7.2. GENERAL FEATURES OF HORMONE CLASSES

The hormones in group I are lipophilic and, with the exception of 3,5,3'-triiodothyronine (T₃) and thyroxine (T₄), are derived from cholesterol. After secretion, these hormones associate with transport proteins, a process that circumvents the solubility problem while prolonging the plasma half-life. These hormones readily traverse the plasma membrane of all cells and encounter receptors in the cytosol or in the nucleus of target cells. The ligand–receptor complex is assumed to be the intracellular messenger in this group.

The second major group consists of water-soluble hormones that bind to the plasma membrane of the target cell. Such hormones regulate intracellular metabolic processes through intermediary molecules, called *second messengers* (the hormone itself is the first messenger), which are generated as a consequence of the ligand–receptor interaction. Hormones that employ cAMP as the second messenger are shown in [Table 7.1](#). The atriopeptins use cGMP as a second messenger, as do other potent nonhormonal substances, including nitric oxide and nitroglycerin. Several hormones use calcium or phosphatidylinositide metabolites (or both) as the intracellular signal. Several hormones have been found to mediate biologic effects by initiating a protein kinase cascade. A few hormones fit in more than one category; for example, there is increasing evidence that some hormones act through cAMP and Ca²⁺.

MECHANISM OF ACTION OF GROUP I HORMONES

The lipophilic molecules of group I hormones diffuse through the plasma membrane of all cells but only encounter their specific, high-affinity receptor within target cells. The hormone–receptor complex then undergoes an activation reaction that results in size, conformation, and surface charge changes that allow it to bind to DNA. In some cases—the glucocorticoid receptor for example—this process involves the disruption of a receptor–heat-shock protein complex. Whether the association and activation processes occur in the cytoplasm or the nucleus appears to depend on the specific hormone in question. The hormone–receptor complex binds to specific regions of DNA called hormone response elements (HREs), and this initiates the assembly of a multicomponent complex that regulates the rate of transcription of specific genes. By selectively affecting gene transcription and production of the respective mRNAs, the amounts of specific proteins are changed, and metabolic processes are influenced. The effect of each of these hormones is specific; generally the hormone affects fewer than 1% of the proteins or mRNAs in a target cell.

In recent years it has become apparent that a simple HRE is not sufficient to mediate the effects of a hormone on a specific gene. Genes have at least two separate regulatory regions in the DNA sequence immediately 5' of the transcription initiation site. The first of these, the basal promoter element (BPE), is generic because it is present in some form in all genes. The BPE generally contains the TATA box and one or more additional DNA elements. The BPE specifies the site of RNA polymerase II attachment to DNA and therefore the accuracy of transcription initiation.

A second regulatory region is located slightly farther upstream than the BPE and this may also consist of several discrete elements. This region modulates the frequency of transcript initiation and is less dependent on position and orientation. In these respects, it resembles the transcription enhancer elements found in other genes. The regulatory region consists of two types of DNA elements in genes that respond to hormones. The HREs described above are short segments of DNA that bind a specific hormone receptor–ligand complex. The GRE binds the ligand–glucocorticoid receptor complex, the ERE binds the ligand–estrogen receptor complex, etc. The HREs are often capable of regulating transcription from test promoter–reporter gene constructs, but in most physiologic circumstances other DNA element–protein complexes are required.

The HRE must interact with other elements (and associated binding proteins) to function optimally. Such assemblies of cis-acting DNA elements and trans-acting factors are called *hormone response units* (HRUs) or *composite elements*. An HRU therefore consists of one or more HREs and one or more DNA elements with associated accessory factors ([Fig. 7.3](#)). In complex promoters—regulated by a variety of hormones—certain accessory factor components of one HRU (glucocorticoid) may be part of that for another (cAMP). This arrangement may provide for the hormonal integration of complex metabolic responses.

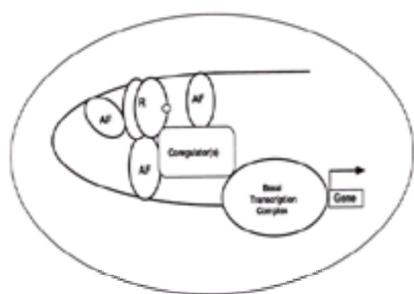

FIGURE 7.3. The hormone response unit, an assembly of DNA elements and bound proteins. An essential component is the hormone response element with ligand-bound receptor. Also important are the accessory factor (AF) elements with bound transcription factors. More than two dozen of these accessory factors have been linked to hormone effects on transcription. The AFs can interact with each other or with the nuclear receptors. The components of the hormone response unit communicate with the basal transcription machinery through a coactivator complex. (Adapted from Murray RK, Granner DK, Mayes PA, et al. *Harper's biochemistry*, twenty-fifth ed. East Norwalk, CT: Appleton & Lange, 1999.)

The communication between an HRU and the basal transcription apparatus is facilitated by coregulator molecules ([Fig. 7.3](#)). The first of these described was the CREB-binding protein, so-called CBP. This protein, through an amino terminal domain, binds to phosphorylated serine 137 of CREB and facilitates transactivation in response to cAMP. It thus is described as a coactivator. The CREB-activating protein and its close relative, p300, interact with a number of signaling molecules, including activator protein–1 (AP-1), signal transducers and activators of transcription (STATS), nuclear receptors, and CREB.

The CREB-binding protein/p300 also binds to the p160 family of coactivators described below and to a number of other proteins. Some of the many actions of CBP/p300 appear to depend on intrinsic enzyme activities and the ability of this protein to serve as a scaffold for the binding of other proteins. It is important to note that CBP/p300 also has intrinsic histone acetyltransferase (HAT) activity. The importance of this is described below. Three other families of coactivator molecules, all of about 160 kd, have been described. These members of the p160 family of coactivators include (a) SRC-1 and NCoA-1; (b) GRIP 1, TIF2, and NCoA-2; and (c) p/CIP, ACTR, AIB1, RAC3, and TRAM-1.

The role of these many coactivators is still evolving. It appears that certain combinations are responsible for specific ligand-induced actions through various receptors. The role of HAT is particularly interesting. Mutations of the HAT domain disable many of these transcription factors. Current thinking holds that these HAT activities acetylate histones and result in the remodeling of chromatin into a transcription-efficient environment. In keeping with this hypothesis, histone deacetylation is

associated with the inactivation of transcription.

In certain instances, the removal of a corepressor complex through a ligand–receptor interaction results in the activation of transcription. For example, in the absence of hormone, the thyroid or retinoic acid receptors are bound to a corepressor complex containing N-CoR or SMRT and associated proteins, some of which have histone deacetylase activity. The target gene is repressed until the binding of hormone to the thyroid receptor results in the dissociation of this complex, and gene activation then ensues.

The nuclear actions of steroid hormones are reasonably well defined, but direct actions of these hormones in the cytoplasm and on various organelles and membranes have also been described. Although steroid hormones affect nuclear mRNA processing, mRNA degradation rates, and post-translational processing, most evidence suggests that these hormones exert their predominant effect on the transcription of specific genes.

MECHANISM OF ACTION OF GROUP II POLYPEPTIDE HORMONES

The majority of hormones are water-soluble, have no transport proteins (with the exception of insulin-like growth factors IGF-I and IGF-II), and therefore have a short plasma half-life. They initiate a response by binding to a receptor located in the plasma membrane, an interaction that results in the generation of an intracellular signal or messenger that then mediates the action of the hormone (Table 7.1 and Table 7.2). The mechanisms of action of this group of hormones can be discussed best in terms of their intracellular messengers.

CYCLIC AMP AS THE SECOND MESSENGER

Cyclic AMP, a ubiquitous nucleotide derived from ATP through the action of the enzyme adenylate cyclase (located on the inner surface of the plasma membrane), plays a crucial role in the action of several hormones. The intracellular level of cAMP is increased or decreased by various hormones that activate or inactivate adenylate cyclase (Table 7.3). This process is mediated by at least two types of GTP-dependent regulatory protein complexes, designated G_s (stimulatory) and G_i (inhibitory). Hormones that bind to receptors coupled to G_s activate adenylate cyclase and increase cAMP production, and hormones that bind to receptors coupled to G_i decrease cAMP production. G_q is a pertussis-resistant G protein that can activate phosphoinositidase C.

Hormones That Stimulate Adenylate Cyclase (G_s)
Adrenocorticotropic hormone
Antidiuretic hormone
β -Adrenergics
Calcitonin
Corticotropin stimulating hormone
Follicle stimulating hormone
Glucagon
Human chorionic gonadotropin
Luteinizing hormone
Lipotropin
Melanocyte-stimulating hormone
Parathyroid hormone
Thyroid stimulating hormone
Hormones That Inhibit Adenylate Cyclase (G_i)
α_2 -Adrenergics
Acetylcholine (muscarinic)
Angiotensin II
Opioids
Somatostatin

TABLE 7.3. SUBCLASSIFICATION OF GROUP II HORMONES FOR WHICH THE SECOND MESSENGER IS cAMP

The components of the cyclase system have been purified, revealing a large family of G proteins. The G-protein complexes are heterotrimers consisting of α , β , and γ peptide chain subunits. There are at least 16 α subunits, 6 β subunits, 12 γ subunits, and 8 different adenylate cyclases, so that many different combinations are possible. The α subunit, active when bound to GTP, contains an intrinsic GTPase activity that hydrolyzes GTP to GDP. The α subunit is inactive when bound to GDP, providing a tightly regulated on–off mechanism. The α subunits, in addition to regulating adenylate cyclase activity, can also regulate ion channel activity. Some forms of α_s stimulate K^+ channels and inactivate Ca^{2+} channels, and some α_i isoforms inhibit K^+ channels and activate Ca^{2+} channels. The G_q heterocomplexes activate phospholipase C. The $\beta\gamma$ -subunit complexes have also been shown to activate K^+ channels and phospholipase C. In addition to hormone-regulated metabolic processes, such as gluconeogenesis, lipolysis, and glycogenolysis, G proteins are involved in many other important and diverse biologic processes, including neuronal activity, heart rate, blood pressure control, muscle contraction, cell replication, vision, and smell.

In eukaryotic cells, cAMP activates a protein kinase that is a heterotetrameric molecule consisting of two regulatory subunits (R) and two catalytic subunits (C). cAMP binds to the regulatory subunits and results in the following reaction: $4 \text{ cAMP} + R_2C_2 \rightleftharpoons R_2 \times (4 \text{ cAMP}) + 2C$. The R_2C_2 complex has no enzymatic activity, but the binding of cAMP by R dissociates R from C, thereby activating the latter. The active C subunit catalyzes the transfer of the γ -phosphate of adenosine triphosphate (ATP) in an Mg^{2+} -dependent reaction to a serine or threonine residue in a variety of proteins, resulting in altered activity of the protein.

Reactions caused by hormones in this class can be terminated in several ways, including the hydrolysis of cAMP by phosphodiesterases. The presence of these hydrolytic enzymes ensures a rapid turnover of the signal (cAMP); termination of the biologic process is rapid after the hormonal stimulus is removed. The cAMP phosphodiesterases are themselves subject to regulation by hormones and by intracellular messengers such as calcium, probably acting through calmodulin. Inhibitors of phosphodiesterase, most notably xanthine derivatives (e.g., caffeine, theophylline), increase intracellular cAMP and mimic or prolong the actions of hormones. Another means of controlling hormone action is the regulation of the protein dephosphorylation reaction. The phosphoprotein phosphatases are themselves subject to regulation by phosphorylation–dephosphorylation reactions and by a variety of other mechanisms, often as a consequence of the action of a hormone.

CYCLIC GMP AS THE SECOND MESSENGER

Cyclic GMP is made from GTP by the enzyme guanylate cyclase, which exists in soluble and membrane-bound forms. Each of these isozymes has unique kinetic, physiochemical, and antigenic properties. The atriopeptins, a family of peptides produced in cardiac atrial tissue, cause natriuresis, diuresis, vasodilatation, and inhibition of aldosterone secretion. These peptides (e.g., atrial natriuretic factor) bind to and activate the membrane-bound form of guanylate cyclase. This action increases the concentration of cGMP, by as much as 50-fold in some cases, which is thought to mediate the effects of these peptides.

Other evidence links cGMP to vasodilatation. A series of compounds, including nitroprusside, nitroglycerin, sodium nitrite, and sodium azide, cause smooth muscle relaxation and are potent vasodilators. These agents activate nitric oxide synthase, which catalyzes the formation of nitric oxide. Nitric oxide activates guanylate cyclase, which produces cGMP. The increased cGMP concentration activates cGMP-dependent protein kinase, which phosphorylates several smooth muscle proteins, including the myosin light chain. Presumably, this mechanism is involved in relaxation of smooth muscle and vasodilatation. This reaction is terminated by a specific cGMP-dependent phosphodiesterase, PDE type 5. [PDE5 is the target of sildenafil (Viagra), and this accounts for the smooth muscle relaxation effect of this drug and its activity in erectile dysfunction.]

CALCIUM AND PHOSPHATIDYLINOSITIDES AS SECOND MESSENGERS

Ionized calcium is an important regulator of a variety of cellular processes, including muscle contraction, stimulus–secretion coupling, the blood clotting cascade, enzyme activity, and membrane excitability. It also is an intracellular messenger of hormone action.

A role for ionized calcium in hormone action is suggested by several observations. First, the hormone effect is blunted when tested in Ca^{2+} -free media or when intracellular calcium is depleted. Second, the effect can be mimicked by agents that increase cytosolic Ca^{2+} , such as the Ca^{2+} ionophore A23187. Third, the hormonal effect involves changes of cellular calcium movement. These processes have been studied in some detail in cells of the pituitary, smooth muscle, platelets, and salivary gland, but most is known about how vasopressin and α -adrenergic catecholamines regulate glycogen metabolism in liver.

The extracellular calcium concentration of about 1.2 mmol per L is rigidly controlled. The intracellular free concentration of this ion is much lower, about 100 to 200 nmol per L, and the concentration associated with intracellular organelles is in the range of 1 to 20 μmol per L. Despite this 5000- to 10,000-fold concentration gradient and a favorable transmembrane electrical gradient, Ca^{2+} is restrained from entering the cell. There are three ways of changing cytosolic Ca^{2+} . Certain hormones enhance membrane permeability to Ca^{2+} and thereby increase Ca^{2+} influx. This is probably accomplished by a $3\text{Na}^+/\text{Ca}^{2+}$ exchange mechanism that has a high capacity but a low affinity for Ca^{2+} . There is also a $\text{Ca}^{2+}/2\text{H}^+$ -ATPase-dependent pump that extrudes Ca^{2+} in exchange for H^+ . This has a high affinity for Ca^{2+} but a low capacity, and the mechanism is probably responsible for fine-tuning cytosolic Ca^{2+} concentrations. Ca^{2+} also can be mobilized from or deposited into the mitochondrial and endoplasmic reticulum pools.

The calcium-dependent regulatory protein is now referred to as *calmodulin*, a protein that is homologous to the muscle protein called troponin C in structure and function. Calmodulin has four Ca^{2+} binding sites, and full occupancy of these leads to a marked conformational change that presumably is linked to the ability of calmodulin to activate or inactivate enzymes. The interaction of Ca^{2+} with calmodulin and the resulting change of activity of the latter is conceptually similar to the binding of cAMP to protein kinase and the subsequent activation of this molecule. The cAMP-mediated and Ca^{2+} -mediated systems are linked because calmodulin is involved in regulating various protein kinases and enzymes of cyclic nucleotide generation and degradation (Fig. 7.4).

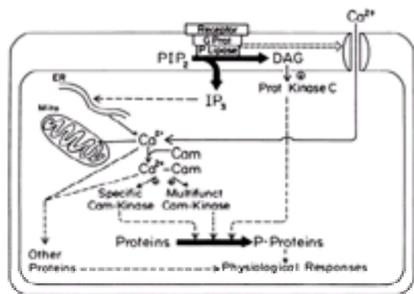

FIGURE 7.4. Mechanisms by which Ca^{2+} -mobilizing agonists exert their effects. G Prot, guanine nucleotide-binding regulatory protein; P Lipase, phospholipase C; PIP_2 , phosphatidylinositol 4,5-bisphosphate; DAG, 1,2-diacylglycerol; IP_3 , *myo*-inositol 1,4,5-trisphosphate; ER, endoplasmic reticulum; Mito, mitochondrion; Cam, calmodulin; Multifunct Cam-Kinase, multifunctional or multisubstrate Ca^{2+} -calmodulin-dependent protein kinase. (Courtesy of J. H. Exton, MD, Vanderbilt University.)

In addition to its effects on enzymes and ion transport, Ca^{2+} -calmodulin regulates the activity of many structural elements in cells. These include the actin-myosin complex of smooth muscle, which is under β -adrenergic control, and various microfilament-mediated processes in noncontractile cells, including cell motility, conformation changes, mitotic apparatus, granule release, and endocytosis. Several critical metabolic enzymes, including glycogen synthetase, pyruvate kinase, pyruvate carboxylase, glycerol 3-phosphate dehydrogenase, and pyruvate dehydrogenase, are regulated by Ca^{2+} , by phosphorylation, or by both. Many of these effects are mediated through activation of a specific calmodulin-dependent protein kinase, and others are mediated through a multifunctional protein kinase (Fig. 7.4). These kinases phosphorylate specific residues on proteins, but a given protein might be phosphorylated by more than one kinase.

Some signal must provide communication between the hormone receptor on the plasma membrane and the intracellular Ca^{2+} reservoirs. The best candidates appear to be products of phosphatidylinositol metabolism. Phosphatidylinositol 4,5-bisphosphate is hydrolyzed to *myo*-inositol 1,4,5-trisphosphate and diacylglycerol through the action of a phospholipase C, which is activated by a member of the G_q family (Fig. 7.4). This reaction occurs within seconds after the addition of vasopressin or epinephrine to hepatocytes. *Myo*-inositol 1,4,5-trisphosphate, at a concentration of 0.1 to 0.4 mmol/L, releases Ca^{2+} from a variety of membrane and organelle preparations with appropriately rapid kinetics. Another product of phosphoinositide hydrolysis, 1,2-diacylglycerol, activates a Ca^{2+} -dependent protein kinase, protein kinase C. The hormones that activate this system generate two intracellular signals: Ca^{2+} and diacylglycerol.

Steroidogenic agents, including adrenocorticotrophic hormone (corticotropin; ACTH) and cAMP in the adrenal cortex; angiotensin II, K^+ , serotonin, ACTH, and dibutyryl cAMP in the zona glomerulosa of the adrenal; luteinizing hormone in the ovary, and luteinizing hormone and cAMP in the Leydig cells of the testes have been associated with increased amounts of phosphatidic acid, phosphatidylinositol, and polyphosphatidylinositides in the respective target tissues. Other examples of the possible role of phosphatidylinositide metabolites in hormone action can be cited. The addition of thyrotropin-releasing hormone to pituitary cells is followed within 15 seconds by a marked increase of inositol degradation by phospholipase C. The intracellular levels of inositol diphosphates and triphosphates increase markedly, resulting in mobilization of intracellular calcium. This activates protein kinase C, which phosphorylates several proteins, one of which presumably is involved in thyroid-stimulating hormone release. Calcium also appears to be the intracellular mediator of gonadotropin-releasing hormone action on luteinizing hormone release. This reaction probably involves calmodulin.

The roles that Ca^{2+} and phosphoinositide breakdown products might play in hormone action are presented in Figure 7.4. In this scheme, the phosphoinositide products are the second messengers and Ca^{2+} is a tertiary messenger. It is likely that more examples of the complex networking of intracellular messengers will be discovered.

PROTEIN KINASE CASCADES PROVIDE THE SECOND MESSENGER

Phosphorylation is perhaps the most common post-translational modification of proteins. The usual amino acid residues modified by this process are serine or threonine. The phosphorylation of tyrosine residues accounts for only 0.03% of phosphorylated amino acids, but it is extremely important for hormone action. The seminal discovery was that the epidermal growth factor receptor contained an intrinsic tyrosine kinase that was activated when epidermal growth factor was bound. Shortly thereafter, the insulin and IGF-I receptors were shown to contain ligand-activated tyrosine kinases. Many studies, including extensive mutational analysis of these receptors, provided conclusive evidence of the importance of receptor-associated tyrosine kinase in the action of insulin, IGF-I, epidermal growth factor, and other growth factors.

Not explained was how this activity coupled to specific biologic effects, but a clue came from further analysis of insulin action. Activation of the receptor tyrosine kinase results in the phosphorylation of a family of proteins, called the insulin receptor substrates (IRS 1 to 4), on tyrosine residues. For example, phosphorylated IRS-1 associates with so-called docking proteins through Src homology 2 (SH2) domains. One of these SH2 domain-containing docking proteins, GRB-2, results in activation of a kinase cascade, the last member of which is a microtubule-associated protein kinase. This kinase is thought to phosphorylate target proteins on serine and threonine residues and thereby influence biologic processes. In insulin action this pathway is associated with cell growth and replication events. Phosphorylated IRS-2 binds to the SH2 domain of phosphoinositide-3 kinase, linking tyrosine phosphorylation to phosphoinositide metabolism and action. This pathway has been associated with certain metabolic effects of insulin, such as glucose transporter translocation and the regulation of genes involved in metabolism. Many of the components of this complex system remain to be identified and placed in order, and it is not clear as to how hormone specificity is achieved, but a major advance has been made in understanding how this class of hormones works.

Growth hormone, prolactin, erythropoietin, and cytokine receptors do not have intrinsic tyrosine kinase activity, but tyrosine phosphorylation is involved in the action of this group of hormones. The hormone receptor interaction attracts and activates cytoplasmic protein tyrosine kinases, such as Tyk-2, Jak-1, and Jak-2. These activated kinases phosphorylate one or more cytoplasmic proteins that then associate with other proteins through SH2 domains. One target appears to be the signal transduction and activators of transcription (STAT) family of proteins. Activated STAT proteins translocate from the cytoplasm to the nucleus wherein they regulate the transcription of specific genes.

The exact components of these pathways, the docking proteins, kinases, and phosphatases must be established, and it is particularly important to link these pathways to the well-established physiologic and biochemical actions of the hormones.

contain recommendations for some components, such as fiber and cholesterol, for which there is no RDI. An understanding of the new food labels should enable patients to maintain more readily an adequate intake of micronutrients; physicians should have the same facility with this information.

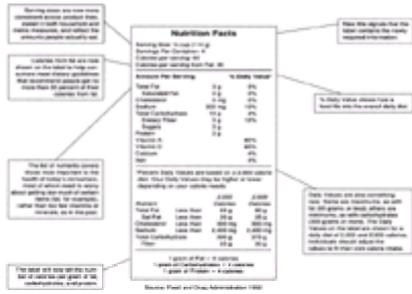

FIGURE 8.1. Chart of nutrition facts showing how daily values (recommended daily intake) fit into a person's diet. (Reproduced with permission from Bull Publishing Company.)

5. *Maintain adequate calcium intake.* The principal source of readily available calcium is dairy products. For those people who are lactose-intolerant, intake can be maintained by ingestion of green leafy vegetables or by calcium supplements. As with other nutrients, there is no information that ingestion of excess calcium is beneficial, unless the person has a disease associated with excess nutrient loss or malabsorption.

6. *Limit total daily intake of salt (NaCl) to 6 g or less.* Limit the use of salt in cooking and avoid adding it to food at the table. Salty, highly processed salty, salt-preserved, and salt-pickled foods should be consumed sparingly. The average intake of salt in the United States is 4 g per day. For patients with hypertension or edema, the limitation of salt intake is especially important.

7. *Alcohol consumption is not recommended.* If alcoholic beverages are consumed, they should be limited to less than 1 oz of pure alcohol daily. This is the equivalent of two cans of beer, two small glasses of wine, or two average cocktails. Pregnant women should avoid alcoholic beverages. Alcohol ingestion cannot yet be recommended for prevention of disorders such as coronary artery disease. Even if it could be, many experts believe that the risks of alcohol abuse outweigh the potential benefits of modest consumption. Moreover, alcohol is a concentrated caloric source. To estimate the caloric content (in kilocalories) of an alcoholic beverage, calculate $0.8 \times \text{beverage proof (\%)} \times \text{number of ounces}$.

8. *Avoid taking dietary supplements in excess of the RDA in any one day.* Most studies show that people who consume vitamin or mineral supplements also consume an adequate diet. For people following the dietary recommendations outlined here, there is no known benefit from nutrient supplementation. Also, for the general population, there is no evidence that pharmacologic doses of nutrients are beneficial. Large amounts of individual nutrients have, however, been useful in some diseases (e.g., vitamin A in promyelocytic leukemia).

9. *Maintain an optimal intake of fluoride, particularly during the years of primary and secondary tooth formation and growth.* Most fluoride is now provided in the water supply.

IMPLEMENTATION OF GUIDELINES

The US Department of Agriculture Food Guide Pyramid (Fig. 8.2) is a schematic diagram designed to reinforce visually the recommendations for dietary health and to aid people in meal planning. The relative sizes of the blocks reflect the relative proportions of the components to overall energy intake. Examples of recommended serving number and portion sizes are as follows:

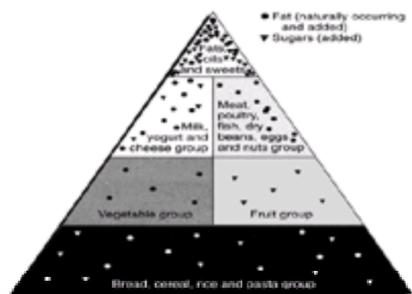

FIGURE 8.2. The USDA Food Guide Pyramid.

Breads, cereals (6 to 11 servings per day): 1 slice, 1/2 cup of cooked rice, pasta, or cereal

Vegetables (3 to 5 servings per day): 1/2 cup of chopped raw or cooked vegetables, 1 cup of leafy vegetables

Fruits (2 to 4 servings per day): 1 piece, 3/4 cup of juice, 1/4 cup dried fruit

Dairy products (2 to 3 servings per day): 1 cup milk or yogurt, 1/2 to 2 oz of cheese

Meat, fish, eggs, nuts (2 to 3 servings per day): 2-1/2 to 3 oz cooked lean meat, poultry, fish; 1 egg, 1/2 cup cooked beans, 2 tablespoons (tbsp) peanut butter = 1 oz meat

Fats, oils, sweets: use sparingly

The new food labels (1994) have been developed to assist the consumer (and patient; Fig. 8.1). Nearly all processed foods now carry this label in the United States; the label highlights fat and caloric content, but also protein, carbohydrate, sodium, calcium, iron, and vitamins A and C. The fat content of foods can be decreased by steaming, baking, broiling, or microwaving.

Patients may have difficulty in maintaining nutrient intake because of their underlying illness, which can produce anorexia or nausea. A major cause of altered food intake, either increased or decreased, is prescription medications. Table 8.6 lists some of the drugs producing these effects, including those that alter taste. Other major causes of altered taste include menopause, depression, and local oral factors.

WHAT IS THE CURRENT DEGREE OF BODY PROTEIN AND FAT DEPLETION?

As mentioned, the existing measures correlate better with severity of illness than with precise deficiency states. In the absence of large fluid shifts, however, weight is a good overall measure of caloric deficiency due to decreased intake, increased utilization, or both. The initial degree of depletion is relevant, particularly during a long illness, because most well-nourished patients tolerate negative energy and protein balance fairly well during self-limited illnesses. The cumulative effect of negative calorie balance in pure starvation can be estimated by calculating 3,500 kcal per lb. Thus, in the absence of illness causing marked protein breakdown, a negative calorie balance of 1,000 kcal per day would lead to loss of 2 lb per week. If the amount of weight loss exceeds that estimated by decreased caloric intake alone, the difference might be attributable to underlying illness. Regardless of the cause of the weight loss, this estimate helps to answer the next question.

WHAT IS THE ANTICIPATED LENGTH OF TIME NEEDED FOR NUTRITIONAL SUPPORT?

If the patient is well nourished at the start of the illness, even large caloric deficits can be tolerated for a matter of weeks. If the patient is poorly nourished, the clinician could calculate how many calories would be needed daily to maintain body weight at 90% of ideal weight, for example. The major dangers in planning nutritional support are overestimating need, and trying to recapture lost weight and protein mass during the acute phase of the illness. Delivery of high loads of calories and protein by enteral or parenteral feeding requires the use of large fluid volumes and salt loads. Excessive use of tube feedings may cause diarrhea or pulmonary aspiration. Inappropriate use of total parenteral nutrition (TPN) may lead to all of the potential complications of that technique. The most important decision in providing calorie and protein support is the first one: what is the goal of the therapy, and how vigorously should it be pursued?

IS THE INTESTINAL TRACT AVAILABLE AND ADEQUATE?

If supplementary treatment is needed, the clinician must decide whether to use enteral or parenteral routes. Total parenteral nutrition is discussed in [Chapter 130](#). Whenever possible, the gastrointestinal tract should be used. Sometimes the oral route can be used, but more often forced enteral feeding is needed if the supplement must be large. If gastric emptying is normal, infusion into the stomach is possible. If the stomach is abnormal, jejunal or duodenal infusion must be used. The presence of diarrhea can make enteral supplementation difficult.

ENTERAL NUTRITION THERAPY

USE OF DIETS IN THE MANAGEMENT OF DISEASE

Modification of the basic diet is needed for management of certain diseases ([Table 8.13](#)). Such modifications may or may not use commercial supplements. Diets can be used to alter consistency of the meal (e.g., soft diets for patients with difficulty chewing), to restrict certain elements (e.g., low-lactose or gluten-restricted diets), or to add specific elements (e.g., calcium, fiber, pancreatic enzymes). Discussion of the specific diseases is included in [Chapter 109](#), [Chapter 110](#), [Chapter 111](#) and [Chapter 117](#).

Diet	Possible Indications
Low fat	Steatorrhea of any cause, especially when colon is present; protein-losing enteropathy
Reduced calorie	Obesity; preventive measure for good health
Low lactose	Lactose intolerance
Low fructose	Fructo-oligosaccharide intolerance
High fiber	Prevention of recurrent diverticulitis; irritable bowel syndrome with alternating bowel habits
Low fiber	Acute diarrhea, bowel preparation
Low sodium	Edema-forming conditions, hypertension
Low oxalate	Steatorrhea with hyperoxaluria
Elimination diet	Food allergies

TABLE 8.13. MODIFIED DIETS

MICRONUTRIENT DEFICIENCIES

Vitamin and mineral deficiencies are treated by addition of specific nutrients or by use of nutritional supplements that are fortified with vitamins or minerals.

ESSENTIAL FATTY ACID DEFICIENCY

The uncommon disorder known as essential fatty acid deficiency was seen formerly in patients treated with TPN but without fatty acid supplementation. Today three-in-one TPN therapy using intravenous lipid is routine, and fatty acid deficiency is rarely encountered. When it is, 1 to 2 tbsp of vegetable oil per day by mouth is usually sufficient for treatment.

ORAL SUPPLEMENTATION

Most often, protein and calorie supplements are used to improve diets in a reliable way. The usual sources of protein in table foods that are appropriate for use as supplements include milk products, eggs, peanut butter, fish, and meat. When low fat (triglyceride) content is desirable, skim milk, chicken or turkey without skin, shellfish, and flat fish are useful. The most commonly used commercial supplements add a defined nutrient content and are prescribed as medications. There are a large number of available products, and new ones are introduced frequently. Although the best diet for a given patient provides for individual needs, there is seldom a single product that is "best" for a given patient. Many calorie supplements are lactose free and are available in multiple flavors to improve taste selection over a long period. Milk-based supplements are usually less expensive, but they cannot be used by lactose-intolerant patients, who can tolerate on average less than 8 oz of milk daily. Fiber supplements are commonly used, usually in the form of psyllium extract (hemicellulose) when prescribed alone, but soy polysaccharide is now added to many protein-calorie supplements to increase their fiber content. Hemicellulose has a high water-holding capacity, but other fiber components, such as cellulose and pectins, also retain water. Any of these fiber components is usually included when it is desirable to alter the consistency of the stool, although this is not a consistent benefit of such supplements. Dietary fiber is converted to short-chain fatty acids in the colon, with potential benefits to colonic mucosal integrity; however, such usefulness in critically ill patients has not been demonstrated.

A number of supplements are available that are designed for very special needs (e.g., chronic renal failure, hepatic encephalopathy), but these are expensive and in general are designed for forced enteral feeding. There are several products designed for use in pulmonary failure because high carbohydrate load can lead to excess production of carbon dioxide and, rarely, to worsening hypercapnia. However, the amount of carbon dioxide produced by a person is more a function of the total caloric load than of the macronutrient source of the calories, and hypercapnia is rarely related to dietary intake. Glutamine is a nonessential amino acid that is highly abundant and an important fuel for the intestinal mucosa. Although all enteral protein-calorie supplements contain glutamine, some contain high levels. There are not yet sufficient data demonstrating improved outcome to support the routine use of glutamine supplementation.

ORAL REHYDRATION THERAPY

Although well described for the treatment of dehydrated children and for adults with cholera, oral rehydration therapy has not been widely used for rehydration of adults after or during acute diarrheal or other illness. If signs of dehydration are present (especially postural hypotension) and the patient's clinical status does not require hospitalization, oral rehydration can be effective and rapid. It is based on the concept that coupled sodium-glucose absorption is preserved during diarrheal illness and such absorption carries with it free water. Most of the commercially available rehydration solutions are formulated in pediatric doses, but some (e.g., Pedialyte) are available in liter portions. The World Health Organization has developed an oral rehydration solution that can be made at home and is applicable to

adults. To 1 L of water add 3 to 4 (teaspoons) tsp of table salt; 1/2 tsp of baking soda or 1 tsp of baking powder; 1 cup of orange juice; and 4 tbsp of cane or table sugar (sucrose) or 2 tbsp of honey (enriched in fructose). The usual daily dose for adults is 2 to 3 L. Sports drinks (e.g., Gatorade) were designed to provide energy and to replace electrolytes lost in sweat. When fluid loss from vomiting or diarrhea is not severe, such beverages may be well tolerated and are helpful in maintaining fluid volume. However, they are not useful in replacing lost volume because the sodium concentration is too low. Most soft drinks contain only 1 to 4 mEq per L of sodium and 0.1 to 0.6 mEq per L of potassium with 10% carbohydrate, and thus are inadequate for the treatment of dehydration.

FORCED ENTERAL FEEDING

The term *forced enteral feeding* refers to nutritional support using tube feeding techniques. Usually all, or nearly all, nutritional requirements are delivered to the patient in this way. Such diets therefore should be nutritionally complete, providing protein, calories, and other essential nutrients. Patients who are usual candidates for forced enteral feeding have an available and functioning gastrointestinal tract, and have existing protein-calorie malnutrition and some condition that prevents standard oral supplementation. Such conditions would include coma or depressed mental state, anorexia, or oropharyngeal malfunction preventing normal swallowing. When the period for required supplementation is short, nasogastric or nasoduodenal feeding tubes should be used. When nutritional support must be prolonged to maintain the quality of life agreed on by the patient (or patient's family) and the physician, gastrostomy or jejunostomy may be used as the portal of entry into the gastrointestinal tract.

BASIC CONCEPTS

BODY FLUID COMPARTMENTS

Body fluids, composed predominantly of water, its accompanying electrolytes, and circulating serum proteins and lipoproteins, constitute approximately 60% of total body weight. Thus, in a hypothetical 70-kg individual, total body fluid, or, as commonly referred to, total body water approximates 42 L, with 28 L contained in the intracellular fluid (ICF) and 14 L contained in the extracellular fluid (ECF) compartment as interstitial fluid (that fluid outside cells and outside the capillaries) and as plasma.

The forces that govern the distribution of fluids between the ICF and ECF compartments—the osmotic pressure—are determined by the pressure exerted by the concentration of *effective* osmotic particles in each compartment. In a steady-state condition under virtually all circumstances, the intracellular and extracellular effective osmotic pressures are equal.

In the ECF, different pressures determine the distribution of fluid between the plasma volume and the interstitial fluid volume. Here Starling's forces are the determining factors. Hydrostatic pressure within the capillaries and their accompanying arterioles and venules tends to induce the movement of fluid from the plasma volume to the interstitial volume, whereas oncotic pressure (determined almost exclusively by the concentration of albumin in the plasma) induces the movement from the interstitial compartment to the plasma volume. In reality, these fluids are constantly in motion crossing the capillary membrane. At steady state approximately one-fourth of the ECF volume is contained within the capillaries and three-fourths constitutes the interstitial fluid. This circulation of the interstitial fluid is critically important for the delivery of vital nutrients to the cells and for the removal of waste products from the cellular milieu back into the plasma volume for eventual disposal.

CLINICAL IMPLICATIONS

In a hypothetical patient, it is possible to lose the entire plasma volume iso-osmotically and to be limited to only the interstitial fluid volume to replenish the falling plasma volume (as might happen in severe hemorrhage). Not even 1 mL of intracellular fluid would cross the cellular membrane if there were no change in effective osmotic pressure.

UNITS OF SOLUTE MEASUREMENT

Solute concentration can be expressed in milligrams per deciliter, millimoles per liter or per kilogram of water, milliequivalents per liter, or milliosmoles per liter or per kilogram of water. For example, in the case of the calcium ion (Ca^{2+}), the values 4 mg per dL, 1 mmol per L, 2 mEq per L, and 1 mOsm per L indicate the same concentration of Ca^{2+} . Because of different concentration units, the amount of any given solute can be expressed in several different ways ([Table 9.1](#)).

Substance	Grams (mol wt)	Moles ($\times 10^3$) (molecular)	Equivalents ($\times 10^3$) (charge)		Osmoles ($\times 10^3$) (particles)
			Cation	Anion	
Standard					
Na	23	1	1	1	1
Cl	35.5	1	1	1	1
HCO_3^-	61	1	1	1	1
Ca^{2+}	40	1	2	2	1
Nonionizable					
Urea	60	1	0	0	1
Glucose	180	1	0	0	1
Ionizable					
Univalent					
NaCl	58.5	1	1	1	2
KCl	74.5	1	1	1	2
Divalent					
CaCl_2	111	1	2	2	4
MgCl_2	95	1	2	2	4
Trivalent					
$\text{Ca}_3(\text{PO}_4)_2$	312	1	6	6	12

TABLE 9.1. EXAMPLES OF UNITS OF SOLUTE MEASUREMENT

The simplest way to express the amount of solute is by mass or weight, using gram or kilogram as the unit. More information can be conveyed by employing units based on the molecular weight of the substance. The molecular weight is defined as the quantity (in grams) of any substance that contains 6.023×10^{23} (Avogadro's number) molecules of that substance. This amount is known as 1 mol of the substance. For example, 1 mol of sodium (Na^+) contains the same number of molecules as 1 mol of chloride (Cl^-), although the former weighs 23 g and the latter weighs 35.5 g. Conversely, to convert from mass units, such as grams and milligrams, to moles or millimoles, the weight of the substance is divided by its molecular weight. For example, 1 g of NaCl (molecular weight = $23 + 35.5 = 58.5$) contains $1000 \div 58.5 = 17.1$ mmol NaCl.

With electrically charged compounds (electrolytes and ions), it is often most useful to consider the number of positive or negative charges. Positively charged particles are called cations, and negatively charged particles are called anions. When ions combine, they do so according to their ionic charge, or valence, and not according to molecular weight. The unit used to indicate charge is the chemical equivalent. One equivalent of an anion is defined as the amount that combines with, or replaces, 1 mol of hydrogen ion (H^+). Because Na^+ is a univalent ion (charge +1), 1 mol of Na^+ is equal to 1 equivalent. Because Ca^{2+} is a bivalent ion (charge +2), 1 mol of Ca^{2+} equals 2 equivalents. To convert from units of moles to equivalents, the following simple formula can be used:

$$\text{Equivalents} = \text{moles} \times \text{valence}$$

The most common term used for expressing concentrations of electrolytes in serum is milliequivalents per liter. There are two advantages in using this unit of concentration. First, it reinforces the principle that ions combine milliequivalent for milliequivalent, not millimole for millimole or milligram for milligram. Second, to maintain electroneutrality, there must be an equal number of cations and anions in each fluid compartment of the body.

Not all ions are easily measured in milliequivalents per liter. For instance, the total calcium concentration in serum is about 10 mg per dL, or 5 mEq per L. Because 50% to 55% of the plasma calcium is bound to albumin, the free ionized (unbound) calcium concentration in plasma is 2.0 to 2.5 mEq per L. For these reasons, the precise concentration of ionized calcium is difficult to determine with present clinical laboratory techniques. Consequently, the total serum calcium is routinely reported in mass units (mg per dL) rather than equivalence units (mEq per L).

A different problem occurs with phosphate because it exists in several different ionic forms: H_2PO_4^- , HPO_4^{2-} , and PO_4^{3-} . Although an exact valence cannot be given, an approximate valence of 1.8 can be assigned because roughly 80% of extracellular phosphate exists as HPO_4^{2-} and 20% as H_2PO_4^- in serum at a pH of 7.4.

Because of the imprecision of valance and equivalence for this electrolyte, serum phosphorus concentrations are routinely reported in mass units (milligrams per deciliter).

OSMOLALITY

The osmolality of a given body fluid is determined by the concentration of the circulating dissociated ionic and nonionic particles contained in that fluid. In the extracellular fluid volume, since sodium makes up more than 95% of the circulating cationic ionized particles, and glucose and urea account for virtually all of the normally occurring circulating nonionic particles, the total plasma osmolality can be easily approximated by the formula: plasma osmolality = $2 \times$ [plasma sodium concentration] + glucose concentration (mg %) \div 18 + BUN \div 2.8. This value is referred to as the calculated plasma osmolality and, as mentioned above, equals the osmolality of the entire ECF and the osmolality of the ICF as well. The pathology laboratory confirms the measurement of plasma osmolality by use of a technique that measures the concentration of osmotically active particles through its effect on depressing the freezing point of any given solution. In general, the difference between the calculated plasma osmolality and the measured plasma osmolality is less than 5 to 10 mOsm per L.

While determination of the plasma osmolality is important, it is vital to recognize that not all particles contributing to the plasma osmolality are osmotically effective. The most significant exception is urea. Because of its permeability across cell membranes, intracellular and extracellular urea concentrations are equal; in effect, the osmotic pressure that they would generate across these fluid compartments "cancels itself out." Hence, clinicians are much better served by calculating the *effective plasma osmolality* by the formula noted above with the urea term removed. Effective osmolality is also known as tonicity, a term that many find useful in distinguishing between total osmolality and effective osmolality.

TONICITY AND CELL VOLUME

As noted above, when water is added to the body it is distributed between the two major body fluid compartments such that at steady state two-thirds is located in the ICF and one-third in the ECF. Similarly, a pure water deficit is distributed such that at steady state two-thirds of the net loss is derived from the ICF and one-third from the ECF. Because the gain or loss of pure water is shared proportionately by the two major body fluid compartments, it does not alter the relative volumes of these two compartments.

If an effective solute (e.g., sodium, glucose) is added to the ECF, the ECF tonicity increases and water moves out of the cells. The ECF volume increases at the expense of the ICF volume until the tonicity of the two fluid compartments is equalized. Conversely, if an effective solute is removed from the ECF, the ECF tonicity decreases and water moves into the cells. The ICF volume increases at the expense of ECF volume until the tonicity of the two fluid compartments is equalized. In contrast, if an ineffective solute (e.g., urea) is added to or removed from the ECF, the ECF tonicity does not change and cell volume remains constant.

Changes in body fluid tonicity are associated with characteristic alterations in cell volume. Hypertonicity leads to ICF contraction (cell shrinkage or dehydration), while hypotonicity leads to ICF expansion (cell swelling or edema). The major clinical features of disorders of water homeostasis are largely attributable to changes in cell volume.

CLINICAL IMPLICATIONS

As a consequence of these physiologic parameters it becomes relatively easy to assess the effect of intravenous replacement solutions on patients with various body fluid deficits. The administration of 5% dextrose in water, while effectively addressing a water deficit, does little to expand plasma volume in particular. One liter of 5% dextrose in water, for example, in the absence of diabetes, will distribute 667 mL to the ICF and 333 mL to the ECF. Three-fourths of that fluid will be retained in the interstitial compartment, leaving approximately 85 mL of the original liter to distribute to the plasma volume, a poor plasma expander indeed.

Administration of Ringer's lactate, normal saline, or any other isotonic sodium containing solution is far more effective in plasma volume expansion. One liter of normal saline will remain entirely in the extracellular fluid (sodium being limited from entry to the intracellular compartment by active extrusion from virtually all cells). Of the liter retained in the ECF compartment, 250 mL distributes to the plasma volume—a far better effect. For the ultimate volume expander, plasma infusion is theoretically ideal. An entire liter of infused plasma (because of its iso-osmotic and iso-oncotic pressures) remains in the plasma volume and would be most effective in emergency plasma volume expansion.

The converse physiologic circumstance to that noted above is also true. Water loss is well tolerated with regard to hemodynamics; salt loss (with its accompanying water) is more significant; and plasma loss can be fatal.

SERUM SODIUM CONCENTRATION

Sodium salts make up more than 95% of ECF effective solutes, and in most circumstances, the serum sodium concentration (S_{Na}) accurately reflects body fluid tonicity. Because the symptoms and signs of abnormal body fluid tonicity are generally nonspecific, disorders of water homeostasis are often detected clinically by the presence of an abnormal S_{Na} . The features of altered body fluid tonicity relate to changes in tonicity and not to associated changes in S_{Na} . Consequently, tonicity and S_{Na} need not always change concordantly. Although hypernatremia always implies hypertonicity, the converse is not always true; hyponatremia does not always imply hypotonicity.

Hypertonicity can occur in the absence of hypernatremia when an effective solute other than sodium (e.g., glucose) is present in excessive amounts in the ECF. The osmotic pressure exerted by the nonsodium solute leads to redistribution of water from the ICF to the ECF and consequently leads to hyponatremia and intracellular volume depletion. Hyperglycemic hypertonicity is common in patients with uncontrolled diabetes mellitus.

Hyponatremia can occur in the absence of hypotonicity if an effective solute other than sodium is present in significant quantity in the ECF (hypertonic hyponatremia) or when large amounts of lipids or proteins are present in the plasma (isotonic hyponatremia). The latter circumstance, also known as pseudohyponatremia, is discussed in [Chapter 144](#).

WATER BALANCE

Water balance in a normal person is maintained through a series of hemodynamic, hormonal, and molecular mechanisms. Balance is so finely tuned that neither water retention nor water loss will occur despite changes in fluid intake of 10-fold or greater (e.g., 1 L to 10 L per day). One of the characteristics of chronic renal disease (see [Chapter 133](#) and [Chapter 141](#)) is that this broad range over which water balance can be achieved is narrowed significantly because the homeostatic mechanisms have themselves been compromised by the process, causing injury to the kidney.

The following sequence of events occurs after the ingestion of water in a normal individual ([Fig. 9.1](#)). Plasma osmolality is transiently diluted and the effective osmolality falls; extracellular fluid volume is expanded, albeit minimally. This expansion results in a minimal, clinically undetectable increase in glomerular filtration rate and delivery of more sodium to the proximal tubule of the kidney (see below). As a consequence of the dilution of effective plasma osmolality, antidiuretic hormone (ADH; also known as vasopressin) production and release is inhibited at the level of the hypothalamus. This inhibition lowers the level of circulating ADH and decreases its effects on the distal portions of the nephron: the distal cortical tubule, the collecting tubule, and the collecting duct. Also, the increase in extracellular fluid volume and increased perfusion of the hypothalamus sends a signal of hypervolemia to a variety of volume receptors throughout the body, which further inhibit ADH synthesis and release. The increased sodium delivered to the proximal tubule is for the most part reabsorbed, but a greater absolute amount of the filtered sodium travels down to the prime diluting site in the ascending limb of the loop of Henle, where chloride (with sodium following passively) is removed and water stays behind. This segment of the nephron is unalterably impermeable to water. The increased volume of hypotonic fluid enters the cortical distal tubule, collecting tubule, and collecting duct (these structures are impermeable to water due to the absence of ADH), and increased urine volume accompanied by increased excretion of water results. Subsequently, the plasma osmolality, extracellular fluid volume, and glomerular filtration rate return to normal.

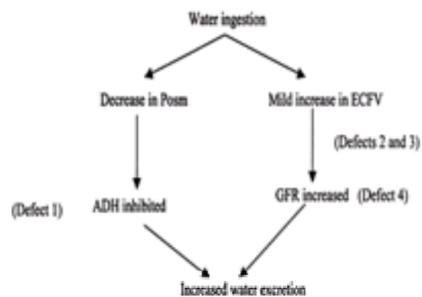

FIGURE 9.1. Water homeostasis and defects producing hyponatremia. 1, defect in SIADH; 2, defect in volume depletion; 3, defect in edematous disorders; 4, defect in renal failure.

In states of fluid restriction, the opposite sequence of events occurs. Increased plasma osmolality increases ADH release. Decreased extracellular fluid volume results in a decrease in glomerular filtration rate and sodium delivery. In this setting, more water is reabsorbed (conserved). These same homeostatic mechanisms are responsible for minimizing the effect of low fluid intake on plasma osmolality and serum sodium concentration.

SODIUM BALANCE

The kidney increases the excretion of sodium in states of sodium excess and retains sodium in states of sodium deprivation, controlling the extracellular fluid volume (since osmolality is also controlled and the accompanying quantity of water is appropriate for the absolute quantity of sodium) within narrow limits. Regulation of the ECF volume depends upon a number of afferent stimuli by which the kidney senses changes in extracellular or intravascular volume. Furthermore, there are efferent pathways by which the kidney alters the excretion of sodium in response to these volume changes ([Fig. 9.2](#)).

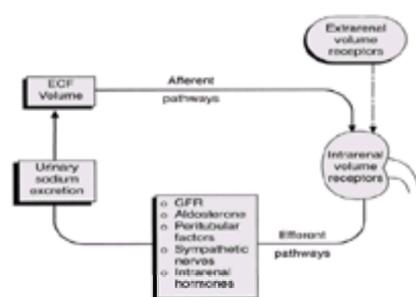

FIGURE 9.2. Afferent and efferent pathways for renal sodium excretion. Renal excretion of sodium is regulated by afferent mechanisms, by which changes in extracellular fluid (ECF) volume are signaled to the kidney, and efferent mechanisms, in which the kidney changes the rate of sodium excretion in response to changes in ECF. The most critical afferent pathways may be intrarenal rather than extrarenal.

AFFERENT PATHWAYS

The receptors that control renal sodium excretion have not all been clearly defined, but there is evidence for the existence of volume receptors in the low-pressure central venous circulation and the high-pressure arterial circulation. The cardiac atria contain the best examined receptors within the low-pressure circulation. Distention of the atria suppresses hypothalamic sympathetic output to the kidney and the sympathetic vasculature, and inhibits ADH release from the neurohypophysis (see above). Besides the neural effects of atrial distention, atrial myocytes contain atrial natriuretic peptide, the release of which is directly proportional to the central venous pressure. Atrial natriuretic peptide is strongly natriuretic.

Volume receptors also exist in the arterial side of the circulation. One such very important receptor is the juxtaglomerular apparatus within the kidney. Secretion of renin by granular cells in the afferent arterial of the juxtaglomerular apparatus is sensitive to ECF volume and renal perfusion pressure. When pressure falls, renin release increases. Renin stimulates angiotensin II production, which promotes an increase in the circulating levels of aldosterone, a hormone that is an important modulator of sodium homeostasis. Although the exact sensing mechanism and precise location of other high-pressure sensors remains unclear, baroreceptors, which respond to wall tension, appear to be located in the carotid arteries and aorta. Stimulation of these receptors results in a natriuresis that depends on intact renal sympathetic innervation. From such data, the concept of effective arterial blood volume (EABV), which is that portion of the arterial blood volume capable of stimulating high-pressure volume receptors, has evolved as a major factor in the regulation of renal sodium excretion. In normal circumstances, EABV and ECF volume are closely and directly related. In disease states, EABV and ECF volume may not change in the same direction. The distinction between the conceptual EABV and the real measurable ECF volume becomes important in understanding the pathogenesis of sodium retention states. These states are discussed in greater detail in [Chapter 143](#). The EABV is a concept with no, or only poorly identified, structural correlates, and extrarenal perception of changes in ECF volume or EABV might not be a prerequisite for alterations in renal sodium handling.

EFFERENT PATHWAYS

Once the kidneys, by whatever afferent pathways, perceive an increase in ECF volume or EABV, a wide variety of efferent mechanisms come into play to modify renal sodium excretion.

Glomerular Filtration Rate

The renal excretion of sodium is ultimately determined by the relation between the glomerular filtration rate (GFR) and the rate of tubular sodium reabsorption. Were there no correlation between filtration and reabsorption, changes in GFR would result in significant volume expansion or depletion. Instead, a rise in GFR is accompanied by an increase in sodium reabsorption and a fall by a decrease in sodium reabsorption. This association between GFR and tubular reabsorption is called glomerulotubular balance. As a result of glomerulotubular balance, the fractional reabsorption of sodium (the fraction of the filtered load of sodium that undergoes tubular reabsorption) remains relatively constant unless disease processes supervene.

Peritubular Capillary Forces

Peritubular capillary forces, the so-called physical factors, exert an important influence on renal sodium handling, primarily at the level of the proximal tubule. The proximal tubule normally reabsorbs 50% to 65% of the filtered load of sodium. Net sodium transport in the proximal tubule appears to be governed by a pump-leak system. Filtered sodium is actively transported across the renal tubule cell to the intercellular (interstitial) space. Sodium salts and water that accumulate in this space may be taken up into the systemic circulation by the peritubular capillaries or may leak back into the lumen across the tight junctions between epithelial cells. The modulation of proximal tubule sodium reabsorption appears to be governed primarily by changes in the rate of back flux into the lumen and not in the rate of active sodium transport. Factors that increase peritubular capillary oncotic pressure or decrease peritubular capillary hydrostatic pressure favor fluid reabsorption, and factors that produce the opposite changes decrease fluid reabsorption.

The efferent arteriole has a major role in modulating proximal tubular fluid reabsorption. Efferent arteriolar constriction decreases peritubular capillary hydrostatic

pressure and, by increasing the fraction of plasma filtered at the glomerulus (filtration fraction), increases peritubular capillary oncotic pressure. Both of these effects favor increased proximal tubular fluid reabsorption. Efferent arteriolar dilatation has the opposite effect and leads to a fall in proximal tubular fluid reabsorption.

The uptake of sodium and water by the peritubular capillaries ultimately controls the net rate of sodium transport by the proximal tubule. As with all capillaries, the movement of fluid from the intercellular space into the peritubular capillary is governed by Starling's forces. These intrarenal physical factors control the rate of fluid reabsorption in the proximal tubule and are responsible for the maintenance of glomerulotubular balance. Because the magnitude of proximal tubular sodium reabsorption alone does not account for the maintenance of sodium balance, other mechanisms must regulate sodium transport in more distal segments of the nephron. Aldosterone, acting at the site of the sodium–potassium exchanger, is one of these mechanisms and can account for up to 1% of the filtered sodium reabsorption.

ACID–BASE BALANCE

DAILY PRODUCTION AND EXCRETION

Each day during the course of metabolism of ingested foodstuffs, two types of acid waste products are produced. The first, so-called volatile acid, in the form of CO_2 gas is produced in large quantities (15,000 to 20,000 mM/day) but is eliminated normally without great difficulty by the lungs. The second type of acid residue, so-called fixed or metabolic acid, is produced in much smaller quantities (1.0 to 1.5 mEq per kg of body weight per day) but requires a much more elaborate and complex mechanism for elimination.

If one were to consider the consequences of 100 mEq of metabolic hydrogen ion in the form of sulfuric acid (H_2SO_4) or phosphoric acid (H_3PO_4) added to the ECF volume each day as a consequence of the metabolism of primarily protein-containing food, the result would be dramatic. While metabolic acid is known to be buffered approximately 50% intracellularly (by the protonation of intracellular proteins), 50 mEq would remain to be buffered extracellularly. Sodium bicarbonate is the circulating extracellular buffer system responsible for protection against body fluid acidity and exists in the ECF in a concentration of approximately 25 mEq per L. Simple arithmetic would demonstrate that the entire quantity of circulating bicarbonate would be consumed in 7 days or less were there not a mechanism to (a) replenish bicarbonate stores and (b) eliminate so-called metabolic hydrogen ion.

RENAL ELIMINATION OF METABOLIC HYDROGEN ION (ACIDIFICATION)

Consider for a moment the challenge the kidney faces in eliminating 100 mEq of metabolic or strong acid in 1 L of urine per day. An elementary knowledge of logarithms would suggest that the pH of that urine would have to be 1.0 (hydrogen ion concentration 10^{-1}) to “contain” 100 mEq of hydrogen ion. The circumstance is not improved greatly even if urine output is increased drastically to 10 L per day. One hundred milliequivalents of free hydrogen ion and 10 L of urine would result in a hydrogen ion concentration of 10^{-2} equivalents per liter and the resultant urine would have a pH of 2.0. It is obvious that the excretion of free metabolic hydrogen ion in the urine in either circumstance is a physiologic impossibility.

Nonetheless, the kidney must eliminate that much hydrogen ion and do so by a series of mechanisms that do not destroy the epithelial lining of the renal tubules. At the same time, the consumed bicarbonate used to buffer the hydrogen ion at its source must be regenerated. As [Figure 9.3](#) clearly illustrates, there are two major processes involved in hydrogen ion elimination and bicarbonate conservation and regeneration. First, virtually all filtered bicarbonate is reclaimed in the proximal tubule. The mechanism is illustrated in the figure and involves the intracellular production of carbonic acid, the passive diffusion down a concentration gradient of hydrogen ion, the interaction of hydrogen ion with bicarbonate in the tubular lumen to form CO_2 and water, and increasing intracellular production of bicarbonate, which is then reabsorbed with sodium as has been discussed earlier in this chapter.

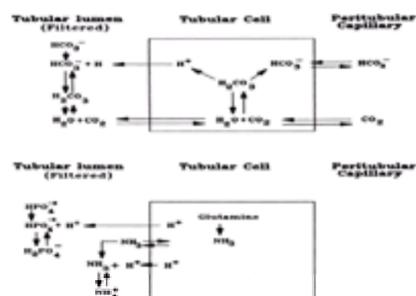

FIGURE 9.3. Cellular and luminal events in the renal tubular cell resorption of filtered HCO_3^- and formation of titratable acids and NH_4^+ .

Much more complex is the regeneration of the previously consumed bicarbonate and the simultaneous excretion of hydrogen ion into the urine in a safe and nonreactive form. This is accomplished by two major mechanisms illustrated in [Figure 9-3](#). Approximately one-third of the metabolic hydrogen ion (formed inside the cell in a mechanism virtually identical to that referred to above in the proximal tubule) is actively transported against a concentration gradient into the tubular lumen of the distal nephron. This concentration gradient is very important: depending on circumstances, there are between 100 and 1,000 molecules of hydrogen in the tubular lumen for each inside the cell, resulting in a gradient between 100:1 and 1,000:1, or an intracellular pH of 7 to 7.4 and a tubular pH of 4.5 to 5.0. In the face of hydrogen ion concentrations so significant the phosphate moiety of sodium phosphate is able to accept a second hydrogen ion and as long as the urine remains acidic will transport that hydrogen ion from the tubular lumen to the urine and out of the body. Since the hydrogen ion is eliminated in this circumstance, a bicarbonate ion is generated, reabsorbed by the peritubular capillary, and restored to the bicarbonate pool. Two-thirds of the hydrogen ion (or the remaining load) require the manufacture of ammonia and the diffusion of ammonia into the tubular lumen from the distal tubular cell. Once again, a hydrogen ion concentration far in excess of that inside the cell is required to protonate the ammonia gas to form ammonium (NH_4^+). In a process similar to that just described for phosphate, two-thirds of the metabolically produced hydrogen ion is removed from the body and two-thirds of the bicarbonate regeneration is accomplished to maintain acid–base balance. It should be obvious that the higher the hydrogen ion concentration gradient in the tubular lumen, the more easily the phosphate moiety and ammonia can be protonated and become hydrogen ion receptors.

In states of metabolic acidosis where hydrogen ion production increases beyond that of normal, the ammonia buffering system can increase ammonia production 10-fold to account for that degree of increase in hydrogen ion production. This increase is the circumstance which might obtain, for example, in chronic diabetic ketoacidosis and is one of the reasons for the serum bicarbonate concentrations never reaching zero.

Other consequences of the failure to achieve hydrogen ion gradients in the distal tubule between 1:100 and 1:1000 are discussed in [Chapter 155](#).

HORMONES

The renin–angiotensin–aldosterone system influences renal sodium handling. Renin release and the subsequent generation of angiotensin II have several effects on the ECF volume. Angiotensin II is a potent vasoconstrictor, especially in the volume-depleted state, that helps to maintain blood pressure while decreasing tissue perfusion. Within the kidney, angiotensin II causes efferent arteriolar vasoconstriction disproportionately to any effects it might have on the afferent arteriole. This increases the filtration fraction and serves to maintain GFR in the presence of decreased renal blood flow. By decreasing peritubular capillary hydrostatic pressure and increasing peritubular capillary oncotic pressure, angiotensin II enhances proximal tubular fluid reabsorption.

Angiotensin II also stimulates the synthesis and release of aldosterone, a steroid hormone produced in the adrenal gland. The secretion of this mineralocorticoid hormone is largely controlled by sodium balance. Volume depletion (i.e., increased angiotensin II levels) stimulates aldosterone secretion; volume expansion (i.e., decreased angiotensin II levels) suppresses aldosterone secretion. The sodium-retaining action of the hormone occurs primarily in the distal nephron but also

operates in a variety of other transporting tissues, such as gut and skin.

Atrial natriuretic peptide (ANP) is a hormone synthesized in the atrium of the heart. This hormone has potent natriuretic properties. It is secreted into the circulation in proportion to central blood volume (degree of atrial stretch). It may play an important role in normal sodium homeostasis by promoting urinary sodium excretion acutely by virtue of a prominent renal vasodilatation effect and chronically by directly suppressing aldosterone secretion from the adrenal gland. Direct inhibition of medullary and papillary collecting duct sodium reabsorption by ANP may also occur. Atrial natriuretic peptide also inhibits renin release, which may be secondary to a direct effect on juxtaglomerular cells or related to increased salt and water delivery to the macula densa. All of these actions are directed at restoring a more normal volume in response to an overfilled vasculature.

Prostaglandins and the kinin–kallikrein system may also participate in sodium homeostasis. These hormone systems interact with each other and with the renin–angiotensin system. Specific roles for these hormones in sodium homeostasis have yet to be defined.

POTASSIUM BALANCE

Despite its low concentration in the ECF fluid compartment, potassium is the predominant cation in the human body. Total body potassium content is about 3,500 mEq, with only about 60 mEq in the extracellular space. Skeletal muscle has a high potassium content per unit of dry weight and, because of its mass, contains most of the total body potassium stores. Potassium is readily absorbed by the gastrointestinal tract, and less than 10% of the daily ingested load is found in stool under normal circumstances. Potassium balance can be maintained on various diets that contain as little as 30 mEq per day or as much as 700 mEq per day. This ability to maintain potassium balance despite varying oral intake results from the ability of the kidney to greatly adjust potassium excretion.

Under normal circumstances, the kidney accounts for 90% of potassium excretion, although the gastrointestinal tract can be an important excretory route when renal function is severely compromised. The renal handling of potassium begins with glomerular filtration, at which point potassium is freely filterable. Potassium is reabsorbed and secreted along the distal nephron. The dynamic balance of potassium reabsorption and secretion along distal sites determines the amount of potassium excreted in the urine, and several factors can alter secretion along these distal nephron sites. Potassium secretion is increased by elevated serum potassium concentrations, elevated delivery of sodium and water to the distal nephron, and elevated aldosterone levels. Urinary excretion of potassium is further modified by acid–base alterations.

Plasma potassium concentration is determined by dietary intake and renal excretion and by factors that affect internal potassium distribution. The intracellular–extracellular potassium ratio is roughly 30:1. This ratio is critically important for the function of excitable membranes, predominantly muscle and nerve. Of these multiple factors that control internal potassium distribution, insulin and β_2 -adrenergic activity stimulate cellular potassium uptake secondary to increases in the activity of the Na^+, K^+ -ATPase. Metabolic acidosis induced by mineral acids raises plasma potassium concentration through potassium efflux from cells, but metabolic acidosis induced by organic acids does not seem to affect the plasma potassium concentration.

CALCIUM, PHOSPHORUS, AND MAGNESIUM BALANCE

The daily urinary excretion of calcium varies considerably in normal persons. This excretion is only modestly affected by changes in oral calcium intake. Only the ionized portion of calcium in the plasma is ultrafiltered at the glomerulus. Most calcium is reabsorbed along the proximal tubule, where it is closely linked to sodium transport. The final urinary excretion of calcium is therefore influenced by factors that alter renal sodium handling, including extracellular volume expansion and contraction as well as administration of diuretics. The last 5% to 10% of the filtered load of calcium is reabsorbed along the distal portions of the nephron, where the reabsorption of sodium and calcium are dissociated. It is along these distal segments that the homeostatic regulation of urinary calcium excretion occurs. Various factors alter urinary calcium excretion, including serum calcium level, parathyroid hormone, thiazide diuretics, metabolic acidosis and alkalosis, and phosphate depletion by changing calcium transport along the distal nephron. Of these factors, the most important are the state of the ECF volume, which regulates calcium transport at sites along the proximal tubule, and parathyroid hormone, which controls reabsorption along the distal nephron.

The renal handling of phosphate begins at the glomerulus, where it is freely filterable. Most filtered phosphate is reabsorbed along the proximal tubule. Additional phosphate is reabsorbed by the distal portion of the nephron, with about 10% of filtered phosphate appearing in the final urine. The two most important regulatory factors on renal transport are parathyroid hormone and dietary phosphate intake. Parathyroid hormone reduces phosphate reabsorption along the proximal tubule and produces the well-described phosphaturia of elevated parathyroid hormone activity. The effect of dietary phosphate intake on urinary phosphate excretion is seen acutely when a decrease in dietary phosphate occurs. Normal persons respond with a marked reduction in urinary phosphate excretion. This effect is substantial and may result in a diminution in the phosphaturic response to parathyroid hormone and other phosphaturic maneuvers applied during continuous low dietary phosphate ingestion.

Magnesium is second only to potassium as the most abundant intracellular cation. The kidney is a major regulatory organ for control of serum magnesium concentration. About 80% of magnesium is not protein-bound in plasma and is available for glomerular filtration. Of this filtered magnesium only 20% is reabsorbed in the proximal tubule and most is reabsorbed along the loop of Henle. This transport process is stimulated by parathyroid hormone and inhibited by hypercalcemia or hypermagnesemia and loop diuretics such as furosemide.

CHAPTER 10: PULMONARY GAS EXCHANGE

JOHN J. MARINI AND DAVID R. DANTZKER

[Pulmonary Mechanics](#)
[Pulmonary Gas Exchange](#)

PULMONARY MECHANICS

STRUCTURE OF THE RESPIRATORY SYSTEM

Chest Wall

Twelve pairs of ribs, actuated by the intercostal muscles and tendons, originate at the thoracic spinal column and attach to the sternum with cartilage ([Fig. 10.1](#)). The phrenic nerve (C3–C5) innervates the diaphragm, and the spinal nerves (T2–L4) innervate the muscles of the rib cage and abdomen.

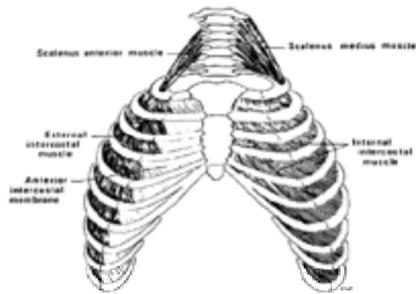

FIGURE 10.1. Intercostal and scalene muscles. On the left side of the chest, the external intercostal muscles and anterior intercostal membrane have been removed to reveal the intercostal muscles, and the left scalenus anterior has been removed to display the scalenus medius. (From Roussos C, Macklem PT. *The thorax*, second ed. New York: Marcel Dekker, 1994:430, with permission.)

The diaphragm powers ventilation by displacing the abdominal contents and splaying the lower ribs outward and upward. During quiet breathing, inspiratory activity also can be demonstrated among certain muscles of the chest cage (scalenes, parasternals, and upper external intercostals). Changing position alters the relative contributions of the intercostals and the diaphragm, with the diaphragmatic component being greatest in the supine horizontal posture. As breathing effort intensifies, the intercostals and accessory muscles of the chest cage are recruited cephalocaudally. Although exhalation is normally passive, the expiratory muscles and the internal intercostals activate at high levels of minute ventilation (more than 15 to 20 L per minute), during loaded breathing, and during expulsive maneuvers (e.g., coughing or straining).

Skeletal muscle fibers vary in their content of oxidative and glycolytic enzymes. Slow-twitch (type I) motor units consist of fibers that are rich in oxidative enzymes and resistant to fatigue. Their fast-twitch (type II) counterparts show a wide range of fatigability, reflecting varying enzyme composition. Although the diaphragm has a mixed fiber composition, it is relatively resistant to fatigue. As in most skeletal muscles, fatigue-resistant units are recruited first in response to inspiratory efforts of graded severity.

Three fundamental properties of skeletal muscle influence its force-generating behavior: the force–length relation, the force–frequency relation, and the force–velocity relation. The force–length relation ([Fig. 10.2](#)) indicates that the maximal force that a muscle fiber can generate is a function of the length from which contraction begins. For the diaphragmatic fibers, maximal inspiratory force can be developed at functional residual capacity (FRC). Force development is a nonlinear function of the frequency with which the fiber is stimulated. As efferent nerve traffic increases, so do firing frequency and the tension developed by the fiber until tetany (sustained maximal contraction) is achieved. Force development is an inverse function of the speed of contraction ([Fig. 10.3](#)). Maximal force is developed under static (isometric) conditions, whereas the unloaded fiber develops no tension when it contracts at maximal velocity.

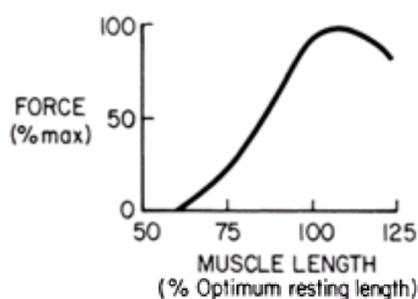

FIGURE 10.2. Stylized force–length (length–tension) curve of normal muscle. Force is expressed as percentage of maximum force (tension) developed during contraction. Length is expressed as percentage of optimum resting length. (From Rochester DF, Arora NS. Respiratory muscle failure. *Med Clin North Am* 1983;67:573, with permission.)

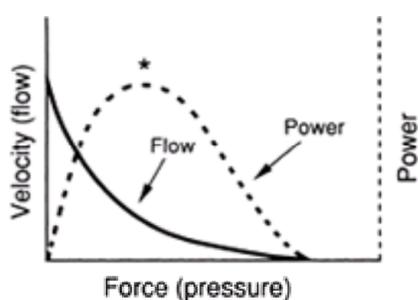

FIGURE 10.3. Relations among pressure, flow, and power. At a given level of neural stimulation, the ventilatory pump has a spectrum of available options for generating pressure and flow, depending on the impedance-to-volume change. From the standpoint of power (rate of performing external work), there is an optimal choice of pressure development and flow (*).

Lung

Airway

A conducting pathway warms and humidifies the inspired air and delivers the gas mixture to the alveoli, where gas exchange occurs. The conducting airway is a network of branching tubes, averaging 10 to 28 generations, depending on the proximity of parenchyma to the hilum. Total cross-sectional area increases by a factor of 1.8 at each branch point, so that airway resistance and gas velocity fall dramatically at the periphery. Cartilage supports the first seven generations of bronchi. At usual breathing frequencies, bulk flow carries the airstream to the level of the terminal bronchioles, beyond which point gas transport depends on diffusion. Gas-exchanging air sacs bud off the terminal seven generations (the respiratory bronchioles and alveolar ducts).

Parenchyma

The delicate alveolar membrane, composed of juxtaposed epithelial and endothelial cell layers, is draped over a scaffold of fibroelastic connective tissue. This understructure firmly anchors the parenchyma to the hilum and visceral pleura, and is largely responsible for tissue recoil. Most afferent information from the airways and lung parenchyma is conducted through the vagus nerve. Although most efferent signals are believed to flow through the vagus as well, receptors abound for b_2 -adrenergic and for noncholinergic, nonadrenergic stimulants.

To achieve the same volume, saline-filled lungs require much less pressure than air-filled lungs, indicating that surface forces at the air-liquid interface add to tissue elastance in determining the total recoil tension (Fig. 10.4.) The surface-active material that lines the air-liquid boundary (surfactant) opposes the tendency for expiratory collapse. Surfactant's complex lipoprotein structure changes conformation during different segments of the inflation-deflation cycle, attenuating surface tension at low lung volumes and reducing the tendency for alveolar collapse. Renewal of these unique properties might require periodic stretching.

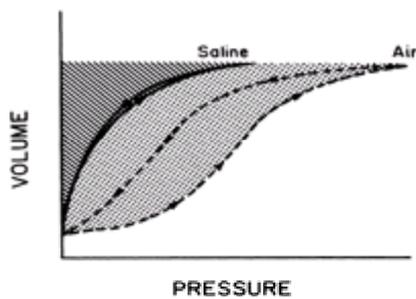

FIGURE 10.4. Relation of static distending pressure to volume for lungs filled with physiologic saline and air. The higher pressure requirement of air-filled lungs indicates the contribution of surface tension to total elastic recoil, an effect that is especially prominent at low lung volumes. The cross-hatched area depicts the elastic mechanical work performed against tissue forces during lung inflation, whereas the stippled area indicates the additional elastic work resulting from the opposition of surface tension forces.

Pulmonary Vessels

Two distinct vascular networks, the pulmonary and bronchial circulations, perfuse the lung. Within the pulmonary circulation, the arteries conduct blood from the right ventricle to the capillary bed, where gas exchange occurs. Because nearly all cardiac output flows through the lung, the pulmonary circulation filters macroscopic particles (e.g., clot) from the venous blood. Oxygenated postcapillary blood flows to the left atrium in the pulmonary veins. Three types of pulmonary arteries can be distinguished: elastic arteries, muscular arteries, and pulmonary arterioles. Unlike the pulmonary veins, they course alongside the airways of similar size, an arrangement that helps to preserve the matching of ventilation to perfusion. Normal pulmonary arteries and veins share a similar structure, consistent with the uniformly low pressures in this circuit. However, the pulmonary veins are more plentiful, providing an effective reservoir to buffer minor variations in right ventricular output.

The bronchial circulation, a lower volume, higher pressure system, normally receives only 1% to 2% of cardiac output. The bronchial arteries vary in number and may arise from the aorta directly or from the intercostal, internal mammary, or subclavian arteries. Like the pulmonary arteries, they distribute with the airways, providing the bulk of nutrient flow to all pulmonary structures other than the parenchyma itself. Communication between the pulmonary and bronchial circulations has been described at both the arterial and the capillary level. Such interconnections can maintain parenchymal nutrition and prevent infarction subsequent to pulmonary artery occlusion.

EVENTS OF THE INFLATION-DEFLATION CYCLE

Subdivisions of Lung Volume

During passive exhalation, the end-expiratory resting position of the lung (FRC) occurs at the volume at which the recoil forces of the lung and chest wall counterbalance. The volume of gas remaining in the chest after a maximal effort to exhale defines the residual volume (RV). Like the FRC, the RV must be measured by techniques other than external gas collection (spirometry). From any known starting point, gas dilution methods (helium equilibration or nitrogen washout), plethysmography, and planimetry of chest radiographs can be used to estimate absolute lung volume. Once the FRC or the RV is known, total lung capacity (TLC) can be computed from simple spirographic measurements.

Pressure Distribution Across the Thorax

As a first approximation, pressures in the extra-alveolar interstitial spaces are believed to be similar to pleural pressures. At FRC, normal airways, extra-alveolar vessels, and alveoli are surrounded by pressures similar to the pleural value at the same horizontal level, even in locations remote from the lung surface. Because the lung always remains a passive element, the effective transpulmonary pressure is the measured difference between airway (P_{aw}) and intrapleural (P_{pl}) pressures. At any moment, the difference between P_{aw} and the alveolar pressure (P_{alv}) drives gas to or from the alveoli, and the difference between P_{alv} and P_{pl} distends the lung.

Static Pressure-Volume Relations

Under static conditions, the difference between P_{alv} and P_{pl} reflects elastic lung recoil. During inspiration, however, this difference is slightly more than it would be with flow stopped at the same volume because a small pressure increment is needed to overcome tissue resistance. The effective pressure distending the chest wall cannot be directly measured during spontaneous breathing because the relevant forcing pressures are generated within the muscle fibers of the structure itself. Only when the chest wall is passively inflated can its distensibility be assessed.

The lung and chest wall occupy an identical volume, except when air or fluid separates them. The volume of each structure is uniquely determined by its compliance (distensibility) and the trans-structural pressure acting across it (Fig. 10.5). For the lung, tissue elastance and surface tension together determine the static (recoil) pressure corresponding to any specified volume. At low lung volume, surface forces contribute more to total recoil than at high lung volume, where tissue elastance predominates. The limits of distensibility are reached at TLC. Because lung tissue tends to collapse at low volumes, additional pressure must be applied to achieve a

given volume on the inflation limb. Processes that deplete surfactant accentuate such hysteresis.

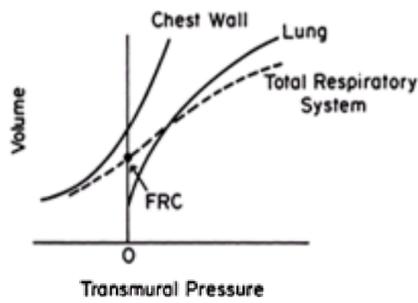

FIGURE 10.5. Static pressure–volume relations for the passive respiratory system. Transmural trans-structural pressures for the lung, chest wall, and total respiratory system are the alveolar–pleural pressure difference, the pleural pressure, and the alveolar pressure, respectively. At rest, the equilibrium volume (functional reserve capacity) occurs when recoil pressures for the lung and chest wall counterbalance. Note that the chest wall has a tendency to spring outward (balanced by a negative transmural pressure) at volumes less than about 60% vital capacity.

Although nearly linear in the usual tidal volume (V_T) range, the compliance of the lung, defined as the unit change in volume that occurs with any unit change in pressure, is greatest in the midportion of the vital capacity. To reflect tissue recoil properties, compliance should be expressed relative to absolute volume. Specific compliance, defined as the ratio of compliance to absolute volume, compensates for size differences that otherwise render compliance meaningless as a measure of elastic properties. After pneumonectomy, the calculated compliance of the “lungs,” for example, would be seriously reduced from the preoperative value, but specific compliance would remain unchanged.

The pressure–volume relation of the chest wall is also curvilinear. Although flexible early in life, the rib cage stiffens with age. The passive chest wall tends to spring outward at volumes less than 60% of vital capacity. Attempts to compress the rib cage to volumes below its equilibrium position meet increasing opposition. The diaphragm also has an elastic limit to cephalad movement.

A thin liquid film seals the lung against the chest wall. Normally, a negative force is created at the lung surface by the opposing actions of lung recoil and chest wall expansion. The elastance (the inverse of compliance) of the lung (C_L) and chest wall (C_W) are additive. Consequently, the inspiratory compliance of the entire respiratory system (C_{RS}) is less than the compliance of either of its individual elements: $1/C_{RS} = (1/C_L) + (1/C_W)$. In the up- right position, C_L , C_W , and C_{RS} approximate 200, 200, and 100 mL per cm H₂O, respectively, over the usual V_T range.

Positional Changes in Thoracic Volume

Changing position alters the effective C_W . Lung volume normally increases about 750 to 1,000 mL in moving from the horizontal to the fully upright position, with a major portion gained in peridiaphragmatic regions. Because C_{RS} at 45° averages about 100 mL per cm H₂O, moving from horizontal to upright causes a volume change comparable to about 10 cm H₂O of applied positive end-expiratory pressure (PEEP). This position-related volume increment corresponds roughly to the sine of the angle to the horizontal plane and diminishes with advancing age.

Patients with symptomatic airflow obstruction lose less lung volume than age-matched normal subjects in assuming recumbency, perhaps because normal losses of volume would increase the frictional work of breathing intolerably or because air trapping occurs. Lung volume is marginally lower in the prone versus the supine-horizontal position. Resting lung volume, however, is about 20% greater in the lateral decubitus position than in the supine position. When lateral, the upper lung is held distended at a volume similar to the upright value, whereas the lower lung is compressed.

Relation of Alveolar and Pleural Pressures

Two clinically useful relations relate changes in alveolar and pleural pressures during conditions of passive inflation. Alterations of pleural pressure influence the pressures in the heart chambers and great vessels, thereby affecting venous return and the interpretation of hemodynamic data.

Assuming that equal volume changes occur in the lung (DV_L) and chest wall (DV_W),

$$\Delta P_{pl} = \Delta P_{alv} * C_L / (C_L + C_W)$$

At end-exhalation, DP_{alv} equals DPEEP, so that the fractional change in pleural pressure expected from a change in PEEP is $C_L / (C_L + C_W)$. For the normal passive chest, the compliances of the lung and chest wall are about equivalent near FRC, so that about half of a PEEP increment normally transmits to the pleural space. An infinitely stiff chest wall ($C_W = 0$ mL per cm H₂O) would allow no volume change of the lung but would permit complete transmission of alveolar pressure to the pleural space. Conversely, an infinitely stiff lung would transmit none. In either event, no volume increment would result from the PEEP change. The volume change (DV) resulting from PEEP applied to the passive thorax can also be estimated:

$$\Delta V = [C_L * C_W / (C_W + C_L)] * \text{PEEP distribution of pressure along the pleural surface}$$

Local pressures range widely along the pleural surface (Fig. 10.6). Pleural pressures at the top of the lung are more negative than pressures in more dependent areas, normally following a gradient of about 0.2 to 0.3 cm H₂O per centimeter of vertical distance. The weight of the lung exerting lateral pressure at the lower pleural surface may explain this phenomenon. An alternative explanation invokes regional differences in lung recoil. The topography of pleural pressure is influenced by the irregular contours of bony and vascular structures in the rib cage and mediastinum. Pleural and pulmonary edema fluid accentuates the gravitational gradient; pneumothorax obliterates it.

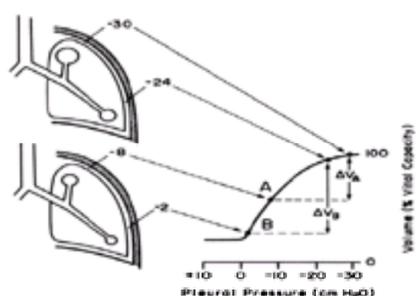

FIGURE 10.6. Vertical distribution of pleural pressure and regional fluctuations of transpulmonary pressure over a major portion of the vital capacity range. Because alveoli in dependent lung regions (**B**) rest on a more highly compliant portion of the pressure–volume relationship than do alveoli located elsewhere (**A**), they undergo

disproportionate shifts in volume (DV) for an equivalent change in pleural pressure.

Regional compliance of the chest wall varies greatly with position, especially along the surface of the diaphragm. The rib cage is most flexible anteriorly, accounting for the reduction in compliance observed when these regions are braced by the supporting surface in the prone position. In the upright position, the abdominal contents retract from the undersurface of the resting diaphragm, causing reduced and rather uniform pressure in that region. (Abdominal pressures rise during inspiration.) In the supine position, however, the hydrostatic forces of the abdominal contents generate about 1 cm H₂O per centimeter of vertical distance from the anterior abdominal surface, so that pressures in dependent regions exceed those along the anterosuperior surface. As a result, the dependent portion of the diaphragm rises to a position of better mechanical advantage. Therefore, although reduced abdominal pressure in the upper regions allows a higher resting lung volume and better distensibility, regional ventilation is lower during spontaneous efforts. Conversely, higher effective compliance in superior regions of the supine chest enables them to accept a larger than normal fraction of any passive tidal breath delivered by positive pressure or any volume increment resulting from PEEP.

INTERDEPENDENCE AND COLLATERAL VENTILATION

Wherever they are located in the lung, disadvantaged alveolar units tend to collapse when ventilated at uniformly small tidal volumes, a phenomenon partially explained by the effects of surface tension, regionally varying pleural pressures, and size differences among adjacent alveolar units. This tendency is opposed by interdependence and collateral ventilation.

Although directly vented through the main airway, adjacent alveolar sacs share pores and channels that provide collateral routes for ventilation. Furthermore, alveoli are linked through their connective tissue framework in such a fashion that increased mechanical forces of expansion are brought to bear on collapsing tissue. Contiguous units are not allowed fully independent movement. Selective deflation of any single unit increases the recoil tension of its neighbors, tending to halt the collapse. Interdependence also operates on a higher level of anatomical organization. As a lobe collapses, the adjacent pleural pressure falls, increasing the transpulmonary pressure and distending force. Both processes combating alveolar collapse—collateral ventilation and interdependence—are amplified at high lung volumes.

EFFECTS OF LUNG VOLUME ON CHEST MECHANICS

Airway Resistance

Enhanced recoil tethers open the airways and boost the driving pressure for expiratory airflow. Because airway resistance relates inversely to the fourth power of the bronchial radius, airway resistance bears a hyperbolic relation to lung volumes lower than FRC. Above FRC, resistance normally improves only modestly with increasing volume. In severe peripheral airflow obstruction, however, increasing volume well above the equilibrium position may greatly reduce breathing effort.

Pulmonary Vascular Resistance

Increasing volume has a biphasic and largely detrimental impact on pulmonary vascular resistance (Fig. 10.7). As lung volume rises, forces similar to those that affect the airways tether and dilate extra-alveolar vessels. However, increasing wall tension compresses the capillaries embedded in the alveolus. As a result, net pulmonary vascular resistance reaches its nadir near FRC. At volumes above FRC, alveolar vessel compression predominates; below FRC, vascular resistance rises again because of compression of extra-alveolar vessels.

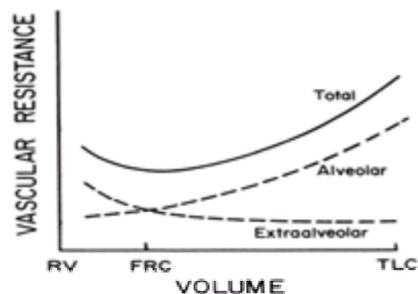

FIGURE 10.7. Relationship of pulmonary vascular resistance to lung volume. Increasing lung volume improves resistance within extra-alveolar vessels but compresses the alveolar capillary bed. Consequently, vascular resistance normally reaches a minimum at a lung volume close to the resting equilibrium (functional reserve capacity).

Respiratory Muscle Strength

As with all striated muscles, force generation in the respiratory system depends on the fiber length at which contraction begins. On this basis alone, inspiratory muscles are primed for maximal pressure generation at RV, whereas expiratory force can be maximized at TLC (Fig. 10.8). The geometric configuration of the diaphragm is also optimized at low lung volumes because fiber tension generates its most useful inspiratory force vector with the diaphragm maximally curved. Conversely, near TLC, the flattened diaphragm may actually produce an expiratory action because muscle shortening fails to displace the abdomen and draws the ribs inward at the points of insertion (Hoover's sign). Total lung capacity is the most appropriate volume from which to initiate an effective cough because the expiratory muscles contract best from this position.

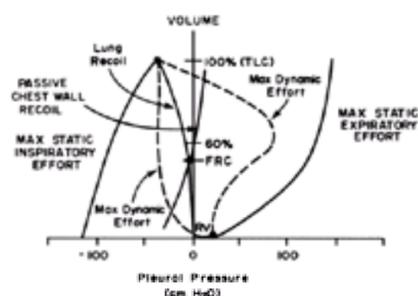

FIGURE 10.8. Relationship of lung volume to maximal inspiratory and expiratory force under isometric (*unbroken lines*) and dynamic (*dashed lines*) conditions in a normal subject. Static inspiratory force is maximized at residual volume, whereas maximal static expiratory pressures are generated at total lung capacity. Maximal values of pleural pressure are greatly attenuated during forceful efforts through an open airway. Pleural pressure values result from the combined actions of the respiratory muscles and the volume-dependent recoil tendency of the passive lung.

EFFECTS OF AIR TRAPPING

Dynamic hyperinflation (air trapping) occurs when lung volume must be maintained above its resting equilibrium position, either to minimize breathing effort or to exhale the selected tidal volume in the available time (Fig. 10.9). The usual setting is airflow obstruction and high minute ventilation requirements. Although breathing at an elevated lung volume is costly in terms of elastic work, the savings in frictional work compensates for this. Unfortunately, there is an important additional cost: acute hyperinflation foreshortens inspiratory muscle fibers, compromises the geometric configuration of the diaphragm, and forces the costal and crural portions of the diaphragm to abandon their normal parallel configuration. Moreover, increased pleural pressures and vena caval resistance may impede venous return.

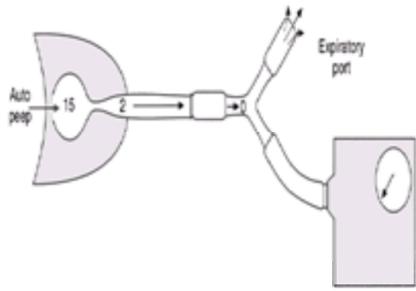

FIGURE 10.9. Dynamic hyperinflation with auto-PEEP (see below). When the respiratory system has insufficient time to empty to its relaxed equilibrium position between inspiratory cycles, the trans-respiratory system pressure remains elevated with respect to airway opening pressure throughout the respiratory cycle. The difference between alveolar pressure at end-expiration and the pressure at the central airway opening at end-expiration is termed *auto-PEEP*. In this instance, 15 cm of water pressure drives airflow through severely narrowed airways at end-expiration.

During spontaneous breathing, air trapping implies a background tension in the inspiratory muscle fibers. Expiratory flow continues throughout the exhalation half cycle, and an abrupt inspiratory “braking” pressure to counter the recoil of the thorax must be applied before inhalation can begin. In the setting of mechanical ventilation, this recoil pressure has been variably described as intrinsic, unintentional, inadvertent, or auto-PEEP. Under passive conditions, auto-PEEP elevates pleural and vascular pressures. This effect increases the elastic work of inspiration and makes it more difficult to trigger machine-aided cycles. Applied PEEP or continuous positive airway pressure (CPAP) can often counterbalance auto-PEEP and reduce breathing effort without causing a major further increase in lung volume.

Pneumothorax and Pleural Effusion

If gas or liquid accumulates under tension, the lung becomes difficult to expand and the muscles are forced into a mechanically inefficient, hyperinflated position. In the setting of pneumothorax, the exact coupling provided by the normal liquid interface is lost, and additional inspiratory pressure dissipates in pleural gas rarefaction. Obliteration of the pleural pressure gradient surrounding the lung worsens ventilation–perfusion mismatching.

In the upright position, large pleural effusions generate hydrostatic pressure that distorts the diaphragm and might even invert it. These effects are reversed when a large effusion is tapped from the pleural space. After the tap, the patient might experience less dyspnea, even though the aerated lung volume is no greater than before.

Atelectasis

At low lung volumes, alveolar instability and airway closure encourage parenchymal collapse, opposed by surfactant and tissue interdependence. As noted, a closing volume can often be identified at which small airways in dependent regions seal (anatomically or functionally) as the lung deflates. Absorption collapse may follow. Airway disease, mucosal edema, and retained secretions raise the closing volume, and recumbency and obesity reduce the resting lung volume. The tendency for closure is countered by deep breathing, which improves collateral ventilation and accentuates tissue interdependence. When the lung is ventilated at unvaryingly small tidal volumes, factors acting to close dependent or regionally compromised alveoli are ineffectively opposed, and widespread microcollapse or platelike atelectasis may develop.

In the postoperative period, numerous factors interact to force the closure of dependent airways. Apart from the nearly 30% decline in FRC that accompanies the supine position, general anesthesia causes an additional loss of resting volume as a result of diaphragmatic relaxation and cephalad displacement of the relaxed diaphragm. Airway intubation and anesthesia disrupt the function of the mucociliary escalator and may stimulate the outpouring of airway secretions. Thoracic mechanics are severely disturbed by surgical incisions in the chest or abdomen. All lung volumes, including TLC, FRC, and subdivisions of vital capacity, are reduced for at least the first 7 days after upper abdominal surgery. Diaphragmatic dysfunction and the incidence of clinically important atelectasis increase with the proximity of the incision of the diaphragm. Pain and analgesia disrupt the sighing rhythm, whereas coughing and secretion clearance are made inefficient by intubation and pain.

Frequent positional changes are crucial in the treatment and prophylaxis of atelectasis. For example, in the decubitus position, the upper lung is stretched to a greater than normal resting volume and secretions are drained along a gravitational gradient. Conversely, the lower lung may be better ventilated during spontaneous breathing owing to improved diaphragmatic advantage.

Diaphragmatic Paralysis and Quadriplegia: Effects of Volume and Position

Patients with selectively impaired diaphragmatic function have orthopnea when supine but may be comfortable when upright. In the upright position, gravity pulls the diaphragm inferiorly, so that significant negative pressure can be developed by the intercostal and accessory muscles of ventilation. Furthermore, contraction of the expiratory musculature thrusts the diaphragm cephalad, producing a caudal inspiratory action when released.

Conversely, the diaphragm and accessory muscles may be the only ones spared in quadriplegia. In this case, the patient may experience platypnea (intensified dyspnea in the upright position). The diaphragm is flattened and made less efficient when pulled inferiorly by diminished or negative pressures in the abdomen.

Hydrostatic Pulmonary Edema and Adult Respiratory Distress Syndrome

In the early phase of hydrostatic pulmonary edema or adult respiratory distress syndrome (ARDS), alveolar flooding and microatelectasis are the primary abnormalities of mechanics. In the early phase of ARDS, the lung may be viewed as comprising two populations of alveoli: those that are well ventilated and normally compliant (most prevalent in nondependent regions), and those that are consolidated or atelectatic and poorly compliant (most prevalent in dependent regions). Thus, impaired overall compliance in this disease is as much a function of a loss of aeratable lung as a function of an overall increase in tissue elastance. The number of aerated lung units may be greatly reduced (to one-third or less of normal), but their elasticity remains essentially unaffected. The resting position of the chest wall may be normal or even expanded. Positive end-expiratory pressure tends to maintain recruited alveolar units and to redistribute lung water from the alveolar space to the interstitium. In the process, more alveoli are made available to accept the V_T . Without a measurement of absolute lung volume, tissue elastance cannot be deduced from pressure and V_T data alone.

Close inspection of the inspiratory limb of the pressure–volume relation of the total respiratory system can give important clues to the presence of potentially recruitable volume that collapses during the tidal cycle. A distinctly biphasic limb of the pressure–volume curve suggests that the effective compliance of the lung improves once a critical “opening pressure” has been surpassed that enlarges the effective size of the aerated lung. Alveoli in dependent regions are the most difficult to keep open. Unless sufficient PEEP prevents reclosure of these difficult-to-recruit units, the process of opening and reclosure is repeated with each ventilatory cycle. Close monitoring of the pressure–volume curve (as well as indexes of gas exchange and oxygen delivery) may aid the clinician greatly in selecting the

appropriate level of end-expiratory pressure ([Fig. 10.10](#)).

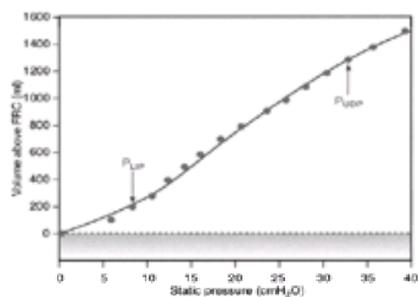

FIGURE 10.10. Static pressure volume curve of the respiratory system in a patient with acute lung injury. The filled circles represent actual measurements of static pressure during inflation from the equilibrium volume. The curved solid line connecting these points represents the third-degree polynomial that best fits the data. Note that the curve is essentially linear in its midportion but demonstrates a lower inflexion point (P_{LIP}) and an upper deflexion point (P_{UDP}).

AIRWAY MECHANICS

Airflow and Resistance

Gas flowing in a straight tube can adopt two basic patterns: laminar and turbulent. Laminar, or streamline, flow describes a pattern of movement in which adjacent layers of gas slip alongside one another in concentric cylinders. The modest energy investment required per unit of laminar flow relates to frictional losses along the tube walls and between adjacent gas layers. Viscosity is the primary gas characteristic that affects laminar energy losses. When flow becomes turbulent, adjacent layers of gas molecules collide at cross angles to the tube axis, increasing the pressure losses. Unlike the laminar flow profile, the turbulent wave front is flat (“square”), and density, not viscosity, affects pressure requirements. In a smooth, straight tube, flow converts from laminar to turbulent at high values of Reynold’s number, a dimensionless value determined by the quotient: (gas density \times velocity \times diameter)/gas viscosity. Low gas velocities and narrow airway diameters (the conditions prevailing in small bronchi) favor laminar flow, whereas rapid flows and larger calibers favor turbulence. Turbulence also tends to develop at points of airway irregularity. Reducing gas density (e.g., by using helium to replace nitrogen as a carrier gas for oxygen) can improve breathing effort strikingly in patients with obstructing lesions of the central airways.

Distribution of Airway Resistance

Resistance partitions unevenly along the airway. With the mouth closed, the normal nasal passage accounts for about half of total resistance to airflow (R_{aw}) during quiet breathing and a higher percentage of R_{aw} during forceful efforts, when turbulence accentuates intranasal pressure losses. Under such conditions, opening the mouth greatly lessens the resistance to breathing. With the mouth widely open, the oropharynx and larynx normally account for about 40% of R_{aw} during quiet breathing and a higher percentage as flow increases. Resistance along the normal tracheobronchial tree divides about equally between airways that are smaller and larger than 2 to 3 mm in diameter. Peripheral airway resistance markedly increases in diffuse airflow obstruction (e.g., asthma, chronic bronchitis, emphysema).

Expiratory Airflow

When exhalation is passive, gas empties from the normal lung exponentially, driven by recoil pressure. The product of resistance (R) and compliance (C) is known as the *time constant*, the time required to exhale 63% of the V_T . Increases in R or C delay emptying. Similar principles apply to the rate of lung filling at a constant inflating pressure. In diseased lungs, the time constants of adjacent regions may vary markedly, filling and emptying at different rates when exposed to a common pressure gradient.

If the airways were rigid and resistance were independent of flow, flow would remain proportional to the difference between alveolar and airway opening pressures during both phases of the ventilatory cycle and throughout the effort range. Forceful expiratory efforts raise pleural pressure, adding to recoil pressure and narrowing the compressible intrathoracic airway downstream of what has become known as the equal pressure point (EPP) ([Fig. 10.11](#)). At efforts that exceed about two-thirds of maximal, each increment of pleural pressure narrows the airway downstream of the EPP sufficiently to offset the increment in alveolar pressure. The effective driving pressure for flow then becomes alveolar minus pleural pressure, or the recoil pressure itself, which is a volume-dependent quantity. The effective resistance resides in the segment upstream from the critical point of compression. For each lung volume, there is a maximal rate of expiratory airflow that cannot be exceeded, defined by the recoil pressure of the lung and the intrinsic properties of the airway itself. This flow-limiting mechanism does not affect the first 15% to 20% of exhaled volume or any portion of inspiration, which remains dependent on effort.

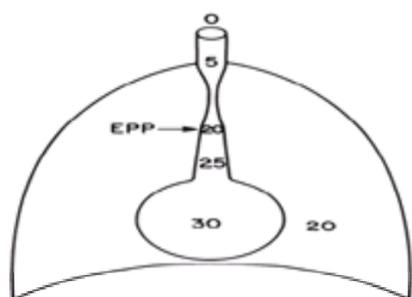

FIGURE 10.11. Dynamics of airway compression and flow limitation during forceful exhalation. At some site along the airway (the equal pressure point), transmural airway pressure becomes zero. Direct compressive forces or wave speed limitations develop at all points closer to the airway opening, offsetting any effort-related boost in alveolar pressure and limiting the maximal rate of airflow achievable at that volume.

However attractive the EPP theory may be to explain the phenomenon of flow limitation, the precise mechanism by which flow limitation occurs remains open to debate. For example, whether the point of narrowing occurs precisely at the EPP or at a point determined by a critical transmural pressure further downstream (Starling’s resistor model) is unclear. Indeed, the phenomenon of flow limitation (effort independence) may be best explained on another basis entirely—the “wave speed” theory. The speed with which a pressure wave propagates through a compressible tube (the wave speed) is reduced by decreasing the cross-sectional area and by decreasing transmural pressure, two properties that characterize the central airways. Thus, as gas accelerates in approaching the airway opening, it encounters a “choke point” at which its velocity equals the wave speed limit. Further attempts to accelerate gas flow merely compress the downstream segment.

Whatever the actual cause for flow limitation, compression of downstream airway segments produces low-volume, high-velocity gas flow that shears mucus free from the airway walls during coughing. The effort independence of maximal flow also confers reproducibility on the forced spirometric indices of airflow obstruction (e.g., the second forced expiratory volume, FEV_2).

CLINICAL MEASUREMENT OF LUNG MECHANICS

Intrapleural Pressure

The least invasive and most commonly used technique for estimating P_{pl} remains esophageal manometry. A thin latex balloon nearly devoid of air is tied to a multiperforated supporting catheter. The balloon usually is 10 cm long, so that an adequate region can be sampled. In the horizontal position, the mediastinal contents weigh on the balloon, elevating the baseline esophageal pressure. Changes in pleural pressure are somewhat more reliable than absolute pressures. The lateral decubitus, prone, and upright positions are preferred for absolute pressure measurements. When a balloon cannot be placed, variations in central venous pressure provide a crude but effective estimate of fluctuations in P_{pl} .

Alveolar Pressure

P_{alv} cannot be directly sampled but is needed to estimate lung compliance and resistance. When air ceases to flow, central airway pressure provides a close estimate of P_{alv} . This event occurs naturally at the extremes of the V_T cycle (the "zero-flow" points) or can be induced at any intermediate lung volume by transient airway occlusion.

Work of Breathing

Mechanical work (W , the product of force and distance) is performed when a pressure gradient (force/area) moves a passive structure through a volume change (distance * area). For example, when the passive thorax is expanded by a positive-pressure ventilator, the airway is pressurized and the machine performs work. Although mechanical work is done against elastic, frictional, and inertial forces, the inertial component is negligible, except at very high rates of gas flow. The inspiratory work of expanding the lungs or chest wall can be quantified as the integral of the rate of volume change of the structure (flow, \dot{V}) and the pressure change that caused it (the trans-structural pressure, P_{TM}). These pressure-volume (work) integrals can be computed electronically by integrating the product of P_{TM} and \dot{V} , or graphically by plotting cumulated inspired volume against P_{TM} , quantifying the area enclosed by the relevant portion of the resulting figure (Fig. 10.12).

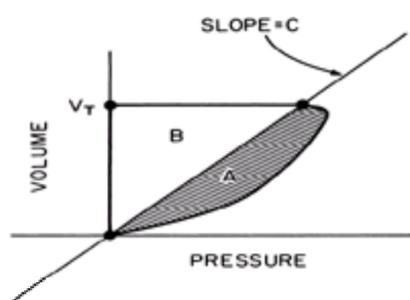

FIGURE 10.12. Calculation of the mechanical work of breathing from the relationship of volume to inflating pressure. In the tidal range, the pressure-volume curve of the lungs and thorax is nearly linear, with a slope equal to compliance, C . The elastic work performed in achieving the tidal volume (V_T) is proportional to area B . The frictional work performed varies with flow rate and resistance and is estimated by area A .

The measurement of external work does not necessarily reflect the energy consumed by the respiratory muscles. The mechanical work of breathing (W_B) is rather easily measured but correlates imprecisely with ventilation-associated oxygen consumption (V_{O_2}). These two values are interrelated by way of the expression $W_B = V_{O_2} * w$, where w is the efficiency of converting oxygen consumed in the breathing effort to useful mechanical work. Although equal amounts of mechanical work may be done in moving a large volume of air against low resistance or in moving a modest volume of air against high resistance, the latter requires greater oxygen consumption. Furthermore, the timing of contraction and the distribution of force among different muscle groups greatly influence pump efficiency. Therefore, external work relates imprecisely to the total tension developed by the muscle fibers, particularly when loading conditions vary. At the bedside, the product of the external pressure developed by the muscles and the time over which it is generated (the product of pressure and time) may be a preferable index of effort under conditions of changing afterload.

RESPIRATORY MUSCLE WEAKNESS AND FATIGUE

Muscle fatigue must be distinguished from muscle weakness. *Weakness* is the suboptimal generation of force in the resting (and rested) state; *fatigue* is the progressive inability to sustain a targeted force during a single protracted effort or (more commonly) during repeated contractions. Among other causes, muscle weakness can be the result of diminished muscle bulk, ischemia, electrolyte imbalance (e.g., due to K^+ , Mg^{2+} , or PO_4^- depletion), hypoxemia, acidemia, acute hypercarbia, systemic illness (e.g., sepsis), neuromuscular disease, or acute hyperinflation (see above). Adequate nutrition and muscle blood flow, correction of electrolyte abnormalities, and reversal of pathogenetic stimuli are essential to improving contractile function.

Fatigue is the result of sustained or repetitive overload and may reflect an imbalance of metabolic energy delivery and consumption. For example, respiratory muscle fatigue may occur in the setting of circulatory shock, even when muscle loads remain within normal limits. Continued overstimulation in the face of fatigue eventually depletes energy reserves and results in irreversible cross bridging of actin-myosin proteins, producing rigor. For this reason, it is believed that neural stimulation to the overloaded muscle spontaneously attenuates well before fatal rigor is produced. (Such a mechanism might help to explain the evolution of respiratory arrest in some critically ill patients.) It has been empirically determined, both for peripheral skeletal muscle and for the intact diaphragm of normal subjects, that force and percentage contraction time influence endurance independently. Thus, the integrative tension-time index correlates well with endurance:

$$(\text{Tension/breath/maximal tension}) * (T_f/T_{TOT})$$

Loads that produce values exceeding 0.20 cannot be sustained indefinitely and result in fatigue. An early (if not infallible) indication of eventual fatigue is provided by electromyographic power spectrum analysis. Shifts to lower values in the centroid frequency or a high/low frequency ratio reliably indicate a fatiguing stress. Physical signs of muscle overload include tachypnea, paradoxical abdominal motion, respiratory alternans, vigorous use of accessory muscles, and dysrhythmic breathing patterns. Once fatigued, a muscle might require 24 hours or more to restore energy reserves and contractile function. Reversal of fatigue requires a reduction in the workload/capacity ratio to a sustainable level. Apart from reducing minute ventilation and pressure generation requirements, improving energy delivery and repleting reserves (nutrition, cardiovascular function), as well as restoring contractile strength (by the measures already noted), are primary clinical objectives.

PULMONARY GAS EXCHANGE

Oxygen is required for the efficient production of energy, and carbon dioxide is produced as a by-product. Continuous exchange of these gases between the tissues and the surrounding environment is necessary to maintain concentrations that are consistent with adequate tissue function. The efficiency with which the lungs accomplish this task is reflected in the arterial blood gas analysis, which, when properly interpreted, provides insight into the pathophysiology of lung disease.

NORMAL GAS EXCHANGE

The lung's functional unit of gas exchange is the acinus, which comprises a terminal airway and its surrounding alveoli (about 2,000). There are about 300 million alveoli in the adult lung, each about 0.25 mm in diameter. Because of the way the alveoli are packaged and connected, they can provide an internal surface area of

over 100 m² (the size of a tennis court). The alveoli are surrounded by a capillary network of similar surface area containing at any one time about 200 mL of blood. The alveolar–capillary interface (the air–blood barrier) is exceedingly thin (only 0.2 mm at some points).

The alveoli are connected to the environment by a series of conducting airways within which no gas exchange takes place. On inspiration, the amount of fresh gas that reaches the alveoli (V_A) is less than the V_T , by the volume of the physiologic dead space (V_{DS}): $V_A = V_T - V_{DS}$. For healthy lungs breathing at normal V_T , the V_{DS} is largely accounted for by the volume of the conducting airways, which approximates 1 mL per pound of lean body weight. In a normal lung, each breath increases the alveolar PO_2 (P_{AO_2}) and reduces the alveolar PCO_2 ($P_{ALV}CO_2$) by 5% to 10%. The small changes are due to the buffering effect of the gas remaining in the lungs at the end of a normal breath (FRC). The normal V_T is about 300 mL, and the normal FRC is about 3,000 mL—a 10-fold difference.

The pulmonary arterial blood (systemic venous) entering the lung has a mixed venous oxygen tension ($P_{\bar{v}O_2}$) and a mixed venous carbon dioxide tension ($P_{\bar{v}CO_2}$) determined by the cardiac output and the metabolic rate of the tissues. The rate at which gas transfers between the alveolus and the pulmonary arterial blood depends on the inspired gas concentration, the $P_{\bar{v}O_2}$ and $P_{\bar{v}CO_2}$, the ability of the blood and gas phases to equilibrate fully, and the adequacy with which the lung matches alveolar ventilation (\dot{V}_A) and blood flow on perfusion (\dot{Q}) in each lung unit, the ventilation/perfusion (\dot{V}/\dot{Q}) ratio. An abnormality of any of these leads to disordered pulmonary gas exchange.

In the blood, the respiratory gases are carried both dissolved in the plasma and combined with hemoglobin. Hemoglobin is a complex molecule composed of globin folded around heme, an iron-containing O₂ carrier. Each gram of hemoglobin binds 1.39 mL of O₂ when fully saturated. The degree to which the hemoglobin saturates with oxygen depends on the PO_2 to which the hemoglobin is exposed. The avidity for binding O₂ decreases as each of the four binding sites on the heme molecule is occupied, resulting in the nonlinear relation between the P_{O_2} and the O₂ saturation described by the oxyhemoglobin dissociation curve (Fig. 10.13). The O₂ is also carried in much smaller amounts dissolved in the plasma (0.003 mL O₂ per mm Hg per dL blood). The total amount of O₂ carried, the O₂ content, can be calculated from the sum of the dissolved and bound forms:

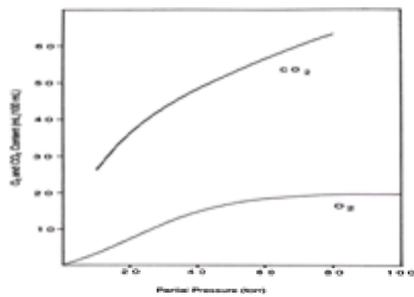

FIGURE 10.13. The oxyhemoglobin and carbon dioxide dissociation curves. The difference in shape of the relationship between partial pressure and content, sigmoid for O₂ and linear for CO₂, has important physiologic consequences. (From Dantzker DR. Pulmonary gas exchange. In: Dantzker DR, ed. *Cardiopulmonary critical care*. Philadelphia: WB Saunders, 1991:34, with permission.)

$$O_2 \text{ content (mL/dL blood)} = [\text{hemoglobin content (g)} \times O_2 \text{ saturation (\%)}] + 0.003 \times PO_2$$

Carbon dioxide is transported in the blood in three forms. Ninety percent is carried in the form of bicarbonate (HCO_3^-) after hydration within the red blood cell in a reaction catalyzed by carbonic anhydrase: $CO_2 + H_2O \rightleftharpoons H_2CO_3 \rightleftharpoons HCO_3^- + H^+$. The H^+ is buffered by the hemoglobin and the HCO_3^- diffuses into the plasma. Five percent of the CO₂ is carried as carbamino compounds, with CO₂ binding to terminal amine groups on hemoglobin. The remaining 5% dissolves in plasma. The relation between the PCO_2 and the total CO₂ content of the blood is described by the carboxyhemoglobin dissociation curve, which is steeper and more linear than the oxyhemoglobin binding curve (Fig. 10.13).

Many factors influence the relation between the partial pressures of the respiratory gases and their respective blood contents. These can be described by alterations in the shape or, more importantly, in the position of the dissociation curves. Factors commonly found in the setting of increased O₂ use (increased PCO_2 and higher temperature and reduced pH) decrease the affinity of hemoglobin for O₂, causing a rightward shift of the curve and facilitating the release of O₂ to the tissues. Opposite changes shift the curve leftward, increasing the affinity of hemoglobin for O₂. This leftward shift expedites the loading of O₂ in the lung. Chronic tissue O₂ insufficiency increases the production of 2,3-diphosphoglycerate, which also displaces the curve to the right. Carbon monoxide competes with O₂ for hemoglobin binding sites and shifts the curve leftward, impeding the release of O₂. Finally, various genetically determined hemoglobin variants have curves that may be located to the left or the right of normal. The position of the oxyhemoglobin dissociation curve is usually described by calculating the P_{O_2} at which the hemoglobin is 50% saturated (P_{50}). The normal P_{50} is about 27 mm Hg. The position of the carboxyhemoglobin curve is influenced most by the O₂ saturation. Increases in O₂ saturation shift the curve to the right, and the decreased affinity facilitates the unloading of CO₂ in the lungs. The falling O₂ saturation in the tissues shifts it in the opposite direction, making it easier to remove the CO₂ produced by metabolism.

The mature red blood cell is packed with hemoglobin but cannot synthesize protein, making it vulnerable to injury. Its biconcave shape increases the surface area for gas exchange and permits greater deformability, which facilitates its ability to squeeze through capillaries of similar dimension.

PULMONARY MECHANISMS OF ABNORMAL GAS EXCHANGE

Reduction of the Inspired PO_2

During ascent from sea level, the inspired PO_2 ($P_{I}O_2$) decreases exponentially with barometric pressure:

$$P_{I}O_2 = 0.2093 \times (\text{barometric pressure} - \text{water vapor pressure})$$

In the alveolus, water vapor pressure remains at 47 mm Hg when measured at body temperature. The $P_{I}O_2$ is 150 mm Hg at sea level and falls to about 38 mm Hg on the summit of Mount Everest. Exposure to a reduced $P_{I}O_2$ is quite common in our mobile society. The cabins of commercial aircraft are pressurized to simulate altitudes as high as 8,000 to 10,000 feet, producing a $P_{I}O_2$ as low as 100 mm Hg.

The alveolar gas equation calculates a mean “ideal” alveolar P_{O_2} by considering the lung to be a single homogeneous compartment that receives all ventilation and perfusion. The equation can be simplified as:

$$P_{ALV}O_2 = P_{I}O_2 - P_aCO_2/R$$

where R is the respiratory exchange ratio (CO₂ production divided by O₂ consumption, or \dot{V}_{O_2} divided by \dot{V}_{CO_2}). Normally, the difference between the calculated “ideal” $P_{a}O_2$ and the measured $P_{a}O_2$ is small. In patients with lung disease, however, the alveolar–arterial difference for O₂ ($P_{ALV}O_2 - P_{a}O_2$) widens. The reduction in $P_{a}CO_2$ that occurs subsequent to hyperventilation increases the alveolar P_{O_2} by 1 to 1.25 mm Hg per mm Hg fall in $P_{a}CO_2$, depending on R. During maximal hypoxic stimulation, a normal subject can maintain $P_{a}CO_2$ as low as 7 mm Hg. Patients with lung disease, however, may not be able to increase minute ventilation (\dot{V}_E) to the same degree.

Abnormal Diffusion

The transfer of gas across the alveolar capillary membrane is accomplished by diffusion:

$$\text{Gas transfer} = \text{diffusing capacity of the lung} \times (P_A - P_{cap})$$

The diffusing capacity of the lung (D_L) is a lumped parameter encompassing a series of resistances to gas flow. Direct measurements of the D_L for O_2 and CO_2 are difficult to obtain because they require the capillary partial pressures (P_{cap}) of each gas, which are impossible to measure directly.

At rest, an individual blood cell spends about 0.75 second in the pulmonary capillaries but usually can equilibrate fully with alveolar gas within one-third of the time available. This allows for increased diffusion capability when the system is required to transfer increasing amounts of gas, as during exercise. Under certain circumstances, the system may be stressed sufficiently so that diffusion limits gas transfer. Three situations can be hypothesized: an increase in the diffusion pathway, as might be seen subsequent to inflammation or fibrosis; a reduction in the time of contact between alveolar gas and blood, as with a marked increase in cardiac output (such as during exercise) or with a reduction in the cross-sectional area of the vascular bed due to primary vascular disease or diffuse alveolar destruction; and a reduction in the driving pressure ($P_A - P_{cap}$), as would be seen at extreme altitudes or perhaps in individual lung units where the alveolar P_{O_2} is reduced due to \dot{V}/\dot{Q} mismatching. In clinical disease, abnormal diffusion plays only a small role in causing hypoxemia, and even this component is easily overcome by a modest increase in F_{I,O_2} .

Hypoventilation

Metabolic production of CO_2 ($\dot{V}CO_2$) adds almost 17,000 mEq of acid to the blood each day that must be removed at the same rate at which it is produced. The alveolar, and thus arterial, level of CO_2 depends on the relation between production and excretion:

$$\text{Alveolar } PCO_2 = \dot{V}CO_2 / \dot{V}_A$$

In the normal lung, the \dot{V}_A is a relatively fixed proportion of the \dot{V}_E , and it is useful to think of the P_aCO_2 as inversely proportional to the \dot{V}_E . Hypoventilation is best defined as a rate of ventilation inadequate to prevent respiratory acidosis. Hyperventilation is the opposite. Because the anatomical dead space is a relatively fixed volume, the proportion of the \dot{V}_T that it comprises varies inversely with the V_T . Therefore, if the same minute ventilation is achieved with a small V_T and increased frequency, the \dot{V}_A decreases and hypoventilation ensues. The \dot{V}_A can also fall in the face of an unchanged (or even increased) \dot{V}_E if an increase in alveolar dead space develops.

Hypoxemia that results from hypoventilation is not due to inefficient O_2 transfer (unless atelectasis supervenes). Normally, \dot{V}_E is closely coupled to $\dot{V}CO_2$. Hypoventilation thus represents an abnormality of ventilatory control or a failure of the respiratory pump to respond to a normal input signal. Such pump failure is most commonly noted in the setting of cerebrovascular accident, deep sedation or narcosis, neuromuscular disease, or skeletal abnormalities of the chest wall such as kyphoscoliosis. Although small increases in F_{I,O_2} correct hypoventilation-associated hypoxemia, therapy must be directed at the low \dot{V}_A and its underlying, often nonpulmonary, etiology to prevent progressive respiratory acidosis.

Differentiation between pulmonary and nonpulmonary causes of hypoxemia can usually be made by calculating the $P_{ac}O_2 - P_aO_2$. With hypoventilation, the $P_{AO_2} - P_aO_2$ remains normal. In patients with \dot{V}/\dot{Q} inequality, the falling P_aO_2 and increasing P_aCO_2 are accompanied by a widening of this index.

Ventilation-Perfusion Inequality

Under ideal conditions, the alveoli would all receive exactly matching amounts of blood flow and ventilation, ensuring maximal transfer of O_2 and CO_2 . Even in the normal lung, however, regional differences in the distribution of blood flow and ventilation lead to variability in the \dot{V}/\dot{Q} ratios. Any mismatching of blood flow and ventilation (\dot{V}/\dot{Q} inequality) disrupts pulmonary gas exchange. The \dot{V}/\dot{Q} can vary from 0.0 in shunt units that are perfused but not ventilated to infinity in those that are ventilated but not perfused (dead space).

Influenced by posture and gravity, the \dot{V}/\dot{Q} distribution usually ranges from 0.6 to 3.0, with most units approximating 1.0 (Fig. 10.14). There is also a small shunt (1% to 3%) due to blood flow from the bronchial and thebesian veins that drain directly into the left side of the heart. The normal dead space consists mainly of the non-gas-exchanging airways and during quiet breathing approximates 33% of the V_T . With increasing age, there is a gradual increase in the degree of \dot{V}/\dot{Q} inequality, which explains the increased $P_{A,O_2} - P_aO_2$ usually seen in older normal subjects.

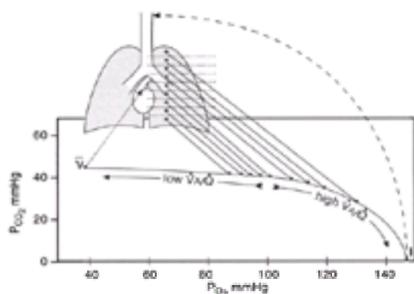

FIGURE 10.14. Composition of pulmonary venous blood leaving different regions of the upright lung. Note the spectrum of ventilation/perfusion ratios and their resultant contributions to the mixture that forms the arterial blood. (From West JB. *Ventilation/blood flow in gas exchange*, fourth ed. Oxford: Blackwell Scientific, 1985, with permission.)

In lung disease, units with low or high \dot{V}/\dot{Q} may predominate. Low \dot{V}/\dot{Q} units usually develop as the result of regionally reduced ventilation secondary to airway disease. They may also be caused by overperfusion of normally ventilated lung units, as for example after acute pulmonary embolism, when blood flow is suddenly diverted from embolized to nonembolized areas of the lung. The embolized units, by contrast, develop high \dot{V}/\dot{Q} or become dead space, depending on the completeness of occlusion. A more common cause of high \dot{V}/\dot{Q} units is emphysema, a disease in which the loss of blood flow secondary to alveolar wall destruction is even greater than the decrease in \dot{V}_E .

Because \dot{V}/\dot{Q} inequality dramatically affects both O_2 and CO_2 transfer, it would invariably lead to both hypoxemia and hypercapnia if \dot{V}_E remained unchanged (Fig. 10.14). However, in patients with intact ventilatory drive and muscle function, any increase in the P_aCO_2 due to developing \dot{V}/\dot{Q} inequality leads to an increased \dot{V}_E

mediated by chemoreceptor drive. To the extent that this increased \dot{V}_E can affect lung units with low \dot{V}/\dot{Q} , increasing their ratios back toward normal improves both arterial P_{O_2} and P_{CO_2} . Noteworthy improvement is possible, however, only when the low \dot{V}/\dot{Q} is caused by overperfusion and the airways are relatively normal. In patients in whom the low \dot{V}/\dot{Q} ratios are caused by significant airway obstruction, any additional ventilation tends to go to the normal, already well-ventilated alveoli. When blood from these units combines with the blood coming from the low \dot{V}/\dot{Q} units, the P_{O_2} remains relatively unchanged. Conversely, the carboxyhemoglobin dissociation curve is linear throughout the physiologic range (Fig. 10.13). The low P_{aCO_2} in the capillary blood of the well-ventilated units nearly compensates for the decreased removal of CO_2 by the units with low \dot{V}/\dot{Q} ratios. Patients with lung disease often have additional inputs to the respiratory center from stretch and irritant receptors within the lung and airways as well as from hypoxic stimulation, and thus the degree of hyperventilation may exceed the amount required to compensate for the low \dot{V}/\dot{Q} units. Raising the inspired fraction of oxygen may dramatically improve arterial P_{O_2} , depending on the severity of \dot{V}/\dot{Q} mismatching and the range over which F_{IO_2} is increased (Fig. 10.15).

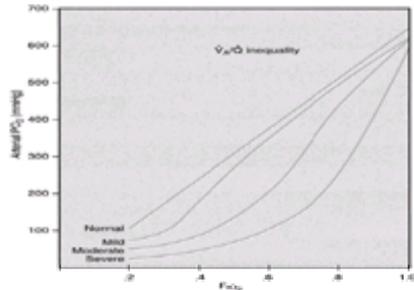

FIGURE 10.15. Effect of increasing ventilation/perfusion inequality on the arterial P_{O_2} at different inspired oxygen fractions (F_{IO_2}). Note that an F_{IO_2} of 1.0 essentially eliminates the depression in arterial P_{O_2} caused by any degree of ventilation/perfusion inequality. (From Dantzker DR. *Cardiopulmonary critical care*, second ed. Philadelphia: WB Saunders, 1991:39, with permission.)

As \dot{V}/\dot{Q} inequality increases, however, the work of breathing may rise to the level where further increases in ventilation are impossible, dyspnea becomes intolerable, or the metabolic cost of breathing results in no gain in overall gas exchange. At this point, the only way to eliminate the metabolic CO_2 load is to allow P_{aCO_2} to rise. Hypercapnia permits the CO_2 to be cleared at a higher concentration per liter of ventilation, thus making more efficient use of the remaining ventilatory capacity. Two patients with obstructive pulmonary disease might have equal reductions in flow rates and increases in \dot{V}/\dot{Q} inequality, but one might be hypercapnic and the other hypocapnic. The major difference between them is the higher \dot{V}_E in the hypocapnic patient, which is believed to reflect, among other things, a difference in the gain control of the chemoreceptors.

Hypoxic vasoconstriction is a conservative reflex in the lung that minimizes \dot{V}/\dot{Q} inequality when P_{aO_2} ranges within 30 to 150 mm Hg. Variations in P_{aO_2} result in adjustments of tone within the perfusing arteriole in an attempt to increase the \dot{V}/\dot{Q} ratio. When regional abnormalities are present, hypoxic vasoconstriction can minimize the impact of \dot{V}/\dot{Q} inequality on gas exchange by diverting blood flow away from these abnormal areas. With generalized hypoxia, however, as is seen with diffuse lung disease or in normal persons exposed to high altitude, any beneficial effect on gas exchange is often overshadowed by the increased pulmonary arterial pressure that develops from global increases in pulmonary vascular resistance. This pulmonary hypertension and sensitivity to hypoxia is particularly intense in patients with a reduced capillary bed (as occurs in emphysema with cor pulmonale). Many drugs interfere with effective hypoxic vasoconstriction, including nitroglycerin, β -adrenergic agonists, calcium channel blockers, various direct arterial vasodilators, and inhalational anesthetics. Because of this, the use of these drugs in patients with lung disease may result in worsened hypoxemia. Nitric oxide is believed to mediate alveolar vasodilatation. Exciting recent work indicates that inhaled nitric oxide preferentially improves blood flow in well-ventilated regions, thereby improving oxygen exchange in acutely diseased lungs.

As the degree of \dot{V}/\dot{Q} inequality worsens, there is an increasing resistance to correct P_{aO_2} by raising F_{IO_2} . When marked \dot{V}/\dot{Q} inequality is present, as might be seen in the terminal stages of many diffuse pulmonary processes, there may be no substantial rise in P_{aO_2} until the F_{IO_2} exceeds 0.40.

Shunt

The shunting of venous blood through non-gas-exchanging units dramatically alters gas exchange. Shunts most commonly result from blood passing through pulmonary capillaries in the walls of alveoli that are atelectatic or filled with edema fluid or inflammatory exudate. Less frequently, right-to-left shunting occurs through atrial or ventricular defects, driven by favorable pressure gradients across them. Rarely, the shunting may be through anatomical arteriovenous channels within the lung such as arteriovenous malformations or the vascular malformations occasionally seen in the lungs of patients with far-advanced hepatic cirrhosis. Whatever the cause, the percentage of cardiac output shunted across the lung tends to parallel cardiac output. The impact on P_{aO_2} depends, however, on any simultaneous changes that occur in P_{VO_2} and hypoxic vasoconstriction in shunt regions.

Shunt is the cause of hypoxemia in both cardiac and noncardiac pulmonary edema; it constitutes the major abnormality of oxygen exchange seen with pneumonia. The physiologic behavior of shunt demands an approach to therapy that is different from that associated with \dot{V}/\dot{Q} inequality.

Shunt is a potent cause of hypoxemia because of the low saturation of the mixed venous blood. Even a small increase in shunt leads to a significant fall in the P_{aO_2} . Hypercapnia is not generally seen. A low P_{aCO_2} is, in fact, more common because ventilation is usually stimulated in excess of metabolic requirements by the developing hypoxemia as well as by inputs from intrapulmonary stretch receptors.

Unlike \dot{V}/\dot{Q} inequality, the hypoxemia caused by shunt resists correction by increases in F_{IO_2} . This feature is often used clinically to differentiate the two mechanisms. As the shunt gets larger, the breathing of even pure O_2 makes only a small impact on the P_{aO_2} , again unlike the problem of \dot{V}/\dot{Q} inequality. However, even the small increases in P_{aO_2} that are seen can be physiologically significant. Small changes in P_{aO_2} lead to significant changes in O_2 content because these patients are usually so hypoxemic that P_{aO_2} is on the steep portion of the oxyhemoglobin dissociation curve.

Because of the poor response of shunt hypoxemia to supplemental O_2 , and considering the risks of exposing the lung to high F_{IO_2} , other strategies for treatment are required. Recruitment of collapsed lung units or redistribution of lung liquids and blood flow by PEEP, repositioning, or pharmacologic relaxing of the chest wall is often effective. Inhaled vasodilators (prostaglandin or nitric oxide), intensifiers of hypoxic vasoconstriction (almitrine), or measures to improve the O_2 content of the mixed venous blood can also improve P_{aO_2} in the setting of acute lung injury.

NONPULMONARY FACTORS AFFECTING GAS EXCHANGE

The degree to which variations in mixed venous P_2 ($P\dot{V}O_2$) alters the end-capillary P_{O_2} depends on the \dot{V}/\dot{Q} ratio of the unit. For ventilated lung units, the influence of the $P\dot{V}O_2$ is greatest in units with a \dot{V}/\dot{Q} ratio of less than 1.0 and negligible for those with a \dot{V}/\dot{Q} ratio greater than 10. The ability of the $P\dot{V}O_2$ to affect the P_{aO_2} increases as the degree of \dot{V}/\dot{Q} inequality or shunt increases.

A low $P_{\dot{V}}O_2$ occurs when there is a disparity between O_2 delivery and the O_2 requirements of the tissues. This is most common in the setting of an inappropriately low cardiac output, O_2 content, and hemoglobin concentration. It is accentuated when the O_2 requirements are increased, as in exercise, fever, vigorous hyperpnea, agitation, or hypermetabolic states.

In normal lung, the effect of a low $P_{\dot{V}}O_2$ on the P_aO_2 can be overcome by increasing \dot{V}/\dot{Q}_E , which effectively increases the \dot{V}/\dot{Q} ratio of all units in the lung. This explains why little or no fall in P_aO_2 occurs in normal subjects during exercise, despite marked venous desaturation. In abnormal lungs, however, this correction is much less effective because the increased \dot{V}_E exerts minimal impact on the poorly ventilated units and no impact on the shunt.

Mixed venous desaturation is the primary cause for the fall in P_aO_2 often noted during exercise in patients with both obstructive and restrictive lung disease when an improving match of ventilation and blood flow cannot compensate for the increased O_2 extraction. It is also a common cause for alterations of P_aO_2 in critically ill patients who are poised at the margin between adequate and inadequate O_2 delivery.

CHAPTER 11: VASCULAR BIOLOGY

ELIZABETH G. NABEL

[The Normal Artery](#)
[The Intima](#)
[The Media](#)
[The Adventitia](#)
[Cells of the Artery](#)
[Conclusion](#)

THE NORMAL ARTERY

The normal artery consists of three layers. An intima lined by endothelium is on the inner or luminal aspect of the vessel and is bounded by the internal elastic lamina. The media consists of smooth muscle cells intertwined by elastic fibers. The media is bounded by the internal elastic lamina and by an external elastic lamina. The adventitia is the outer layer of the artery and is bounded by the external elastic lamina and the exterior of the vessel ([Fig. 11.1](#)).

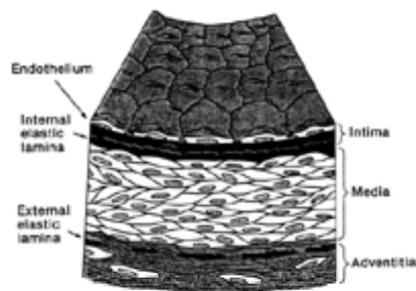

FIGURE 11.1. Structure of a normal muscular artery. (From Ross R, Glomset J. The pathogenesis of atherosclerosis. *N Engl J Med* 1996;295:369, with permission.)

THE INTIMA

In the human being at birth, the intima contains a thin layer of connective tissue and occasional smooth muscle cells. Over time, there is a concentric increase in the number of smooth muscle cells in the intima, referred to as diffuse intimal thickening. The intima is lined by a single layer of endothelial cells that abuts the lumen of the blood vessel.

Atherosclerotic lesions form in the intima. There are several ways in which lesions develop. The typical lesions of atherosclerosis are characterized by an asymmetric thickening of the intima that encroaches on the lumen of the blood vessel, resulting in a decrease in blood flow. A second form of intimal thickening is due to an increase in the intima associated with continued dilatation of the artery such that the actual lumen size does not change. These lesions tend to be concentric and consist of diffuse intimal thickening due to smooth muscle cell hyperplasia, commonly found as a sequela of hypertension.

THE MEDIA

The media is the muscular wall of the artery, bounded by the internal and external elastic lamina. The function of the media is to contract or dilate the blood vessel. Two different types of arteries are present in the human circulation: muscular arteries and elastic arteries. The media of muscular arteries consists of spiraling layers of smooth muscle cells attached to one another. Each smooth muscle cell is surrounded by a discontinuous basement membrane and interspersed collagen fibrils. Elastic arteries contain multiple layers of smooth muscle cells, each equivalent to a single media in a smaller muscular artery. Each layer of smooth muscle cells is bounded by an elastic lamina on its inner and outer aspects. The number of layers or lamellar units in elastic arteries is proportional to the size of the animal and depends on other factors, such as the anatomical position of the artery.

THE ADVENTITIA

The adventitia is the outer layer and the support structure of the artery. The adventitia consists of dense collagenous structures, including collagen fibrils, elastic fibers, and some smooth muscle cells. The adventitia contains the vasovasorum, which contains small nerves and arterioles. The adventitia provides the outermost portion of the media its nutrition via the vasovasorum, along with lymphatic channels and nerve fibers. The inner layer of the media receives its nutrition via blood derived from the lumen of the blood vessel. There is an increase in the number of microvessels in the adventitia opposite intimas containing atherosclerotic plaques. An increase in adventitial vessels as well as an increase in microvessels within the plaque may play important roles in the hemorrhage and thrombosis that follows plaque rupture in unstable atherosclerotic lesions.

CELLS OF THE ARTERY

ENDOTHELIUM

The entire circulatory system is lined by a continuous, single-cell-thick vascular endothelium. In healthy vessels, the vascular endothelium comprises a container for blood within the lumen of the artery and forms the biologic interface between the circulating blood components and all tissues of the artery. Endothelial cells probably represent the largest and most extensive tissue in the body because they line the entire vascular tree. The endothelium is the principal barrier between elements of the blood and the artery wall. In adults, the turnover of endothelial cells is very slow, on the order of 120 days. The endothelium has several very important functions: it forms a highly selective permeability barrier; it provides a nonthrombogenic surface; it is a highly active metabolic tissue; it forms several vasoactive substances; and it participates in the conversion of bloodborne monocytes to tissue-derived macrophages.

Endothelial cells morphologically are very similar throughout the circulatory system. However, there are functional differences in endothelial cells in different anatomical sites. This is important since endothelial cells respond to injury after exposure to various injurious agents in different parts of the arterial tree. This might include infectious agents, which act primarily at the capillary level; or oxidized low-density lipoprotein (LDL) particles that enter the subintima in large elastic and muscular arteries; or the response on the part of the endothelium to shear stress from systemic hypertension. Endothelial cells are normally attached to each other by gap junctions. They transport substances in both directions across these cells via the process called transcytosis. Transendothelial channels have been observed primarily in capillary endothelium; however, it has been suggested that junctions between endothelial cells serve as potential sites of transendothelial migration by macrophages in large arteries as well.

Endothelial cells rest on a basement membrane that contains type IV collagen. These endothelial cells are capable of synthesis of connective tissue molecules. The basement membrane in addition to the internal elastic lamina serves as a crude type of filter. When the endothelium is removed or the artery is stretched, pores are present in the internal elastic lamina that permit the migration of macromolecules from the lumen to the media or the migration of smooth muscle cells from the media to the intima.

Endothelial cells are highly active cells with multiple functions ([Fig. 11.2](#)). Endothelial cells mediate several functions including a selective permeability barrier;

hemostasis and thrombosis; vasoconstriction and vasodilatation; regulation of cytokines and growth-regulatory molecules; and transduction of biomechanical forces. These are adaptive processes that contribute to normal homeostasis of the blood vessel. However, when the endothelium is damaged or removed, alterations occur in the blood vessel including enhanced permeability, adhesiveness for leukocytes and other inflammatory molecules, thrombosis, stimulation of smooth muscle cell growth, and disruption of normal regulation of vascular tone, often leading to vasoconstriction. These manifestations are collectively termed endothelial dysfunction (Fig. 11.3), and they play a critical role in the initiation, progression, and clinical complications of inflammatory and degenerative vascular diseases.

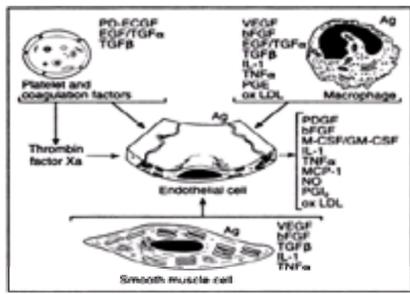

FIGURE 11.2. The endothelial cell presents a barrier to the artery wall, has nonthrombogenic properties, metabolizes vasoactive substances, produces growth factors, and forms connective tissue matrix. (From Ross R. The pathogenesis of atherosclerosis: a perspective for the 1990s. *Nature* 1993;362:108, with permission.)

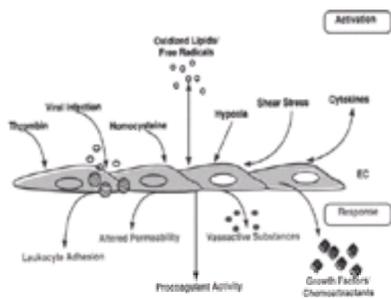

FIGURE 11.3. Generation of a dysfunctional endothelium. Stimulatory or injury provoking agents activate the endothelial cell. In response to injury, endothelial cell function is altered, resulting in a dysfunctional endothelium and leading to progression of vascular disease. (From Dicorleto PE, Gimbrone MA. Vascular endothelium. In: Fuster V, Ross R, Topol EJ, eds. *Atherosclerosis and coronary artery disease*. Philadelphia: Lippincott-Raven Publishers, 1996, with permission.)

Hemostatic–Thrombotic Balance

Blood normally does not clot inside its endothelial barrier. Failure of the endothelium to activate the coagulation cascade is referred to as nonthrombogenicity. Endothelial cells synthesize an arachidonic metabolite, prostaglandin I_2 (PGI_2 ; also called prostacyclin) that is an extraordinarily potent inhibitor of platelet aggregation. The discovery of PGI_2 led to the concept that the endothelium plays an active thrombotic role by preventing platelet aggregation on its surface. The endothelium also plays a pivotal role in regulating the coagulation and fibrinolytic systems. Most of these functions are antithrombotic in nature. The endothelium synthesizes a number of natural coagulants including heparin, protein C, thrombomodulin, and tissue plasminogen activator, to name a few. The molecular mechanisms of the coagulation system and its interface with the endothelium are described in greater detail in [Chapter 13](#), [Chapter 237](#), and [Chapter 238](#).

In contrast to the normal antithrombotic functions that occur in healthy endothelium, dysfunctional endothelial cells are prothrombotic. The endothelium, when damaged, synthesizes adhesive cofactors for platelets, such as von Willebrand's factor, fibronectin, thrombospondin, and procoagulant components like factor V, and is a trigger for the fibrin-generating coagulation cascade. The endothelium also synthesizes an inhibitor of the fibrinolytic pathway, called plasminogen activator inhibitor 1 (PAI-1), which reduces the rate of fibrin breakdown.

Thus, the endothelium functions in a hemostatic and thrombotic manner. This is relevant to maintain normal blood fluidity, stopping hemorrhage at sites of vascular injury, and altering pathologic thrombosis. These endothelium-dependent mechanisms contribute to a dynamic physiological balance between hemostatic and thrombotic factors.

Vasoconstrictor–Vasodilator Balance

The maintenance of arterial tone has traditionally been viewed of a function of the vascular smooth muscle cell within the media that responds to sympathetic or parasympathetic nervous activity. This concept was dramatically altered in the 1980s with the discovery of a potent endothelium-derived relaxing factor (EDRF), subsequently identified as nitric oxide. Landmark experiments performed by Furchgott and Zawadzki identified an EDRF produced by the endothelium that led to dilatation of smooth muscle cells. In the absence of the endothelium, EDRF was not produced, and smooth muscle cells underwent a paradoxical vasoconstriction leading to an increase in arterial tone. This was a new concept in vascular biology; that is, the vascular endothelium locally regulates vascular smooth muscle cells and vascular tone through the synthesis of vasoactive substances. Endothelium-derived relaxing factor was subsequently discovered to be nitric oxide. Studies of its metabolic pathway, the generation of nitric oxide synthase, and the cellular mechanisms of nitric oxide action that result in arterial vasodilatation have added a new dimension to our understanding of the role of endothelial cell–smooth muscle cell interactions and the regulation of vascular function. Nitric oxide along with PGI_2 and other related compounds constitute a class of natural endothelium-derived relaxing substances.

There are also endothelial-derived substances that have vasoconstrictor activity. These include angiotensin II, generated by the conversion of angiotensin I to angiotensin II by angiotensin-converting enzyme at the endothelial surface; platelet-derived growth factor (PDGF), secreted by endothelial cells; and endothelin 1. Endothelin 1 is the most potent vasoconstrictor known. It is generated by the proteolytic cleavage of a larger precursor, big endothelin. There are other prostaglandins that have vasoconstrictor properties.

Cytokines and Growth-Regulatory Molecules

The endothelium synthesizes many cytokines and growth factors that act locally on arteries to promote growth of smooth muscle cells and macrophage as well as mediate inflammatory changes. Thus, the endothelium has often been referred to as an endocrine organ having both paracrine (acting on neighbors) or autocrine (acting on self) functions.

The endothelium maintains a balance between cytokine and growth-regulatory molecules with regard to their primary effect on vascular smooth muscle cell migration and proliferation. Some of the endothelium-derived cytokines include interleukin 1a, IL-1b, IL-6, IL-8, and monocyte chemotactic protein (MCP-1). The endothelium is also the source of growth factors that stimulate smooth muscle cell migration and proliferation. These include PDGF, fibroblast growth factor (FGF), transforming growth factor b (TGF-b), insulin-like growth factor 1 (IGF-1), and heparin-binding epidermal growth factor (EGF). Platelet-derived growth factor is a growth factor for fibroblasts and smooth muscle cells but not endothelial cells. When injured, endothelial cells secrete PDGF that acts as a mitogen and chemoattractant for smooth muscle cells. It stimulates migration of smooth muscle cells from the media into the intima where smooth muscle cells then form atherosclerotic lesions. Another mitogen is FGF, which has angiogenic and growth-promoting effects on endothelium and smooth muscle cells. Transforming growth factor b stimulates smooth muscle

cells to synthesize and secrete extracellular matrix, predominantly collagen.

Transducer of Biomechanical Forces

The endothelium is constantly exposed to biomechanical stimuli due to its position in direct contact with flowing blood. These stimuli include mechanical forces generated by pulsatile blood flow, fluid stress, wall tension, and intramural pressure. Some forces are passively transduced across the endothelial layer to other cells and the extracellular matrix, whereas some forces act directly on the endothelial cell to alter its metabolic state and regulate gene expression. Some of the biomechanically induced effects include changes in growth factors, vasoconstrictors, vasodilators, and fibrinolytic factors. For example, a shear stress response element (SSRE) has been described in the promoter region of PDGF B. Increased shear stress leads to activation of a promoter element, causing transcription of the PDGF gene and an increase in PDGF protein synthesis by endothelial cells. The PDGF protein stimulates smooth muscle cells to migrate and proliferate. This shear stress response element is also present in the promoter of some leukocyte adhesion molecules, such as intercellular adhesion molecule 1 (ICAM-1). The role of the endothelium as a transducer of biomechanical forces is important in the context of atherosclerosis. It is now appreciated that the early lesions of atherosclerosis arise at sites of increased shear stress with a predilection for branch points and lesions of curvature. These areas are characterized by disturbed blood flow.

Thus, the endothelium forms an obligate monolayer that lines the arterial tree, is metabolically active, produces vasoactive substances, has a nonthrombogenic surface, and can form procoagulant materials. It serves as the permeability barrier that regulates the passage of molecules into the artery. It forms nitric oxide, the principle means by which vasodilatation is maintained. It oxidizes LDL and facilitates incorporation into tissue macrophages to rid excess cholesterol particles from the circulation. These events are described in [Chapter 13](#).

SMOOTH MUSCLE CELLS

The vascular smooth muscle cell has been described as a multifunctional mesenchymal cell. The smooth muscle cell normally functions as a contractile cell in the media to maintain vascular tone. However, the smooth muscle cell also proliferates in the arterial intima to form the intermediate and advanced lesions of atherosclerosis. It is widely believed that the accumulation of smooth muscle cells in the intima represents the *sine qua non* of atherosclerotic lesions.

There have been considerable advances in our understanding of the biology of smooth muscle cells. Thirty years ago it was widely believed that the only function of smooth muscle cells was to contract within the vessel wall. In the early 1970s it became possible to culture smooth muscle cells. Tissue culture studies then led to a greater understanding of the multiple functions of smooth muscle cells. The smooth muscle cell synthesizes and secretes several forms of collagen, elastic fibers, and proteoglycans. Smooth muscle cells, like fibroblasts, contain high-affinity receptors for a number of ligands. These ligands include LDL, insulin, PDGF, FGF, and TGF- β , to name a few. Smooth muscle cells also synthesize and secrete growth regulatory molecules such as PDGF.

The principal role of the smooth muscle cell in the adult artery is to maintain the tone of the arterial wall. The basic mechanism of contraction involves interaction of the contractile proteins actin and myosin. The contractile force is produced by the sliding of smooth muscle actin and myosin filaments across one another. The smooth muscle cell responds to numerous vasoactive substances, such as epinephrine and angiotensin, that induce contraction and vasoconstriction. It responds to vasodilatory substances as well, including PGI₂ and nitric oxide, which produce vasorelaxation.

Smooth muscle cells present two different phenotypes in culture. The first is the contractile phenotype ([Fig. 11.4](#)). This is associated with cell contractility because these cells contain extensive myofibrils throughout the cytoplasm consisting of actin and myosin filaments. These contractile smooth muscle cells do not respond to mitogens such as PDGF. When a smooth muscle cell is injured or appropriately stimulated, it changes from a contractile to a synthetic phenotype. The synthetic phenotype has fewer myofilaments. Synthetic smooth muscle cells synthesize and secrete numerous proteins, including growth factors, connective tissue molecules, and other macromolecules.

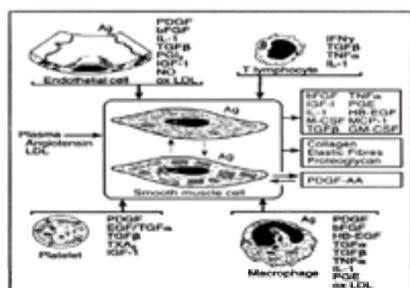

FIGURE 11.4. The smooth muscle cell undergoes phenotypic modulation from a contractile to a synthetic phenotype. In the synthetic phenotype, smooth muscle cells synthesize connective tissue molecules, growth factors, and interact with neighboring T lymphocytes, platelets, and macrophages. The genes that are expressed by each cell type that interacts with the smooth muscle cell are listed to the right of the cell type. (From Ross R. The pathogenesis of atherosclerosis: a perspective for the 1990s. *Nature* 1993;362:801, with permission.)

The phenotypic modulation of smooth muscle cells from a contractile to a synthetic phenotype underlies the pathogenesis of atherosclerotic lesions. Smooth muscle cells in the contractile phenotype are nonresponsive to mitogens, whereas those in the synthetic phenotype are responsive to mitogens, such as PDGF and FGF. For the lesions of atherosclerosis to develop, the smooth muscle cell must convert from a contractile to a synthetic phenotype, migrate from the media to the intima, and proliferate in the intima, forming the atherosclerotic lesion. As the smooth muscle cell proliferates within the intima, it also secretes connective tissue macromolecules and metabolizes oxidized LDL, along with macrophages and endothelial cells. Smooth muscle cells are also stimulated to proliferate in the presence of inflammatory cytokines, produced by activated endothelium and macrophages. Consequently, control of the phenotypic state of the smooth muscle cell is critical to understanding and preventing the development of atherosclerosis.

PLATELETS

Platelets are clearly important in the genesis of lesions of atherosclerosis. Platelets are the inciting molecules that adhere and aggregate to the subintima during rupture of the atherosclerotic plaque and formation of an occlusive thrombosis on the platelet-rich clot, leading to unstable angina and myocardial infarction. Platelets are interesting cells in that they synthesize little or no protein. They contain numerous prepackaged, highly potent molecules sequestered in their granules. Among these are a number of factors that are important in the coagulation cascade and are potent growth factors or mitogens. These growth factors include PDGF, FGF, TGF- β , and EGF. The vasoactive substances within platelet granules include serotonin, thromboxane A₂, platelet factor IV, and calcium.

When platelets are exposed to a disrupted endothelial surface, they adhere to the subendothelium. Growth factors are released. The coagulation cascade is initiated. Thus, at sites of injury in which collagen exposure, thrombin and fibrin formation, or ADP release occurs, platelet aggregation and thrombosis follow, leading to the release of vasoactive, stimulatory, and proliferative agents carried by the platelets. Thus, platelets also participate in the response to injury and to the pathogenesis of atherosclerosis. During rupture of an atherosclerotic plaque, the subintima is exposed, and platelets adhere to the vasculature via several adhesive molecules, including von Willebrand's factor and tissue factor. Platelets also contain receptors for numerous ligands. The glycoprotein IIB–IIIa receptor plays an essential role in platelet aggregation and adhesion during plaque rupture and the clinical syndromes of unstable angina and myocardial infarction. Inhibitors of the glycoprotein IIB–IIIa receptor have now led to major advances in the treatment of acute coronary syndromes by disruption of platelet adhesion and aggregation.

MACROPHAGES

Macrophages are derived from circulating monocytes. When the monocyte enters the tissue, it takes on characteristics of the host tissue. In most inflammatory sites, the monocyte converts to a tissue macrophage where it acts as a scavenger cell to remove foreign substances by phagocytosis and acts as a second line of defense to neutrophils against microbial organisms. As a scavenger cell, the macrophage removes injurious substances such as oxidized LDL via scavenger receptors.

Macrophages also oxidize LDL by 15-lipoxygenase. Macrophages play an important role in the pathogenesis of atherosclerosis and the response to injury. Macrophages act as scavenger cells to ingest oxidized LDL and microbial organisms in the vessel wall. Macrophages secrete a large number of biologically active substances, including leukotrienes, IL-1, oxygen metabolites such as superoxide anion, PDGF, FGF, EGF, TGF- β , and macrophage colony-stimulating factor, a growth factor from monocyte-macrophages. These growth factors then act in an autocrine and paracrine manner to stimulate macrophage and smooth muscle cell replication. Macrophages accumulate in lesions and contribute to the pathogenesis of atherosclerosis. Indeed, plaque rupture commonly occurs at the shoulder region of the plaque at sites of macrophage accumulation and inflammation.

The macrophage is a key cell responsible for promotion of connective tissue proliferation, commonly associated with chronic inflammatory responses. Macrophages are the principal cell in the fatty streak, the initial lesion of atherosclerosis. They accumulate large amounts of lipid in the form of droplets that contain cholesterol ester. Macrophages and smooth muscle cells proliferate in atherosclerotic lesions.

T-LYMPHOCYTES

The CD8⁺ and CD4⁺ T lymphocytes have been observed in all phases of atherosclerosis. Their presence in atherosclerotic lesions lends evidence to the hypothesis that atherosclerosis may develop in part as a result of an immune reaction. Also, T lymphocytes are present in transplant atherosclerosis following cardiac transplantation. While the lesions observed in common atherosclerosis are eccentric in nature, the lesions of transplant atherosclerosis are concentric in nature. The nature of the antigens that play a role in common atherosclerosis have been incompletely characterized; however, *Chlamydia pneumoniae*, cytomegalovirus, and other viral antigens have been proposed. The interactions between T lymphocytes and activated macrophages suggest that antigen presentation and the release of cytokines and growth factors are important steps in the inflammatory reaction. In addition, oxidized LDL may be a potential major antigen that stimulates macrophage-T-cell interactions.

CONCLUSION

Knowledge in the field of vascular biology has exploded in the past decade. The tools of molecular and cellular biology have facilitated rapid expansion of our understanding of the principal cells involved in atherosclerosis: endothelium, smooth muscle, platelets, macrophages, and T cells. Studies in transgenic and knockout mice have increased our understanding of the interaction of these cells and the pathogenesis of vascular diseases. Gene transfer and gene therapy are providing new therapeutic approaches to the treatment of atherosclerosis and other vascular diseases (Fig. 11.5). At present, one of the most critical aspects of vascular disease is the need to understand the basis of genetic susceptibility. A major thrust for future research in vascular biology will focus on the molecular genetics of complex cardiovascular diseases. An understanding of the gene sequences, genetic loci, and complex trait interactions will lend itself to new possibilities for novel therapeutics, including gene therapy.

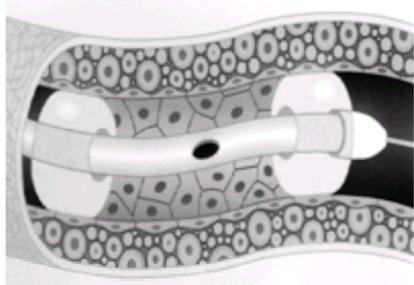

FIGURE 11.5. Gene transfer within an artery. A double-balloon catheter is inserted into an artery. Inflation of the proximal and distal balloon creates an interprotected space into which a vector and recombinant DNA can be introduced into the blood vessel. The gene enters endothelial cells and smooth muscle cells, and recombinant protein is expressed. The recombinant protein can have autocrine and paracrine effects on adjacent endothelial cells, smooth muscle cells, platelets, and macrophages. (From Nabel E. Gene therapy: cardiovascular gene therapy. *Sci Med* 1997;4–5, with permission.)

CHAPTER 12: DISORDERS OF LIPID METABOLISM

DANIEL J. RADER

[Lipoprotein Structure and Metabolism](#)
[Disorders of Lipoprotein Metabolism](#)
[Primary Hyperlipoproteinemias Due to Known Single-Gene Disorders](#)
[Primary Hyperlipoproteinemias of Unknown Cause](#)
[Secondary Forms of Hyperlipidemia](#)
[Elevated Lipoprotein\(A\)](#)
[Disorders Affecting HDL Cholesterol Levels](#)
[Selected Genetic Disorders of Intracellular Cholesterol Metabolism](#)

Lipoproteins are macromolecular complexes that transport nonpolar lipids (primarily triglycerides, cholesteryl esters, and fat-soluble vitamins) through body fluids (lymph, plasma, and interstitial fluid) to tissues that require them for normal metabolic function and from tissues that cannot catabolize them. Therefore, lipoproteins are important for the absorption of dietary cholesterol, long-chain fatty acids, and fat-soluble vitamins; the transport of triglycerides, cholesterol, and vitamin E from the liver to peripheral tissues; and the transport of cholesterol from peripheral tissues to the liver, where it is secreted into bile, converted to bile acids, or recycled into lipoproteins.

LIPOPROTEIN STRUCTURE AND METABOLISM

The general structure of lipoproteins is illustrated in [Figure 12.1](#). Lipoproteins are discoidal or spherical particles that contain a core of nonpolar lipids (triglycerides and cholesteryl esters) surrounded by polar components (phospholipids, unesterified cholesterol, and proteins) that interact with body fluids. The plasma lipoproteins are divided into five major families ([Table 12.1](#)): chylomicrons, very low density lipoproteins (VLDLs), intermediate-density lipoproteins (IDLs), low-density lipoproteins (LDLs), and high-density lipoproteins (HDLs). Each family contains a spectrum of particles differentiated from one another by their apolipoprotein composition or by certain physicochemical properties such as their density, size, or migration during electrophoresis. The density of a lipoprotein is determined by the ratio of lipid (less dense) to protein (more dense) in the particle. As the lipid content in a lipoprotein decreases relative to protein, the density increases. Chylomicrons and VLDLs are the largest and least dense lipoproteins and contain the greatest amount of lipid per protein. In contrast, HDL particles are the smallest and densest lipoproteins and contain the least amount of lipid per protein.

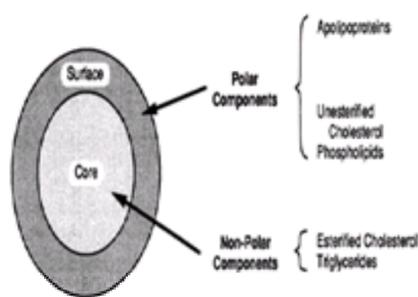

FIGURE 12.1. General structure of a lipoprotein.

Lipoprotein	Density Range (g/mL)	Particle Size (nm)	Electrophoretic Mobility	Major Apolipoprotein
Chylomicrons	0.91	75–120	Origin	ApoB-48
Chylomicron remnants	1.015–1.036	30–40	Slow neg	ApoB-48
VLDL	1.015–1.036	30–40	Preβ	ApoB-100
IDL	1.030–1.035	25–35	Slow neg	ApoB-100
LDL	1.015–1.032	18–25	β	ApoB-100
HDL ₂	1.063–1.070	5–12	α	ApoA-I
HDL ₃	1.025–1.070	5–8	α	ApoA-I
Lp(a)	1.035–1.070	25	Preβ	Apo(a)

IDL, very low density lipoprotein; VLDL, very low density lipoprotein; LDL, low density lipoprotein; HDL, high density lipoprotein; Lp(a), lipoprotein(a).

TABLE 12.1. CHARACTERISTICS OF THE MAJOR LIPOPROTEINS

The proteins of lipoproteins, called apolipoproteins ([Table 12.2](#)), are required for important metabolic functions: the assembly and structural integrity of lipoproteins, the activation of enzymes important in lipoprotein metabolism, and the interaction of lipoproteins with cell surface receptors that promote the cellular uptake of lipoproteins. Certain apolipoproteins are markers for specific families of lipoproteins. For example, there are two forms of apolipoprotein B—apoB-48 and apoB-100 ([Fig. 12.2](#))—both derived from the same gene on chromosome 2. In the liver, the full-length apoB mRNA is translated to produce apoB-100, which is found in lipoproteins derived from the liver (VLDLs, IDLs, LDLs). However, in the intestine, the apoB mRNA is “edited” by a complex that introduces a stop codon sequence slightly before the midpoint of the coding sequence, resulting in the synthesis of a smaller protein (apoB-48), which is then found in lipoproteins derived from the intestine (chylomicrons). Apolipoprotein A-I, which is made in both liver and intestine, is found on virtually all HDL particles and serves as a marker for this lipoprotein family.

Apolipoprotein	Primary Tissue Source	Lipoprotein Distribution	Physiologic Functions
ApoA-I	Intestine, liver	HDL	Structural protein for HDL; Activator of LCAT
ApoA-II	Liver	HDL	Structural
ApoA-IV	Intestine	HDL, chylomicrons	Structural
ApoB-48	Intestine	Chylomicrons	Chylomicron synthesis and secretion
ApoB-100	Liver	VLDL, IDL, LDL, Lp(a)	VLDL synthesis and secretion; Ligand for binding to LDL receptor
ApoC-I	Liver	Chylomicrons, VLDL, HDL	Structural
ApoC-II	Liver	Chylomicrons, VLDL, HDL	Co-factor for lipase
ApoC-III	Liver	Chylomicrons, VLDL, HDL	Inhibitor of lipoprotein binding to receptors
ApoE	Liver	Chylomicron remnants, VLDL, IDL, HDL	Ligand for binding to LDL receptor and SR-BI
Apo(a)	Liver	Lp(a)	Structural

HDL, high-density lipoprotein; VLDL, very low density lipoprotein; IDL, intermediate-density lipoprotein; Lp(a), lipoprotein(a); SR-BI, scavenger receptor class B type I.

TABLE 12.2. CHARACTERISTICS OF THE MAJOR APOLIPOPROTEINS

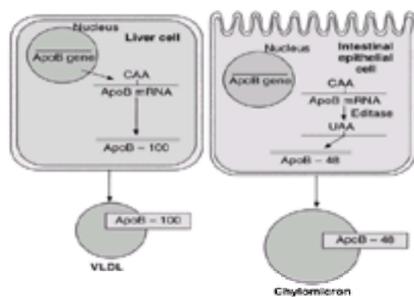

FIGURE 12.2. Synthesis of apoB-100 by the liver and apoB-48 by the intestine from the same gene. In the liver, the apoB mRNA is translated into full-length apoB-100 protein. In the intestine, a CAA codon in the apoB mRNA is edited to a UAA stop codon, resulting in the production of shorter apoB-48.

EXOGENOUS PATHWAY OF LIPOPROTEIN METABOLISM (FIG. 12.3)

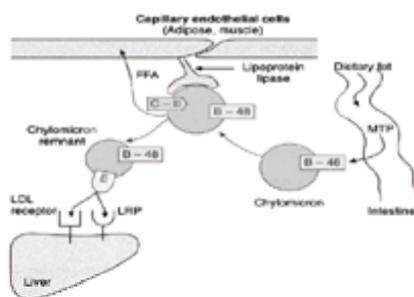

FIGURE 12.3. Exogenous pathway of lipoprotein metabolism. B-48, apoB-48; C-II, apoC-II; E, apoE; FFA, free fatty acids; LRP, LDL receptor-related protein; MTP, microsomal transfer protein.

Chylomicrons are synthesized in intestinal epithelial cells in response to the ingestion of dietary fat. The longer chain fatty acids (those with more than 12 to 14 carbons) are converted to triglyceride for incorporation into chylomicrons, whereas shorter chain fatty acids are absorbed directly into the portal circulation. Newly synthesized triglycerides and dietary cholesterol are combined with apoB-48 in a process that requires the microsomal transfer protein (Fig. 12.3). Chylomicrons are secreted into the intestinal lymph and enter the plasma, where they acquire apoC and apoE by exchange from other lipoproteins, especially HDLs. As chylomicrons enter capillaries, they attach to the enzyme lipoprotein lipase (LPL), which is anchored to capillary endothelial cells via proteoglycans (Fig. 12.3). Lipoprotein lipase is activated by apoC-II on the chylomicron surface to hydrolyze the core triglyceride to free fatty acids, which are taken into tissues for oxidation (e.g., muscle) or storage for future use (e.g., adipose tissue). Some of the free fatty acids bind to plasma albumin and are returned to the liver for oxidation or reesterification to triglyceride.

After much of the chylomicron triglyceride core is hydrolyzed, the particle dissociates from LPL as a chylomicron remnant. These remnants are depleted of triglyceride and apoC but retain apoB-48, apoE, and most of the dietary cholesterol. The remnant particles are rapidly removed from the circulation by the liver through the binding of apoE on the remnant particle surface to heparan sulfate proteoglycans and subsequently the LDL receptor or the LDL receptor-related protein (LRP) (Fig. 12.3).

ENDOGENOUS PATHWAY OF LIPOPROTEIN METABOLISM (FIG. 12.4)

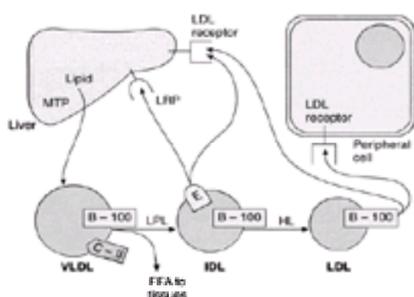

FIGURE 12.4. Endogenous pathway of lipoprotein metabolism. B-100, apoB-100; C-II, apoC-II; E, apoE FFA, free fatty acids; HL, hepatic lipase; LPL, lipoprotein lipase; LRP, LDL receptor-related protein; MTP, microsomal transfer protein.

Very low density lipoproteins are triglyceride-rich lipoproteins that are smaller and more dense than chylomicrons and are produced by hepatic parenchymal cells. Hepatic triglycerides and cholesterol are combined with apoB-100 within the endoplasmic reticulum in a process that also requires the microsomal transfer protein (Fig. 12.4). Vitamin E is also packaged into the assembling VLDL particle by a protein known as the tocopherol-binding protein. After secretion into the plasma, VLDLs acquire apoC and apoE by transfer from other lipoproteins, especially HDLs. Like chylomicrons, VLDL triglycerides are hydrolyzed by capillary LPL, especially in muscle and adipose tissue. When VLDL remnants dissociate from LPL, they are called IDLs. The IDL particles may be taken up by receptors on the liver or they may be converted further to LDL (Fig. 12.4). Apolipoprotein E mediates the hepatic uptake of IDL via either the LDL receptor or LR. The IDL particles not catabolized by this route are converted to LDL by a process that involves hepatic lipase (Fig. 12.4).

Low-density lipoproteins are cholesterol-rich lipoproteins that supply cholesterol and vitamin E to cells. The LDL receptors are found in most tissues throughout the body, and apoB-100 serves as the recognition site for binding to the LDL receptor. Approximately 70% to 80% of total clearance of LDL from the plasma is by the liver. Therefore, the amount of LDL receptors expressed by the liver is an important factor in the regulation of plasma levels of LDL.

Knowledge of the normal lipoprotein metabolism allows prediction of the consequences of molecular defects in apolipoproteins, lipolytic enzymes, and lipoprotein receptors. For example, patients with a genetic deficiency of LPL or apoC-II cannot hydrolyze triglycerides and therefore have elevated chylomicrons and VLDLs. In contrast, patients with abnormal forms of apoE cannot clear remnant lipoproteins efficiently and accumulate them in the plasma. Finally, patients with defects in the LDL receptor or in apoB-100 that affect its binding to the LDL receptor have delayed clearance of LDL from the blood and therefore have hypercholesterolemia due to high levels of LDL.

HIGH-DENSITY LIPOPROTEIN METABOLISM (FIG. 12.5)

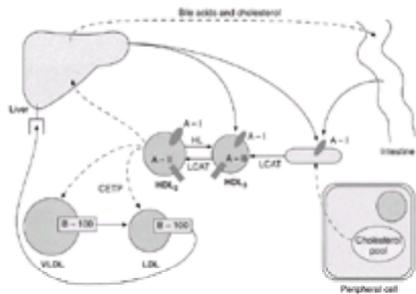

FIGURE 12.5. Pathways of HDL metabolism. Solid lines trace the conversion of lipoprotein particles. Broken lines trace the transfer of free cholesterol or cholesteryl ester between different lipoprotein classes or between lipoprotein and cells. ABC1, ATP-binding cassette protein 1; CESTP, cholesteryl ester transfer protein; HL, hepatic lipase; LCAT, lecithin:cholesterol acyltransferase; SR-BI, scavenger receptor class BI.

High-density lipoproteins are believed to participate in a process termed “reverse cholesterol transport” in which excess peripheral cholesterol is acquired by HDLs and returned to the liver for excretion into the bile (Fig. 12.5). Apolipoprotein A-I, the major HDL apolipoprotein, is synthesized by both the intestine and the liver. Nascent HDLs are thought to be discoidal particles that acquire unesterified cholesterol from peripheral tissues, a process facilitated by a cellular protein called ATP-binding cassette protein 1 (ABC1). Unesterified cholesterol is esterified on HDLs by the enzyme lecithin:cholesterol acyltransferase (LCAT), a plasma enzyme associated with HDLs. As nascent HDLs generate more cholesteryl ester, they evolve into spherical particles, which enlarge further as they acquire additional lipid and protein constituents from chylomicrons and VLDLs when the triglyceride core of these lipoproteins is hydrolyzed. The HDL cholesteryl esters can be transferred to the liver through at least two pathways. First, HDL cholesteryl esters can be transferred to apoB-containing lipoproteins in exchange for triglyceride through the action of cholesteryl ester transfer protein (CESTP). Some of these apoB-containing lipoproteins are then removed from the plasma by the liver via the LDL receptor or LRP. Triglyceride-enriched HDL is a substrate for hepatic lipase, which hydrolyzes HDL triglycerides and phospholipids and generates smaller HDL particles. Second, HDL cholesteryl esters can be taken up directly by the liver in a process termed selective cholesterol uptake. This process is mediated by scavenger receptor class BI (SR-BI), a cell surface receptor that facilitates uptake of HDL cholesteryl ester but not of the entire lipoprotein particle. Thus, the metabolism of HDL cholesteryl ester and HDL apoA-I are dissociated. Eventually, apoA-I is removed from the circulation by a process that is not well understood but involves both the kidneys and the liver.

ApoA-II is the second most abundant HDL apolipoprotein. Unlike apoA-I, apoA-II is synthesized only by the liver, not by the intestine. Apolipoprotein A-II is found on approximately two-thirds of all HDL particles. This results in two major classes of HDL particles: one containing apoA-I and apoA-II and the other containing apoA-I without apoA-II. These two classes of HDL particles may have different physiologic roles and metabolic pathways, but their significance for human pathophysiology is uncertain.

LIPOPROTEIN(A) (FIG. 12.6)

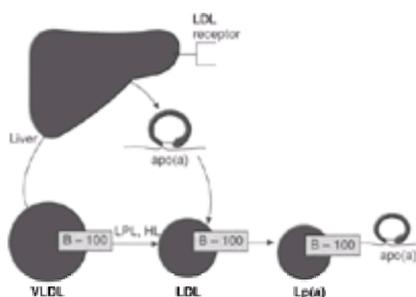

FIGURE 12.6. Pathways of lipoprotein(a) metabolism. Apolipoprotein(a) is secreted by the hepatocyte independently of LDL and subsequently binds to LDL or a precursor to form Lp(a). HL, hepatic lipase; LPL, lipoprotein lipase.

Lipoprotein(a), or Lp(a), is another lipoprotein found to a variable extent in human plasma. It is related in structure to LDL in that it contains apoB-100 and a core of cholesteryl ester. Lipoprotein(a) is distinguished structurally from LDL by the presence of a unique protein, apolipoprotein(a) [apo(a)], which is linked by a single disulfide bond to the apoB. Apolipoprotein(a) bears a strong resemblance to plasminogen and varies substantially in its molecular weight among different persons. It is synthesized by the liver, and the association of apo(a) with apoB may occur after apo(a) is secreted into the plasma. Once intact, the metabolism of Lp(a) is distinct from that of LDL. Lipoprotein(a) generally has a longer half-life than that of LDL and is not removed from the plasma by the LDL receptor. However, the site and mechanism of its catabolism are unknown. Lipoprotein(a) is generally considered to be an independent risk factor for atherosclerotic vascular disease.

INTRACELLULAR CHOLESTEROL METABOLISM (FIG. 12.7)

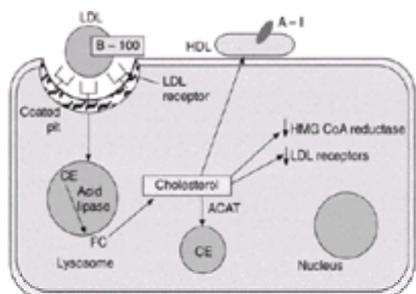

FIGURE 12.7. Intracellular cholesterol metabolism. Low-density lipoprotein (LDL) is targeted to lysosomes by the LDL receptor and LDL cholesteryl esters are hydrolyzed to free cholesterol by the lysosomal acid lipase. The Niemann-Pick C gene 1 is required for transfer of lysosomal free cholesterol to the cytoplasmic pool. Free cholesterol can then be esterified to cholesteryl esters by acyl coenzyme A:cholesterol acyltransferase and stored as lipid droplets or be released to acceptor particles such as HDL. Free cholesterol within the cell down-regulates the expression of genes such as b-hydroxy-b-methylglutaryl-coenzyme A reductase and the LDL receptor. ACAT, acyl coenzyme A:cholesterol acyltransferase; CE, cholesteryl ester; FC, free cholesterol; NPC1, Niemann-Pick C gene 1.

Cells require cholesterol for normal function, and they obtain it from two sources: biosynthesis from acetyl CoA and uptake of lipoprotein cholesterol from the interstitial fluid. Most cells can take up cholesterol in the form of LDL through the LDL receptor, with the interaction mediated by apoB-100. The LDL receptor is a glycoprotein that, after insertion into the plasma membrane, migrates laterally to coated pits, regions specialized for the rapid uptake of macromolecules such as LDL. After binding to the receptor, LDL is internalized in endosome and dissociated from the receptor, which then recycles to the cell surface to take in more LDL. The

endocytosed LDL is targeted to the lysosome, where the apoB is degraded and the cholesteryl esters are hydrolyzed by lysosomal acid lipase. Some cells, especially hepatocytes and steroidogenic tissues, can also selectively take up cholesteryl ester from HDL via SR-BI.

Unesterified cholesterol is transported from the lysosome to other cellular compartments by the Niemann–Pick C1 (NPC1) gene product. It can then be used for cellular functions such as new membrane formation, bile acid formation (liver), estrogen production (ovary), testosterone production (testis), or mineralocorticoid and glucocorticoid production (adrenal). When adequate exogenous cholesterol is entering cells, they suppress their endogenous synthesis, as reflected by decreased activity of b-hydroxy-b-methylglutaryl coenzyme A (HMG-CoA) reductase, the rate-limiting enzyme in cholesterol biosynthesis. Cells also decrease the number of LDL receptors and increase the activity of acyl coenzyme A:cholesterol acyltransferase (ACAT) to esterify any excess cholesterol for storage as cholesteryl ester droplets.

Cells must also be able to release excess cholesterol, as they lack the enzymes to catabolize the sterol nucleus. The process of cholesterol removal from cells is not completely understood. Spontaneous desorption of unesterified cholesterol from the plasma membrane occurs and is enhanced by the presence of an acceptor of cholesterol, such as HDL. The ATP-binding cassette protein 1 (ABC1) provides a mechanism for the active facilitation of cholesterol removal from cells. High-density lipoprotein has many characteristics consistent with an acceptor particle and probably plays an important role in the efficient removal of excess cholesterol from cells.

DISORDERS OF LIPOPROTEIN METABOLISM

Disorders of lipoprotein metabolism are associated with various clinical features, the most prominent of which are pancreatitis, atherosclerosis, and xanthoma formation. These disorders are usually identified by measuring plasma triglycerides, total cholesterol, and HDL cholesterol after a 12- to 14-hour fast. In the fasting state, chylomicrons are not usually present except in pathologic conditions, and most of the triglycerides are found in VLDL. Because chylomicrons are normally not present in the fasting state, the total cholesterol level is generally equal to the sum of the cholesterol in VLDL, LDL, and HDL. Usually, the cholesterol content of VLDL is about equal to the fasting plasma triglyceride level divided by 5, provided the plasma triglyceride level does not exceed 400 mg per dL. Therefore, the plasma LDL cholesterol level is usually determined by the formula:

$$\text{LDL cholesterol} = \text{total cholesterol} - (\text{triglyceride} \div 5) - \text{HDL cholesterol}$$

This simple calculation usually permits the clinician to estimate the LDL cholesterol level accurately enough. The LDL cholesterol can also be measured directly, and use of these assays is becoming more commonplace in clinical laboratories.

Disorders of lipid metabolism include any disorder that causes substantially elevated or decreased levels of any of the major plasma lipoproteins; such a disorder is often referred to as a dyslipidemia. The term *hyperlipidemia* (or *hyperlipoproteinemia*) is applied when the plasma triglyceride or cholesterol level is increased. The definition of dyslipidemia or hyperlipidemia is based on statistical cutoff points derived from the distribution of lipid and lipoprotein levels found in the general population. These cutoff points are arbitrary, but dyslipidemia is considered to be present when plasma lipid or lipoprotein levels exceed the 90th percentile or fall below the 10th percentile for age and gender. Selected reference values for fasting lipid and lipoprotein levels in adults are listed in [Table 12.3](#).

Age (y)	Total Cholesterol		LDL Cholesterol		HDL Cholesterol		Triglycerides	
	Mean	SD	Mean	SD	Mean	SD	Mean	SD
18-24	173	33	103	20	49	15	100	20
25-34	178	35	108	21	51	16	105	21
35-44	183	37	113	22	53	17	110	22
45-54	188	39	118	23	55	18	115	23
55-64	193	41	123	24	57	19	120	24
65-74	198	43	128	25	59	20	125	25
75-84	203	45	133	26	61	21	130	26
85-94	208	47	138	27	63	22	135	27
95-104	213	49	143	28	65	23	140	28

TABLE 12.3. SELECTED REFERENCE VALUES FOR FASTING LIPID AND LIPOPROTEIN LEVELS IN ADULTS STRATIFIED BY GENDER, RACE, AND AGE

The statistical norms for LDL cholesterol levels are not considered desirable because significant cardiovascular risk occurs at LDL cholesterol levels considerably lower than the 90th percentile cutoff. The relation of lipid and lipoprotein levels to cardiovascular risk is discussed in [Chapter 31](#).

Dyslipidemia is caused by various disorders, either primary (inherited) or secondary to some other disease process. Lipoprotein disorders have been classified in various ways, but no one system is ideal. A classification based on the type of lipoprotein that is elevated (lipoprotein phenotypes; [Table 12.4](#)) has been used for years but has several shortcomings: the phenotype in a patient may change over time; a phenotype may be primary (genetic) or secondary; a single phenotype may be caused by different genetic defects; and a single genetic defect may be associated with multiple phenotypes.

	I	IIa	IIb	III	IV	V
Lipoprotein elevation	Chylomicrons	LDL	LDL, HDL	Chylomicrons and VLDL remnants	VLDL	Chylomicrons and VLDL
Plasma triglycerides	+++	±	±	±	±	+++
Plasma cholesterol	±	±	±	±	±	±
Appearance of plasma lipids	Lactescent	Clear	Clear	Turbid	Turbid	Lactescent
Associated metabolic abnormalities	None	Insulin resistance	None	None	None	None
Renovascular potential	±	±	±	±	±	±
Allergic potential	±	±	±	±	±	±
Primary molecular defects	Lipoprotein lipase and ApoC-II	LDL receptor and ApoB-100	Unknown	ApoC-II	Unknown	Unknown

TABLE 12.4. DEFINITION AND CHARACTERISTICS OF PLASMA LIPOPROTEIN PHENOTYPES

In this chapter, the lipoprotein disorders are grouped as primary or secondary. The primary disorders are subdivided by the primary lipoprotein that is affected, then further subdivided by the specific gene responsible for the disorder (when known). Some of these disorders cause elevated lipoprotein levels; others cause abnormally low levels of specific lipoproteins.

PRIMARY HYPERLIPOPROTEINEMIAS DUE TO KNOWN SINGLE-GENE DISORDERS

FAMILIAL CHYLOMICRONEMIA SYNDROMES (LIPOPROTEIN LIPASE DEFICIENCY AND APOLIPOPROTEIN C-II DEFICIENCY)

Definition

Familial chylomicronemia syndromes ([Table 12.5](#)) are characterized by markedly elevated levels of chylomicrons in fasting plasma. The major clinical features are eruptive xanthomas and recurrent episodes of pancreatitis. These are autosomal recessive disorders caused by mutations in either LPL or its essential cofactor

lower than average cholesterol and LDL cholesterol levels. However, homozygosity for the E2 allele (the E2/E2 genotype), which has an incidence of about 1 in 200 in North America, is associated with familial dysbetalipoproteinemia. Persons with the E2/E2 genotype develop familial dysbetalipoproteinemia if an additional predisposing factor is also present; some of these factors are obesity, diabetes mellitus, hypothyroidism, renal disease, and alcohol use, but many patients with familial dysbetalipoproteinemia do not have an obvious predisposing factor in addition to the E2/E2 genotype. The apoE2 protein does not bind adequately to the remnant and LDL receptors, resulting in a defect in the catabolism of chylomicron and VLDL remnants.

The autosomal dominant forms of familial dysbetalipoproteinemia are caused by less common mutations in the apoE gene. These mutations generally result in the synthesis of an apoE protein that is severely defective in its ability to bind to the remnant and LDL receptors, even to the degree that it interferes with the ability of the normal apoE3 from the other allele to bind to the receptors. As a result, patients with "dominant" familial dysbetalipoproteinemia generally do not require other factors for expression of the disease, and often multiple members of a family are affected. Several different mutations in the apoE gene, all in the region of the protein that binds to the receptors, have been described in kindreds with the dominant form of the disease. Finally, several families have been described with complete deficiency of apoE, which causes a severe form of familial dysbetalipoproteinemia.

Clinical Findings

Patients with familial dysbetalipoproteinemia usually present in adulthood, although the dominant form of the disease can present in childhood or adolescence. Patients present with distinctive xanthomas, premature atherosclerosis, or asymptomatic hyperlipidemia. Two forms of xanthomas are observed in this disease and can provide important clues to the diagnosis. Tuberoeruptive xanthomas begin as small papules at pressure points such as elbows, knees, and buttocks, and are yellowish lesions that can grow to several centimeters if the hyperlipidemia is not treated. Palmar xanthomas begin as an orange–yellow discoloration to the creases of the palms and wrists. If the condition goes untreated, small nodules several millimeters in length can develop on the fingers or palms. Premature atherosclerosis is often seen in this disorder and can involve any of the major arterial beds. Compared with other lipid disorders, peripheral vascular disease is particularly common in patients with familial dysbetalipoproteinemia.

Laboratory Findings

Patients have hypertriglyceridemia and hypercholesterolemia, often to relatively similar degrees. Hyperlipidemia can be relatively mild or severe, depending on the presence of other associated metabolic abnormalities. The diagnosis is suggested by the presence of one or both of the characteristic xanthomas or by substantial elevation in both triglyceride and cholesterol levels in relatively similar proportion. In contrast to other conditions associated with elevated triglycerides, HDL cholesterol levels are usually normal in patients with familial dysbetalipoproteinemia. Lipoprotein electrophoresis demonstrates a prominent broad b band due to the presence of remnant lipoproteins. The diagnosis can be supported at special centers by lipoprotein ultracentrifugation demonstrating a ratio of VLDL cholesterol to plasma triglyceride greater than 0.3 (suggesting cholesterol-enriched VLDL particles). The diagnosis is confirmed by documenting the apoE2/E2 phenotype (using isoelectric focusing of plasma) or the apoE2/E2 genotype (using molecular methods). However, because mutations in apoE other than E2 can cause familial dysbetalipoproteinemia, the absence of an E2/E2 pattern does not rule out the diagnosis, which must then be made on clinical grounds.

Optimal Management

A thorough search for other metabolic conditions known to exacerbate hyperlipidemia should be made. General therapeutic measures include diet, weight loss, and discontinuance of alcohol. Postmenopausal women with familial dysbetalipoproteinemia respond favorably to estrogen replacement therapy. Because this disorder is associated with increased cardiovascular risk, drug therapy should be utilized if necessary. Fibrates (such as gemfibrozil and fenofibrate) and nicotinic acid are effective in treating this disorder. The HMG-CoA reductase inhibitors have also been used successfully in some patients.

HEPATIC LIPASE DEFICIENCY

Definition

Hepatic lipase deficiency is a rare autosomal recessive disorder characterized by the absence of hepatic lipase activity and the accumulation of lipoprotein remnants in plasma.

Incidence and Epidemiology

Only several kindreds with hepatic lipase deficiency have been described, although because this syndrome can be difficult to recognize it may be more common than currently appreciated.

Etiologic Factors

This disorder is caused by mutations in the hepatic lipase gene.

Pathogenesis

Hepatic lipase is responsible for converting VLDL remnants and IDL to LDL by hydrolysis of triglycerides and phospholipids ([Fig. 12.4](#)). Deficiency of hepatic lipase due to mutations in the gene results in a defect in the metabolism of VLDL remnants and IDL, and their subsequent accumulation in the plasma.

Clinical Findings

Patients with hepatic lipase deficiency may present with premature atherosclerosis or asymptomatic hyperlipidemia. Xanthomas are not a consistent feature of this disorder.

Laboratory Findings

Patients have both hypertriglyceridemia and hypercholesterolemia. However, in contrast with most hyperlipidemic patients, HDL cholesterol levels are normal or even elevated—a clue to this diagnosis. The lipoprotein profile can resemble familial dysbetalipoproteinemia. Lipoprotein electrophoresis demonstrates a broad b band, but the apoE genotype is not the apoE2/E2 pattern characteristic of familial dysbetalipoproteinemia. The diagnosis can be confirmed by measurement of hepatic lipase in postheparin plasma by specialized laboratories. Acquired (usually partial) deficiency in hepatic lipase can be seen in hypothyroidism, chronic renal insufficiency, and chronic liver disease.

Optimal Management

Secondary causes of hepatic lipase deficiency should be excluded. After dietary therapy, a trial of lipid-lowering drug therapy with fibrates, nicotinic acid, or a statin should be considered, but experience in this area is limited.

FAMILIAL HYPERCHOLESTEROLEMIA

Definition

Familial hypercholesterolemia is caused by mutations in the LDL receptor and characterized by elevated LDL cholesterol, tendon xanthomas, and an increased risk of premature atherosclerosis. Familial hypercholesterolemia is an autosomal codominant disorder: heterozygotes have elevated LDL cholesterol levels and increased risk of atherosclerosis as adults, whereas homozygotes have markedly elevated LDL cholesterol levels and develop atherosclerotic cardiovascular disease as children and adolescents.

Incidence and Epidemiology

Familial hypercholesterolemia is found worldwide and is exceptionally common in certain populations, such as Afrikaners, Christian Lebanese, and French Canadians, in which a founder effect is present. Heterozygous familial hypercholesterolemia occurs in about 1 in 500 persons worldwide. Homozygous familial hypercholesterolemia occurs with a frequency of about 1 in a million persons worldwide.

Etiologic Factors

Familial hypercholesterolemia (FH) is caused by mutations in the gene for the LDL receptor that prevent its appearance on the cell surface or impair its ability to bind and internalize LDL. Over 150 different LDL receptor mutations have been described in patients with familial hypercholesterolemia. Familial hypercholesterolemia heterozygotes inherit one normal and one mutant allele for the LDL receptor and therefore produce only about half the normal number of LDL receptors. Homozygotes have two mutant alleles at the LDL receptor locus and therefore produce little or no LDL receptor. Homozygous FH patients are often classified based on the amount of LDL receptor activity measured in their skin fibroblasts as “receptor-negative” (less than 2% of normal activity) or “receptor-defective” (2% to 25% of normal activity). Many apparent familial hypercholesterolemia homozygotes have actually inherited a different mutant allele from each parent and are more properly called compound heterozygotes.

Pathogenesis

The efficient removal of LDL from the plasma requires the LDL receptor ([Fig. 12.4](#)). The liver is quantitatively the most important tissue responsible for regulating levels of LDL cholesterol and does so in large part by regulating the expression of the LDL receptor. The elevated LDL cholesterol levels in familial hypercholesterolemia are directly due to the LDL receptor defect causing delayed removal of LDL from the blood as well as increased rates of LDL production in some patients. Elevated LDL cholesterol levels lead to accelerated deposition of cholesterol in the artery wall, cornea, tendons, and skin, producing the manifestations of premature atherosclerosis, corneal arcus, tendon xanthomas, and cutaneous xanthomas. The clinical heterogeneity among familial hypercholesterolemia patients is related at least in part to genetic heterogeneity of the LDL receptor gene mutations.

Clinical Findings

Patients with heterozygous familial hypercholesterolemia have hypercholesterolemia from birth but are often not detected until adulthood, usually due to complications of premature atherosclerosis, tendon xanthomas, or asymptomatic hypercholesterolemia on routine screening. Tendon xanthomas are a major feature of this disease and are found in various locations including the dorsum of the hands, elbows, knees, and especially the Achilles tendons. Arcus cornea is common but not specific for this disorder. Premature atherosclerosis is often seen in this disorder and can involve any of the major arterial beds, usually including the coronary arteries. The age of onset of cardiovascular disease is highly variable and in part depends on other coexisting risk factors. Family history is usually notable for hypercholesterolemia and/or premature cardiovascular disease on one side of the family.

Patients with receptor-negative homozygous familial hypercholesterolemia often present with cutaneous xanthomas as children. These occur in the web spaces between fingers and on the elbows, knees, heels, and buttocks. Patients with receptor-defective homozygous familial hypercholesterolemia often do not have cutaneous xanthomas but develop tuberous or tendon xanthomas on the elbows, knees, or Achilles tendons as older children or adolescents. Arcus cornea is virtually always present to some degree. Atherosclerosis is severe and affects the aortic root as well as all the major arterial beds. A systolic murmur consistent with aortic valvular or supra-aortic stenosis is usually present. The coronary artery disease often first involves the coronary ostia. Homozygous familial hypercholesterolemia patients are often asymptomatic despite severe atherosclerotic disease, and when symptoms occur they are often atypical, such as exertional throat pain. Sudden death in the asymptomatic patient with homozygous familial hypercholesterolemia has been described. Survival of the untreated receptor-negative homozygous familial hypercholesterolemia patient into the third decade of life is unusual.

Laboratory Findings

In heterozygous familial hypercholesterolemia, total cholesterol levels are usually above 240 mg per dL and are often above 300 mg per dL, LDL cholesterol levels are generally greater than 190 mg per dL, triglycerides are usually normal, and HDL cholesterol levels are often modestly reduced. In homozygous familial hypercholesterolemia, total cholesterol levels are usually above 600 mg per dL and can be as high as about 1,200 mg per dL. The LDL cholesterol levels are elevated to a similar degree. Receptor-negative patients have higher cholesterol levels than receptor-defective patients. Triglycerides are generally normal. The diagnosis can be confirmed at specialized centers by obtaining a skin biopsy and performing an assay of the LDL receptor activity in skin fibroblasts or by sequencing or other molecular testing of the LDL receptor.

Optimal Management

The diagnosis of heterozygous familial hypercholesterolemia is strongly suggested by hypercholesterolemia above 350 mg per dL in the presence of normal triglyceride levels, but the diagnosis should also be entertained in patients with cholesterol levels above 240 mg per dL, especially if there is a family history of hypercholesterolemia or premature coronary disease. The metacarpophalangeal and Achilles tendons should be examined for the presence of tendon xanthomas, which strongly supports the diagnosis of familial hypercholesterolemia. Hypothyroidism and obstructive liver disease should be excluded as potential secondary causes of hypercholesterolemia. Most heterozygous familial hypercholesterolemia patients require lipid-lowering drug therapy, and statins are the drug class of choice for this disorder ([Chapter 31](#)). Many heterozygous familial hypercholesterolemia patients can achieve desired LDL cholesterol goals with statin therapy, but frequently combination drug therapy with the addition of a bile acid sequestrant or nicotinic acid is required. Rarely, heterozygous familial hypercholesterolemia patients cannot be adequately controlled on combination drug therapy or do not tolerate drug therapy. Ileal bypass surgery has been used in some familial hypercholesterolemia heterozygotes; however, it can produce bile salt-induced diarrhea and vitamin B₁₂ deficiency, and therefore is not generally recommended. The current optimal approach to heterozygous familial hypercholesterolemia patients with refractory hypercholesterolemia or drug intolerance is LDL apheresis ([Chapter 31](#)).

Family screening of relatives, including children, is an important means for detecting other affected persons.

The finding of severe hypercholesterolemia (more than 600 mg per dL) with normal triglycerides in a child without obstructive liver disease strongly suggests homozygous familial hypercholesterolemia and cutaneous, tuberous, or tendon xanthomas support the diagnosis. Further supportive evidence of the diagnosis is derived from the testing of the biologic parents, both of whom have hypercholesterolemia if the diagnosis of homozygous familial hypercholesterolemia is correct. Patients with suspected homozygous familial hypercholesterolemia should be referred to a specialized center for diagnosis and therapy. Careful monitoring for the development of cardiovascular disease is important. A trial of drug therapy with statins is generally attempted and some patients, particularly those who are receptor-defective, may have a modest response. Optimal therapy is LDL apheresis, which can promote regression of xanthomas and retard progression of atherosclerosis. However, venous access is often problematic, especially in young children, and the optimal timing of initiation of LDL apheresis is uncertain. Homozygous familial hypercholesterolemia is a model for the development of liver-directed somatic gene therapy.

FAMILIAL DEFECTIVE APOLIPOPROTEIN B-100

Definition

Familial defective apoB-100 (FDB) is caused by mutations in the receptor-binding region of apolipoprotein B and is characterized by elevated LDL cholesterol and an increased risk of premature atherosclerosis.

Incidence and Epidemiology

Familial defective apoB-100 is a dominantly inherited disorder and occurs in about 1 in 700 persons in Europe and North America.

Etiologic Factors

Familial defective apoB-100 is caused by specific missense mutations in the region of the apoB gene responsible for binding to the LDL receptor. The most common mutation causing FDB is a substitution of glutamine for arginine at position 3500 in apoB, but other mutations have been described as well.

Pathogenesis

These substitutions in the receptor binding region of apoB prevent it from binding effectively to the LDL receptor, resulting in delayed clearance of LDL from the plasma and subsequent hypercholesterolemia. Patients with this condition are generally heterozygotes for the mutation and therefore have both normal and defective LDL; the LDL containing the mutant apoB is present in higher relative amounts in the plasma because it is cleared more slowly.

Clinical Findings

Patients with heterozygous FDB present in adulthood, usually with complications of premature atherosclerosis or with asymptomatic hypercholesterolemia. Premature atherosclerosis is often seen in this disorder and can involve any of the major arterial beds, although coronary artery disease is most prevalent. Tendon xanthomas are sometimes seen in FDB. Therefore, FDB strongly resembles familial hypercholesterolemia clinically and cannot be differentiated on purely clinical grounds.

Laboratory Findings

In FDB, total cholesterol levels are usually above 240 mg per dL and are often above 300 mg per dL, LDL cholesterol levels are generally greater than 190 mg per dL, triglycerides are usually normal, and HDL cholesterol levels are often modestly reduced.

Optimal Management

The diagnosis is suggested by hypercholesterolemia in the presence of normal triglyceride levels. This condition can appear clinically to be very similar to heterozygous familial hypercholesterolemia. However, because it is frequently caused by a single mutation, it can be diagnosed using routine molecular screening techniques available in specialized laboratories. The management of FDB is similar to that of heterozygous familial hypercholesterolemia ([Chapter 31](#)).

PRIMARY HYPERLIPOPROTEINEMIAS OF UNKNOWN CAUSE

FAMILIAL HYPERTRIGLYCERIDEMIA

Definition

Familial hypertriglyceridemia (FHTG) is an autosomal dominant trait characterized by elevated triglycerides and VLDL cholesterol (type IV pattern). Some patients may have chylomicronemia and more severe elevations in triglycerides (type V pattern).

Incidence and Epidemiology

Familial hypertriglyceridemia occurs in about 1 in 500 persons. It is inherited but is not usually expressed until adulthood; approximately 10% of children at risk have hypertriglyceridemia.

Etiologic Factors

The genetic cause of FHTG is unknown.

Pathogenesis

The metabolic basis of this disorder is probably heterogeneous and related to impaired catabolism or lipolysis of triglycerides without any obvious defect in LPL or apoC-II. Increased production of VLDL by the liver has been observed in some patients with this phenotype. Very low density lipoprotein or chylomicron overproduction may overload the normal catabolic processes and produce hypertriglyceridemia in some patients. Genetic overproduction of apoC-III could cause this syndrome, but this remains unproven. Obesity, physical inactivity, insulin resistance, alcohol use, and estrogens can all exacerbate the hypertriglyceridemia.

Clinical Findings

No unique clinical features are associated with FHTG. Patients often come to medical attention after hypertriglyceridemia is detected by a routine blood test.

Laboratory Findings

Triglyceride levels usually range from 250 to 1,000 mg per dL, with normal to modestly increased cholesterol levels. The HDL cholesterol levels are usually decreased. Some patients may have more severely elevated triglyceride levels (more than 1,000 mg per dL), indicating the presence of chylomicrons and placing these patients at risk for acute pancreatitis and eruptive xanthomas. The major clinical difference between this severe form of FHTG and the familial chylomicronemia syndrome due to LPL or apoC-II deficiency is that this disorder presents in adulthood, whereas LPL and apoC-II deficiencies present in childhood. The lipid levels alone do not permit the assignment of this diagnosis, which requires data in first-degree relatives demonstrating hypertriglyceridemia without significant hypercholesterolemia. In kindreds with FHTG, hypertriglyceridemia is found in approximately half of adult first-degree relatives. Measurement of the plasma apoB level may help to differentiate FHTG from familial combined hyperlipidemia (FCHL), with a substantially elevated apoB level more suggestive of FCHL (below). Hyperglycemia, hyperinsulinemia, and hyperuricemia are often associated with this syndrome.

Optimal Management

The differential diagnosis of this lipoprotein phenotype includes familial dysbetalipoproteinemia, familial combined hyperlipidemia, sporadic hypertriglyceridemia, and secondary causes. Secondary factors such as diabetes mellitus, hypothyroidism, nephrotic syndrome, and excessive alcohol use should be excluded. Therapy should start with the identification and control of aggravating factors, including obesity, diabetes, alcohol use, and medications such as thiazide diuretics and estrogens. Lipid-lowering drug therapy should be considered in patients who have not responded adequately to diet and control of secondary factors ([Chapter 31](#)).

FAMILIAL COMBINED HYPERLIPIDEMIA

Definition

Familial combined hyperlipidemia is an inherited autosomal dominant trait characterized by variably elevated triglyceride or cholesterol levels, elevated plasma apoB levels, and a family history of hyperlipidemia and premature cardiovascular disease.

Incidence and Epidemiology

Familial combined hyperlipidemia occurs in about 1 in 200 persons worldwide and is often not expressed until adulthood. An estimated 15% of patients with premature coronary artery disease have FCHL.

Etiologic Factors

The genetic cause of FCHL is unknown. Some patients with the FCHL phenotype may be heterozygous for LPL deficiency, but this remains to be definitively established. Several different molecular defects can probably produce the phenotype of FCHL.

Pathogenesis

Studies of lipoprotein metabolism in carefully selected persons have indicated that overproduction of VLDL or LDL, or both, may be a common metabolic basis of this condition.

Clinical Findings

No unique clinical features are associated with this disorder. Patients often come to medical attention after hyperlipidemia is detected by a routine blood test or after being diagnosed with premature cardiovascular (usually coronary) disease. Atherosclerotic cardiovascular disease is very common in patients with FCHL and the risk is often out of proportion to the modest degree of hyperlipoproteinemia. Obesity and hypertension are sometimes associated with FCHL but xanthomas are not. The formal diagnosis of FCHL requires the history of dyslipidemia in at least two first-degree relatives; a family history of premature coronary disease supports the diagnosis.

Laboratory Findings

Triglyceride levels usually range from 150 to 500 mg per dL, total cholesterol levels are 200 to 400 mg per dL, and HDL cholesterol levels are almost always decreased. The hallmark biochemical finding is a significantly elevated apoB level, often disproportionate to the degree of hyperlipidemia. This indicates the presence of small dense LDL particles, which are particularly characteristic of this syndrome and are considered highly atherogenic. The term *hyperapobetalipoproteinemia* describes the syndrome of elevated apoB with normal lipid levels and is probably a subset of FCHL. Some specialized assays can specifically detect the presence of increased small dense LDL and a nuclear magnetic resonance (NMR)-based assay can determine the concentration of different types of LDL particles. Greater clinical utilization of such assays may permit more specific diagnoses of FCHL and its subsets. Hyperglycemia, hyperinsulinemia, and hyperuricemia are often, but not invariably, associated with FCHL.

Optimal Management

Secondary disorders are other possible causes of this lipoprotein phenotype. In particular, diabetes mellitus, hypothyroidism, renal disease, alcohol use, and certain medications should be excluded. Patients with FCHL are at significantly increased risk of premature coronary disease. Therefore, once the diagnosis of FCHL has been made, attempts should be made to modify the lipid abnormalities to decrease cardiovascular risk ([Chapter 31](#)). General measures include diet, exercise, and weight loss, but most patients with FCHL also require lipid-lowering drug therapy. The HMG-CoA reductase inhibitors are generally the drugs of first choice. Nicotinic acid can be useful in reducing triglycerides and LDL cholesterol, either alone or in combination with statins. Fibric acid derivatives can help control triglycerides but are not as effective as statins in decreasing LDL cholesterol or apoB levels. Bile acid sequestrants can be used together with other drugs, but only after triglyceride levels have been controlled.

POLYGENIC HYPERCHOLESTEROLEMIA

Definition

Polygenic hypercholesterolemia is defined as hypercholesterolemia exceeding the 95th percentile for the population in the absence of a defined genetic or secondary cause.

Incidence and Epidemiology

Polygenic hypercholesterolemia is relatively common, occurring (by definition) in up to 5% of the general population.

Etiologic Factors

Polygenic hypercholesterolemia is attributed to a complex interaction of multiple genetic factors with environmental factors.

Pathogenesis

Genetic differences in metabolic pathways such as cholesterol absorption, cholesterol synthesis, apolipoprotein structure, or rates of bile acid formation may interact with each other and with environmental factors, such as diet, to generate hypercholesterolemia.

Clinical Findings

There are no specific clinical findings. Tendon xanthomas are not observed. The risk of premature atherosclerosis is increased.

Laboratory Findings

Polygenic hypercholesterolemia can usually be differentiated from familial hypercholesterolemia, FDB, and FCHL through laboratory findings. In polygenic hypercholesterolemia, the elevation in total and LDL cholesterol level is milder than in familial hypercholesterolemia and FDB. In FCHL, triglycerides are usually higher and apoB levels are significantly higher relative to the LDL cholesterol level than in polygenic hypercholesterolemia. Family studies are also helpful: only approximately 7% of first-degree relatives of patients with polygenic hypercholesterolemia are hypercholesterolemic, whereas approximately half of relatives with the above disorders have dyslipidemia.

Optimal Management

Treatment of polygenic hypercholesterolemia should start with lifestyle interventions of diet, exercise, and weight loss. Sometimes drug therapy is necessary, and statins, nicotinic acid, or bile acid sequestrants are all reasonable as first-line agents ([Chapter 31](#)).

SECONDARY FORMS OF HYPERLIPIDEMIA

The major secondary forms of hyperlipidemia are listed in [Table 12.6](#). Usually the lipid abnormality is relatively mild compared with some of the primary disorders. If the hyperlipidemia is severe, the patient probably has a genetic predisposition to hyperlipidemia that has been aggravated by the secondary disorder. In these cases, correction or control of the secondary disorder may ameliorate, but not fully correct, the lipoprotein abnormality. These patients may then require specific treatment of the hyperlipidemia, especially if they are at risk for pancreatitis or atherosclerosis.

Disorder	LDL-C	HDL-C	Triglycerides	Other Lipoproteins
Primary hyperlipidemia	↑	↓	↑	↑
Secondary hyperlipidemia	↑	↓	↑	↑
Diabetes mellitus	↑	↓	↑	↑
Hypothyroidism	↑	↓	↑	↑
Renal disease	↑	↓	↑	↑
Estrogens and progestins	↓	↑	↓	↓

TABLE 12.6. DISORDERS ASSOCIATED WITH SECONDARY FORMS OF HYPERLIPIDEMIA

DIETARY INFLUENCES

Epidemiologic evidence indicates that higher cholesterol levels relate directly to a greater consumption of saturated fat and cholesterol. Diets rich in saturated fat and cholesterol suppress hepatic LDL receptor activity and thereby raise the LDL cholesterol level. Substituting polyunsaturated or monounsaturated fats for saturated fats results in lower LDL cholesterol levels. Decreasing total and saturated fat in the diet usually results in a decrease in HDL cholesterol levels as well. Another dietary factor contributing to hyperlipidemia is excess calorie consumption, which promotes increased VLDL production by the liver, both directly and as a result of obesity. This may lead to elevated triglycerides and possibly to elevated LDL cholesterol levels, especially if LDL receptor activity is suppressed. Diets restricted in saturated fats and cholesterol and reduced in calories to maintain ideal body weight often correct mild hyperlipidemia and form the cornerstone of therapy for most forms of hyperlipidemia ([Chapter 31](#)).

ALCOHOL

Excess alcohol intake is a common cause of hyperlipidemia. Regular alcohol consumption increases lipid levels in most people, but the response is highly variable. The greatest effects of alcohol are on triglyceride levels. Alcohol consumption stimulates hepatic secretion of VLDL, presumably because hepatic metabolism of ethanol by alcohol dehydrogenase increases levels of nicotinamide adenine dinucleotide, which inhibits oxidation of free fatty acids. The excess free fatty acids in the liver may be used for synthesis of triglyceride, which is then secreted as part of VLDL. The usual lipoprotein pattern with alcohol consumption is type IV (increased VLDL), but persons with an underlying predisposition to defective clearance of triglyceride-rich lipoproteins may develop severe hypertriglyceridemia (type V pattern). Regular alcohol use also raises the HDL cholesterol level by a mechanism that is not completely understood.

DIABETES MELLITUS

Several forms of hyperlipidemia are recognized clinically in patients with diabetes mellitus. Patients with type I diabetes mellitus in diabetic ketoacidosis may have severe hypertriglyceridemia due to excess release of free fatty acids from adipose tissue, followed by conversion to VLDL triglycerides in the liver. Administration of insulin usually results in the gradual normalization of lipid levels. Patients with type I diabetes mellitus who are under adequate glycemic control do not usually have hyperlipidemia; the presence of hyperlipidemia in such patients suggests an underlying lipoprotein abnormality. In contrast, patients with type II diabetes mellitus often have associated hyperlipidemia. There are at least two causes of the hyperlipidemia: insulin resistance causes decreased LPL activity and reduced capacity to catabolize chylomicrons and VLDL; insulin resistance and obesity itself may stimulate excess VLDL production. Many patients with type II diabetes mellitus have a constellation of lipid abnormalities, including elevated triglyceride (VLDL, lipoprotein remnants), elevated dense LDL, and decreased HDL cholesterol levels. In some diabetic patients who have another underlying lipoprotein abnormality, the triglycerides can be extremely elevated (type V pattern), predisposing to eruptive xanthomas and acute pancreatitis. Significant elevation of LDL cholesterol in the type II diabetic patient often suggests an additional lipoprotein abnormality.

HYPOTHYROIDISM

Hypothyroidism is associated with elevated LDL cholesterol levels due primarily to down-regulation of the LDL receptor and therefore delayed clearance of LDL. Because hypothyroidism can be subtle in its clinical presentation and is eminently treatable, all patients presenting with hypercholesterolemia due to elevated LDL should be screened to rule out hypothyroidism. Thyroid replacement therapy usually results in resolution of the hypercholesterolemia. Hypothyroid patients who remain hypercholesterolemic after adequate replacement probably have an underlying lipoprotein disorder and might require lipid-lowering drug therapy.

RENAL DISEASES

End-stage renal disease (ESRD) is often associated with mild hypertriglyceridemia because of increased VLDL and remnant lipoproteins due to a defect in triglyceride lipolysis and remnant clearance. Plasma levels of Lp(a) are also significantly increased in ESRD. Nephrotic syndrome is always associated with a more pronounced hyperlipoproteinemia involving both elevated triglyceride and cholesterol levels. The mechanism appears to be hepatic overproduction of VLDL with subsequent increased production of LDL. Effective treatment of the nephrotic syndrome normalizes the lipid profile, but patients with chronic nephrotic syndrome may require lipid-lowering drug therapy.

ESTROGENS AND PROGESTINS

In most women, estrogens have relatively little effect on triglyceride and cholesterol levels but result in increased HDL cholesterol levels. In familial dysbetalipoproteinemia (type III), estrogens can result in significant lowering of triglyceride and cholesterol levels. However, in patients with other familial forms of hyperlipidemia, such as FCHL, FHTG, and familial type V hyperlipidemia, estrogens may markedly exacerbate the hypertriglyceridemia, predisposing the patient to acute pancreatitis. Therefore, estrogens should be used cautiously in patients with familial disorders causing hypertriglyceridemia. Women being considered for postmenopausal estrogen replacement therapy should be screened with a fasting lipid profile before starting therapy.

ELEVATED LIPOPROTEIN(A)

Definition

Elevated Lp(a) is defined as a plasma Lp(a) level above 30 mg per dL in the absence of metabolic factors (such as ESRD) known to increase Lp(a) levels. It is often associated with a family history of premature atherosclerotic cardiovascular disease.

Incidence and Epidemiology

In the United States, approximately 20% of whites and 50% of blacks have Lp(a) levels above 30 mg per dL.

Etiologic Factors

Lipoprotein(a) levels are highly genetically determined and are inherited as an autosomal codominant trait with expression in childhood.

Pathogenesis

The gene for apo(a) is the major genetic factor controlling the plasma level of Lp(a). The apo(a) gene exhibits a striking size polymorphism, with well over 30 different apo(a) phenotypes described in humans. The apo(a) gene directly affects the production rate of apo(a) by the liver, probably both by transcriptional and post-translational mechanisms. The apo(a) alleles inherited from both parents contribute additively to the Lp(a) concentration in the plasma. Lipoprotein(a) levels

deficiency.

A second type of LCAT deficiency is a partial enzyme deficiency, also called fish-eye disease. The clinical features are similar to those of classic LCAT deficiency and include corneal opacities and low levels of HDL cholesterol (less than 10 mg per dL). However, patients with fish-eye disease have no anemia or renal disease, the fraction of plasma cholesteryl ester is normal, and there is clearly detectable cholesterol esterification activity in the plasma. The initial patients reported with fish-eye disease had evidence of cholesterol esterification in apoB-containing lipoproteins but not in HDL, but this has not been a consistent finding. Several molecular defects in the LCAT gene have been described in patients with fish-eye disease.

In addition to the low plasma levels of HDL cholesterol, both types of LCAT deficiency are associated with low plasma levels of apoA-I and especially apoA-II due to rapid catabolism. Despite the markedly low levels of HDL cholesterol and apoA-I, there is no apparent increased risk of premature atherosclerotic cardiovascular disease in either complete or partial LCAT deficiency.

Tangier Disease

Tangier disease is a rare autosomal codominant inherited disorder of HDL metabolism. It is caused by mutations in the gene encoding the ATP-binding cassette protein 1, which facilitates the efflux of excess cholesterol from cells, particularly macrophages. Tangier disease homozygotes have HDL cholesterol levels below 5 mg per dL and extremely low levels of apoA-I. The metabolic defect is not failure of apoA-I biosynthesis, as in apoA-I deficiency, but rather markedly accelerated HDL catabolism due to the impaired ability of HDL to acquire lipids from cells. Clinical features include accumulation of cholesterol in the reticuloendothelial system, resulting in hepatosplenomegaly, intestinal mucosal abnormalities, and the pathognomonic enlarged orange tonsils seen in this disease. Intermittent peripheral neuropathy can also be seen due to cholesterol accumulation in Schwann cells. Premature atherosclerotic disease is seen but is not a prominent feature of homozygous Tangier disease. Heterozygotes have moderately reduced HDL cholesterol and apoA-I levels, have no evidence of reticuloendothelial cholesterol accumulation, and may have some increased risk of premature atherosclerosis.

Primary Hypoalphalipoproteinemia

Primary hypoalphalipoproteinemia is the term used for familial low HDL cholesterol levels (below the 10th percentile) in the setting of relatively normal cholesterol and triglyceride levels. High-density lipoprotein cholesterol levels are usually approximately 15 to 35 mg per dL, and patients have no clinical evidence of Tangier disease or LCAT deficiency. Transmission is that of an autosomal dominant trait. The genetic cause in some families may be mutations in ABC1 but in others is unknown. There are no unique clinical features of this disorder other than possibly an increased risk of premature atherosclerotic cardiovascular disease. However, families have been described with familial transmission of low HDL cholesterol levels but no evidence of increased atherosclerosis. Therefore, the direct relationship of primary hypoalphalipoproteinemia to premature coronary disease is uncertain and may depend on the specific nature of the gene defect or metabolic cause of the low HDL cholesterol level.

PRIMARY CAUSES OF HIGH HDL CHOLESTEROL LEVELS

Cholesteryl Ester Transfer Protein Deficiency

Cholesteryl ester transfer protein facilitates the transfer of cholesteryl esters among lipoproteins, especially from HDL to apoB-containing lipoproteins. Homozygous genetic deficiency of CETP results in very high levels of HDL cholesterol (more than 160 mg per dL) due to the accumulation of large, cholesterol-rich HDL particles. The initial reports of homozygous CETP deficiency were in Japanese kindreds all having the same splice site mutation in the CETP gene, but CETP deficiency due to other mutations in the CETP gene have been reported as well. Other than the markedly elevated HDL cholesterol level, there are no distinguishing clinical features and no obvious clinical sequelae of CETP deficiency. Heterozygotes for CETP deficiency have modestly elevated HDL cholesterol levels. Despite the very high levels of HDL cholesterol, homozygous CETP deficiency is not clearly associated with a decreased risk of atherosclerotic cardiovascular disease. In fact, one large epidemiologic study suggested that heterozygosity for CETP deficiency was associated with an increased risk of coronary disease.

Primary Hyperalphalipoproteinemia

Primary hyperalphalipoproteinemia is a term used for familial elevated HDL cholesterol levels (above the 90th percentile). It is inherited as an autosomal dominant trait and is associated with HDL cholesterol levels usually above 80 mg per dL in women and 70 mg per dL in men. The genetic basis is unknown. Some people with familial hyperalphalipoproteinemia may have increased production of apoA-I, but others likely have reduced catabolism of HDL cholesterol and apoA-I. This syndrome has been associated with decreased risk of coronary heart disease and increased longevity.

Primary Hypolipidemias

Some rare genetic disorders of lipoprotein metabolism result in extremely low cholesterol levels ([Table 12.8](#)). Although rare, these disorders are important to recognize and diagnose so that appropriate referral and effective therapy can be provided.

Disorder	Metabolic Defect	Metabolic Defect	Genotype	Clinical Findings	Genetic Transmission
Abetalipoproteinemia	Absent apoB-48	Absent apoB-100	Total cholesterol < 100 mg/dL; apoB absent	Severe malabsorption, neurologic degeneration, pigmented retinopathy, acanthocytosis	Autosomal recessive
Tangier disease	Absent LCAT	Absent LCAT	Total cholesterol < 100 mg/dL; apoA-I < 10 mg/dL; apoA-II < 10 mg/dL	Enlarged orange tonsils, hepatosplenomegaly, neuropathy	Autosomal codominant
Primary hypoalphalipoproteinemia	Defective ABCA1	Defective ABCA1	Total cholesterol < 100 mg/dL; apoA-I < 10 mg/dL; apoA-II < 10 mg/dL	Low HDL cholesterol	Autosomal dominant
Primary hyperalphalipoproteinemia	Defective ABCA1	Defective ABCA1	Total cholesterol > 100 mg/dL; apoA-I > 10 mg/dL; apoA-II > 10 mg/dL	High HDL cholesterol	Autosomal dominant
Primary hypolipidemia	Defective ABCA1	Defective ABCA1	Total cholesterol < 100 mg/dL; apoA-I < 10 mg/dL; apoA-II < 10 mg/dL	Low HDL cholesterol	Autosomal dominant

TABLE 12.8. GENETIC DISORDERS CAUSING LOW CHOLESTEROL LEVELS

Abetalipoproteinemia

Abetalipoproteinemia is a rare autosomal recessive disease characterized clinically by fat malabsorption, spinocerebellar degeneration, pigmented retinopathy, and acanthocytosis. The biochemical hallmark is the strikingly abnormal plasma lipid and lipoprotein profile. Total cholesterol and triglyceride levels are extremely low; there are no detectable plasma chylomicrons, VLDLs, or LDLs; and apoB is absent from the plasma. This disease is caused by mutations in the gene for the microsomal transfer protein (MTP), which mediates the intracellular transport of membrane-associated lipids in the intestine and liver and is necessary for the normal formation of chylomicrons in the enterocyte and VLDLs in the hepatocyte.

The most prominent and debilitating symptoms of abetalipoproteinemia are neurologic and ophthalmologic. They usually begin in the second decade of life. The first neurologic sign of disease is usually the loss of deep tendon reflexes, followed by decreased distal lower extremity vibratory and proprioceptive senses and cerebellar signs such as dysmetria, ataxia, and spastic gait. The clinical outcome varies, but the result in untreated patients is often severe ataxia and spasticity by the third or fourth decade. These severe central nervous system effects are the ultimate cause of death in most patients, which often occurs by the fifth decade or earlier. Patients with abetalipoproteinemia also develop a progressive pigmented retinopathy. The first ophthalmic symptoms are decreased night and color vision. Daytime visual acuity usually deteriorates inexorably to virtual blindness by the fourth decade. The presence of spinocerebellar degeneration and pigmented retinopathy in this disease has often resulted in a misdiagnosis of Friedreich's ataxia.

Most of the clinical symptoms of abetalipoproteinemia are the result of defects in the absorption and transport of fat-soluble vitamins, especially vitamin E. Vitamin E is

transported from the intestine to the liver, then “repackaged” in the liver and incorporated into the assembling VLDL particle by a specific protein, the tocopherol-binding protein. In the circulation, VLDLs are converted to LDL, and vitamin E is transported by LDL to peripheral tissues and delivered to cells via the LDL receptor. Patients with abetalipoproteinemia are markedly deficient in vitamin E. Vitamin E metabolism is markedly altered in patients with abetalipoproteinemia because the plasma transport of vitamin E requires hepatic secretion of apoB-containing lipoproteins. Most of the major clinical symptoms, especially those of the nervous system and retina, are primarily due to vitamin E deficiency. This concept is supported by the fact that other diseases involving vitamin E deficiency, such as cholestasis and isolated vitamin E deficiency, are characterized by similar symptoms and pathologic changes.

Patients with suspected abetalipoproteinemia should be referred to specialized centers for confirmation of the diagnosis and appropriate therapy.

Obligate heterozygotes (such as the parents of patients with abetalipoproteinemia) have no symptoms and no evidence of reduced plasma lipids. Thus, family studies are important in distinguishing abetalipoproteinemia from clinically similar homozygous hypobetalipoproteinemia (see below), in which obligate heterozygotes have decreased LDL cholesterol and apoB levels.

Hypobetalipoproteinemia

Familial hypobetalipoproteinemia, in contrast to abetalipoproteinemia, is autosomal codominant; heterozygotes' levels of LDL cholesterol and apoB are approximately half of normal or less, whereas homozygotes have very low or absent plasma apoB. Heterozygous familial hypobetalipoproteinemia is not associated with symptoms, but some homozygous patients have symptoms similar to those of patients with abetalipoproteinemia. The gene defect in this disorder resides in most or all cases within the apoB gene itself. Many are nonsense mutations resulting in a truncated apoB protein; at least 25 such mutations have been described. One patient initially described as having “normotriglyceridemic abetalipoproteinemia” was subsequently demonstrated to be homozygous for a truncated apoB and was therefore diagnosed with homozygous hypobetalipoproteinemia.

Clinically, heterozygous hypobetalipoproteinemia is associated with LDL cholesterol levels of approximately 40 to 80 mg per dL, is not associated with clinical sequelae, and requires no specific therapy. However, patients with homozygous hypobetalipoproteinemia have markedly reduced to absent LDL cholesterol and apoB levels, and they might be at risk for many of the sequelae seen in abetalipoproteinemia. Such patients should therefore be referred to specialized centers for confirmation of the diagnosis and appropriate therapy.

Chylomicron Retention Disease

Chylomicron retention disease, or Anderson's disease, is associated with selective inability to secrete apoB from intestinal enterocytes, resulting in fat malabsorption and sometimes neurologic disease similar to that seen in abetalipoproteinemia and homozygous hypobetalipoproteinemia. In contrast to these two disorders, apoB-100 can be detected in the plasma of patients with chylomicron retention disease, as hepatic VLDL secretion is normal. The molecular defect is unknown but appears to be distinct from both the microsomal triglyceride transfer protein and apoB genes.

SELECTED GENETIC DISORDERS OF INTRACELLULAR CHOLESTEROL METABOLISM

Several rare genetic disorders of intracellular cholesterol and lipid metabolism exist ([Table 12.9](#)). In some of these diseases the molecular cause is established; in other cases it remains unknown. As more of the genes regulating intracellular cholesterol and lipid metabolism are identified, more of these syndromes will undoubtedly be recognized and defined at the molecular level.

Disorder	Enzyme Defect	Substrate	Product	Clinical Findings	Genetics
Cholesterol ester storage disease	Cholesteryl ester hydrolase	Cholesteryl ester	Cholesterol and fatty acid	Hypercholesterolemia, tendon xanthomas, hepatomegaly	Autosomal recessive
Wolman's disease	Acid lipase	Cholesteryl ester	Cholesterol and fatty acid	Hypercholesterolemia, hepatomegaly, adrenal calcification	Autosomal recessive
Niemann-Pick C disease	NPC1	Cholesterol	Cholesterol	Hypercholesterolemia, hepatomegaly, neurodegeneration	Autosomal recessive

TABLE 12.9. OTHER RARE GENETIC DISORDERS OF LIPID AND LIPOPROTEIN METABOLISM

CEREBROTENDINOUS XANTHOMATOSIS

Cerebrotendinous xanthomatosis is an autosomal recessive disorder caused by mutations in the gene for sterol 27-hydroxylase, a mitochondrial enzyme involved in the normal biosynthesis of bile acids in the liver. As a result of the deficiency in sterol 27-hydroxylase, bile acid intermediates are shunted into the synthesis of cholestanol, which then accumulates in multiple tissues. Untreated patients develop cataracts, tendon xanthomas, and progressive disease of the central and peripheral nervous system in the second decade of life. Early diagnosis is crucial, as treatment with chenodeoxycholic acid reduces plasma cholestanol levels and prevents the progression of clinical symptoms.

SITOSTEROLEMIA

Sitosterolemia is a rare autosomal recessive disease associated with excess intestinal absorption and tissue accumulation of plant-derived sterols such as sitosterol and cholestanol. The molecular cause is unknown. This disease can present with severe hypercholesterolemia, premature atherosclerosis, and tendon xanthomas similar to those of patients with homozygous or severe heterozygous familial hypercholesterolemia. Sitosterolemia should be ruled out in patients presenting with this constellation of findings. There is no LDL receptor abnormality in sitosterolemia. Patients often benefit from treatment with bile acid sequestrants but generally do not benefit from HMG-CoA reductase inhibition. Patients suspected of having sitosterolemia should be referred to specialized centers for further evaluation.

CHOLESTERYL ESTER STORAGE DISEASE AND WOLMAN'S DISEASE

Cholesteryl ester storage disease is an autosomal recessive disorder caused by mutations in the gene for lysosomal acid lipase, a lysosomal enzyme required for hydrolysis of cholesteryl esters and triglycerides in the lysosome. As a result of the deficiency in acid lipase, cholesteryl esters and triglycerides accumulate in lysosomes. Patients with this disorder present with hepatomegaly and usually hyperlipidemia in childhood. Hepatic dysfunction in childhood can be a consequence of this disease, although some patients have no clinical problems until hepatic fibrosis develops in adulthood. Premature atherosclerosis has been associated with this disease in some patients.

A more severe form of this disease is known as Wolman's disease. Within the first weeks of life, infants develop hepatosplenomegaly, steatorrhea, adrenal calcification, and failure to thrive. This form of the disease is usually fatal by the second year of life. The cause of the phenotypic difference between these two presentations of acid lipase deficiency is unknown but may relate to the specific molecular defects underlying the lipase deficiency.

NIEMANN–PICK C DISEASE

Niemann–Pick C is an autosomal recessive disease characterized by the accumulation of cholesterol and sphingomyelin in tissues, especially the liver, reticuloendothelial system, and central nervous system. It is a disorder of intracellular cholesterol transport caused by mutations in the NPC1 gene, which encodes an intracellular protein that is involved in cholesterol transport and signaling. Niemann–Pick C disease is characterized by hepatosplenomegaly and progressive

neurologic disease, often resulting in severe disability and death by the second decade.

CHAPTER 13: PATHOGENESIS OF ATHEROSCLEROSIS

ALAN M. FOGELMAN, FRANKLIN L. MURPHY AND PETER A. EDWARDS

[Lesion Development](#)
[Genetic Predisposition to Atherosclerosis](#)
[Treatment Strategies](#)

LESION DEVELOPMENT

The earliest morphologic change in the development of most atherosclerotic lesions is the appearance of mononuclear cells at sites that are destined to become lesions. At least 90% of these cells are blood monocytes. They diapedese between endothelial cells and come to rest in the subendothelial space. Here they convert to macrophages and accumulate lipid droplets rich in cholesteryl esters. Because of the high lipid content, their cytoplasm has a foamy appearance in histologic sections—hence the name *foam cells*. The number of these cells markedly increases in the subendothelial space and deforms the overlying endothelium. With time the endothelial monolayer may develop microscopic separations between cells that expose the underlying foam cells and extracellular matrix. These exposed areas serve as sites of platelet adherence, aggregation, and release.

Mitogenic substances from platelets (e.g., platelet-derived growth factor), endothelial cells, and monocytes stimulate the proliferation of smooth muscle cells that migrate into the sub-endothelial space. As cells die, their cytoplasmic contents are released, and together with plasma-derived lipoproteins the lipid-rich extracellular matrix increases in size. The cellular and extracellular components are continuously replaced in the subendothelial space, and some foam cells migrate back into the bloodstream. The expanding lesion pushes out from the subendothelial space to the adventitia. In some species, including humans, a compensatory hypertrophy of the artery wall allows further expansion toward the adventitia. If the process continues unabated, however, eventually outward expansion is no longer possible and encroachment on the lumen begins.

The spatial nature of this process is clinically important because it means that normal angiograms may be seen in subjects with extensive lesions that have not yet produced luminal narrowing. It is not rare to see patients with an essentially normal angiogram a year before an angiogram showing extensive three-vessel luminal narrowing. Presumably, the process was present extensively at the time of the first angiogram but was confined to the artery wall. In some cases, the episode of chest pain that led to the first angiogram was induced by vasospasm at the site of such an intramural lesion.

Evidence suggests that the atherosclerotic process impairs the normal ability of the artery wall to generate endothelial-derived relaxing factors. Consequently, instead of the normal response (dilatation) to various stimuli (e.g., exercise), the atherosclerotic artery contracts. Subsequently, in the course of only 1 or 2 years, such intramural lesions may expand into the lumen, particularly in hyperlipidemic subjects.

As the lesion develops, its character can change. Many early lesions contain only macrophage foam cells. These are called fatty streaks and do not cause luminal narrowing. Many fatty streaks do not progress. At predictable sites in the arterial tree, however, these lesions can develop a fibrous cap, and prominent smooth muscle proliferation may occur. Advanced lesions contain a necrotic lipid core and proteins that are associated with calcification. Neovascularization of some advanced lesions is quite extensive, being derived from the adventitia. Thus, in the same subject one can see a wide spectrum of lesions. Some lesions are rich in lipids and others are lipid-poor; some are macrophage-rich and others have only a rare macrophage, and smooth muscle cells are the dominant cell type. Still other lesions are largely acellular. The picture may depend on the stage of lesion development or may even represent different mechanisms of lesion development. Some atherosclerotic plaques contain genetic material similar to oncogenes that may induce a clonal growth of smooth muscle cells; in such lesions, smooth muscle cells would predominate.

More than 90% of all myocardial infarctions are caused by the formation of a thrombus at the site of an atherosclerotic lesion. Most myocardial infarctions occur with clot formation at sites that were narrowed less than that necessary to obstruct flow before the acute event (the average luminal narrowing in infarct arteries is about 50% to 55%). Thrombus formation usually occurs at sites of plaque rupture. Most plaques that rupture are in segments that contain arterial calcification, and the rupture occurs in the shoulder region at the site of intense monocyte infiltration. Arterial calcification has been found to occur as a result of the induction of the same set of genes as those induced in bone formation. Indeed, the calcification that results often cannot be distinguished from bone and may even include bone marrow. Oxidized sterols and transforming growth factor β seem capable of inducing a subset of artery wall cells to undergo osteoblastic differentiation and form bone. As a result of the presence of bone in the lesion, very high shear stress develops at the shoulders of the lesion at sites of inflammation, where monocyte-macrophages release enzymes that destroy the normal arterial matrix. These areas rupture and expose the flowing blood to tissue factor that normally is expressed only in the adventitia but is expressed in atherosclerotic lesions in the intima and media. The result is thrombus formation.

If the thrombus completely occludes the vessel lumen, an infarction occurs, unless collaterals are present to sustain viability. If the thrombus is only partially occlusive, it may contribute to unstable angina, and it can later be incorporated into the plaque, causing further narrowing of the lumen. Unstable angina results from the formation of platelet aggregates at these sites. The aggregates grow and obstruct flow, causing pain and electrocardiographic changes. In unstable angina, however, the platelet plug is washed away before thrombosis is completed, thus averting a myocardial infarction.

ROLE OF LIPIDS AND LIPOPROTEINS

It is rare to find a patient with clinically important atherosclerosis without at least one of the following: a low-density lipoprotein (LDL) cholesterol concentration above 120 mg per dL; a high-density lipoprotein (HDL) cholesterol concentration below 40 mg per dL; triglyceride values above 175 mg per dL on fasting; and a lipoprotein(a) [Lp(a)] concentration above 30 mg per dL. Occasionally, patients have clinically important atherosclerosis without one of these findings, but almost always, upon questioning, it is learned that the patient has changed his or her diet and lost weight before referral but shortly before or after the onset of symptoms. The mechanisms by which these lipid abnormalities participate in the pathogenesis of atherosclerosis is an area of intense investigation.

Low-density lipoproteins are cholesteryl ester-rich lipoproteins that contain a large protein designated apolipoprotein B-100 (apoB-100). This protein is synthesized in the liver and has a molecular weight of about 500 kd. The gene for this protein has been isolated and sequenced. Portions of this protein mediate the binding of LDL to heparin and to the LDL receptor. Predictably, abnormalities in this protein are being recognized as causes of hypercholesterolemia because of changes in the receptor-binding domain. In most persons with atherosclerosis, LDL binds normally to normal LDL receptors. The concentration of apoB at sites of the arterial tree where lesions are predictably found is substantially greater than the plasma concentration, indicating an accumulation of this protein at these sites. It appears that arterial LDL accumulates at these sites because of an interaction between the extracellular components of the artery wall, such as proteoglycans and glycosaminoglycans that bind LDL. Injection of LDL into a normal rabbit's femoral vein resulted in accumulation of the LDL in the subendothelial space within hours. Ultrastructural studies demonstrated that the LDL was intimately associated with the matrix molecules that constitute the subendothelial space. This indicates that LDL can cross an intact endothelium and bind to the extracellular matrix. The trapped LDL appears to be seeded with oxidative waste products from the artery wall cells. As a consequence, an oxidized phospholipid is generated that induces the expression of the genes and proteins for an endothelial binding protein that binds monocytes but not neutrophils or lymphocytes. This oxidized phospholipid also induces the artery wall cells to express the genes and proteins for monocyte chemoattractant protein 1 (MCP-1) and macrophage colony-stimulating factor (M-CSF). As a result, monocytes bind to the endothelium, migrate down the MCP-1 gradient, and, under the influence of M-CSF, convert to macrophages. The macrophages release oxidative waste and oxidative enzymes that convert the mildly oxidized LDL to highly oxidized LDL. The mildly oxidized LDL is recognized by the normal LDL receptor; the highly oxidized LDL is not but is recognized by scavenger receptors and possibly an oxidized LDL receptor. In contrast to the LDL receptor, these latter receptors are not regulated by the cell's cholesterol content, and the accumulation of cholesterol characteristic of foam cells occurs.

In contrast to LDLs, high-density lipoproteins (HDLs) have no apoB and are not substantially concentrated in the artery wall. The strong inverse relation between HDL levels and atherosclerosis has been thought to be due to the role of HDL in reverse cholesterol transport. Although this hypothesis has many attractive features, it is not proven, and the inverse relation of HDL cholesterol levels to atherosclerosis may be the result of unrelated factors. Some HDL particles (1% to 10%) carry enzymes capable of destroying oxidized lipids; it may be that the content of these enzymes is critical to the protective effect of HDL. Another possibility relates to the formation of HDL during the lipolysis of intestinally derived lipoproteins. High-density lipoproteins are formed as a by-product during the lipolysis of chylomicrons by the enzyme lipoprotein lipase. Thus, in some subjects, low levels of HDL simply may reflect impaired lipolysis. Such subjects have low HDL cholesterol levels and high triglyceride levels. The accelerated atherosclerosis frequently seen in such persons may not be due to a failure of reverse cholesterol transport as much as it is

due to the accumulation of chylomicron remnants.

Chylomicrons contain apoB-48. This protein derives from the same gene as apoB-100. However, apoB-48 is synthesized only in the intestine and not to any significant extent in the liver of humans.

In the intestine, an RNA-editing mechanism results in a single nucleotide substitution in the mRNA for apoB, producing a stop codon that results in a truncated protein. This truncated protein contains only 48% of the amino acids found in apoB-100 and hence is known as apoB-48. The truncated protein contains the amino-terminal portion of apoB-100 but lacks the portion necessary for recognition by the LDL receptor. These intestinally derived lipoproteins, however, become enriched in another apolipoprotein that is recognized by the LDL receptor apoE. Apolipoprotein E is recognized by both the LDL receptor and a receptor on liver cells that does not recognize apoB-100.

Normally, these particles are acted on by lipoprotein lipase as the particles circulate through the heart and adipose tissue, where lipoprotein lipase is abundant. The resulting triglyceride-depleted remnants are cleared rapidly in normal subjects by hepatic receptors. Under conditions of impaired lipolysis, however, the metabolism of these particles is slowed, and the remnant lipoproteins can be found even in fasting plasma. Many diabetics are prone to accumulate such chylomicron remnants in their plasma. Considerable evidence suggests that these chylomicron remnants are atherogenic. Thus, the failure of lipolysis in these diabetics results in low HDL levels and the presence of circulating atherogenic particles.

In patients with type III hyperlipoproteinemia (also known as broad β disease), single amino acid substitutions have been found in both alleles of apoE that result in defective binding of the remnant lipoproteins to the E receptor and to the LDL receptor. Consequently, these subjects accumulate remnant particles in their plasma. A required cofactor for lipoprotein lipase is an apolipoprotein designated apoC-II. Homozygotes lacking this apolipoprotein have been found to have impaired lipolysis that is corrected by infusion of apoC-II.

Another lipoprotein that has been associated with increased risk for atherosclerosis is Lp(a). This lipoprotein contains a full copy of apoB-100 that is linked by a disulfide bridge to a remarkable duplication of portions of plasminogen. This lipoprotein contains 37 copies of kringle 4 and one copy of kringle 5 of plasminogen. However, the protease domain differs from plasminogen in such a way that it cannot become proteolytically active on exposure to tissue plasminogen activator. However, Lp(a) competes with plasminogen for the plasminogen binding site with similar affinity and capacity. It has been estimated that at plasma concentrations of 30 mg per dL, plasminogen binding to endothelial cells would be reduced by 20%, thereby decreasing fibrinolysis and favoring a procoagulant state. Lp(a) is found in trace amounts in virtually everyone; it is present in high concentrations in some persons who are at high risk for atherosclerosis.

Free cholesterol exits from cells into plasma, but esterified cholesterol is found as the major form in lipoproteins. The enzyme lecithin:cholesterol acyltransferase is responsible for esterifying free cholesterol entering the plasma compartment. This esterified cholesterol is found initially in the HDL fraction. Subsequently, the esterified cholesterol is transferred to the very low density lipoprotein (VLDL) and LDL fractions by cholesteryl ester transfer proteins in plasma. Abnormalities in the distribution of cholesterol in the plasma compartment have been associated with premature atherosclerosis, particularly in diabetics and in patients on hemodialysis.

Although almost all cells can synthesize cholesterol, most of the circulating plasma cholesterol is synthesized in the liver and intestine. A series of enzymes tightly regulates cholesterol biosynthesis; central among these is 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase. This enzyme is particularly important, as specific inhibitors such as lovastatin are clinically useful.

ROLE OF RECEPTORS

After a person eats, chylomicrons are synthesized in the intestine. These large triglyceride-rich particles are acted on by lipoprotein lipase and are metabolized through particles with the density of VLDL ($d \approx 1.006$ g per mL) to particles of intermediate density ($d = 1.006$ to 1.019 g/mL). These particles, called IDLs, are derived from chylomicrons that contain both apoB-48 and apoE. The liver contains two receptors capable of removing these particles: the E receptor and the LDL receptor. The former recognizes apoE; the latter apoB and apoE. After receiving these particles, the liver secretes triglyceride-rich particles that are found in the VLDLs. Unlike those derived from intestinal chylomicrons, these VLDLs contain apoB-100 but not apoB-48.

These hepatic VLDLs are metabolized by lipoprotein lipase to particles in the IDL class, which in turn are converted to LDL ($d = 1.019$ to 1.063 g per mL) by an unknown mechanism that may involve hepatic triglyceride lipase. All of the apoB-100 lipoproteins—VLDL, IDL, and LDL—are recognized and cleared by the hepatic LDL receptor. The apoE receptor appears to be closely related to the LDL receptor. Additionally, there appears to be a VLDL receptor.

In patients with a severe deficiency of the LDL receptor (familial hypercholesterolemia homozygotes), there is some accumulation of remnant particles and a marked accumulation of LDL. The latter results in part because the lack of LDL receptors allows that fraction of VLDL normally cleared by the liver to accumulate, enhancing conversion of VLDL to LDL. Patients with heterozygous familial hypercholesterolemia have one normal and one abnormal LDL receptor allele, resulting in half the number of functional LDL receptors; thus, plasma LDL concentrations are roughly twice normal. Treatment of such patients with bile-sequestering agents or an HMG-CoA reductase inhibitor results in depletion of hepatocyte cholesterol pools. Consequently, there is a compensatory increase in hepatic LDL receptors mediated by the normal allele. This mechanism is largely responsible for the clinical utility of the bile-sequestering agents. Unfortunately, these agents also induce a compensatory increase in the rate-controlling enzymes in the cholesterol biosynthetic pathway (e.g., HMG-CoA reductase), and in more than 50% of cases the plasma LDL concentration returns to normal after a year's treatment. The addition of a specific agent to block cholesterol biosynthesis (e.g., lovastatin, which blocks HMG-CoA reductase) prevents the compensatory increase in cholesterol biosynthesis and contributes to the induction of hepatic LDL receptors. The combination of a bile-sequestering agent and lovastatin is thus very effective in lowering LDL levels.

The conversion of monocyte-macrophages in the artery wall to foam cells depends on the uptake of cholesterol from plasma lipoproteins. Most lipoprotein cholesterol is carried as the esterified form. After endocytosis, these cholesteryl esters are hydrolyzed and the free cholesterol is re-esterified in the endoplasmic reticulum by the enzyme acyl coenzyme A:cholesterol acyltransferase. Normally, human monocyte-macrophages contain little cholesteryl ester (about 2% of total cellular cholesterol). In foam cells, however, more than half the cellular cholesterol is esterified. Human monocyte-macrophages have normal LDL receptors, but as is the case with LDL receptors elsewhere, these are tightly regulated by the cellular cholesterol content. As the level of cellular cholesterol rises, the synthesis of LDL receptors decreases and the synthesis of the rate-limiting enzymes in cholesterol biosynthesis (e.g., HMG-CoA reductase) also is decreased. Thus, the cell is protected from cholesterol accumulation. Moreover, patients who are receptor-negative (have no detectable LDL receptor) accumulate massive amounts of cholesterol in the monocyte-macrophages of their artery walls.

In the Watanabe heritable hyperlipidemic (WHHL) rabbit, a hypolipidemic agent with antioxidant properties (probuco) has been shown to retard the development of atherosclerosis in the aorta. Moreover, direct examination of the atherosclerotic lesions of these animals disclosed apoB-100, which had been modified by products of lipid peroxidation. The acetyl LDL receptor (or scavenger receptor) is found on macrophages and endothelial cells, but not on smooth muscle cells or fibroblasts. Another high-affinity process for internalizing cholesterol-rich particles is the LDL-dextran sulfate pathway. The LDL complexed to high molecular weight dextran is internalized, causing massive cholesterol accumulation in macrophages. The dextran sulfate pathway may have relevance to LDL bound to proteoglycans or glycosaminoglycans in the artery wall.

Previously it was thought that a macrophage receptor genetically distinct from the LDL receptor recognized b-VLDL (cholesterol ester-rich VLDL found in cholesterol-fed animals and in patients with type III hyperlipoproteinemia). Evidence now suggests that this receptor is immunologically similar, if not identical, to the LDL receptor. Chylomicron remnants and b-VLDL are taken up in cholesterol-loaded human monocyte-macrophages by a lower affinity, high-capacity process—in contrast to LDL, which is taken up by a high-affinity, low-capacity process. Diabetics have increased levels of various glycosylated proteins (e.g., hemoglobin A_{1c}). They also have glycosylated LDL, and some diabetics have antibodies to these glycosylated proteins. In such subjects, LDL-antibody complexes may be taken up by the Fc receptor on human monocyte-macrophages. This receptor is not regulated by cellular cholesterol levels, and consequently this pathway could mediate the cholesteryl ester accumulation seen in arterial foam cells in some diabetics.

Smooth muscle cells also can become foam cells. Although they have a normal LDL receptor pathway, they do not have separate pathways for modified lipoproteins and for remnants. In vitro it has been shown that the cholesteryl ester droplets released from macrophages after they were loaded by the scavenger receptor pathway could be taken up by smooth muscle cells. Presumably, phagocytosis by smooth muscle cells of the lipid droplets released from dying macrophages in the artery wall could explain the origin of smooth muscle cell foam cells.

GENETIC PREDISPOSITION TO ATHEROSCLEROSIS

On average, patients with myocardial infarction are age 65 years or older. Only about 20% of all infarcts occur in patients under age 60 years. Many of these patients have a genetic abnormality in lipid metabolism; indeed, about two-thirds of those with myocardial infarction at age 55 or younger have such a genetic disorder. Abnormalities in HDL levels are common. A rare but informative mutation results in an abnormality in apolipoproteins A-1 and C-III. This is due to an inversion in the DNA sequences for these two proteins, whose genes are adjacent to each other. As a consequence of this mutation, tendon xanthomas, corneal clouding, and severe atherosclerosis result, with total cholesterol levels of less than 200 mg per dL and HDL cholesterol concentrations of less than 10 mg per dL. Early results suggest that restriction fragment length polymorphisms for apoB are also associated with premature coronary atherosclerosis.

Several other disorders are also commonly associated with premature atherosclerosis. Familial hypercholesterolemia is the best understood of the metabolic disorders associated with premature atherosclerosis. This autosomal dominant disorder occurs in both humans and rabbits. Four basic defects in the gene for the LDL receptor have been identified. In some patients, no functional receptor protein or receptor mRNA is observed. These *null* mutants presumably have deletions, insertions, or other mutations in the LDL receptor gene that prevent expression of the receptor. One such abnormality has been recognized as being caused by a 5-kilobase deletion that joins a coding sequence in exon 13 to an *Alu* repetitive element in intron 15. A second defect results in an abnormal protein that is slowly processed in the Golgi apparatus, and 95% of the receptors are destroyed before they can be carried to the cell surface. This defect has been found in the WHHL rabbit and is due to a deletion in the cysteine-rich, ligand-binding domain of the LDL receptor. A third class of defects results from mutations that allow receptor insertion into the cell membrane, but with abnormal receptor binding of ligands. In one family, a deletion due to homologous recombination between repetitive *Alu* sequences in introns 4 and 5 of the LDL receptor gene resulted in a receptor that binds apoE normally but does not bind apoB. This mutant receptor thus binds b-VLDL but not LDL. The fourth class of mutations results in receptors that are inserted into the membrane and can bind LDL normally; however, due to a defect in the cytoplasmic tail of the receptor, the receptor fails to cluster in coated pits. In these mutants there is normal binding of ligand, but there is an abnormality in internalization of the LDL receptor complex into the cell.

Homozygous or compound heterozygous familial hypercholesterolemia is rare, with fewer than 100 cases identified in the United States. In these subjects, LDL levels are elevated at birth and typically are 600 to 1,000 mg of LDL cholesterol per milliliter. These children have palmar, tuberous, and tendon xanthomas, as well as a form of supravalvular aortic stenosis that results from a xanthomatous deposit distal to the aortic valve. They have coronary artery disease and often die before age 20 when left untreated. Treatment includes plasmapheresis, portacaval shunt, and, rarely, liver transplant.

The heterozygous form of familial hypercholesterolemia is common, occurring in as many as 1 in 500 births. About half of affected families have at least one family member with tendon xanthomas. These xanthomas are diagnostic when present, but their absence does not exclude the disease. Typically, LDL cholesterol levels are about twice normal in heterozygotes. The average age for myocardial infarction in male heterozygotes is 40 to 45, and it is 55 years for female heterozygotes unless they smoke cigarettes. Female heterozygotes who smoke have their first infarcts a decade earlier than those who do not. The protective state of the female gender is common to most forms of atherosclerosis, but the cause for this advantage is not well understood. Of particular clinical interest is the high incidence of left main coronary artery disease in patients with familial hypercholesterolemia: about 40% have left main lesions by their fourth decade. This extraordinarily high incidence is not well understood. The treatment of heterozygous familial hypercholesterolemia generally includes a bile-sequestering agent together with niacin or lovastatin.

Nongenetic causes of altered LDL receptor activity are common and probably are important in many cases of hypercholesterolemia and atherosclerosis. Feeding saturated fat decreases LDL receptor activity and increases plasma LDL levels. Hypothyroidism can be associated with a deficiency of LDL receptor activity that mimics homozygous familial hypercholesterolemia; it is reversible with thyroid hormone replacement.

Familial combined hyperlipidemia is an autosomal dominant disorder that has incomplete penetrance in childhood. By age 30, half the members of affected families have hyperlipidemia and the other half are normolipidemic. About one-third of affected family members have elevated cholesterol levels, one-third have elevated triglyceride levels, and another third have both elevated cholesterol and triglyceride levels. Moreover, a person may have one type of abnormality at one time and another type at a later time. Because of this variability, the disorder has also been called *multiple lipoprotein phenotypes*. Tendon xanthomas are not seen. This common disorder is present in up to 1% of the population. The average age of myocardial infarction ranges from 35 to 55 years, depending on the family. No specific cause has been identified, but many affected persons have elevated apoB levels, regardless of whether their cholesterol or triglyceride levels are elevated. Patients with this disorder are sensitive to excess weight. They often appear not to be overweight when in fact they are. For example, a patient may present who is sedentary, is 5 feet 11 inches tall, and weighs 175 pounds at age 50. On taking a history, it is learned that maximal height was achieved by age 18, and at age 22, when he played college basketball, he only weighed 145 pounds. This person thus weighs 30 pounds more than he did at the same height at a time when he was physically fit. Reduction in weight to lean body mass often results in a marked improvement in the metabolic abnormality and even a complete return of lipid levels to normal. In subjects who do not reduce their weight to lean body mass or who do not correct with weight loss, the use of niacin is often helpful in correcting the metabolic abnormality. In some patients, omega-3 fatty acids decrease VLDL levels by suppressing apoB synthesis. This is not the case in all subjects, and careful monitoring is needed.

Type III hyperlipoproteinemia, or broad β disease, is a rare disorder associated with premature peripheral vascular disease and premature coronary artery disease. This disorder is clinically manifested by xanthomas (palmar, tuberous, or tendon), which are found in 75% of patients. A requirement for this disorder is the homozygous apoE2 phenotype (E2:E2). This occurs in about 1 in 100 persons, and yet the clinical disorder of type III hyperlipoproteinemia occurs in no more than 1 in 5,000 persons. Because of amino acid substitutions (usually a single amino acid), apoE in E2:E2 homozygotes binds poorly to the E receptor and poorly to the LDL receptor. Consequently, remnant particles accumulate that are rich in cholesteryl esters (b-VLDL). Most E2:E2 persons are normolipidemic or even hypolipidemic. All have some increase in remnant particles and low LDL levels, however, because of a block in the normal metabolism of hepatic VLDL to LDL. This suggests that apoE binding may be important in hepatic triglyceride lipase conversion of IDL to LDL, as well as in the removal of apoB-48 intestinally derived particles. Clinically significant hyperlipidemia is associated with this disorder when the person gains weight, becomes diabetic, or becomes hypothyroid. These patients are very sensitive to weight reduction and also respond favorably to therapy with niacin. Some female patients also respond to estrogen treatment for reasons that are not entirely clear.

TREATMENT STRATEGIES

A discussion of profiling patients with lipid disorders is presented in [Chapter 31](#). Several general tenets of therapy can be deduced based on the pathogenesis of atherosclerosis. As the pathogenesis becomes better understood, more rational and specific therapies should become available.

The strong link between abnormalities in lipid metabolism and premature atherosclerosis has led to vigorous treatment of lipid abnormalities in patients with a history of atherosclerosis or in patients who are genetically at high risk. Such patients should be treated with dietary modifications, exercise, and, if necessary, hypolipidemic agents. The introduction of specific inhibitors of HMG-CoA reductase, such as lovastatin, has appreciably increased the means of treating hypercholesterolemia. These agents are competitive inhibitors of the major rate-controlling enzyme in cholesterol biosynthesis. They are well tolerated and have few major side effects, other than in a rare to occasional patient who develops elevated levels of liver or muscle enzymes. Lovastatin often lowers plasma cholesterol levels by one-third. When used in combination with a bile-sequestering agent such as cholestyramine, plasma cholesterol levels often are halved. Numerous angiographic studies have demonstrated that vigorously lowering lipids (i.e., lowering LDL cholesterol levels to less than 100 mg per dL and raising HDL levels as much as possible) produces a profound decrease in the number of clinical events without changing the luminal diameter appreciably. Presumably, lowering LDL levels decreases the substrate for the oxidized lipids that induce the continued inflammatory response. With a reduction in the monocyte-macrophage content of the lesions, the lesions stabilize and plaque rupture is averted. Many would argue that all patients who have a myocardial infarction, angioplasty, or coronary artery bypass grafting should be put on LDL-lowering drugs regardless of their initial LDL levels. Because smoking accelerates clinical atherosclerotic events, such patients should be strongly urged to abstain from smoking.

Because platelets play a role in the development and consequences of atherosclerosis, consideration should be given to treating these patients with antiplatelet agents (e.g., aspirin). Epidemiologic evidence suggests that omega-3 fatty acids protect against atherosclerotic events, and some in vitro evidence suggests that omega-3 fatty acids decrease monocyte adherence to endothelial cells. Omega-3 fatty acids prolong the bleeding time. Based on these relatively weak data, it may be reasonable to encourage the use of omega-3 fatty acids in some subjects. In these patients, however, it is important to monitor HDL and LDL levels, as in some patients omega-3 fatty acid feeding leads to a decrease in HDL and an increase in LDL levels. The reader should refer to [Chapter 12](#) and [Chapter 29](#).

CHAPTER 14: SOME FUNCTIONAL PATHWAYS IN THE CENTRAL NERVOUS SYSTEM

JOHN A. KIERNAN

[Descending Motor Pathways](#)
[Pathways Necessary for Motor Coordination](#)
[Pathways for Somatic Sensation](#)
[Pathways for Sleep, Arousal, and Consciousness](#)
[Pathways for Memory and Emotion](#)
[Functional Localization in the Cerebral Cortex](#)

This chapter reviews the major central pathways for control of movement, somatic sensation, consciousness, memory, and emotion. The localization of functions in the cerebral cortex is also summarized. An understanding of functional connections in the central nervous system (CNS) is needed for the diagnosis of many neurologic disorders.

DESCENDING MOTOR PATHWAYS

The contractions and relaxations of muscles result in movements that occur voluntarily (willed movements) and subconsciously (automatic movements). Even the most skilled movements include major automatic components because the conscious brain does not deliberately stimulate or inhibit individual muscles.

The cells that innervate skeletal muscles are known singly as motor neurons and collectively as “the lower motor neuron.” They are in the ventral horn of the spinal gray matter and in the motor nuclei of most of the cranial nerves. The following account applies to the control of motor neurons in the spinal cord and is applicable in modified form to movements mediated by cranial nerves V, VII, IX, X, XI, and XII. Motor neurons do not fire spontaneously; consequently, muscles can contract only when their pathways are intact. The axons that synapse with the dendrites and perikarya of motor neurons are (a) primary sensory fibers, principally proprioceptive, from the dorsal roots; (b) some fibers of some of the descending tracts; and (c) spinal interneurons that fire in response to activity in primary afferents and descending tracts. When motor neurons are deprived of the influence of the descending tracts, they respond excessively to segmental proprioceptive stimulation. A stretch reflex is continuously in operation, so that the muscles are spastic. Contractions in response to additional stretch (the tendon jerk reflexes) or painful stimulation of the limb (withdrawal reflexes) are exaggerated. Movements other than those resulting from spinal reflexes cannot be made.

In humans, three major motor pathways project from the brain to the spinal cord ([Fig. 14.1](#)). Equivalent projections exist for the motor nuclei of cranial nerves V, VII, IX, X, XI, and XII. (The rubrospinal and tectospinal tracts, once considered important, are now believed to be virtually nonexistent in the human CNS. There are also pathways, not considered here, for controlling the oculomotor nuclei, and there are descending tracts that are not concerned with the activities of motor neurons.)

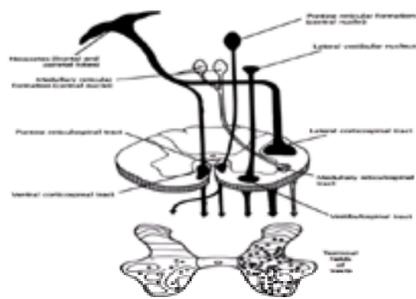

FIGURE 14.1. Descending motor tracts in the spinal cord. (From Kiernan JA. *Barr's The Human Nervous System*, seventh ed. Philadelphia: Lippincott-Raven, 1998, with permission.)

CORTICOSPINAL OR PYRAMIDAL TRACT

The largest descending tract in the spinal cord arises from an area of cortex that extends from the premotor area of the frontal lobe across the central sulcus to the postcentral and nearby gyri. The fibers pass through the posterior limb of the internal capsule into the basis pedunculi of the midbrain. From there, the tract passes through the ventral part of the pons into the medullary pyramids. Most of the pyramidal fibers decussate at the lower end of the medulla. The crossed axons descend in the dorsal half of the lateral funiculus of spinal white matter, whereas the uncrossed axons remain near the ventral sulcus of the cord. In a few persons, most of the pyramidal fibers are uncrossed. The uncrossed corticospinal fibers eventually decussate at segmental levels before terminating in the spinal gray matter alongside the crossed tract. Axons from the somatosensory areas of the parietal lobe end in the dorsal horn, and most of the fibers from the primary motor and premotor areas end in contact with interneurons in the intermediate gray matter. A few pyramidal axons synapse directly with the cell bodies and larger dendrites of motor neurons.

Investigation of those rare cases in which the human pyramidal tract has been selectively transected in the midbrain or medulla confirms experimental studies in monkeys. Such lesions cause a flaccid hemiparesis that, on recovery, leaves residual weakness that is largely confined to the hands. Similar but more localized changes follow small lesions in the primary motor area of the cerebral cortex. The normal function of the motor component of the corticospinal pathway is therefore presumed to be performing skilled (least automatic) movements that need some direct control from the highest levels of the neuraxis. The classical upper motor neuron spastic paralysis results from interruption of more than just the pyramidal system. Lesions involving the premotor cortex cause paresis of muscles that work on the shoulder and hip joints, indicating that a major function of the premotor area may be to bring the distal parts of the limbs into position for the performance of skilled tasks.

RETICULOSPINAL TRACTS

Neurons in the central group of nuclei of the reticular formation give rise to the axons constituting the medullary reticulospinal tract (in the lateral white matter of the spinal cord) and the pontine reticulospinal tract (in the ventral spinal white matter). These tracts terminate bilaterally in the spinal gray matter. Studies in laboratory animals indicate that these pathways mediate control over most movements that do not require dexterity or the maintenance of balance. The central nuclei of the reticular formation receive projections from the spinal cord, the cerebellum, the hypothalamus, and the premotor area of the cerebral cortex. Some parts of the reticular formation serve as pattern generators for frequently performed movements, including those of respiration and locomotion.

The reticulospinal tracts may mediate much of the normal inhibition of spinal reflexes, and spastic paralysis may result from transection either of the tracts themselves or of the fibers that descend through the internal capsule to the reticular formation.

VESTIBULOSPINAL TRACTS

The large neurons of the lateral vestibular nucleus (of Deiters) are in the floor of the lateral part of the fourth ventricle, at the rostral end of the medulla. Their axons descend in the ventral white matter of the cord and end ipsilaterally in the medial zone of the ventral horn among neurons that supply the axial trunk musculature and the postural muscles of the lower limbs. The neurons in Deiters' nucleus, which are driven by the sensory signals from the vestibular nerve, cause contraction of extensors and relaxation of the opposing flexors. Consequently, unilateral destruction of the vestibular labyrinth causes a tendency to fall to the side of the lesion, due to unopposed stimulation of the contralateral antigravity muscles. The vestibular nuclei do not receive descending afferents from the cerebrum.

The motor cortex of the frontal lobe should not be thought of as a command center for willed movements but as part of a larger system. Afferent fibers come to the

motor areas from the other cortical regions and from the ventral lateral nucleus of the thalamus. This thalamic nucleus receives the output of the basal ganglia and the cerebellum.

PATHWAYS NECESSARY FOR MOTOR COORDINATION

The parts of the CNS most conspicuously concerned with the production of orderly movement are the basal ganglia and the cerebellum.

BASAL GANGLIA

To the physiologist or clinician, the basal ganglia comprise the corpus striatum (caudate nucleus, putamen, and globus pallidus), the subthalamic nucleus (or corpus Luysii), and the two parts (compacta and reticulata) of the substantia nigra. These structures are in the base of the cerebral hemisphere and nearby parts of the diencephalon and midbrain. Functionally, the system has five components. The striatum consists of the caudate nucleus and the putamen. The lateral pallidum is the lateral division of the globus pallidus. The medial pallidum consists of the medial division of the globus pallidus together with the pars reticulata of the substantia nigra. The other two components are the subthalamic nucleus and the substantia nigra pars compacta. These regions, which are connected with one another and with the thalamus, cerebral cortex, and other parts of the brain, are involved in the automatic execution of learned movements and probably also in cognitive functions. Destruction of neuronal populations in this system results in abnormalities of movement known as dyskinesias. The effects of the basal ganglia on movement are mediated principally through descending pathways from the motor areas of the cerebral cortex, and they affect the contralateral musculature.

The principal connections of the basal ganglia are summarized in [Figure 14.2](#). There it can be seen that the inputs are excitatory, with glutamate as the probable transmitter: first from the whole cerebral cortex to the striatum, second from the intralaminar thalamic nuclei to the striatum, and third from the motor cortical areas to the subthalamic nucleus. The output consists of inhibitory neurons, with their somata in the medial pallidum, which use g-aminobutyric acid (GABA) as their transmitter. The largest pathway from the medial pallidum is to the anterior division of the ventrolateral nucleus of the thalamus, which projects to the premotor and supplementary motor areas of the cerebral cortex. Thus, the cortex and the basal ganglia can modulate the activity of a large proportion of the motor fibers of the pyramidal system and of the corticoreticulospinal pathway. Pallidal efferents go also to the superior colliculus, the intralaminar thalamic nuclei, and the pedunculopontine nucleus in the reticular formation of the brain stem. The superior colliculus is concerned with the control of eye movements. The intralaminar thalamic nuclei and pedunculopontine nucleus have connections with many parts of the brain and may provide links between the basal ganglia and pathways for consciousness and sensation. Many other known connections of the basal ganglia are not shown in [Figure 14.2](#).

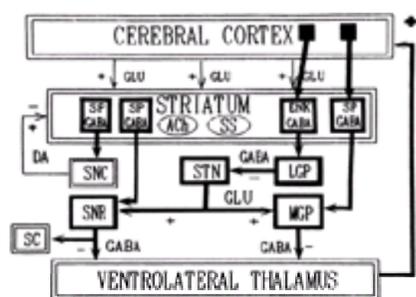

FIGURE 14.2. Connections of the basal ganglia. Shows excitatory (+) and inhibitory (-) synapses and probable neurotransmitters. LGP, lateral pallidum; MGP, medial pallidum; SC, superior colliculus; SNC, substantia nigra pars compacta; SNR, substantia nigra pars reticulata; STN, subthalamic nucleus; ACh, acetylcholine; DA, dopamine; ENK, enkephalins; GABA, g-aminobutyric acid; GLU, glutamate; SP, substance P; SS, somatostatin. (From Albin RL, Young AB, Penney JB. Functional anatomy of basal ganglia disorders. *Trends Neurosci* 1989;12:366, with permission.)

The striatum contains two populations of principal neurons, both causing inhibition at their synapses: those containing GABA and enkephalins that project to the lateral pallidum, and those containing GABA and substance P that project to the medial pallidum and to the substantia nigra pars compacta. The cells of the substantia nigra pars compacta are dopaminergic. Their best known projection is to the striatum, where the two populations of GABAergic cells respond differently to dopamine. The striatal neurons that contain substance P are excited, whereas those that contain enkephalins are inhibited. Knowledge of neurotransmitters and their actions may explain some features of disorders that result from diseases of the basal ganglia, as in the following two examples.

In *hemiballismus*, destruction of the subthalamic nucleus deprives the medial pallidum of excitatory stimuli, resulting in decreased activity of the pallidothalamic neurons and decreased inhibition of the cells in the ventrolateral nucleus of the thalamus. Excessive activity of the ventrolateral nucleus causes excessive stimulation of the premotor cortex, leading to large spontaneous movements at the proximal joints of the contralateral limbs.

In *parkinsonism*, degeneration of nigral dopaminergic neurons leads to decreased activity of striatal neurons containing substance P and increased activity of striatal neurons containing enkephalins. Both types of striatal neuron are inhibitory to pallidal cells ([Fig. 14.2](#)). Consequently, in Parkinson's disease, the neurons in the medial pallidum become more active and those in the lateral pallidum become less active. The reduced activity of the lateral pallidum permits a stronger excitatory effect of the subthalamic nucleus on the medial pallidum. The output of the medial pallidum is therefore increased for two reasons, and the stimulation of the motor cortical areas by the thalamus is suppressed. These events account in a simple way for the reduced motor activity of the parkinsonian patient, but not for the associated tremor and rigidity.

Similar reasoning can be invoked to account for choreiform movements (fragments of learned motor patterns) after degeneration of both types of striatal principal cell in Huntington's disease, and for abnormal saccadic eye movements associated with chorea and parkinsonism.

CEREBELLUM

Some of the circuitry of the cerebellum is summarized in [Figure 14.3](#). All parts of the cerebellum receive input from the inferior olivary complex of nuclei in the contralateral half of the medulla. The olivary nuclei receive their afferents from the motor areas of the cerebral cortex and from the red nucleus. The olivocerebellar system is thought to supply programs of instructions for movement patterns; the programs are stored in the cerebellum. Fibers that reach the cerebellum from other sources, including the vestibular nuclei, the spinal cord, and the pontine nuclei, are active when motor programs are being executed. Another source of fibers to the whole of the cerebellum is the locus ceruleus. This nucleus, in the upper brain stem, contains noradrenergic neurons with greatly branched axons that go to most parts of the CNS. They may have a general modulatory action on the whole cerebellum.

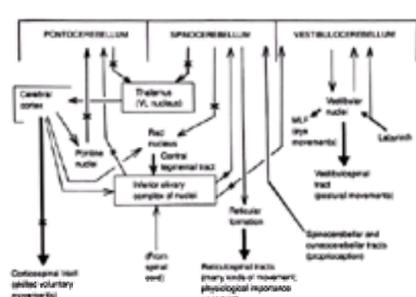

FIGURE 14.3. Major neuronal circuitry of the three functional divisions of the cerebellum. X indicates tracts that cross the midline. (From Kiernan JA. *An introduction to*

The nonolivary and non-noradrenergic cerebellar afferent fibers are not uniformly distributed. Those from the vestibular system end in the flocculus and nodule, and those from the spinal cord end ipsilaterally in the vermis (cerebellar midline) and paravermal zones. Movements for equilibration and gait, which rely on vestibular and proprioceptive input, are associated with these parts of the cerebellum. The contralateral pontine nuclei, which receive afferent fibers from most of the cerebral cortex, project to the large cerebellar hemispheres and are the source of the largest contingent of afferent fibers. The corticopontocerebellar system controls the force, extent, and timing of muscular contractions and is therefore necessary for performing skilled movements.

The functional deficits that result from damage to the cerebellum vary with the neuroanatomical subdivisions involved in the lesions. Thus, diseases affecting the parts in and around the midline, which receive vestibular and proprioceptive input, cause ataxia. More lateral lesions cause disordered motor coordination that is most pronounced when trying to make precise movements of the hands or feet.

Projections to the vestibular nuclei and the reticular formation enable the cerebellum to influence the vestibulospinal and reticulospinal pathways directly. The largest numbers of cerebellar efferent fibers course rostrally to the posterior division of the ventrolateral nucleus of the contralateral thalamus. The posterior division of the ventrolateral nucleus projects to the primary motor area of the cerebral cortex. In contrast to the cerebral cortex, basal ganglia, and thalamus, the cerebellum has its functional connections with the muscles of the same side of the body.

PATHWAYS FOR SOMATIC SENSATION

Receptors in skin, deep connective tissue, skeletal muscle, tendons, and joints transduce mechanical, thermal, and noxious stimuli, sending ordered patterns of impulses through spinal nerves and their dorsal roots to the spinal cord and through cranial nerves to the brain stem. Somatic sensory pathways are traced from peripheral receptors to the postcentral gyrus, which is the primary somatosensory area of the contralateral cerebral cortex. Different routes, each a series of three or four populations of neurons, are followed by the pathways for different kinds of sensation. For all these pathways, the first-order neurons are unipolar, with their cell bodies in dorsal root (or cranial nerve) ganglia. The distal branches of the axons of these cells are directed peripherally, and the central branches enter the CNS. The last neuron in the series is also the same in all pathways, having its cell body and dendrites in the ventroposterior nucleus of the thalamus and an axon that passes through the posterior limb of the internal capsule before ending in the primary somatosensory area. The positions of the cell bodies and axons of the second- and (when present) third-order neurons vary according to the type of sensation.

Distinct ascending pathways exist for pain and temperature, discriminative tactile sensation, and conscious awareness of position and movement of parts of the body (proprioception; Fig. 14.4). Simple (nondiscriminative) touch is served by the pain/temperature sensation pathways. From the positions of the pathways at different levels of the neuraxis, it is possible to predict the effects of lesions on sensation:

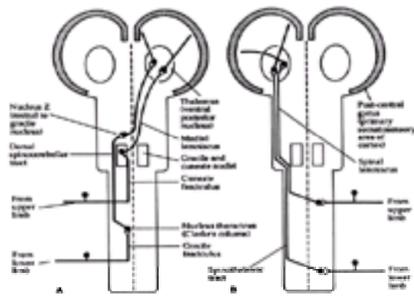

FIGURE 14.4. Ascending pathways for somatic sensation. **A:** Pathways for conscious proprioception for the upper and lower limbs. The pathway shown for the upper limb also conveys discriminative touch sensation. Signals for discriminative touch from the lower limb travel to the medulla in the ipsilateral gracile fasciculus. **B:** Spinothalamic pathway for pain, temperature, and nondiscriminative tactile sensation.

1. The pathway for pain and temperature crosses the midline at segmental levels.
2. The pathways for discriminative touch and conscious proprioception cross the midline in the caudal part of the medulla.
3. The spinothalamic tract, for pain and temperature, ascends in the ventral half of the lateral funiculus of spinal white matter and is laterally located in the brain stem.
4. Fibers for discriminative touch ascend in the dorsal spinal white matter and in the medial lemniscus in the brain stem. The medial lemniscus is next to the midline in the medulla and caudal pons. More rostrally, this tract shifts dorsally and laterally, so that in the midbrain it is close to the spinothalamic tract.
5. There are different pathways for conscious proprioception from the upper and lower limbs (Fig. 14.4). At cervical levels, the dorsal funiculus of the spinal cord does not contain proprioceptive fibers from the lower limb.
6. The central branches of the first-order neurons in the pathway for pain and temperature originating in the face, mouth, and head (not shown in Fig. 14.4) descend into the caudal part of the medulla before ending in the spinal trigeminal nucleus. The trigeminothalamic fibers cross the midline before ascending in the trigeminal lemniscus, which is medial to the spinal lemniscus in the caudal half of the pons, and between the spinal and medial lemnisci in the rostral pons and midbrain.
7. The flow of somatosensory information from the spinal cord and brain stem is modulated by activity in descending pathways. These include the corticospinal (pyramidal) tracts; corticobulbar fibers ending in the gracile, cuneate, and trigeminal sensory nuclei; and reticulospinal fibers from various sources. Of the latter, the serotonergic raphe spinal tract from nuclei in the midline of the medulla is best known. These raphe spinal neurons, which can be activated by stimulation of the periaqueductal gray matter of the midbrain, can simulate the analgesic action of morphine and other opiates. The corticospinal and corticobulbar fibers may help to ensure that all peripheral stimuli are not consciously perceived.

PATHWAYS FOR SLEEP, AROUSAL, AND CONSCIOUSNESS

Two groups of nuclei of the reticular formation of the brain stem are involved in arousal, consciousness, and sleep.

CENTRAL GROUP OF RETICULAR NUCLEI

The central group includes the gigantocellular reticular nucleus in the medulla, the caudal and oral pontine reticular nuclei, and the cuneiform and subcuneiform nuclei in the midbrain. The two latter are laterally located, but their connections and functions place them in the central group. The two pontine reticular nuclei include the neurons constituting the paramedian pontine reticular formation (PPRF), which is involved in eye movements. The nuclei of the central group receive afferent fibers from the spinal cord, the sensory nuclei of the cranial nerves, the vestibulocerebellum, the reticular formation of the midbrain, the tectum, the hypothalamus, and the premotor area of the cerebral cortex (Fig. 14.5). The ascending afferents include collateral branches from the spinothalamic and trigeminothalamic tracts.

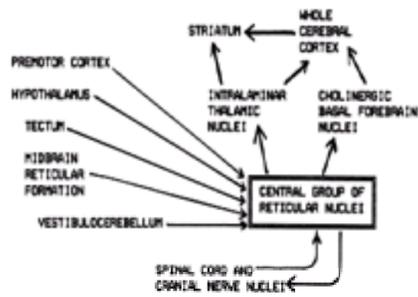

FIGURE 14.5. Some connections of the central group of nuclei of the reticular formation.

Neurons of the central reticular nuclei typically have axons with long ascending and descending branches and numerous collaterals that synapse with other neurons in the brain stem. The long descending fibers constitute the reticulospinal tracts, discussed elsewhere in this chapter. Ascending axons go to the intralaminar thalamic nuclei and the basal cholinergic nuclei of the substantia innominata in the base of the forebrain. The latter cell groups include the nucleus basalis of Meynert, the nucleus of the diagonal band, and certain nuclei of the septal area. The intralaminar and basal forebrain nuclei project diffusely to the whole cerebral cortex, and the intralaminar nuclei also provide a major input to the striatum.

The central or medial group of reticular nuclei was once believed to be the major part of the ascending reticular activating system, conveying to the thalamus and thence to the whole cerebral cortex trains of impulses initiated by all types of sensation. Such a view accords with many experimental and clinical observations, including the irreversible coma that follows bilateral destruction of the medial part of the reticular formation at or above upper pontine levels. The projections of the central group of nuclei are probably also involved in the poorly localized perception of pain that persists after transection of the spinothalamic tracts. In addition, there are neurons that actively induce sleep; these have somata in the serotonergic raphe nuclei, with axons distributed to all parts of the CNS.

RAPHE NUCLEI

Raphe nuclei are groups of neuronal somata that are in or next to the midline, from the caudal medulla to the rostral midbrain. Many of the raphe neurons synthesize and secrete serotonin (5-hydroxytryptamine), and this amine is believed to be their principal synaptic transmitter. The axons of the serotonergic neurons are unmyelinated and greatly branched. They are distributed to gray matter throughout the CNS ([Fig. 14.6](#)). The medullary raphe nuclei are involved in the suppression of pain. Those of the pons and midbrain have inhibitory effects on arousal and consciousness.

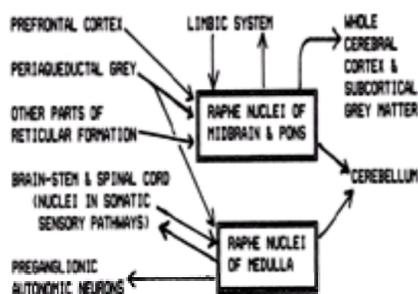

FIGURE 14.6. Some connections of the serotonergic raphe nuclei of the brain stem.

Afferents to the more rostral raphe nuclei come from the prefrontal cortex, the periaqueductal gray matter, various other nuclei of the reticular formation (including the PPRF), and several components of the limbic system. The latter include the hippocampal formation, the hypothalamus, the interpeduncular nucleus, and the ventral tegmental area (a group of dopaminergic neurons in the rostral midbrain). The axons of the neurons in the rostral raphe nuclei extend to all parts of the forebrain.

The raphe neurons are active in deep sleep, which may be due in part to a widespread inhibitory action of serotonin in the thalamus and cerebral cortex. Occasional release of the PPRF from serotonergic inhibition may account for the eye movements in rapid eye movement (REM) sleep. The dreaming that occurs in this phase of sleep may be due to a similar reduction of the inhibition of telencephalic neurons. Desynchronization of the electroencephalogram in the awake subject and in REM sleep is attributed to the activity of thalamocortical neurons in causing large fluctuations in the membrane potentials of cortical pyramidal neurons. The electroencephalogram recorded from the hippocampus, however, is quiescent in the wakeful state and desynchronized in sleep.

In summary, it seems that the maintenance of a conscious state requires the integrity of projections from the reticular formation to the forebrain. Both the central group of reticular nuclei (active in the alert state) and the serotonergic raphe nuclei (active in sleep) are involved, along with the thalamus, the basal forebrain cholinergic nuclei, and the whole cerebral cortex, including the hippocampal formation.

PATHWAYS FOR MEMORY AND EMOTION

The term *limbic system* embraces the cingulate and parahippocampal gyri, the hippocampal formation, the amygdala, the habenular nuclei, the hypothalamus, and various nuclei of the thalamus and midbrain. The tracts that connect these gray masses include the fornix, stria terminalis, stria medullaris thalami, central tegmental tract, and dorsal longitudinal fasciculus. The exact connections of these structures are known only from tracing experiments in animals, but there is no reason to believe that the connectivity in the human limbic system is different. The limbic structures are larger in the human than in any other species, as would be expected from their involvement in higher behavioral and mental functions.

The connections of the hippocampus, amygdala, and other components of the limbic system are shown in [Figure 14.7](#), which summarizes the circuitry in one hemisphere. The left and right hippocampi are connected by small numbers of fibers that cross in the body of the fornix. Commissural fibers also interconnect the habenular nuclei and at least some of the nuclei in the hypothalamus and midbrain. Furthermore, the neocortical input to the limbic system is from areas connected across the midline by the corpus callosum and anterior commissure. All the functions of the limbic system are duplicated bilaterally, and destructive lesions on one side do not cause disordered function. Unilateral excitation (an epileptogenic focus in the temporal lobe) can result in abnormal behavior or unreal states of awareness. Such episodes are known as uncinata attacks because hallucinations of smell result from stimulation of the uncus, which is at the anterior end of the parahippocampal gyrus. The uncus is the principal site of termination of the olfactory tract.

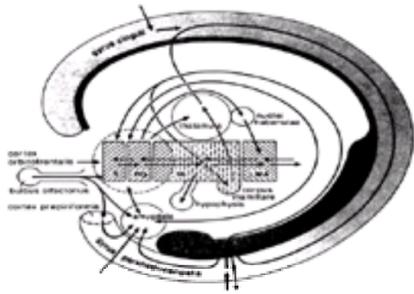

FIGURE 14.7. The limbic system. S, septal area; PO, preoptic area; H, hypothalamus; LMA, limbic midbrain area. (From Nieuwenhuys R, Voogd J, van Huijzen C. *The human central nervous system: a synopsis and atlas*, third ed. Berlin: Springer-Verlag, 1988, with permission.)

The functions of the human limbic system are deduced from clinical studies and by extrapolation from the results of experiments in animals. Traditional teaching emphasizes the “circuit of Papez”:

Hippocampus ® fornix

- ® Posterior hypothalamus
- ® Anterior and lateral-dorsal thalamic nuclei
- ® Cingulate gyrus
- ® Cingulum
- ® Parahippocampal gyrus (= entorhinal cortex)
- ® Hippocampus

Interruption of this loop bilaterally causes inability to remember recent events or to form new memories. The lesions may be in the mamillary bodies, the thalami (mamillothalamic fibers passing through and near the mediodorsal nucleus), or the hippocampi. Hippocampal damage may contribute to the dementia in Alzheimer's disease, but in this condition there is also loss of neurons in the basal cholinergic forebrain nuclei and, eventually, throughout the neocortex. Defective memory is only one of the mental derangements associated with limbic lesions. The dopaminergic “mesolimbic” projection from the ventral tegmental area of the midbrain to the limbic structures of the forebrain may function abnormally in schizophrenia. Some thymoleptic drugs block the action of dopamine on postsynaptic cells. Their parkinsonian side effects are due to interference with the other major dopaminergic projection, that from the substantia nigra to the striatum.

FUNCTIONAL LOCALIZATION IN THE CEREBRAL CORTEX

The functions of specific areas of the cerebral cortex were revealed by clinicopathologic studies and by investigations in which the surface of the brain was stimulated electrically in conscious patients undergoing neurosurgery. Recently, it has been possible to correlate physical and mental activities with regional changes in blood flow and in oxygen and glucose metabolism. Many of the functional areas defined by these methods correspond to regions that can also be identified histologically. The most popular histologic classification of cortical areas is the numerical system proposed in 1909 by Brodmann.

The major functional areas in the cortex of the left cerebral hemisphere are shown in [Figure 14.8](#). In most persons, the areas concerned with perceived, spoken, and written language are present only on the left, and the corresponding areas on the right side are concerned with the management of three-dimensional space, including awareness of parts of the body and the tactile recognition of shapes and textures. The cerebral cortex deals with the contralateral side of the body or visual field, except for the auditory system, which is represented bilaterally, the olfactory projection, which is ipsilateral, and the cognitive functions. Symmetric cortical areas are connected by the corpus callosum. An important function of this commissure is to permit the sharing by both hemispheres of sensory and other data received or processed initially on only one side.

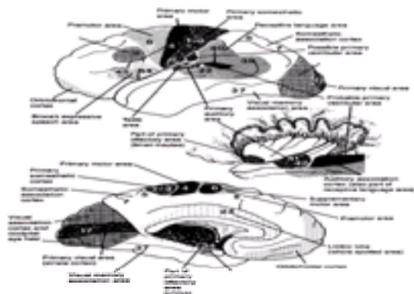

FIGURE 14.8. Functional areas of the cortex of the left cerebral hemisphere. Some of Brodmann's numbers are also shown. In the primary motor and somatosensory area, the contralateral half of the body is represented upside-down, with the mouth and head at the lower end (near the lateral sulcus) and the foot and perineum on the medial surface of the hemisphere. The relation between aging and disease is also a source of much controversy, closely linked to the problem of whether the changes attributed to “normal” aging can be differentiated from those traceable to age-related diseases. Some research questions can be answered intelligently only if the experimenter carefully differentiates between patients who do and do not exhibit signs of one or more specific diseases. An age-related decline in bicycle-exercise tolerance can be interpreted only if one knows whether the elderly group included people with congestive heart failure, osteoarthritis, Alzheimer’s disease, and many other potentially limiting conditions. Most studies naturally exclude such patients from analysis, restricting attention to those deemed apparently healthy. A tougher problem is whether to also exclude persons who may not be under clinical care for a treatable condition but who may nonetheless show subtle signs of early illness. Fine distinctions between exclusion criteria designed to differentiate persons who are exceptionally healthy from those who are somewhat less so can lead to major changes in conclusions about the physiologic effects of aging. Some sets of proposed criteria exclude up to 90% of subjects in the oldest age groups; it seems unreasonable to consider such a selected subset of elderly subjects as typical of normal aging. Similar reservations about studies of aged animals are made less salient, although no less serious, by our relative inability to recognize early signs of disease in animal models.

A typical response to the problem of discriminating aging from disease, particularly among research geriatricians, is to deny any distinction between the aging process *per se* and the diseases and disabilities so widely distributed among elderly subjects and to assert that aging is simply the sum of these pathologic conditions. One way to resolve these problems is to consider aging to be the process that operates throughout adult life to mold the elderly individuals who survive to require geriatric care. Many aspects of aging may be more convenient to investigate in middle-aged adults who are old enough to be different from 20-year-old adults but not so old that they exhibit the decompensation and idiosyncrasies that often accompany late-life disease. From this perspective, the normal aged person is chimerical, an intellectual construct as valuable but ethereal as the sequence of the normal human genome, a sequence none of us actually possesses.

Heterogeneity among the elderly—most dramatically exhibited in the forms of diseases that afflict some elderly persons—should not discourage researchers from seeking common mechanisms, just as the heterogeneity of adult forms, from pygmies to basketball players and from aggressive politicians to shy academics, does not imperil investigation of ontogeny and embryogenesis. This heterogeneity does require careful use of analytic methods that can measure and adjust for the effects of potential confounders, including disease and physiologic idiosyncrasies, and experimental designs that rely more on longitudinal protocols and study of middle-aged subjects than on cross-sectional comparisons of the very oldest with the very youngest adults.

MEASUREMENT OF AGING

A serious obstacle to aging research is the difficulty of measuring aging rates among individuals. Although it is clear that mice, dogs, and humans age at different rates, it is much less clear whether members of the same species exhibit different rates of aging. Evidence based on studies of caloric restriction and genotypic variation suggest that hereditary and noninherited factors can influence aging rate within a species, and it is common in lay and clinical discussions to observe that a certain 60-year-old seems to resemble someone of a younger (or older) chronologic age, but these approaches provide little quantitative guidance for measuring the rate of aging or the *biologic age* of a given subject. This embarrassment has practical and theoretical importance: how would a researcher evaluate the efficacy of a therapeutic maneuver alleged to alter the aging rate?

One traditional strategy has been to rely on life-table analyses. The most influential approach, developed initially by Gompertz, is based on the empirical observation that for humans and for many other species the risk of mortality increases exponentially from an initial nadir at some early stage, typically puberty. Plots of the logarithm of mortality rate as a function of age are linear, with constant slopes, over most of the adult life span for most species for which adequate data exist. This *Gompertz slope* can be taken as a useful measure of the aging rate of the members of the population tested, and demonstrations that two groups exhibit different slopes provide evidence that they are aging at different rates.

An equivalent but more convenient statistic is the *mortality rate doubling time* (MRDT), the period during which the risk of mortality increases twofold. Among mammals, the MRDT varies over a range of at least 25-fold, from 8 or more years in humans and other primates to 0.3 years in rodents; among invertebrates, the MRDT can be as low as 0.005 years. The actual risk of mortality at any age and the mean and maximal life span depend critically on the MRDT and the *initial mortality rate* (IMR), which is the mortality rate at the age at which the mortality risk is lowest. IMRs, like MRDTs, vary widely among species. The MRDT of a species seems to resist alteration by even highly stressful environments; the rate of increase in mortality risk with age does not differ significantly between concentration camp inmates and unincarcerated residents of highly developed countries.

Although in most studies the maximal life span and the MRDT statistics have served as the standard way to evaluate claims that a genetic or environmental intervention could influence aging rate, these actuarial methods have significant limitations. At least for some populations of invertebrates, including fruit flies and nematode worms, the rate of increase in mortality risk is not constant with age and appears to diminish at ages at which most of the original population has died. A very small subpopulation of fruit flies, for example, may live to ages well beyond those predicted on the basis of the Gompertz law; if a similar subpopulation existed among humans, it would lead to life spans of 300 to 600 years for about 1 person per 1 million. The Gompertz law, which was, to begin with, derived from empirical data rather than from a coherent theory of aging, is best viewed as a useful approximation and summary statistic rather than an indication of a fundamental characteristic of aging in all species.

Life-table analyses can provide information about aging rates in groups of subjects but cannot provide a useful measure of aging in any individual. The reliance on life-table data as the key measure of aging rate also places undue emphasis on death itself as an indirect measure of age. Although the risk of mortality is clearly influenced by age, it is also influenced by a wide range of other factors in humans, including access to health care, as well as genetic predisposition to specific diseases, chance encounters with predators and microbial pathogens, and environmental hazards.

The age at death, which is the end point most widely relied on in experimental aging studies, provides an exceptionally indirect and flawed index of individual aging rate. A few laboratories have tried to overcome this obstacle by suggesting and testing candidate biomarkers of aging, such as tests of age-sensitive characteristics, which can be measured without harm to the animal or human subject and which discriminate among persons who differ in other measures of physiologic aging, including vulnerability to disease. Although it is possible to identify risk factors, such as blood cholesterol, smoking history, avoidance of seat belts, and parental age at death, which together can provide a useful index of remaining life expectancy in humans, it has not yet proved feasible for humans or animal models to generate a useful set of indices that can consistently identify persons whose physiologic and biochemical status resembles those of younger or older chronologic age. Because the mechanism of aging is still thoroughly obscure, a set of such surrogate biomarkers for aging would provide a useful tool for experimental gerontologists in the same sense that stock market indices provide a useful tool for economists.

COMPARATIVE AND EVOLUTIONARY PERSPECTIVES

Important clues about the biology of aging can be gleaned from descriptive studies that seek to determine the distribution, rate, and consequences of aging among species and from theoretical arguments that seek to explain from an evolutionary perspective the near universality of aging among metazoan species. Monographs by Comfort and by Finch provide a wealth of citations to the descriptive literature. In reviewing the mass of field and laboratory data, it is important to notice that the high level of natural attrition for most species in unprotected environments often prevents the accumulation of aged individuals among wild populations. The mortality risks in the wild are frequently so high that age-dependent increases in mortality are comparatively trivial. Determination of whether members of such a species can exhibit aging, measured as a correlated decline in physiologic systems or more usually measured as an exponential increase of mortality risk over time, usually requires removal of the animals from environmental hazards and protection in a laboratory or captive situation arguably less risky than the natural one. Most metazoan species, including flies, worms, reptiles, birds, fish, and the familiar farm, pet, and zoo-housed mammals, exhibit aging when so tested.

Some exceptions to this rule provide more insight into semantic niceties of what we mean by aging than into the mechanism of aging in mammals. Some species of fish, for example, show a high early mortality rate, followed by a period of adult life in which the rate of mortality decreases over time, as the fish grow to sizes that make them progressively less vulnerable to predators. Eventually, a population of such fish at very advanced ages would probably begin to show an acceleration of mortality, but testing such a prediction would be expensive and unrewarding. Other species, such as certain salmon and a species of marsupial mouse, exploit a semelparous life history, during which all reproductive effort is concentrated into a single brief episode immediately followed by physiologic decline and death. It seems mistaken to consider this decline a form of accelerated aging that could offer lessons for the analysis of aging in humans or rodents, because salmon prevented from this reproductive frenzy live for many additional years while showing a typical exponential increase in mortality risk. From this perspective, the semelparous life history pattern seems to prevent the progression of adult individuals to ages at which aging would become physiologically significant and actuarially detectable.

Evolutionary biologists have given much thought to the place of senescence in the theory of selection for life history patterns. A coherent analysis of evolutionary

pressures that mold longevity was first produced by Williams and greatly elaborated in a quantitative treatment by Charlesworth. The central points can be summarized qualitatively. Imagine, for example, a species of animal in which aging did not occur, in which the risk of mortality did not increase with age but remained at some constant value throughout life; this constant value would depend on exposure to predators, infectious diseases, and perhaps endogenous processes. In this population, the number of survivors of any starting cohort would decline exponentially over time, just as the amount of a radioisotope decays exponentially at a rate that depends only on the constant half-life of the isotope. If the half-life of our hypothetical species were 5 years, the number of individuals surviving to the age of 25 years would be only 1/32 of the original starting population. The key point is that this unequal distribution of individuals across age categories leads to differences in the selection pressures for or against genetic mutations whose effects are not equivalent at all ages.

Genetic mutations that lead to deleterious effects (e.g., cardiovascular failure, neoplasia, decline in muscle function) only in persons 25 years of age and older would be subject to much less adverse selective pressure than mutations that cripple or kill 5-year-old children. In particular, mutant alleles that have strong positive effects on survival of 5-year-olds would be favored even if they had negative effects on the survival of 25-year-old adults. In a nonaging species, mutations would inevitably accumulate and lead to ill health and diminished physiologic performance in older, but not younger, members of the species. It is not hard to imagine such alleles: alleles that promote rapid growth of wounded skin but also predispose to skin tumors, alleles that promote rapid calcification of bone but also lead to progressive calcification of arterial walls, and many others with similar pleiotropic effects. The sum of these late-life deleterious effects produces the spectrum of disabilities and disease seen in elderly members of each species and leads to the exponential increase in mortality risk over most of the adult life span.

This theory makes a number of testable predictions and has been confirmed in laboratory and field studies. If severe environmental hazards make it highly unlikely for individual members of a species to continue to breed over an extended interval, the pressures against alleles with late-life deleterious effects are especially relaxed, and genotypes may evolve that tend to produce a burst of early reproduction, even if at the expense of diminished late-life function (i.e., more rapid aging). Environmental changes, such as a decline in predator number, which relax the pressure for early fecundity may encourage the emergence of genotypes that postpone the development of senescent changes to allow continued reproductive effort over a wider time interval. In support of this expectation, Austad showed that island opossums, whose environment is free of significant predation, evolve over a period of not more than 3,000 generations so that they age more slowly than mainland opossums to which they are very closely related. As illustrated in [Figure 15.2](#), members of the island population show decelerated Gompertz curves and do not show the precipitous decline in reproductive success shown by 2-year-old mainland opossums. Aging at the biochemical level also seems to be slowed in the island population, as judged by a measure of collagen cross-linking.

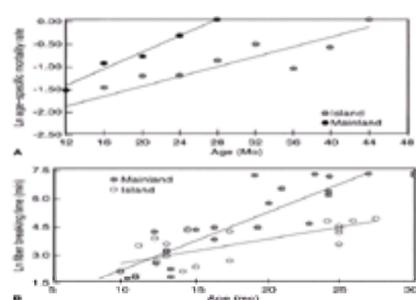

FIGURE 15.2. Diminished rate of aging in opossum populations selected by isolation on a predator-free island for 4,500 years, as predicted by evolutionary genetics. **A:** Gompertz mortality plots; the risk of mortality increases more slowly for island opossums (open circles). **B:** Tail tendon fiber breaking time, an index of collagen cross-linking, which increases with age. Island opossums have a lower rate of age-dependent increase in collagen cross-linking.

A related prediction is the idea that artificially imposed selection in favor of late-life reproduction ought to select for allele combinations that produce not merely delayed reproduction but also declines in the aging rate. Several groups have confirmed this prediction by showing that fruit flies selected for delayed egg laying do indeed routinely exhibit increased longevity. Physiologic comparisons of the selected, long-lived flies with shorter-lived, unselected flies may provide clues about the mechanisms of augmented longevity in this species. Regardless of whether the pathophysiology of aging in flies has any implications for mammalian senescence, the genetic results provide strong confirmation for the underlying theory and suggest that genetically heterogeneous populations may contain alleles that, in combination, can lead to substantial increases in mean and maximal longevity. The opossum data previously discussed suggest that mammalian populations also may contain selectable genetic variants that control the aging rate.

A third implication of the evolutionary argument is that the aging rate should vary inversely with environmental hazard. This suggestion has been strongly supported by comparative analyses. After factoring out the effects of body size, different orders of mammals vary widely in maximal longevity, with bats in particular exhibiting life spans that are about 2.5 to 3.0 times greater than those seen in similarly sized nonflying mammals. Nine species of mammals that exhibit “sailing” behavior, such as the flying squirrels, also have maximal life spans that are on average 1.7 times longer than nonsailing mammals of similar size. Birds live about 2.4 times longer than mammals of similar size. The decline in predation risk conveyed by sailing or flying relaxes the pressure for early life reproduction and permits evolution of genotypes in which the effects of late-life deleterious alleles are postponed to increased ages.

These fortuitous evolutionary experiments provide research opportunities that have yet to be adequately exploited by experimental gerontologists. Birds, for example, have high longevity despite high rates of oxygen consumption and high blood glucose levels, and research into their defenses against damage caused from reactive oxygen intermediates and advanced glycosylation end products may yield valuable insights into mammalian aging.

DECELERATION OF AGING BY CALORIC RESTRICTION

Mice and rats given access to diets containing 30% to 40% fewer calories than they would ordinarily consume if given free access to food show a 25% to 40% increase in mean and maximal longevity and a parallel retardation of most age-related physiologic and biochemical changes. Caloric restriction is the only well-substantiated method for increasing maximal longevity and decelerating aging in mammals and has therefore been intensively studied for clues to the physiologic nature of the aging process itself. Its particular value comes from the breadth of the effect: caloric restriction extends the life span not simply by postponement of one or a small number of common diseases, but by parallel retardation of many age-related changes at the molecular, cellular, and organ system levels. Among other effects, caloric restriction impedes the development of cross-linking in extracellular proteins, including collagen and lens crystallins; delays age-related changes in mRNA abundance for many tissue specific genes; interferes with age-associated shifts in T-cell subsets; blocks changes in central nervous system function; and retards development of neoplastic and degenerative disease of all sorts. It seems highly unlikely that separate biochemical mechanisms are involved in each of these cases and the many other caloric restriction–induced modifications in age-dependent pathophysiology; caloric restriction is presumably acting by a modification of a single, underlying aging process of undetermined nature, which is linked to age-dependent changes at multiple levels.

Several hypotheses about the way in which caloric restriction alters aging have been refuted by experimental data. The effect seems not to be caused by any toxic molecule in a dietary component or by limitation of any specific nutrient; it accompanies almost any dietary manipulation that diminishes total caloric intake while providing adequate amounts of micronutrients to avoid malnutrition. The suggestion that caloric restriction works by retarding growth to adult size has been undermined by data showing that caloric restriction is also highly effective when imposed after the attainment of full adult weight. Caloric restriction apparently does not involve a decline in fuel consumption at the level of individual cells, because calorie-restricted rodents are much smaller than control-fed animals, and the number of calories used per gram of lean body mass is unchanged by the caloric restriction protocol. The additional longevity achieved by caloric restriction is not simply a prolongation of the late-life period of disease and disability, because calorie-restricted rodents remain highly active and physically fit at ages at which most members of the control group have already died ([Fig. 15.3](#)). The suggestion that control rodents are overfed compared with rodents in the wild and that the benefits of caloric restriction merely represent alleviation of the toxic effects of overfeeding is refuted by the data showing that calorie-restricted rodents have severely impaired early-life fertility; if the natural diet were routinely as severely restricted as the calorie-restricted regimen, it would be incompatible with survival of the species.

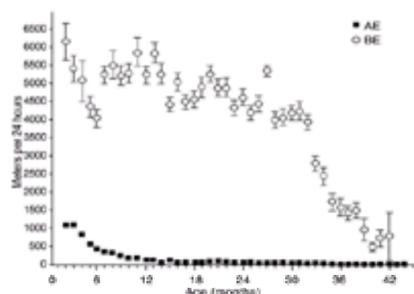

FIGURE 15.3. Spontaneous wheel running by rats on a calorie-restricted diet (*open circles*) compared with rats on a control diet (*squares*). Calorie-restricted rats permitted free access to an exercise wheel run an average of 4 to 5 km per day until the 30th month of life. In contrast, control rats run less than 500 m per day from the sixth month of life. The 50% survival level was 26 months for control rats and 37 months for restricted rats. (Courtesy of Roger J.M. McCarter.)

The growing body of descriptive data on the physiologic characteristics of calorie-restricted rodents has begun to suggest some mechanistic hypotheses worth further evaluation. Although the amount of fuel used per gram of metabolizing tissue seems not to be altered by caloric restriction, the qualitative properties of fuel use do show provocative changes. Compared with controls, calorie-restricted rats show declines in blood glucose and blood insulin levels, suggesting an increase in sensitivity to insulin action. Changes in the ratio of glucocorticoid hormone to glucocorticoid-binding proteins suggest that calorie-restricted rats are likely to have higher than normal levels of free glucocorticoids. An increase in glucocorticoid tone may contribute to their higher resistance in old age to stressful events. Calorie-restricted rats show less evidence of oxidative damage to macromolecules and higher levels of antioxidant defenses; prevention of damage by oxygen-containing reactants may contribute to the antiaging effects of the calorie-restricted protocol.

Although the effects of caloric restriction establish the important principle that the aging rate can be modified in mammals, it is not yet clear if calorie-restricted diets would achieve similar results in longer-lived species, including humans. At least three research groups have now embarked on a longitudinal study of calorie-restricted diets in nonhuman primates. Preliminary results from one of these studies suggest that caloric restriction may be able to retard the development of age-associated diseases in rhesus monkeys. In a group of 33 control animals, median survival was approximately 20 years, but only one of eight calorie-restricted monkeys had died by 20 years of age. The degree of caloric restriction required for optimal longevity in rodents is too severe to be practical as a human therapeutic maneuver, but some of the studies underway incorporate detailed analysis of the metabolic and physiologic concomitants of food restriction. Further understanding of the mechanism by which caloric restriction works in rodents may suggest more practical interventions for human application.

GENETICS OF LONGEVITY

Experimental gerontologists face two genetic problems: elucidating the basis for interspecies differences in aging and longevity and assessing the role of allelic differences within a species that influence aging and life span. The former problem is hard to approach with current methods, but work on the latter has begun to generate valuable insights. Most of the studies use life span as the sole index of aging rate, and this can present interpretative difficulties, making it difficult to disentangle genetic effects on aging from the effects on specific, common diseases.

The results discussed earlier for selected populations of fruit flies and opossum populations suggest that there may be considerable effects of genotype on maximal longevity and the aging rate within a species. Human twin studies have shown that, for individuals dying after the age of 15 years in modern Denmark, about one-third of the variation in life span can be attributed to genetic effects. Much of the genetic variation was of the nonadditive type; it was attributable to dominance effects and to interactions among alleles at different genetic loci. In some twin pairs, the genetic effects could not be attributed solely to occurrence of diseases that lead to relatively early death (before 60 years of age), because genetic effects were demonstrable even in subsets of twins that lived to older ages.

Screens of a few polymorphic loci have shown that very-long-lived persons (centenarians) have statistically higher probabilities of having inherited the E2 allele of the gene for apolipoprotein E at the expense of the E4 allele, which is associated with atherosclerosis and Alzheimer's disease. It is surprising that centenarians also tend to have inherited in homozygous form the D allele at the angiotensin-converting enzyme locus, even though the D allele is thought to predispose to coronary heart disease. It remains to be seen if these or other human polymorphisms have an effect on age-associated physiologic or pathologic processes unconnected to a specific, common, lethal disease or have predictive value in those who do not live to the age of 100.

Human genetic studies are handicapped by the inability to test the progeny of experimental matings, and much of what is known about the genetic control of aging has emerged from studies of rodents and invertebrates. The most informative study of longevity in mice involved life-span determinations for 360 female mice of 20 different inbred strains, each of which had a different combination of alleles from two parental mouse strains. The mean life span differed substantially between the longest- and shortest-lived strains (904 and 479 days). Genetic variation accounted for only 29% of the total variation in life span, a value consistent with the heritability estimates derived from human twin studies. A surprisingly large proportion, 44%, of the 101 distinguishable genetic markers were significantly correlated with variations in life span when considered individually; this number remains large (16%) even after adjustment for multiple comparison artifacts. Much of the genetic variation could be accounted for by groups of as few as six to seven influential loci.

Analysis of life-span statistics among breeds of dogs are also consistent with the idea that fairly small numbers of genetic alleles may, in concert, lead to significant variation in aging rate within a species. Artificial selection for differences in body size among dog breeds, for example, has led to differences of as much as 50% in mean longevity (Fig. 15.4). Although the number of relevant genetic alleles has not been determined, it is noteworthy that 56% of the variation in breed longevity can be attributed to interbreed variations in size alone, and that the size differences have been shown in some cases to represent differences in production of or response to growth hormone.

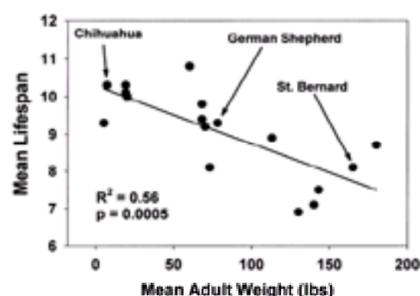

FIGURE 15.4. Big dogs die young: correlation of mean weight with mean longevity for 17 breeds of dogs. Each symbol represents a separate breed. (Data from Y. Li, B. Deeb, W. Pendergrass, and N. Wolf. Cellular proliferative capacity and lifespan in small and large dogs. *J Gerontol Biol Sc.* 1996;51:B403–B408, with permission.)

Studies of the effects of single genetic loci on aging have progressed most rapidly in invertebrate species, particularly the nematode *Caenorhabditis elegans*, which presents special technical advantages for genetic analysis. Several laboratories have identified single-locus mutations that lead to increased life span in *C. elegans*. The most potent of these lead by themselves to a doubling of life span, and the most potent combinations can lead to a four-fold increase in longevity. Some of the loci have now been cloned and shown to resemble human genes that code, respectively, for the insulin receptor, for a lipid kinase involved in cell activation, and for a transcription factor that is likely to regulate expression of multiple other genes. Three aspects of this work are particularly provocative.

First, it is noteworthy that many, perhaps most, of the genetic alleles that convey extended life span in the worm also render the mutant animals more resistant to a fairly wide range of cellular stresses, such as high temperature, exposure to oxidizing agents, and ultraviolet radiation. It is possible that increased cellular stress resistance is *per se* the common element connecting these genetic changes to life span, and, if so, studies of the molecular basis for stress resistance in mammals might have important implications. [Figure 15.5](#), for example, illustrates the remarkable resistance to heat stress seen in two distinct mutations that extend life span in the nematode. Second, the genetic analysis has shown that normal (nonmutant) worms have a protein, *daf-16*, that ordinarily acts in the adult to turn off a set of genes that would otherwise lead to life span prolongation. Many of the long-lived mutants act by turning off this life-span–shortening gene program in adults. Why this short-life-span *daf-16* gene is helpful to the normal worm, what genes it activates to shorten life span, and whether a similar set of genes lead to late life illness in humans all are important goals for future work. Third, it is interesting to note that several of the life-span–prolonging alleles are arguably related in some way to fuel utilization or food consumption, consistent with the speculation that the pathways they control might be analogous to those used to extend life span in the food-restricted rodent. Thus, it is possible, although still speculative, that analysis of the human or mouse equivalents of these genes and the biochemical pathways that they regulate, might help to tease apart the genetic controls of aging in vertebrates.

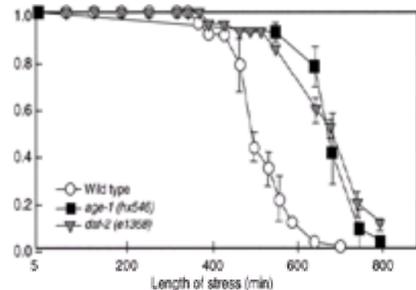

FIGURE 15.5. Survival of nematode worms subjected to acute thermal stress (35° C) for periods of up to 800 minutes. Worms of the two long-lived mutant strains, *age-1* and *daf-2*, are more resistant to heat-induced death than are control worms. (Courtesy of Gordon Lithgow.)

There are currently only two examples of mammalian single gene mutations that can extend life span beyond that of nonmutant controls. The “df” (Ames dwarf) and “dw” (Snell dwarf) mutations both prevent normal development of the anterior pituitary, and therefore contribute to the lifelong absence of growth hormone, thyroid hormone, and prolactin. The mutant mice are dwarfs, with an adult weight about one-third of that of their normal siblings, although they become quite obese as adults. Bartke and his colleagues have shown that males of the Ames dwarf genotype live about 50% longer, and females 75% longer, than nonmutant controls, and two groups have similar unpublished data for the Snell dwarf mice ([Fig. 15.6](#)). More work is needed to determine which other aspects of normal aging (aside from mortality risk) are decelerated in these mutant mouse lines, and to learn whether the improvement in life span is due to diminished influences of growth hormone or thyroid hormone *per se*, or rather to some more general effect of small body size.

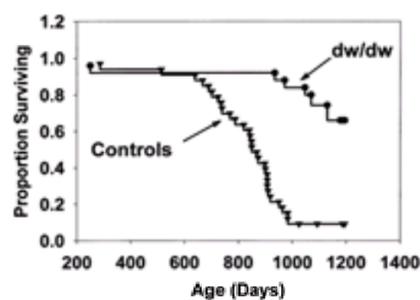

FIGURE 15.6. Extended life span in the *dw/dw* Snell dwarf mutant mice, on the relatively long-lived (DW × C3H)F1 background stock. These mutant mice lack pituitary hormones including growth hormone, prolactin, and thyroid hormone.

THEORIES OF AGING

Many authorities have attempted to explain aging in terms of physical, biochemical, or developmental processes, and it is fair to state that none of these theories has yet provided a comprehensive, internally consistent, mechanistic explanation for the phenotype of aged subjects, the differences in aging rates across species, or the timing of aging itself. Incisive experiments and analyses have, however, begun to refute some of the most popular of the proposed ideas.

The *error hypothesis* proposed by Orgel suggested that alterations in the biochemical machinery responsible for fidelity of DNA replication, RNA transcription, and translation of mRNA into protein might become self-amplifying through a form of positive feedback, as changes that led to diminished fidelity (e.g., defects in the genes encoding portions of the ribosomal proteins or transfer RNAs) led to further errors or diminished error-correction capability. Although work to test this idea has led to provocative insights into protein folding and degradation rates in cells from older donors, the hypothesis itself has been disproved by data showing no systematic change with age in the primary amino acid sequences of translated proteins.

The *rate of living theory* proposed by Pearl began by observing that larger animals tended to have lower basal metabolic rates and greater longevity; it suggested in its strongest form that cells had a fixed capacity for metabolism, expressed in calories used per gram of lean tissue, with senescence and death a result of reaching this intrinsic limit. The weaker form of this theory suggested that high metabolic rates would lead to shorter life spans, perhaps through the effects of toxic byproducts of metabolic pathways, including reactive oxygen intermediates. Detailed analyses of the relation between metabolic rate and longevity, however, fail to support the proposed association. Lifetime energy expenditure per gram varies over a 25-fold range within mammals and over an 8-fold range even among species within a mammalian order. Bats and birds tend to have increased longevity despite metabolic rates that are as high as or higher than nonflying species of similar size. Marsupials, which tend to have metabolic rates about 20% lower than nonmarsupial mammals of similar size, have lower life spans than nonmarsupials, in direct contrast to the prediction of the rate of living idea.

The general relation between metabolic rate and life span now seems well explained on the basis of other considerations: large animals, which tend to be less subject to predation and tend to require more time for development and nurturance of their young, also have a lower ratio of surface area to body mass and need to devote less fuel to maintenance of body temperature. Other provocative ideas, including the proposal that high brain-to-body-weight ratios accompany increased longevity across species, similarly fail when tested against a sufficiently wide range of comparative data.

Despite this progress in testing theories, experimental gerontology is still embarrassed by its rich supply of superficially plausible and largely untested general theories of how aging works. The key timing mechanism has been variously attributed to damage caused by free radicals or other highly reactive oxygen species, to unremovable glycosylation adducts, to changes in the composition and fluidity of plasma membranes, to autoimmune hypersensitivity, to clonal exhaustion by repeated mitosis of proliferative cell populations, to cross-linked extracellular proteins, to deletion of mitochondrial genes, and to alterations in protein synthesis and degradation rates, among numerous others. Each of these ideas is supported by some indirectly supportive circumstantial evidence involving age-associated damage in at least one cell type or tissue in at least one organism.

Critical tests of these notions are difficult to devise and are rarely proposed or carried out. A convincing test of a general theory of aging would need to meet at least

two criteria. First, it would need to explain differences between young and old adults in the properties of connective tissues, proliferative cells, nonproliferating cells, and system integration. Second, it would need to account for the wide variations in aging rates among animal species that, like mice and humans, have very similar basic body plans and metabolic pathways.

PROMISING ISSUES IN MODERN BIOGERONTOLOGY

It is impossible to describe here more than a small fraction of the interesting work in progress in experimental gerontology, but a synopsis of a few, highly selected research areas can give some impression of what is underway.

GENETIC MANIPULATION OF THE AGING RATE

Studies of aging have used the nematode *C. elegans* to search for single-gene mutations that extend life span and have selected for delayed reproduction in the fly *Drosophila melanogaster* to generate long-lived lines of fruit flies. Other genetic manipulations designed to test specific theories of aging have begun to produce provocative results. One group, for example, has shown that overexpression of the antioxidant enzyme superoxide dismutase (SOD) in fly motor neurons led to a 40% increase in overall longevity, even though the enzyme was present in only one specific cell type (Fig. 15.7). A second group has suggested that overexpression of both SOD and catalase in flies can lead to improvements in life span that are not seen, in their stocks, when either enzyme is overexpressed by itself. These data support the theory that accumulation of oxidant-mediated damage may limit adult life span, at least in fruit flies.

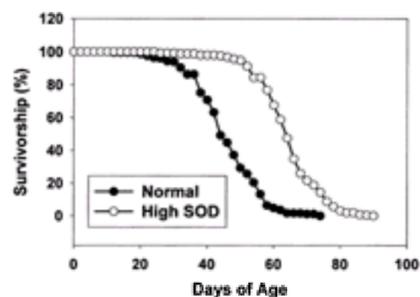

FIGURE 15.7. Increased longevity in transgenic fruit flies overexpressing human superoxide dismutase in motor neuron cells alone. (Courtesy of John Phillips: see *Nature Genetics* 1998;19:171–174.)

The idea that diminished immune function might contribute to the development of late-life disease in mammals has been tested by an analysis of mouse lines selectively bred over many generations for high or for low levels of immune responsiveness. Mice bred for high immunity were found to have almost twofold increases in mean and maximal longevity compared with mice bred for low immunity. Within the backcross population, the mice with the highest levels of immunity also tended to have the highest life expectancy. Age-adjusted incidence rates for hematopoietic and solid tumors were lower in the high-immunity animals. Although this study did not include a key control—unselected mice—and may have been complicated by exposure to microorganisms typically present in a conventional mouse colony, the results provide some evidence that selection for high immunity may produce genotypes with extended longevity. Quantitative analyses of the variance among these selected lines showed that as few as three to nine loci were involved in determining the interline differences in immunity and longevity. Additional attempts to manipulate mammalian and nonmammalian genotypes are likely to provide valuable insights into the genetic and physiologic bases of extreme longevity.

AGE-SPECIFIC GENE EXPRESSION

Some of the diseases and physiologic changes seen in old age may represent alterations in gene expression, including diminished production of necessary gene products and ectopic expression of genes not usually expressed in young adults. Exploration of the bases for expression of genes at the wrong times or in the wrong cell types may suggest mechanistic clues, such as age-specific expression of responsible transcriptional regulators.

Invertebrate and mammalian systems have begun to generate interesting results. In fruit flies, for example, enhancer-trap lines can be developed in which cells that express genes of interest can be identified throughout the life span. More than 100 such lines have been developed in some laboratories, and genes whose expression is ordinarily prominent and important in embryogenesis, including those called *engrailed*, *hedgehog*, and *wingless*, have been found to be expressed with different patterns in adult life, for reasons and with consequences still to be determined. In studies of mouse B lymphocytes, late-life shifts occur in the patterns of antibody gene selection and intersegment gene splicing systems. These shifts could have an impact on antimicrobial defenses, and analysis of their mechanism could throw light on underlying alterations in gene control mechanisms.

Numerous examples can be seen of age-specific alterations in production of mRNA for tissue-specific genes in rodents. Such changes are likely to represent a complex set of intercellular regulatory pathways, compensations for alterations in hormone and cytokine levels, and reactions to early or late stages of diseases, and it is difficult to find in such data indications of primary aging processes. The advent of array-based techniques for automated quantitation of hundreds or thousands of specific mRNA species in tissue samples will soon make it possible to acquire massive amounts of data relevant to age effects on gene expression. These new methods may give useful clues to how aging alters gene expression, and how these changes in gene expression affect tissue and cell function, but the approaches will not by themselves make it easier to deal with the complications of cellular heterogeneity and intercellular interactions, nor make it a simple matter to decide which few of the scores of age-dependent alterations in gene expression are primary or significant for optimal physiologic function and good health.

An alternative to the gene-screening approach involves construction of transgenic mice in which transcription of reporter genes is driven by promoters with interesting age-specific behavior. One group, for example, has shown that transcription from the human transferrin promoter region declines in transgenic mice, reflecting the typical age-dependent decline of human (but not mouse) transferrin expression. This provocative result suggests the promoter complexes may be able to recognize control factors that reflect organismic age and then interpret these signals in a way that reflects the gene and the species of origin. This system also provides an opportunity for examining specific regions of the promoter sequences for effects on the pattern of expression in the aging mice. Similar work based on genes that encode age-sensitive clotting proteins, or proteins involved in late-life diseases, is likely to give useful insights into how aging alters gene expression.

A third research avenue involves genetic engineering, in animal models, to enable the visualization in specific tissues of genes thought to play a role in life-span determination and disease prevention.

CHANGES IN CHROMOSOMAL STRUCTURE

Several lines of evidence suggest age-dependent alterations in higher levels of chromosomal organization with potential implications for gene expression and cellular behavior. One set of investigations showed that cells from female mice can reactivate X-chromosomal loci that had been inactivated early in embryonic life. In one such study, up to 3% of liver cells from older mice were shown to have reactivated the repressed allele of the liver-specific enzyme ornithine carbamoyl transferase. Similar results have emerged from some, but not all, such systems analyzed, and more work is needed to determine the factors that influence age-specific reactivation on the X chromosome to test for possible reactivation of inactivated genes on other chromosomes and to decipher the clinical implications of this heterochronic gene expression.

A second provocative line of research has focused on the effects of aging on the telomeres, which are regions at the tips of the chromosomes. Replication of the ends of DNA molecules requires the activity of an enzyme, telomerase, which is not ordinarily present in somatic cells. Continued cellular replication is accompanied by progressive shortening of the telomeric DNA. There is a reduction with donor age in the length of the telomeric DNA in cell types that are continually generated by mitosis in adult life, including colonic mucosal cells and lymphocytes. It seems plausible—although still speculative—that continued diminution of telomeric DNA may ultimately lead in some cells in old organisms to reexpression of deleterious genes ordinarily repressed in these cell types by their proximity to telomeres or may lead to chromosomal rearrangements that predispose to neoplasia. It is noteworthy, however, that mice genetically engineered to have no functional telomerase appear to

be viable, healthy, and fertile, although the decline in telomere length gradually leads to impaired wound healing and lower fertility three to six generations later.

CLONAL SENESENCE IN CULTURED CELLS

The observation by Hayflick and Moorhead that human diploid fibroblasts are capable of only a limited number of doubling divisions in tissue culture has led to a great deal of further investigation, sparked by the idea that this form of clonal exhaustion might contribute to or at least provide insights into the aging process in intact animals. Most effort has gone into dissection of the changes that prevent further mitosis of the end-stage cells produced at the end of the culture's replicative life span, and a sophisticated picture of changes in gene expression that prevent late passage fibroblasts from dividing in response to mitogenic signals has begun to emerge. It now seems likely that diminished telomere length contributes to the growth cessation seen in late-passage cell lines, because forced expression of telomerase leads (in some cell types) to indefinitely prolonged cellular growth in culture. Many cell types, including human vascular endothelial cells, lymphocytes, and secretory epithelial cells, have only a limited capability for clonal expansion *in vivo*, and it is tempting to speculate that a diminished capacity for continued mitotic growth may contribute to physiologic deficits in elderly individuals, including perhaps alterations in wound healing and tissue remodeling, immune responsiveness, and reendothelialization of denuded vascular surfaces. Much more must be done, however, to establish whether cells with the properties of late-passage fibroblasts are present in the tissues of elderly persons and whether clonal senescence has pathophysiologic consequences. There is at present little or no evidence that clonal senescence of this kind actually occurs to a significant extent in intact organisms, or that this process contributes to late-life disease or dysfunction.

HUMAN DISEASES THAT MIMIC ASPECTS OF ACCELERATED AGING

Certain human diseases involve the development in children or young adults of pathophysiologic changes ordinarily seen in normal elderly persons. George Martin has called these diseases *segmental progeroid* syndromes and championed the idea that analysis of their molecular basis could shed light on the molecular biology of aging itself.

Some of the most dramatic examples are found in the rare genetic diseases of Hutchinson–Gilford progeria syndrome and Werner's syndrome, in which patients in their childhood or young adult years, respectively, exhibit a striking variety of age-related features, including decreased skin elasticity, increased bone fragility, atheroma formation, and other abnormalities. Werner's and progeria victims, however, also exhibit characteristics not seen as a part of normal aging and fail to show many of the features of normal aging. Although neither of these two syndromes can be attributed to a simple acceleration of some hypothetical aging clock, elucidation of their genetic bases could provide valuable insights into the mechanism of age-related changes in tissue structure and function and into how these may be timed to occur at different phases of the life span. The recent cloning of the Werner's syndrome gene *WRN*, and the demonstration that the protein has DNA unwinding and exonuclease activities, has sparked new research on the possible involvement of DNA repair processes in some forms of late-life degenerative disease. Although the mutation that leads to classic Werner's syndrome is extremely rare, there is now some indication that more common alleles of the same genetic locus may increase risk of late-life myocardial infarction in elderly Japanese, with similar studies now underway in other populations. Further study of the molecular pathogenesis of Werner's syndrome could provide information about how aging leads to changes of connective and vascular tissue with clinical significance. In the same way, studies of Down's syndrome and early-onset familial dementias have generated important ideas about age-related changes in cognitive function and their basis in central nervous system architecture.

GERONTOLOGY, GERIATRICS, AND THE PUBLIC HEALTH

Much research has been focused on the major diseases of older persons, including cardiovascular disease, diabetes, neoplasia, arthritis, and other degenerative syndromes. Far less effort has been devoted to understanding the aging process, which seems to time the onset of these clinical entities and the progression of the thousand natural shocks that flesh is heir to but that are considered to lie outside the purview of the modern physician.

Demographic projections show that a complete elimination of the mortality attributable to cancer, adult-onset diabetes, and all cardiovascular diseases would lead to an increase in life expectancy at birth of 21% for male infants and 20% for female infants. By comparison, experimental alteration of aging rate by caloric restriction in rodents can improve life expectancy by 40% or more, with at least as great an impact on a healthy life span. Similarly, single gene changes are now known, which can extend mouse life span by 50% or more and give clues to ways in which alterations of endocrine status may stave off disease late in life. Research into the genetics of aging and the basic biology of the aging process may produce valuable insights into the pathogenesis of late-life illness and perhaps lead to interventions with profound effects on the health and well-being of elderly persons.

Acknowledgment

Preparation of this chapter was supported by grants from the National Institute on Aging, including AG08808, AG09801, and AG11687. I am grateful to many colleagues for allowing me to cite their work before its publication and for instructing me about the implications of their findings.

CHAPTER 16: CLINICAL PHYSIOLOGY OF AGING

LEWIS A. LIPSITZ

[Regulation of Oxygen and Metabolic Substrate Delivery to Vital Organs](#)
[Energy Metabolism](#)
[Defense Systems](#)
[Maintaining Structural Integrity](#)
[Mobility and Balance](#)
[Reproductive Function](#)

Physiology is the integration of a complex network of control systems and feedback loops that enable an organism to perform a variety of functions necessary for survival. The control systems of the human body exist at molecular, subcellular, cellular, organ, and systemic levels of organization. Continuous interplay among the electrical, chemical, and mechanical components of these systems ensures that information is constantly exchanged, even as the organism rests. These dynamic processes give rise to a highly adaptive, resilient organism, which is primed and ready to respond to internal and external perturbations.

Recognition of the dynamic nature of regulatory processes challenges the traditional view of physiology, which was based on Walter B. Cannon's concept of homeostasis. The *principle of homeostasis* states that all healthy cells, tissues, and organs maintain static or steady-state conditions in their internal environment. However, with the introduction of techniques that can acquire continuous data from physiologic processes, such as heart rate, blood pressure, nerve activity, or hormonal secretion, it became apparent that these systems are in constant flux, even under so-called steady-state conditions. Dr. Eugene Yates introduced the term *homeodynamics* to convey the fact that the high level of bodily control required to survive depends on a dynamic interplay of multiple regulatory mechanisms rather than constancy in the internal environment.

Although it is often difficult to separate the effects of aging from those of disease and lifestyle changes such as reduced physical activity, even aging without such confounding, secondary factors (primary aging) appears to have a profound impact on physiologic processes. Because of the progressive degeneration of various tissues and organs and the interruption of communication pathways between them, complex physiologic networks break down, become disconnected, and lose some of their capacity to adapt to stress.

There is considerable redundancy in many of these systems; for example, humans have far more muscle mass, neuronal circuitry, renal nephrons, and hormonal stores than are needed to survive. This *physiologic reserve* allows most persons to compensate effectively for age-related changes. Because the network structure of physiologic systems also enables alternate pathways to be used to achieve the same functions, physiologic changes that result from aging alone usually do not have much impact on everyday life. However, these changes may become manifest at times of increased demand, when the body is subjected to high levels of physiologic stress. For this reason, elderly persons are particularly vulnerable to falls, confusion, or incontinence when exposed to environmental, pharmacologic, or emotional stresses.

The traditional approach to the study of physiology is to divide the topic into separate organ-based systems, such as cardiovascular, respiratory, endocrine, immune, and neurologic systems. However, this approach ignores the integrated, cross-system nature of physiology. This chapter addresses the major functional roles of physiologic processes and how they are affected by normal aging.

REGULATION OF OXYGEN AND METABOLIC SUBSTRATE DELIVERY TO VITAL ORGANS

The vitality of all living tissues in the body depends on the delivery of optimal supplies of oxygen and glucose or other metabolic substrates to meet energy requirements during rest and exertion. This critical process relies on a complicated transport system, which picks up oxygen from the lungs and nutrients and metabolic substrates from the gastrointestinal tract or musculature, centrifugally delivers different amounts of these substances to different sites depending on the immediate need, and self-adjusts in response to transient perturbations. In reciprocal centripetal fashion, this system serves to deliver waste products to sites of excretion from the body, notably the kidney and liver. This circulatory system consists of the liquid and cellular components of the blood, vascular tree, cardiac pump, lungs, chemoreceptors, baroreceptors, and neuroendocrine communications between each of these structures. The driving force behind the delivery system is the arterial blood pressure.

AGE-RELATED CHANGES IN BLOOD PRESSURE REGULATION

Blood pressure is the product of heart rate, stroke volume, and systemic vascular resistance. Alterations in the response of any of these parameters may threaten adequate perfusion of vital organs. Normal human aging is associated with several changes that influence these three components of normal blood pressure regulation.

BAROREFLEX SENSITIVITY

The baroreflex maintains a normal blood pressure by increasing heart rate (*cardiovascular baroreflex*) and vascular resistance (*sympathetic vascular baroreflex*) in response to transient reductions in blood pressure and by decreasing these parameters in response to elevations in blood pressure. Reduced sensitivity of the cardiovascular baroreflex is evident in the blunted cardioacceleratory response to stimuli (upright posture, nitroprusside infusions, phase II of the Valsalva maneuver, and lower-body negative pressure, for example) that lower blood pressure, and in a reduced bradycardic response to drugs such as phenylephrine or phase IV of the Valsalva that elevate blood pressure. Alteration of the sympathetic baroreflex is manifested as a blunted vasoconstrictor response to sympathetic outflow from the central nervous system. As a result of abnormal baroreflex function, elderly people have increased blood pressure variability, often with potentially dangerous blood pressure reductions during hypotensive stresses, such as upright posture or meal ingestion.

SYMPATHETIC NERVOUS SYSTEM AND END-ORGAN RESPONSE

Studies of sympathetic nervous system activity in healthy humans demonstrate an age-related increase in resting plasma norepinephrine levels and muscle sympathetic nerve activity, as well as the plasma norepinephrine response to upright posture and exercise. The elevation in plasma norepinephrine results primarily from an increased presynaptic norepinephrine secretion rate and secondarily from decreased clearance. Despite apparent elevations in sympathetic nervous system activity with aging, cardiac and vascular responsiveness is diminished. Infusions of β -adrenergic agonists result in smaller increases in heart rate, left ventricular ejection fraction, cardiac output, and vasodilation in older compared with younger men.

CARDIAC RESPONSE

Age effects on the heart have been attributed to multiple molecular and biochemical changes in β -receptor coupling and postreceptor events. The number of β receptors on cardiac myocytes is unchanged with advancing age, but the affinity of β receptors for agonists is reduced. Postreceptor changes that occur with aging include a decrease in the activity of stimulatory G protein (G_s), the adenylate cyclase catalytic unit, and cAMP (cyclic adenosine monophosphate)-dependent phosphokinase-induced protein phosphorylation. As a result of these changes, G-protein-mediated signal transduction is impaired.

The decrease in cardiac contractile response to β -adrenergic stimulation has been studied in rat ventricular myocytes, where it appears to be related to decreased influx of calcium ions through sarcolemmal calcium channels and a reduction in the amplitude of the cytosolic calcium transit. These changes are similar to those seen in receptor desensitization owing to prolonged exposure of myocardial tissue to β -adrenergic agonists. Age-associated alterations in the β -adrenergic response may result from desensitization of the adenylate cyclase system in response to chronic elevations of plasma catecholamine levels.

VASCULAR RESPONSE

The vascular response to sympathetic stimulation has received less attention, but it also appears to be altered by aging. The vasorelaxation response of arteries and veins to infusions of the β -adrenergic agonist isoproterenol is attenuated in elderly people ([Fig. 16.1](#)). α -Adrenergic vasoconstrictor responses to norepinephrine

infusion also appear to be reduced in healthy elderly subjects (Fig. 16.2). The fact that this impairment is reversed by suppression of sympathetic nervous system activity with guanadrel suggests that it is also caused by receptor desensitization in response to heightened sympathetic nervous system activity. Thus, some of the physiologic changes associated with aging may be reversible.

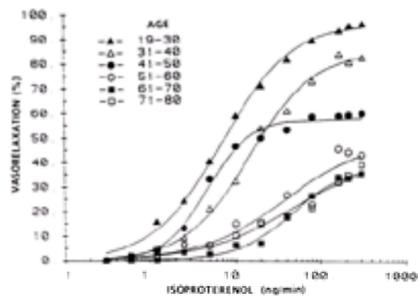

FIGURE 16.1. Effects of isoproterenol infusion in precontracted dorsal hand veins in the six populations studied. (From Pan HY-M, Hoffman BB, Pershe RA, Blaschke TF. Decline in beta adrenergic receptor-mediated vascular relaxation with aging in man. *J Pharmacol Exp Ther* 1986;239:802, with permission.)

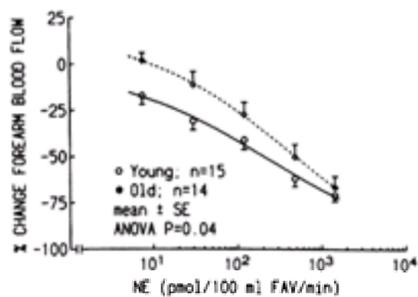

FIGURE 16.2. Group mean data for the percent change in forearm blood flow from the baseline values in response to intra-arterial infusions of norepinephrine (NE) in young (—○—) and older (—●—) subjects. (From Hogikyan RV, Supiano MA. Arterial α -adrenergic responsiveness is decreased and SNS activity is increased in older humans. *Am J Physiol* 1994;266:E717, with permission.)

AUTONOMIC CONTROL OF HEART RATE

Alterations in sympathetic and parasympathetic influences on the heart may also influence the heart rate response to blood pressure changes. Previous studies demonstrating age-related reductions in overall heart rate variability in response to respiration, cough, and the Valsalva maneuver suggest that aging is associated with impaired vagal control of heart rate. Elderly patients with unexplained syncope have even greater impairments in heart rate responses to cough and deep breathing than elderly persons without syncope.

The age-related attenuation of autonomic, neurohumoral, and other influences on heart rate results in a reduction in heart rate variability and in a marked change in the dynamics of beat-to-beat heart rate fluctuations. As shown in Figure 16.3, the highly irregular, complex dynamics of heart rate variability characteristic of healthy young individuals are lost with healthy aging, resulting in a more regular and predictable heart rate time series. This loss of complexity in heart rate dynamics can be generalized to the fluctuating output of many different physiologic processes as they age. For example, measurements of continuous blood pressure, electroencephalographic waves, frequently sampled thyrotropin or luteinizing hormone levels, and center-of-pressure changes during quiet stance all show more regular, less complex behavior with aging. This apparent loss of dynamic range in physiologic functions may reflect fewer regulatory influences as a person ages, leading to an impaired capacity to adapt to stress.

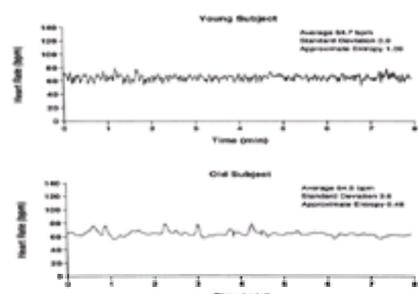

FIGURE 16.3. Heart rate time series for (A) a 22-year-old woman and (B) a 73-year-old man. Approximate entropy is a measure of “nonlinear complexity.” Despite the nearly identical means and standard deviations of heart rate for the two time series, the complexity of the signal from the older subject is markedly reduced. (From Lipsitz LA, Goldberger AL. Loss of “complexity” and aging: potential applications of fractals and chaos theory to senescence. *JAMA* 1992;267:1806, with permission.)

CARDIAC VENTRICULAR FUNCTION

The maintenance of a normal blood pressure also depends on the ability to generate an adequate cardiac output. Cardiac output at rest and during exercise tends to decrease with normal aging because of a reduction in heart rate response to β -adrenergic stimulation and because of changes in systolic and diastolic myocardial performance, which influence stroke volume.

Diastolic Function

As a result of increased cross-linking of myocardial collagen and a prolonged ventricular relaxation time, the aged heart stiffens, and early diastolic ventricular filling becomes impaired (Fig. 16.4). The age-related impairment in early ventricular filling makes the heart depend on adequate preload to fill the ventricle and on atrial contraction during late diastole to maintain stroke volume. Orthostatic hypotension and syncope occur commonly in older persons as a result of volume contraction or venous pooling, which reduces cardiac preload, or as a result of the onset of atrial fibrillation when the atrial contribution to cardiac output is suddenly lost. These changes also render the elderly person more vulnerable to congestive heart failure attributable to diastolic dysfunction.

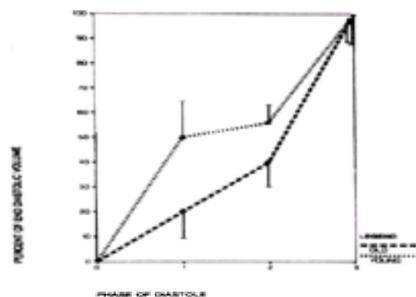

FIGURE 16.4. Cumulative percentage of the left ventricular end-diastolic volume filled during each third of diastole for young (*dotted line*) and old (*dashed line*) subjects. Notice the marked reduction in early diastolic filling and greater percentage of filling in late diastole in elderly subjects compared with young persons. (From Lipsitz LA, Jonsson PV, Marks BL, et al. Reduced supine cardiac volumes and diastolic filling rates in elderly patients with chronic medical conditions: implications for postural blood pressure homeostasis. *JAGS* 1990;38:103, with permission.)

Systolic Function

With aging, myocardial contractile strength is preserved, but left ventricular ejection fraction in response to exertion decreases because of reduced b-adrenergic responsiveness and an increased afterload. Afterload, which represents opposition to left ventricular ejection, increases progressively with aging because of stiffening of the ascending aorta and narrowing of the peripheral vasculature. These changes result in an increase in systolic blood pressure with aging and a decrease in the maximum cardiac output during exercise.

The cardiac response to exercise is different in healthy young and old subjects ([Fig. 16.5](#)). Although the young increase cardiac output by increases in heart rate and decreases in end-systolic volume (greater contractility), the healthy elderly do so by increasing end-diastolic volume (cardiac dilatation). The elderly thus rely on the Frank–Starling relation to achieve an increase in stroke volume during exercise more than do younger persons. A similar mechanism can be demonstrated in young subjects during b-adrenergic blockade, suggesting that the age effect is caused by reduced b-adrenergic responsiveness.

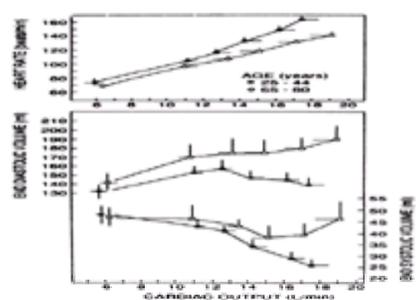

FIGURE 16.5. Heart rate (*top panel*) and cardiac volumes (*bottom panel*) at end diastole and end systole at rest and during graded levels of exercise on a cycle ergometer in older and younger individuals. A blunted heart rate and cardiac dilatation at end diastole and end systole are characteristic features of the exercise response in older persons. (From Rodeheffer RJ, Gerstenblith G, Becker LC, et al. Exercise cardiac output is maintained with advancing age in healthy human subjects: cardiac dilatation and increased stroke volume compensate for a diminished heart rate. *Circulation* 1984;69:203, with permission.)

The age-related decrease in maximal cardiac output during exercise may also be related to a sedentary lifestyle and consequent cardiovascular deconditioning. A 6-month endurance exercise training program has been shown to enhance end-diastolic volume and contractility, thereby increasing ejection fraction, stroke volume, and cardiac output at peak exercise in elderly men. This illustrates the difficulty in teasing apart the changes occurring with aging that may be primary (and irreversible) from those that are secondary to age-associated changes in lifestyle.

INTRAVASCULAR VOLUME REGULATION

Adequate organ perfusion pressure depends on the maintenance of intravascular volume. Aging is associated with a progressive decline in plasma renin, angiotensin II, and aldosterone levels and with elevations in atrial natriuretic peptide, all of which promote salt and water wasting by the kidney. Healthy elderly people do not experience the same sense of thirst as younger persons when they become hyperosmolar during water deprivation. Dehydration and hypotension may develop rapidly during conditions such as a febrile illness, preparation for a medical procedure, or exposure to a warm climate when insensible fluid losses are increased or access to oral fluids is limited. The interaction between volume contraction and impaired diastolic function may threaten cardiac output and result in hypotension and organ ischemia.

REGULATION OF ORGAN BLOOD FLOW

The regulation of blood flow to various circulatory beds depends on complex interactions among the endothelium, local vasoactive peptides, neuroendocrine influences, and mechanical forces. In angiographically normal coronary arteries and forearm resistance vessels, the endothelium-dependent vasodilatory response to acetylcholine is reduced with aging.

Normal human aging is also associated with a reduction in cerebral blood flow, which is further compromised by the presence of risk factors for cerebrovascular disease. Although it is not clear whether the decline in cerebral blood flow results from reduced supply or demand, elderly persons, particularly those with cerebrovascular disease, probably have a resting cerebral blood flow that is closer to the threshold for cerebral ischemia. Consequently, relatively small, short-term reductions in blood pressure may produce cerebral ischemic symptoms.

The brain normally maintains a constant blood flow over a wide range of perfusion pressures through the process of autoregulation. During reductions in blood pressure, resistance vessels in the brain dilate to restore blood flow to normal. Although the effects of aging on cerebral autoregulation have received little attention, limited data suggest that the autoregulation of cerebral blood flow is preserved into old age. However, patients with symptomatic orthostatic hypotension appear to have a reduction in cerebral blood flow in response to decreased perfusion pressure.

CONTROL OF RESPIRATION

The delivery of necessary substrates for oxidative metabolism depends on maintaining an optimal tissue perfusion pressure and on the availability of oxygen from the lungs. Pulmonary and circulatory physiology are closely linked, enabling adjustments in heart rate, cardiac output, blood pressure, and organ flow to be made in response to changing demands for oxygen.

Aging is associated with a reduction in the partial pressure of oxygen in the blood, primarily caused by a mismatch of ventilation and perfusion in the dependent portions of the lungs. This results from a reduction in lung compliance, which causes airways to close prematurely at higher lung volumes (i.e., increased closing volume) within the range of vital capacity. The relative hypoxemia in advanced age was thought to be offset by a reduced tissue demand for oxygen (reduced maximal oxygen uptake). However, much of the reduction in maximum oxygen consumption (VO_2 max) is attributable to reduced muscle mass and is reversible with endurance

exercise training.

Chemoreceptors located in brain stem respiratory centers adjust respiratory amplitude and frequency on a moment-to-moment basis to ensure adequate oxygen availability and carbon dioxide clearance in the blood. Longer-term changes in oxygen supply and demand are matched by finely tuned adjustments in the sensitivity (i.e., gain) of chemoreceptors. With advancing age, chemosensitivity to oxygen and carbon dioxide tension declines, resulting in relative hypoventilation in response to hypoxemia or hypercarbia. Therefore, older persons may be more vulnerable to vital organ ischemia during stresses such as surgery, acute pulmonary infections, or high altitude, when oxygen availability is reduced.

ENERGY METABOLISM

Another critical physiologic function is the production of sufficient energy to meet the metabolic demands of the body. This process requires the intake and processing of energy substrate (carbohydrate, fat, and protein) in the gastrointestinal tract; conversion of these substrates to simple sugars, fatty acids, or amino acids; production of glucose or ketoacids by the liver for oxidative metabolism; insulin-mediated uptake of glucose by metabolically active cells; and participation in the biochemical pathways leading to energy storage in high-energy phosphate bonds (i.e., adenosine triphosphate [ATP] production). Age-related changes in this complex system have not been fully elucidated, and research has focused primarily on the summary measures of resting metabolic rate and daily energy expenditure.

Resting metabolic rate is usually determined by indirect calorimetry, which measures the rate of oxygen consumption ($V O_2$) during quiet, supine rest under fasting and thermoneutral conditions. The resting metabolic rate decreases with aging. Daily energy expenditure, which is measured by the doubly labeled water technique, includes the resting metabolic rate, the thermic response to feeding, and the energy expenditure of physical activity. Daily energy expenditure also declines with advancing age. However, the resting metabolic rate and daily energy expenditure are strongly influenced by physical fitness and activity, nutritional intake, and body composition, all of which may change over time. Many of the changes in energy metabolism observed in the elderly may reflect altered physical activity and loss of fat-free mass rather than biologic aging.

An exercise program that increases fat-free mass and energy intake can enhance energy expenditure in healthy elderly persons. Because the thermic effect of feeding is higher in physically trained than inactive older men, much of the age-associated reduction in energy expenditure is probably attributable to the adoption of a sedentary lifestyle, with its associated reduction in muscle mass.

Age-related changes in body composition may lead to a variety of disease states in the elderly. If energy intake remains constant despite reductions in physical activity, older individuals accumulate body fat. After a 3-week period of overfeeding, young men develop hypophagia and lose their excess body weight, but older men do not. This impairment in control of food intake and accumulation of body fat may lead to obesity, glucose intolerance, and hypertension.

The decline in glucose tolerance with advancing age has been well documented. It is manifested by modest elevations in fasting plasma glucose levels (approximately 1 mg per deciliter per decade) and marked elevations in 2-hour postprandial glucose levels (approximately 5 mg per liter per decade) during an oral glucose tolerance test. The glucose intolerance of aging is related to peripheral insulin resistance, caused by a postreceptor defect in target tissue insulin action. There is no age-related change in the number or affinity of insulin receptors or in maximal tissue responsiveness to insulin. However, healthy elderly subjects require larger quantities of insulin to achieve a level of glucose uptake similar to that of the young ([Fig. 16.6](#)).

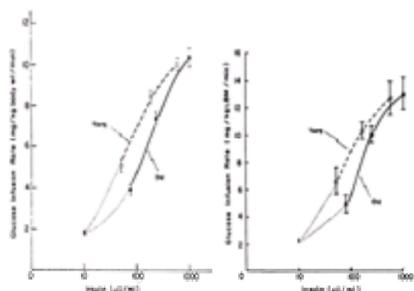

FIGURE 16.6. Dose-response curves for insulin-mediated whole body glucose infusion rates in young (*dashed line*) and old (*solid line*) subjects. **A** (left): Glucose disposal is expressed as milligrams per kilogram of body weight. **B** (right): Glucose infusion rates are normalized for lean body mass. Elderly persons have reduced sensitivity to insulin but no change in maximal glucose disposal. (From Rowe JW, Minaker KL, Pallotta JA. Characterization of the insulin resistance of aging. Reproduced from *J Clin Invest* 1983;71:1581 by copyright permission of the American Society for Clinical Investigation.)

Studies of glucose-stimulated insulin secretion in healthy humans have shown impairments in insulin secretory capacity with advancing age. This is balanced by a reduction in insulin clearance, the net result of which is no change in circulating insulin levels. However, the presence of “normal” circulating insulin levels in the face of hyperglycemia suggests that insulin secretion is inappropriately low. Aging thus appears to be associated with insulin resistance and impaired insulin secretion.

Although insulin resistance was once thought to be a natural consequence of biologic aging independent of carbohydrate intake, body composition, or physical activity, studies have shown elevations in body mass index and mean arterial blood pressure to be significant predictors of reduced insulin sensitivity, regardless of age. Insulin resistance can be improved by exercise training. Glucose intolerance may also result from age-associated decreases in physical activity and fat-free mass. Because of the association between chronic hyperglycemia and the development of atherosclerotic cardiovascular disease, renal disease, neuropathy, and retinopathy, the glucose intolerance of advanced age has profound implications in the pathogenesis and prevention of disease in old age. This condition should not be considered a harmless, age-related process; it should be treated as a significant risk factor for disability, which may be preventable through physical exercise and proper nutrition.

DEFENSE SYSTEMS

The ability of the human body to defend itself from external pathogens and to prevent toxic effects of chemical exposures and metabolic by-products relies on the presence of integrated physiologic networks that cross multiple organ systems. Many of the components of these networks are altered by the aging process, making older persons more vulnerable to infectious disease, toxic drug effects, and malignancy ([Table 16.1](#)).

Defense Mechanism	Age Change
Immune Response	
T Lymphocytes	Impaired antigen or mitogen response
B Lymphocytes	Decreased antigen-specific Ab production
Cytokines	Increased IL-1, IL-2, increased TNF, decreased IL-6, IL-10, decreased IFN-γ formation
Antibody production	
Physiologic Barriers	
Skin	Thinning, loss of subcutaneous fat, decreased blood supply, fewer melanocytes to absorb UV light, decreased collagen and elasticity
Gastrointestinal tract	Decreased mucosal blood flow, decreased mucosal barrier integrity
Respiratory tract	Decreased mucociliary transport and cough reflex
Response of Toxic Chemicals	
Hepatic metabolism	Decreased first pass and induction capability
Renal excretion	Decreased renal blood flow, GFR, and tubular secretion
Autonomic Response	
Baroreceptor reflexes	Reduced high-frequency baroreflex, parasympathetic sensory receptors, and autonomic outflow
Cardiovascular response	Reduced heart rate and stroke volume, increased arterial stiffness, and decreased baroreceptor sensitivity

TABLE 16.1. PHYSIOLOGIC DEFENSES AND THEIR CHANGES WITH AGE

IMMUNE FUNCTION

One of the invariant changes that occurs with advancing age is the progressive atrophy and dissolution of the thymus. As a result, thymic hormones are no longer detectable after 60 years of age, and the number of immature, undifferentiated T lymphocytes increases. The number of circulating B and T cells probably does not change with aging, but the number of T cells able to respond to an antigenic challenge or mitogenic stimulus is greatly reduced. Cells that can respond to a stimulus and enter the cell cycle appear to have a decreased ability to divide sequentially in culture.

The defect in T-lymphocyte response may reflect alterations in various lymphokines, particularly interleukin-2 (IL-2). The production of IL-2 by stimulated CD4 helper cells and the response to IL-2 by proliferating cells are reduced in the elderly, partly because of the loss of thymic hormones that augment IL-2 production by proliferating cells in culture. There appears to be a defect in the ability of lymphocytes to express IL-2 mRNA and in the IL-2 high-affinity receptor (Tac antigen). In addition to alterations in intercellular signaling, many cells lose their intrinsic ability to respond to various stimuli. Alterations in cytoskeletal structures, DNA repair mechanisms, membrane properties, enzyme activity, and protein synthesis all affect cellular responses.

B-cell production of antigen-specific antibodies is reduced with aging, in large part because of a reduction in helper T cells and increased activity of suppressor T cells. It appears as if a breakdown of communication pathways between cells rather than alterations in the intrinsic properties of the cellular components themselves is primarily responsible for immune senescence. Decreased T-cell control of B-cell function also may be responsible for the marked increase in monoclonal immunoglobulin levels seen in the elderly. Elevations of monoclonal immunoglobulins (M components) in the serum may be asymptomatic and benign, or they may be associated with malignancies such as multiple myeloma, Waldenström's macroglobulinemia, primary amyloidosis, or heavy-chain disease. The fact that monoclonal gammopathies can be induced in young mice by ablation of the thymus gland and induction of inflammation by endotoxin lends support to the notion that dysregulation of immune function in the elderly is related in part to loss of thymic hormones.

Aging is also associated with an increase in autoantibodies such as anti-DNA or antithyroglobulin antibodies, although without an associated increase in autoimmune disease. This has been attributed partly to an increase in autoanti-idiotypic antibodies, which react with the antigen-binding portion of the immunoglobulin molecule and suppress the formation of other normal antibodies.

In addition to alterations in cellular components of the immune system, changes in soluble factors other than IL-2 also occur. The synthesis of inflammatory mediators such as tumor necrosis factor- α (TNF- α), IL-6, and interferon- α are increased with aging, although IL-1 has been reported to decrease.

PHYSICAL BARRIERS

Protection against infectious agents, foreign bodies, and chemical exposures depends on an intact immune system and on physical impediments to entry into the body. These defensive barriers include the skin, acid environment in the stomach, and respiratory mucociliary clearance mechanisms. Their changes with aging are summarized in [Table 16.1](#).

CHEMICAL DEFENSES

Several organ systems participate in the metabolism and removal of potentially toxic chemicals and drugs from the body, particularly the liver and kidneys. These organs undergo changes with age that interfere with chemical defense functions. Most important of these are a reduction in hepatic blood flow that reduces first-pass elimination of drugs such as verapamil and propranolol, an impairment in hepatic oxidation and demethylation reactions that metabolize many of the long-acting benzodiazepines, and reduced renal blood flow and glomerular filtration rate, which reduce the clearance of drugs such as digoxin and the aminoglycosides ([Chapter 469](#)).

The kidneys participate in defense of the internal chemical environment of the body by maintaining intravascular volume as discussed previously and by excreting excess acid, sodium, potassium, and water. The ability to excrete an acid load is impaired with aging. This may result from a decrease in nephron mass and resultant reduction in the production of urinary ammonium and phosphorus. The ability to excrete an acute sodium load and, probably, a potassium load is reduced with aging, principally because of a decline in the glomerular filtration rate. Elderly persons require almost twice as long as young persons to excrete equivalent amounts of salt.

Normal aging is associated with an impairment in water excretion. After a water load, the elderly have less free water clearance and a higher minimum urine osmolality than middle-aged or young persons. This is largely attributable to an age-related decrease in the glomerular filtration rate, rather than inappropriate vasopressin secretion.

MAINTAINING STRUCTURAL INTEGRITY

Maintaining a skeletal framework sufficiently strong to withstand the stresses of physical activity is an essential physiologic function that depends on the complex interaction of multiple organ systems, hormones, local growth factors, cytokines, osteocytes, and biochemical pathways leading to calcium deposition in bone. The organs that participate in this function include the skin, kidneys, liver, small intestine, parathyroid and thyroid glands, and bone. They produce various hormonal signals that ultimately regulate calcium deposition and mobilization in bone. These hormones are estrogen or testosterone, vitamin D, parathyroid hormone, and calcitonin.

Maintaining skeletal integrity is a dynamic process, characterized by constant bone turnover or remodeling. Periods of bone resorption, mediated by osteoclasts, alternate with bone formation, mediated by osteoblasts. This cyclic process is normally closely coupled, resulting in no net change in bone mass. However, with aging and particularly after menopause in women, there is a relative increase in resorption over formation, resulting in osteoporosis. The acceleration of bone loss after menopause implicates estrogen deficiency as one of the key factors influencing age-related bone loss. However, bone loss also occurs in men, although at a slower rate than in women. Bone loss may be caused by testosterone deficiency in some elderly men or by calcium malabsorption, which is another major determinant of bone loss in both sexes.

Estrogen regulates the production of cytokines and growth factors that control bone remodeling. Stimulation of peripheral blood monocytes by estrogen decreases IL-1 and TNF- α production, inhibiting IL-6 production by osteoblasts and the effect of this cytokine on osteoclast formation and bone resorption. Estrogen decreases granulocyte-macrophage colony-stimulating factor (GM-CSF), which inhibits osteoclast differentiation. Estrogen also stimulates transforming growth factor- β (TGF- β) production by osteoblasts, which decreases osteoclast-mediated bone resorption. Estrogen deficiency results in an increase in IL-1, TNF- α , GM-CSF, and IL-6 and a decrease in TGF- β production, all of which promote osteoclast formation and bone resorption.

In men, testosterone has anabolic effects that normally enhance bone formation, probably through stimulation of TGF- β and insulin-like growth factor I (IGF-I) and inhibition of prostaglandin E₂ production. Reduced levels of testosterone in late life may impair bone formation, leading to unopposed resorption and progressive bone loss.

Several other age-related changes influence bone metabolism in men and women, including decreased cutaneous production of vitamin D₃ by ultraviolet photoconversion of 7-dehydrocholesterol, impaired 1 α -hydroxylation of 25-hydroxyvitamin D by the kidney, decreased intestinal absorption of calcium, and increased levels of circulating parathyroid hormone. These changes are interrelated. A decline in 1,25-dihydroxyvitamin D as a result of reduced production of precursors in the skin and impaired 1 α -hydroxylation by the kidney, is partly responsible for decreased intestinal calcium absorption. Diminished gastric acid production, which is required for solubilizing and ionizing dietary calcium, and acquired lactase deficiency, which results in avoidance of milk products also contribute to negative calcium balance. The consequent reduction in serum calcium concentration and reduced concentrations of 1,25-dihydroxyvitamin D result in mild, physiologic elevations in parathyroid hormone, which increases osteoclastic bone resorption.

The many age-related changes in calcium and bone metabolism interact with lifestyle and genetic factors to reduce bone volume and predispose elderly persons to fractures. The factors influencing bone loss in the elderly are summarized in [Table 16.2](#).

Sex hormone deficiency
 Estrogen
 Testosterone
 Vitamin D deficiency
 Decreased skin production of vitamin D₃
 Decreased α -hydroxylation by the kidney
 Calcium malabsorption
 Vitamin D deficiency
 Hypochlorhydria
 Calcium regulatory hormone changes
 Increased parathyroid hormone levels
 Genetic factors
 Lifestyle factors
 Obesity
 Decreased calcium and vitamin D intake and lactase deficiency
 Decreased physical activity (i.e., decreased mechanical loading)
 Smoking
 Decreased sunlight exposure

TABLE 16.2. FACTORS INFLUENCING BONE LOSS IN THE ELDERLY

MOBILITY AND BALANCE

Mobility and balance are essential functions for the performance of activities of daily living. They are subserved by the complex interaction of brain, nerve, muscle, joint, cardiovascular, and sensory organ activity. Without coordinated movement, the human organism cannot acquire energy substrates from food, defend itself from external threats, or reproduce. Many of the changes that impair mobility and balance in advanced age are associated with deconditioning and disease rather than normal physiologic aging. The physiologic changes themselves usually do not impair function under normal circumstances, but they may do so under the demands of more severe stress.

Healthy aging is associated with several neurologic and sensory changes that may impair postural control. These changes include the degeneration of neurons in the frontal cortex, resulting in difficulty initiating movement; basal ganglion, responsible for parkinsonian features of aging; and the cerebellum, causing ataxia and impaired balance. A gradual loss of peripheral sensory receptors occurs, including mechanoreceptors in the large joints (predominantly ankles, knees, hips, and facet joints of the cervical spine), which send afferent proprioceptive information to the brain stem about how the body is positioned in space. A reduction in proprioceptive information in addition to decreased nerve conduction velocity and consequent prolongation of reflex time impairs the body's ability to correct its position when spatially perturbed. Older persons consequently demonstrate an increase in body sway, which is most evident with the eyes closed because of increased dependence on visual input to maintain balance when other sensory inputs are compromised. Body sway is greatest in elderly people prone to falling.

Aging is also associated with a loss of muscle mass and strength, which to a large degree is related to the adoption of a sedentary lifestyle and resultant deconditioning. The loss of muscle strength is probably partially due to denervation of motor units. Muscle retains its ability to improve performance with resistance training, even well into the tenth decade of life. Gains in quadriceps muscle strength with resistance training exceed changes in muscle mass, suggesting that training results in neural recruitment of additional motor units.

A reduction in growth hormone secretion may also play a role in the age-related loss of muscle mass. Growth hormone is secreted in pulsatile fashion by the anterior pituitary and stimulates skeletal and muscle growth, amino acid uptake, and lipolysis. Its effects are mediated by the somatomedins, most notably IGF-I. The age-related decline in amplitude and frequency of growth hormone secretion occurs particularly during sleep, when this hormone is released in greatest quantity. The reason for this change with age is not fully understood. Low plasma IGF-I levels seen in healthy elderly persons respond to growth hormone replacement. Initial studies of recombinant human growth hormone administration to elderly subjects demonstrated enhancement of lean body mass, lumbar vertebral bone density, and plasma IGF-I levels and a decrease in adipose tissue mass. However, these findings have not been replicated.

REPRODUCTIVE FUNCTION

Reproduction is another essential physiologic function in all living organisms. In lower-order organisms, the cessation of reproductive function usually coincides with the end of life. In women, reproductive capacity ends in midlife at the time of menopause. This is one of the most striking examples of age-related physiologic changes that subsequently predispose women to the development of pathologic conditions such as cardiovascular disease and osteoporosis. Men do not experience as abrupt a change in reproductive function as women do, but they do undergo gradual alterations in sex steroid metabolism that predispose them to prostate enlargement and bone loss. Although healthy men and women may experience changes in sexual performance with advancing age, their capacity to enjoy sexual activity remains intact.

FEMALE PHYSIOLOGY

In women, normal reproductive physiology is characterized by the following sequence of events, occurring in cyclic fashion:

- Pulsatile release of hypothalamic gonadotropin-releasing hormone (GnRH) into the hypophyseal portal system
- Pituitary gonadotropin secretion
- Gonadotropin stimulation of ovarian follicles to produce estrogen
- Ovulation, corpus luteum development, and progesterone production
- Negative feedback to hypothalamic and pituitary regulatory centers, resulting in menstruation as estrogen and progesterone are withdrawn

In women between the ages of 45 and 55, the ovary becomes less responsive to gonadotropins; plasma levels of 17 β -estradiol, inhibin, and other ovarian hormones decrease; and negative feedback to the hypothalamic-pituitary axis is lost. In response, levels of follicle-stimulating hormone (FSH) and, to a lesser extent, luteinizing hormone (LH) increase. As menopause approaches, the interval between menses lengthens, anovulatory cycles become more common, and menstruation eventually ceases.

After menopause, 17 β -estradiol, the predominant circulating estrogen during reproductive life, declines greatly, and estrone becomes the predominant estrogen. Estrone is produced by the peripheral aromatization of adrenal androstenedione in extraglandular tissues, including fat, bone, muscle, skin, and brain. Estrone levels may be high in obese postmenopausal women, possibly contributing to their reduced risk of osteoporosis. The postmenopausal ovary continues to secrete testosterone under the influence of LH. This may be responsible for the hair growth and virilizing features seen in some women after menopause.

MALE PHYSIOLOGY

In men, normal aging probably results in a modest degree of primary testicular failure, characterized by a decrease in testicular size. There is a decline in numbers of Leydig cells, which make testosterone, and Sertoli cells, which produce sperm and the hormone inhibin. As a result of the decline in circulating testosterone and inhibin, FSH and LH levels increase with age. The age-related decline in testicular function is highly variable, and its clinical implications have not been well established. It may contribute to a decline in the frequency of sexual activity but probably plays a secondary role to social, psychologic, and medical factors that have the greatest influence on sexual dysfunction in late life.

Benign prostatic hypertrophy (BPH) is another consequence of physiologic aging in the male reproductive tract ([Chapter 467](#)). Prostatic growth depends on the presence of dihydrotestosterone (DHT). DHT is the active form of testosterone in sexual tissues, produced by the enzyme 5 α -reductase. Prostate development does not occur in the absence of DHT. A 5 α -reductase inhibitor, finasteride, causes regression of enlarged prostatic tissue. However, levels of DHT do not appear to be

increased in men with BPH.

Estrogens and androgens may play a role in the development of prostatic hypertrophy. Estrogen induces *MYC*-, *RAS*, and *FOS*-encoded mRNA, as well as IGF and epidermal growth factor receptor gene expression. In experimental models, the combination of estrogen and androgen results in greater prostatic growth than androgen alone. As testosterone production declines in advancing age, the decreased androgen/estrogen ratio may promote excessive prostatic growth. However, the exact pathophysiologic mechanism of BPH has not yet been determined.

CHAPTER 17: HEALTH CARE IMPLICATIONS OF AN AGING SOCIETY

JOAN WEINRYB, DENNIS HSIEH AND RISA LAVIZZO-MOUREY

[Understanding the Issues and Problems Facing an Aging Society](#)
[Association Between Aging and the Major Age-Related Diseases](#)
[Prevention and Screening](#)
[Financing the Care of Our Aging Population](#)
[The Solution to Providing Health Care to a Growing Population of Elders](#)

Changes in the demographics of our society, the aging of the “baby boom” generation, and the fiscal imperative of controlling our society’s ever-rising health care costs have increased awareness of the field of geriatrics. Geriatrics does not merely apply the disciplines of internal medicine, surgery, and psychiatry to care of older people. It is a multidisciplinary approach to care, which uses the body of information about biologic and behavioral changes due to aging, in multiple care sites, to minimize the period of dysfunction at the end of life caused by aging and illness.

Geriatricians incorporate the results of current research into clinical practice. Clinical geriatrics combines the age-related effects of biologic and behavioral changes with all the other factors that interact with disease to produce dysfunction. Clinical geriatrics is often challenging because of differences in illness presentation, the presence of multiple diseases or disorders, health-related behaviors of seniors, and limitations of the health care system. Many geriatric patients fail to seek timely treatment. Scarcity of community resources to assist aged persons in avoiding institutionalization impedes care. The geriatrician seeks to apply advances in clinical research to reduce disability, treat modifiable diseases, avoid futile intervention, and promote rational end-of-life decisions. Optimal management of certain recognizable syndromes avoids incomplete medical diagnosis, over- or undermedication, underutilization of rehabilitative or community support services, and inappropriate institutionalization ([Table 17.1](#)).

TABLE 17.1. GERIATRIC SYNDROMES OR CONDITIONS THAT MAY BENEFIT FROM OVERSIGHT BY A GERIATRICIAN

UNDERSTANDING THE ISSUES AND PROBLEMS FACING AN AGING SOCIETY

DEMOGRAPHICS

Older Americans are the fastest-growing segment of the US population. From 1900 to 1997, the percentage of Americans over 65 has tripled from 4.1% in 1990 to 12.7% in 1997, increasing 11-fold in absolute numbers from 3.1 million in 1900 to 34.1 million in 1997. The term elderly is often used generically to define persons 65 years of age or older, a population, however, manifesting considerable variation in physical, mental, and functional capabilities. Thus, the elderly are extraordinarily heterogeneous, a variance that increases progressively with age. Accordingly, some have segmented this group into subpopulations such as the young-old (those 65 to 74 years), the middle-old (those 75 to 80), the old-old (those 80 to 85), and the oldest-old (those 85 and older). All such classifications reveal a central truth; aging is a continuum. For the population as a whole, age is increasingly associated with an exponential rise in the burden of health problems and, hence, with the cost of health care.

The aging of the baby boom generation will increase the older population rapidly by 2030 to twice the number of older persons in 1997 with a progressive shift to older and older median age. During the period of 1990 to 1997, while the 65- to 74-year-old age group grew eight times, the 75- to 84-year-old cohort grew 16 times, and the over-85 age group multiplied itself 31 times. Although the life expectancy of a person who reached age 65 increased by only 2.4 years between 1900 and 1960, an additional increase of 3.3 years occurred between 1960 and 1997. Thus, a child born in 1997 can expect on average to live 76.5 years, or about 29 years longer than a child born in 1900.

The oldest-old (over 85) is expected to be the fastest-growing group. By 2010, the population of those over 85 is expected to grow 56%, compared with 13% for the 65- to 84-year age group. As the baby boom cohort ages, the over-85 group is expected to grow 116% between 2030 and 2050 ([Fig. 17.1](#)).

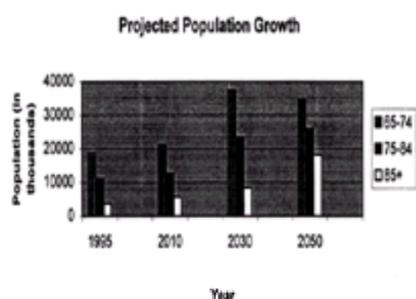

FIGURE 17.1. Projected population growth.

Minorities are projected to increase from 15.3% to 25% of the older US population by 2030. In absolute terms, while the total population of non-Hispanic whites over age 65 is projected to grow by 78%, the total older minority population is estimated to increase by 238%, that is, the older Hispanic population by 368%, non-Hispanic Asians and Pacific Islanders by 354%, Native Americans, Inuits, and Aleuts by 159%, and African Americans by 124%.

Although life expectancy is increasing, there are gender differences in the trends: men turning 65 in 1997 have an average additional life expectancy of 15.8 years, and women, an average additional life expectancy of 6 years. Women predominate in each age group of the elderly, with increasing proportions in the oldest groups. This is dramatically different from the previous century, in which a woman was considered fortunate to live until her 48th birthday. Public health improvements, especially in the areas of gynecologic and obstetric care are major contributors to the improved prospects of women. However, a host of chronic health conditions threaten to deprive aging women of good quality of life during these added years.

Although 75% of aging men are married, only 42% of elderly women are married. Because men have shorter life expectancies and on average are older than their wives, the number of widows far outstrips the number of widowers—for example, in 1997, 8.5 million to 2.1 million. In a society in which historically most women worked within their homes, failing to establish savings accounts or pensions of their own and where assets may have been adequate for the life of the marriage but not of the surviving partner, the increasing longevity of women presents problems of poverty and lack of access to health care.

Fifty-two percent of all people over 65 live in just nine states (California, Florida, New York, Texas, Pennsylvania, Ohio, Illinois, Michigan, and New Jersey). Although people over 65 are less likely than their younger counterparts to live in metropolitan areas, about 29% of seniors live in central cities, and another 48% of seniors live in the suburbs. Seniors are less likely to move. In 1997, only 5% of seniors moved in the past year (compared with 18% for those under 65). Those who move tend to stay nearby. Eighty-one percent of seniors who moved in 1997 stayed in the same state. However, states with the most rapid growth in the over-65 population between 1990 and 1997 include Nevada (49%), Alaska (43%), Hawaii (25%), Arizona (25%), Utah (19%), Colorado (19%), and Delaware (17%).

Most noninstitutionalized elderly people live in a family setting. Eight percent of men and 17% of women over age 65 live with children, siblings, or family members other than a spouse. Only 15% of elderly men live alone, whereas 65% of aging women are solitary. The probability of living alone correlates with age. By age 85 or over, 60% of women are solitary dwellers. Societal contributions to this disparity include the relative youthfulness of wives compared with their husbands and the changes in family composition of the last 50 years. Women now have fewer children than previous generations. In our mobile society, they are less likely to be living near a son or daughter who can provide support. Their female offspring, the traditional caregivers for aging relatives, are more likely to work outside the home and be unavailable for caring for elderly family members.

The percentage of persons living in nursing homes increases with age. Only 1% of those 65 to 74 years old live in a nursing facility, whereas 5% of those 75 to 84 years and 15% of those 85 and over live in nursing homes.

Although they comprise less than 13% of the total population, the elderly accounted for 40% of hospital stays and 49% of inpatient days in 1995. Mortality rates among the oldest-old are declining, but the incidence of disability and chronic illness does not appear to be decreasing or at least not at the same pace as mortality rates. Increasing enrollment in Medicare and increasing use of services threaten to bankrupt the program. Limited resources and a growing elderly population make it imperative that we develop new models of care in which quality and outcome of care are stable or improved and expenditure is stable or decreased. Application of gerontologic research and geriatric management techniques may enable society to assist the elderly in maintaining more vigorous and independent lives. The changes in the demographics of our population and the changes in our society require modification of our medical services and social programs to fulfill the needs of the growing, older population.

ASSOCIATION BETWEEN AGING AND THE MAJOR AGE-RELATED DISEASES

Although recent declines in mortality have led to an increase in life expectancy and proportion of older people in the population, the most common causes of death among the elderly have remained the same over the recent decades.

Over the past century, the leading causes of death have changed. In 1900, the chief cause was influenza and pneumonia. This was followed by tuberculosis, diarrheal diseases, heart disease, and stroke. By the 1980s, the leading cause of death in people over age 65 had become heart disease, followed by cancer, stroke, pulmonary infections, diabetes mellitus, and accidents. The distribution of causes of death does not seem to have changed much since the 1980s, although more people live longer.

A significant proportion of elderly people appear to remain symptom-free and functional until near the time of their death. Others are increasingly disabled, with declining functional status as age increases. Elderly women and African Americans, especially persons with low income, have a higher proportion of functional decrements. There seems to be a bimodal distribution among the elderly of persons who are healthier at advanced ages than their forbears, on the one hand, and significantly disabled persons who because of improved medical care have survived previously fatal illnesses, on the other hand. The most dramatic reduction in deaths has occurred among women and the oldest-old. Seven out of ten deaths in the United States occur in people 65 or older. Twenty-one percent of deaths occur among those 85 and older and this is expected to rise to 30% by 2050. Chronic disease affects a significant percentage of people. Forty-seven percent of those 65 or older have arthritis, 43% have hypertension, 31% have heart disease, and 10% suffer impaired vision. Thus, the typical older person has multiple disorders.

By self-report, 25% of persons age 65 to 74 who do not live in institutions consider themselves to be in poor or fair health. One-third of those 75 years or older consider their health to be poor or fair. The need for personal assistance increases with age. Only 9% of those 65 to 69 years old require such assistance, whereas, by the decade after the 75th birthday, 20% do need assistance. By age 85 or beyond, 50% of people require personal assistance. Although a reduction in age-specific disability rates may occur, the need for long-term care (including assistance in the home and in other institutional settings) is likely to continue to grow. Currently, 4.7% of the US population requires long-term care services. Most such services are provided informally by family and friends, but the demand for formal services is growing. Public policy must support a two-pronged approach to the problem of expanding numbers of older people and the slower growth of public and private resources. The health system must put forth programs that encourage the development of healthy life habits among the young and middle-aged to forestall disease-related disability in old age. At the same time, programs that integrate health services and expand alternatives to institutional care for the frail elderly must be emphasized.

Regardless of age, heart disease is the leading cause of death in men and women. Men are more likely than women to die of heart disease at an earlier age, and African American men at highest rates in earliest years. After age 75, coronary mortality is nearly equal for men and women. Autopsy series show coronary atherosclerosis in 70% of people between ages 70 and 80. Twenty to 30% of those over age 65 have clinical symptoms and signs of cardiac disease. The American Heart Association estimates that 1.5 million Americans had myocardial infarctions in 1997. One-third of those patients die within a year.

The annual cost of myocardial infarction is \$91.7 billion in direct health care costs and \$60 billion in lost productivity. The prevalence of congestive heart failure increases with age, with the most patients hospitalized for heart failure being over age 65. Thirty-seven percent of men and 33% of women diagnosed with heart failure die within 2 years. Mortality is age related. Hospitalization for congestive heart failure increases the risk of hospitalization for any reason within the next 3 to 6 months by up to 47% and is associated with significant decline in functional status.

Preferred treatments for medical management of cardiovascular disease, using evidence from randomized trials, supports use of angiotensin-converting enzyme (ACE) inhibitors in patients with left ventricular dysfunction, aspirin and b-blockers after myocardial infarction, and warfarin for stroke prevention in atrial fibrillation. These treatments are applied only at low rates to patients who are elderly. Studies have shown the use of ACE inhibitors in as few as 47% of those eligible, aspirin in only 50%, and b-blockers in only 19% of those who have suffered myocardial infarction. Warfarin use has been shown in only 17% of elderly persons with atrial fibrillation. Some of this is explained by comorbidity, but, overall, it appears that many elderly people are being deprived of useful treatments because of their health care providers' prejudice or misunderstanding.

Reperfusion therapy for ischemia of less than 6 to 12 hours' duration has changed the treatment of anterior myocardial infarction. Pooled data from several large trials indicate that the absolute reduction in mortality is as great in older as in younger patients. Data on patients older than 80 undergoing thrombolytic therapy indicate a 41% reduction in mortality. Intracranial hemorrhage, the most feared complication of thrombolytic therapy, increases with advancing age from a rate of 0.3% in younger patients to a rate of 0.8% in patients older than 75. Coronary angioplasty in older persons appears to carry an increased risk of progression to coronary artery bypass graft, but has a 30-day mortality risk, which compares favorably with thrombolysis. Increasing data about the use of intracoronary stents indicate that these may be the treatment of preference, especially in very old patients.

CANCER

The incidence of many cancers increases with age. Breast, lung, colorectal, prostate, gastric, and head and neck cancers are more common with aging. Lifetime cumulative exposure to carcinogens, age-related alterations in the immune system, and the accumulation of random genetic mutations all have been postulated as causative. Treatments for cancer include surgery, radiation therapy, and chemotherapy, all of which may be less well tolerated in the aged because of suppressed wound healing and reduced organ reserve. Rates of cardiac and gastrointestinal toxicity and neurotoxicity in response to chemotherapy are higher in the elderly. Despite this, many elderly persons have survived cancer treatment surprisingly well. Decisions to forego treatment should not be based on age alone but on functional status, and likelihood that the benefit of treatment outweighs the burden.

The treatment of prostate cancer is an area of considerable dispute. Prostate cancer is present in about 8 million men in the United States and causes 35,000 deaths. Large numbers of men with prostate cancer are unlikely to suffer significant morbidity or mortality from their disease. Aggressive therapy may therefore lead to unnecessary morbidity in this group.

Other factors must be taken into account when treating the elderly cancer patient. Issues of analgesia, community support, and access to treatment may be paramount.

CEREBROVASCULAR DISEASE

Cerebrovascular disease is the third leading cause of death in the United States. The incidence of stroke increases with increasing age. By age 70, stroke occurs in 300 per 10,000 persons per year. The rate of stroke in elderly women is about 25% less than the rate in men. With improved attention to the control of risk factors, such as hypertension, heart disease, diabetes mellitus, and cigarette smoking, the incidence of stroke is declining in the United States, and with improved treatment, the prevalence of stroke survivors is increasing. The fatality rate within 1 month of an acute stroke is close to one-third across all age groups. However, more than two-thirds of stroke survivors live at least 3 years. Maximal functional recovery is the goal of treatment for stroke victims. Clinical course depends on the type of stroke and its location and size. Complications include aspiration, deep vein thrombosis, contractures, pressure sores, and increased risk of falls and other accidents. Poststroke course can be complicated by depression or reflex sympathetic dystrophy. In terms of best use of societal resources, reliable ways of determining prognosis, therapies to assist recovery and strategies for compensating for disabilities are needed.

PNEUMONIA

Pneumonia remains the fifth leading cause of death, the leading infectious cause of death in people over age 65, and a major reason for hospitalization among elderly people. The incidence and severity of community acquired pneumonia increases with age, with a case rate of 1 to 5 per thousand persons per year in patients aged 5 to 60, and a case rate of 30 per thousand persons per year in patients older than 75. The risk of a complicated course increases after age 65, and advanced age is a significant predictor of hospital mortality. Several studies have confirmed that causative organisms of community acquired pneumonia in adults are similar at any age, and include *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Legionella pneumophila*, *Chlamydia pneumoniae*, and gram-negative bacilli. Eighty percent of influenza deaths occur in people over age 65. Secondary staphylococcal pneumonia is of concern during outbreaks of influenza pneumonia. Outbreaks of respiratory infection in long-term care facilities are common. Aspiration pneumonia, less common among community dwellers than among nursing home residents, remains a significant problem associated with neurodegenerative disorders. The efficacy of pneumococcal and influenza vaccination in preventing mortality and morbidity in elderly patients has been demonstrated repeatedly. These strategies remain underused, with only 10% of eligible elderly persons undergoing pneumococcal vaccination and many remaining at risk from influenza.

DIABETES

Impaired glucose tolerance occurs in 25% of adults over age 65. Nearly 50% of people with type II diabetes mellitus are over age 65. By age 80, the prevalence of diabetes is 20% to 40%, with the diagnosis undiscovered in many. Foot ulcerations are a major cause of morbidity in diabetic patients. Yearly, 50,000 amputations related to diabetes mellitus are performed in the United States, with a direct cost of \$1 billion. Renal insufficiency and diabetic retinopathy contribute to the morbidity, mortality, and health care costs of diabetic patients. Health care expenditures to assist in careful control of hyperglycemia through patient education and access to medication and professional evaluation could result in tremendous cost savings. During the past decade, the focus of diabetic care has shifted from the hospital to ambulatory settings. The American Diabetic Association has recommended guidelines for quality of care for individuals with diabetes, hypertension, and hyperlipidemia. Modifications for frail older people are indicated. Outcome studies are needed to guide clinicians in the selection of optimal treatment goals for older diabetics.

FALLS AND ACCIDENTS

Accidents are the seventh most common cause of death among the elderly. Burns cause 41 annual hospitalizations per 100,000 adult age 85 or older, a rate 50% higher than that of the general population. Residential fires kill 10% as many elderly people as renal failure. Two-thirds of accidental deaths in the elderly are caused by falls at an annual rate of 57 per 100,000 persons of age 75 or greater. Falls and injuries cause considerable health care cost and personal suffering. Conditions characterized by impaired sensorimotor processing, such as Alzheimer's dementia, are associated with falls. Central nervous system impairment due to cerebrovascular disease, motor abnormalities due to arthritis, and other conditions associated with chronic pain, neurologic conditions such as Parkinson's disease, all are complicated by high rates of falls and injuries. Falls in persons 65 years and older are estimated to produce medical costs of \$3.7 billion per year. Fear of falling may reduce quality of life. Multiple falls are a marker of increased risk of death. Accident prevention through environmental modification and therapies to ameliorate muscular weakness and age-related changes in equilibrium and limb coordination can decrease societal cost and personal suffering.

NEURODEGENERATIVE DISORDERS

In the United States, neurodegenerative disorders cause dementia in about 8% of people over age 65. Rates double every 5 years from about 2% at age 65 to about 30% after age 85. Alzheimer's disease is the most common dementing disorder. Currently, 4 million people in the United States have these diseases, and it is projected to rise to 8 million by the end of the year 2000. Depression is commonly found as a coexisting condition in patients with dementia. More intensive clinical management is often required for patients with both disabilities. As Alzheimer's disease progresses, the level of impairment of affected patients increases, requiring more and more support and services from their families and from society. The economic cost of Alzheimer's disease and related disorders, including medical care, long-term care, and loss of productivity, approaches \$100 billion per year. Effective treatment for functional decline, which could delay nursing home placement by even a year, would result in large economic benefit.

PREVENTION AND SCREENING

Disease prevention in elderly persons seeks to render the patient more resistant to illness. Primary prevention includes immunization against communicable diseases, blood pressure management, smoking cessation, obesity control, exercise programs, and social support and environmental modifications.

Another aspect of disease prevention is the early detection of asymptomatic disease in the hope of efficacious treatment. Papanicolaou (Pap) smears, breast examinations, tests for fecal occult blood, screening for hypothyroidism, assessment for the presence of depression or of vision, hearing, or dental abnormalities, and testing for tuberculosis all fall under the rubric of screening.

Screening is influenced by physician knowledge of life expectancy and attitude toward aged patients. Published guidelines for screening, immunization, and risk factor counseling are rarely studied for appropriateness in aging populations, especially among those over age 75. Screening for frail elderly patients may consist of identification of problems that will further add to the burden of disability if uncorrected. Most elderly people are active and functional and have much to gain from health screening. Recommendations for this age group must be based on life expectancy and the natural history of the disease for which the screening is done. Controversy exists about the efficacy of screening when doubt exists about the benefit of early intervention. Prostate cancer is one entity for which mass screening for early intervention in elderly men is not yet clearly justified in terms of decreased mortality and morbidity. In contrast, the usefulness of diagnosis and treatment of gait dysfunction to avoid fracture and disability is clear.

[Table 17.2](#) is a compendium of suggestions that attempt to provide a framework for both disease prevention and case finding. Specific guidelines to provide a comprehensive, but economical evaluation have been chosen from among sometimes contradictory recommendations. Identification of active issues by screening allows more intensive intervention. Health promotion and disease prevention are applicable to the elderly, although logistics and frailty mitigate efficacy of some of the recommendations. Attempts to improve care and to avoid complications in the treatment of elderly patients may include geriatric assessment and foot and dental care.

Health Issue	Benefit
Disability risk assessment	Reduces the burden and cost of chronic disease.
Improved management of chronic conditions	Modulates the impact of these on function.
Creative approaches (e.g., in-home geriatric assessment)	Reduces nursing home placements.
Risk factor reduction strategies	Applied through senior center-based health promotion programs and case management approaches.
	Both resulted in improved status.

TABLE 17.2. GARIATRIC HEALTH ISSUES BENEFITING FROM PERIODIC REVIEW

Disability risk assessment and improved management of chronic conditions to modulate the impact of these on function can reduce the burdens and cost of chronic disease. Creative approaches such as in-home geriatric assessment have led to reduction in nursing home placements. Risk factor reduction strategies applied through senior center-based health promotion programs and case management approaches have both resulted in improved status.

FINANCING THE CARE OF OUR AGING POPULATION

Medicare, implemented in 1966 as part of the Social Security Amendments, covers most people over 65, disabled individuals who have received Social Security benefits for at least 2 years, and persons with end-stage renal disease. Traditionally, Medicare Part A covers inpatient hospital services, limited posthospital skilled nursing facility care services, and hospice care, and Medicare Part B covers outpatient hospital services (such as outpatient studies and same day surgeries), all physician services, and outpatient services from other disciplines (e.g., physical, occupational, and speech therapy). Some in-home nursing care for acute medical problems is covered by Medicare. Patients are responsible for a portion of the charges. Medicines and custodial care are not covered. Long-term skilled nursing facility services remain the responsibility of the individual until mean test requirements permitting Medicaid reimbursement are met, through "spending down" to poverty levels.

Despite federal budget surpluses in the late 1990s, Medicare is expected to become insolvent by 2012. To control costs, the Medicare Part C plan (commonly called Medicare+Choice) was enacted. Patients can choose to switch out of traditional Medicare into a Medicare Part C plan. Types of plans include health maintenance organizations, provider sponsored organizations, preferred provider organizations, medical savings accounts, and private contracting. Part C plans are privately operated insurance programs to which the government makes a predetermined per-capita payment. Medicare Part C is an attempt to have the private sector assume responsibility for the medical costs of the Medicare population. Some plans offer comprehensive services with low deductibles and copayments but charge the patient additional insurance premiums. In exchange for restricted access to care, other plans offer programs with low deductibles and copayments.

The Part C plan has a fixed amount of money to spend for care, but it is responsible for the needs of the whole group of enrolled patients. When resources are limited, the goal is to maximize the value of services provided to the group, even if it means some persons will receive less service than they would under a fee-for-service system. This may create conflict between the needs of an individual patient and the needs of the group. Insurance and health care organizations perform cost/benefit and cost-effectiveness analyses to find the mix of services that maximizes value for a given amount of money spent. Physicians must participate in deciding on how to allocate health care resources so that individual patient needs, quality of care, economic efficiency, and societal needs are balanced.

Changes in Medicare financing represent challenges for the development of better care models. Nursing home care is now financed by a government-mandated system of per-diem payments, based on patient acuity and regional labor costs, out of which all expenses of care must be paid. Home care programs, although time- and labor-intensive, save money. Treating medical problems at home reduces hospital admissions, costly interventions, and hazards of hospitalization in elderly patients. A recent innovation currently spreading nationally, PACE programs (Programs for the All-inclusive Care of the Elderly) allow care at home for seniors who would otherwise require nursing home admission. Medicare and Medicaid provide capitated payments to the PACE program, which in turn provides medical services and custodial care. In some hospitals, Acute Care for Elders (ACE) Units minimize hospital-acquired morbidity. Long-term care insurance, privately purchased, can help pay for custodial care in the home or in a nursing facility without pauperizing the patient.

THE SOLUTION TO PROVIDING HEALTH CARE TO A GROWING POPULATION OF ELDERS

As the population of elderly people grows, the goals of geriatrics remain to promote independence and optimal functioning, to prevent avoidable decline in health status, and to enhance the elder's quality of life.

For many geriatric patients, the format of a routine office visit is not designed to meet their needs. Their problems are too complex and numerous, their psychosocial and emotional needs too great, and their knowledge of self-care and morbidity prevention too small.

The solution to caring for the increasing numbers of elderly who represent heterogeneous populations is to develop a full and coordinated continuum of care in which the different components are linked by teams and disease management guidelines (Fig. 17.2). Each site or component of the continuum—primary care, inpatient care, home care, nursing homes, and alternative arrangements, such as assisted living is essential and presents its own challenges to practice. In the past, life care communities containing all the components in the continuum at a single site were a fast-growing mode of addressing this need but were available and affordable for only a small proportion of the elderly. Increasingly, the growth of managed care is stimulating delivery systems to add components that ensure efficient and more economical access across all parts of the continuum. Clinicians and institutions must develop formal or informal relationships with other providers in the continuum to promote efficient care at the lowest cost.

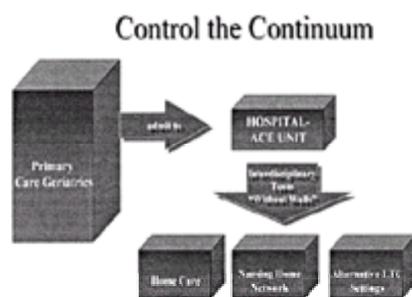

FIGURE 17.2. The continuum of geriatric care.

PRIMARY CARE

The primary care provider focusing on older adults must understand the effects of aging on human physiology and must be knowledgeable about the use of methods that have been shown to improve clinical management of the older adult population. These include risk assessment, comprehensive multidisciplinary assessments and management, proactive use of telephones, health promotion, and preventive services. Because the primary care provider is likely to treat fit, active seniors as well as frail, dependent seniors, screening assessments that allow early identification of persons at risk for disability are effective tools for allocation of scarce, time-consuming, and expensive resources. Many risk assessment instruments have been designed to aid the clinician in the identification of subclinical problems,

unreported symptoms, and situations that increase the probability of functional decline or hospitalization. These tools differ in length, mode of administration, and specificity of risk stratification. Patients scoring in high-risk categories during preliminary evaluation can be investigated more comprehensively. Many Medicare managed care programs and some integrated delivery systems have incorporated periodic risk assessments to determine which patients might benefit from case management.

Through simple, office-based screening tools, primary physicians can identify patients who would benefit from comprehensive geriatric assessment. Typically, these assessments are conducted by a team of professionals consisting of a geriatrician, social worker, nurse, and a variety of other professionals and specialties, such as psychiatry, physiatry, and pharmacy. Multidisciplinary evaluations are resource intensive and their cost-saving potential has not been irrefutably proved. Nonetheless, comprehensive geriatric evaluations' effectiveness in identifying potentially treatable problems that can affect the quality of life of the elderly person is clear. It is therefore reasonable for the primary care provider to be aware of the criteria for efficacy of this approach and to use it judiciously.

Creative solutions such as group outpatient care, which uses nursing staff and others to assist the physician in delivering health care information, in providing socialization opportunities, and in allowing frequent clinical assessment, have been shown to reduce acute and specialist visits, decrease hospitalization, increase rates of immunization and of patient satisfaction, and at the same time decrease costs.

The primary care provider must be equally cognizant of the needs of well elderly persons. Here, health promotion and disease–disability prevention are paramount. The importance of health-promoting behaviors such as exercise cannot be overemphasized. The data on the benefit of both aerobic and strength training exercise, even at very advanced ages, are robust. Similarly, the efficacy of some preventive services warrants their inclusion in the primary care for seniors ([Table 17.2](#)). The US Preventive Services Task Force is currently reconsidering the recommendations for all age groups, including the elderly and will issue a new report in the first years of the new millennium.

INPATIENT CARE

The elderly account for 40% of inpatient hospital days and experience complications that are uncommon in younger age groups. Avoiding preventable complications and maintaining functional status are at the heart of inpatient geriatrics. Complications such as delirium, deconditioning, pressure ulcers, fluid and electrolyte disorders, and adverse medication reactions are common among hospitalized elderly and often result in extended lengths of stay. Practices aimed at avoiding these complications and improving functional outcome at discharge have resulted in growing numbers of Acute Care for Elders (ACE) hospital units and for the urgency of implementing certain treatments.

ACE units, first conceptualized at Case Western University Hospital, use geriatricians and multidisciplinary teams to create inpatient care plans that maximize the function of the elderly. The underlying principles of care, designed to maintain function in the setting of limited physiologic reserve possessed by the elderly, are important in all hospital settings. As previously noted, physiologic changes with aging alter the immune system, body composition, and metabolism of medications. The rapidity of initiating antibiotic administration, the accuracy of fluid replacement, and the appropriate adjustment of medication doses make enormous differences in the outcome of hospitalization in elderly patients. Even when appropriate attention is paid to these unique aspects of hospital care for the elderly, recovery often cannot be accomplished during the hospital stay alone. Nursing home, home care, and house calls may be critical in facilitating recovery and in maintaining or returning function to elderly patients.

HOME CARE, HOUSE CALLS, AND NURSING HOMES

Nursing homes typically have a bimodal population. There are “short-stayers,” who are admitted for rehabilitation or convalescence or for terminal care, and “long-stayers,” who are expected to be institutionalized the rest of their lives. The former may be managed in hospital-based “transitional care,” “subacute care,” or “step-downs” units or in similar facilities in community-based homes. In addition, for every person in a nursing home, there are probably two to four elderly persons living at home with similar levels of frailty and disability. The chronically homebound are perhaps the most neglected subpopulation of elderly. Ambulatory elderly have fewer physician visits per year than many nursing home residents, but homebound elderly claim less than one visit to a physician per year. Despite this, patients frequently express a preference for remaining in their communities, rather than admission to an institutional setting. Many prefer acute illness to be treated in their homes as well. Home care and house calls may allow an elderly person to remain at home. Nursing homes can be used over a broad spectrum of disability to provide a setting for recovery of function and return to the previous living situation. The higher cost of providing the initial therapies and skilled services is often justified by the subsequent lower cost of long-term maintenance in a less skilled setting. The demographic realities illustrate the need for home care, house calls, and nursing homes to be included in the continuum of care for elderly persons.

Treating patients in a nursing home or at home requires a specialized set of skills and knowledge base. The integration of internal medicine and rehabilitation medicine is fundamental to the care of patients in long-term care settings. Mobile diagnostic equipment, such as x-rays, ultrasonography, electrocardiograms, and new medications, have revolutionized the treatment of acute illness in the long-term care or home setting. Simple infections, such as pneumonia, urinary tract infection, and cellulitis, as well as common medical conditions, such as deep venous thrombosis, can now be safely treated either at home or in the nursing home. Despite these advances, much work is needed to move these practice patterns into the mainstream of current medical care.

The dual pressures for the most economical and most effective care will lead to research for better understanding of the unique aspects of *in situ* management, changes in wound care and infection control, new techniques for managing nutritional maladies, and use of computer and telemedicine technologies.

CHRONIC ILLNESS AND PALLIATIVE CARE

Although younger adults tend to have acute and limited illnesses, older adults are more likely to have multiple, chronic illnesses. These illnesses contribute to significant functional limitations, inability to work, and hospitalizations. Congestive heart failure (CHF) and chronic obstructive pulmonary disease (COPD) are the most prevalent of the chronic diseases. More than 3 million Americans have CHF, and approximately 400,000 new cases are diagnosed annually. Fourteen million Americans have COPD, and 100,000 die because of it each year. These two illnesses account for 25% of deaths in the United States.

The traditional focus on cure does not address many of the needs of our aging population. Patients with advanced heart or lung failure are terminally ill. However, many of these patients do not get adequate medical management, are not provided appropriate education, and are never told that their illness is terminal. The gaps in these patients' care is not due to a lack of concern by providers but to a medical system ill equipped to care for these persons. In addition to receiving care from different physicians and nursing agencies, these patients often receive episodic care from multiple hospitals. Care is often fragmented and treatment recommendations may be contradictory. Although treatment for exacerbation of chronic diseases is essential, no good system exists for providing palliative instead of curative care. Hospice care, traditionally targeted at patients with cancer diagnoses and prognoses measured in months, does not manage well the issues of chronically ill patients with longer prognoses.

The solution lies in improving methods for the transfer of medical information and in developing systems to provide long-term palliative care and multidisciplinary team care. Instead of thinking in terms of cure, with a sudden shift to palliative care (e.g., the transition from chemotherapy to hospice care for many cancer patients), we must learn to plan care that gradually integrates palliative care as illness progresses. Our health system must develop ways to draw on medical and nonmedical disciplines to address the physical, mental, and social needs of our elderly patients. In an era of global access to information, we must improve transfer of medical information between the multiple providers involved in the care of a single patient. Improved access to information and multidisciplinary care, an integrated continuum from acute to chronic care, and smooth transition from independent to institutional care will improve the quality of all our lives and assist in controlling our society's burgeoning health care costs.

FINANCIAL AND POLICY CHALLENGES

With the country facing a growing population living longer, many of whom have chronic medical illnesses, careful examination of our allocation of health care resources is imperative. Postponing the onset of chronic disease and disability to the end of life is as important as delaying death, both in terms of preventing suffering and in reducing the massive outlay of funds for medical care currently occurring in the United States.

In theory, the managed care model can teach us to lower health care costs through active management of resources. Portions of a fixed amount of funding can be designated, not only for acute care of hospitalized patients, but also for care of both acute and chronic diseases in less costly settings, including subacute and transitional units, nursing homes, and other living situations. Funds can also be allocated for the prevention of disability through modification of risk factors.

Decreased disability translates to cost savings, despite the initial outlay of funds for risk factor reduction interventions. Experimentation with innovative service delivery models is possible with capitated reimbursement agreements, because they are not circumscribed by what is reimbursable under classic Medicare.

Medicare Part C, the bulk of it being managed Medicare, was touted as a mechanism to optimize the health outcomes of the enrolled beneficiaries, while also saving the government money. Success in managing a Medicare risk contract requires flexibility in recognizing the special health problems of the elderly, the importance of managing functional deficits, and innovation in the delivery of services. Potentially, managed care can offer geriatric patients coordinated specialty care, avoidance of inappropriately applied technology and pharmacology resulting in iatrogenic illness, and a lowering of costs through better organization of care and management of risk factors. Enthusiasm for this approach has been tempered by the perception that managed Medicare companies have skimmed the healthiest of the population, leaving the cost of caring for the more expensive, frailer patients to fee-for-service Medicare, that covered services are not easily available to participants, and that the quality of those services may be in doubt. Managed Medicare does not seem to reduce costs where specialized planning has not occurred and many for-profit companies have dropped their plans.

The intertwining of many of the medical aspects of health care with the social aspects of health care complicates solving the Medicare finance problem. Many of the elderly live below the poverty level and do not have adequate food, shelter, transportation, and safety. Women, people of color, persons living alone, the very elderly, those living in rural areas, and those with a combination of these characteristics are disproportionately represented. The inadequacies of their lives, combined for many with functional limitations, all affect their health and increase their risk of adverse outcomes. The solution is difficult. It requires compromises and changed expectations from taxpayers, health care providers, and the elderly population.

Society must change its view of medical care. The standard of care for the treatment of acute illness in the elderly may no longer be centralization in technologically advanced hospitals. The most advanced studies and medicines often only add marginal value to the outcome of an aged individual. Medicare beneficiaries and their relatives can be educated to understand that transferring spending from "high-tech" medical services to more basic medical and social services can improve quality of life, simultaneously reducing costs. Flexible approaches to care of acutely ill patients such as ACE units, PACE, and home-based interventions including the home hospital, which brings the physician, nurse, medicines, appropriate diagnostic, and treatment methods to the patient, decrease rates and expense of iatrogenic illness and functional decline. There must be allocation of funds for medications. Many of the elderly with easily treatable illness progress to severe and costly complications because they do not have the money to purchase their medicines. Other elderly persons skimp on food and shelter to purchase their medicines. If we are to avoid a negative impact on the health of the individual, funding to provide adequate nutrition, housing, transportation, and safety must be forthcoming either through universal social insurance programs or through some combination of private insurance and public funding. Custodial services, such as supervision and assistance with the activities of daily living, can improve quality of life and can reduce expensive hospital admissions.

A change in expectations throughout our society is needed if we are to improve our current system. This will require understanding the limits of technology and acceptance of both the reality that unlimited care is not possible and that, through redirecting resources to preventive medicine and to innovative health care solutions, quality of life can be improved. Flexibility is required of both health care providers and their patients and of government officials who have such a prominent place in designing our future society.

CHAPTER 18: HOST–MICROBE INTERACTION

HERBERT L. DUPONT AND LILIANA RODRIGUEZ

[Mechanisms of Host Resistance to Infection](#)
[Microbial Virulence](#)
[Microbial Assaults and Evasion Tactics](#)
[Host Genetics and Infectious Diseases](#)
[Clinical Manifestations of Host–Microbe Interactions](#)
[Immunopathology and Immunosuppression During Infection](#)

The normal population of microflora in humans is composed of several complex ecosystems. The organisms occupy space and use substrate on external body mucosal surfaces. The endogenous flora are involved in the body's metabolic activity at all levels.

Disease may be caused by resident organisms and other microbial invaders through three mechanisms: their ability to adhere to host tissues, as characteristically seen in the oral cavity; their sheer numbers, as found on heavily contaminated mucosal surfaces; and their capacity to produce disease or virulence, as in the case of *Neisseria meningitidis* in the upper respiratory tract or *Salmonella typhi* in the gallbladder and gastrointestinal tract. Host defenses must remain on guard continually, because with altered host resistance, even indigenous flora with normally low pathogenic potential may cause disease. Infection usually can be explained by one or more of the following conditions: presence of a virulent organism to which the host is exposed, a large inoculum of the organism, and reduced resistance (increased susceptibility) of the host.

MECHANISMS OF HOST RESISTANCE TO INFECTION

The body possesses many mechanisms, both nonspecific and specific, designed to deter potential invaders ([Table 18.1](#)). Most of the infectious agents encountered are prevented from entering the body by a variety of biochemical and physical barriers. Several critical mechanical barriers to infection include the skin and mucous membranes. The substrate on the skin and the dietary contents of the gastrointestinal tract facilitates the growth of flora that inhibit more hostile organisms in their attempt to gain access to the body. The sebaceous glands on the skin surface produce free fatty acids, which, together with organic acids produced by bacterial flora and locally produced substances such as lysozyme and lactoferrin, inhibit organisms that might otherwise colonize the surfaces. Lysozyme is found in tears, saliva, nasal secretions, and other body fluids. The enzyme lyses the cell wall of certain bacteria. Lactoferrin is an iron-binding protein produced from the granules of polymorphonuclear leukocytes. This substance competes for available iron in the environment, depriving the adjacent microorganisms of a compound essential for their growth.

Nonspecific Mechanisms
Use of substrates and antibacterial catabolites produced by indigenous microflora
Skin and mucous membrane barriers
Lysozymes and lactoferrin
Acid production (e.g., stomach, vagina)
Mucociliary flow apparatus of the respiratory tract
Motility of intestine and urinary system
Macrophages and phagocytes
Specific Mechanisms
Humoral defenses
Cellular defenses

TABLE 18.1. HOST DEFENSES AGAINST MICROBIAL INVADERS

The acidic environment of the stomach and vagina are not suitable for growth by most bacteria, preventing delivery of important numbers of bacteria to the small bowel, which would result in malabsorption and diarrhea, or to the urethra, which may be important in the pathogenesis of urinary tract infection.

Motility of the gastrointestinal tract and ureters, along with frequent voiding of the urinary bladder, limits colonization of potential pathogens. Exfoliation of skin and cell shedding of the respiratory and intestinal epithelium also helps to limit the extent of local infection.

The lining of the respiratory tract entraps inhaled microorganisms larger than 5 μm in diameter and carries them to the upper respiratory tract from the more sensitive lower parts of the lung by means of the mucociliary flow apparatus. Smaller microorganisms are cleared by alveolar macrophages if they are not too numerous or too virulent. Sneezing and coughing help to clear the respiratory tract of microbial colonizers.

Acute inflammation involving capillary dilatation, movement of leukocytes and plasma proteins into the tissue from the circulation, and subsequent phagocytosis represents a primary defense against most bacterial pathogens. The microbes that escape the nonspecific defenses and multiply in body tissues face a sophisticated immune system mounted to localize the process and eradicate them. Other local host defenses include complement, opsonins, a variety of chemical mediators, and other immune factors of humoral and cellular defenses. Monocytes and macrophages may release cytokines, which are important in modulating the immune system. In the defense against certain viral infections, interferons, natural killer cells, and antibody-dependent cytotoxic cells can limit the infection.

MICROBIAL VIRULENCE

The most successful parasites are those living in harmony with the host. Pathogenic organisms that harm their hosts usually possess well-defined virulence characteristics. However, disease can result from relatively nonpathogenic organisms when abnormally high concentrations of the agent are present, as occurs during antibiotic inhibition of normal flora that allows unchecked growth of resistant organisms, or when the host's immunity is depressed. An increased inoculum of a pathologic agent and immunodepression often participate in infections, such as a gram-negative superinfection (new infection) in a diabetic receiving an antimicrobial agent.

Two parameters to measure microbial virulence in experimental animal models are infectious dose (ID) and lethal dose (LD). The ID_{25} is the dose of a microbial strain that infects 25% of the exposed animals (often mice). The LD_{25} is the dose that results in death of 25% of the exposed animals. These measures are used to compare the relative virulence of various bacterial isolates. Specific virulence mechanisms are discussed in a subsequent section.

MICROBIAL ASSAULTS AND EVASION TACTICS

Potential pathogens may attack the body by the oral route through ingestion (e.g., *Shigella*, *Salmonella*, *Brucella*, poliovirus, hepatitis A and E), after inhalation (e.g., *Mycobacterium tuberculosis*, *Legionella pneumophila*, *Histoplasma capsulatum*), or by direct penetration of intact barriers (e.g., *Clostridium tetani*, *Rickettsia*, sexually transmitted diseases). How a microorganism infects humans is often determined by the organism's resistance to stomach acid, its ability to directly invade tissues, the presence of an insect vector, the finding of the organism in the respiratory tract of carriers, a potential for the organism to grow in respiratory equipment or air-conditioning systems, and the fragility of the organism in the environment. Most of the frankly pathogenic organisms possess one or more well-defined virulence mechanisms ([Table 18.2](#)).

Factor	Mechanism
Numbers of organisms	Injured tissue mechanism of the gut, urinary, respiratory tract, ocular and oronasal in the mouth or rapid colonization of invading organisms during antimicrobial therapy may result from an entry of organisms into the body by inoculation or by migration from a contaminated source
Adherence	Non-specific attachment or colonizing properties such as coagulase negative, hydrophobicity on the skin surface. <i>Staphylococcus aureus</i> is the anterior nose. <i>Streptococcus viridans</i> in the mouth, <i>Staphylococcus aureus</i> in the small intestine and anterior proboscis in the genitourinary tract. Highly specialized adhesins that bind to host cell receptors or receptor-ligand interaction (e.g., <i>ETEC</i> , <i>ETEC</i> , <i>E. coli</i> , <i>E. coli</i>)
Resistance to phagocytosis	Encapsulated organisms in phagocytosis
Disease production	Genetic structure, presence of enzymes in the absence of receptors (e.g., <i>M protein</i> for <i>Streptococcus pyogenes</i> , <i>Coagulase</i> of <i>S. aureus</i> , <i>K1 antigen</i> of <i>E. coli</i> in neonates) or the organism (e.g., <i>S. aureus</i> , <i>Streptococcus pyogenes</i>) may release exfoliative toxins that are phagocytosis
Exfoliative proteins	Exfoliative toxins (e.g., <i>Exfoliative toxin A</i> and <i>Exfoliative toxin B</i>) are produced by <i>S. aureus</i> and <i>S. pyogenes</i> respectively. <i>Exfoliative toxin A</i> is a major virulence factor in the pathogenesis of <i>Staphylococcal scalded skin syndrome</i> and <i>Staphylococcal toxic shock syndrome</i> . <i>Exfoliative toxin B</i> is a major virulence factor in the pathogenesis of <i>Staphylococcal toxic shock syndrome</i> . <i>Exfoliative toxin A</i> is a major virulence factor in the pathogenesis of <i>Staphylococcal toxic shock syndrome</i> . <i>Exfoliative toxin B</i> is a major virulence factor in the pathogenesis of <i>Staphylococcal toxic shock syndrome</i> .
Molecular target cell	<i>Staphylococcus aureus</i> , <i>Streptococcus</i> , and the <i>HSV</i> can enter their antigenic matrix, facilitating escape from body immunity
Immunity	Some organisms, particularly, <i>Streptococcus</i> , <i>Staphylococcus</i> , <i>Escherichia coli</i> and <i>Shigella</i> can invade directly through healthy skin or mucous membranes. The invasive strains (e.g., <i>Shigella</i> , <i>Salmonella</i> , <i>Campylobacter jejuni</i>) can invade the gut wall if exposed to sufficient numbers
Adherence	Many factors to possess structures that can compete with host binding proteins for available iron

TABLE 18.2. MICROBIAL FACTORS IMPORTANT IN THE PATHOGENESIS OF INFECTION

NUMBERS OF ORGANISMS

Restriction of the number of organisms colonizing the body is an important factor in preventing invasion. When body surfaces are injured or when growth of commensal organisms reaches very high levels, colonizing flora may obtain access to normally microbe-free deeper structures of the host tissues. In this situation, even without special virulence characteristics, colonization of tissues serves as prelude to infection. Organisms normally colonizing the body may produce infection when they are introduced into normally sterile environments by the respiratory route, during surgery, or when fluids are administered intravenously. A few organisms (e.g., *Shigella* spp., *Cryptosporidium parvum*, *Giardia lamblia*) are capable of producing disease by means of a small inoculum in otherwise healthy persons.

ADHERENCE

A fundamental property of disease production for most pathogenic microbes is attachment to host tissues and cells. High counts of coagulase-negative *Staphylococcus* are usually found on the skin surface. These organisms may colonize plastic intravenous lines, intraventricular shunts, prosthetic heart valves, and joint prostheses during their insertion and subsequently produce low-grade infection. In the oropharynx, bacterial strains attach to mucosal and dental surfaces. Oral streptococci are particularly suited to adherence partly because of the synthesized proteinaceous levans or dextrans that facilitate attachment. Their sticky nature facilitates attachment to the vascular endothelium as well as to dental structures, explaining why these strains are associated with infective endocarditis and dental caries. Similarly, nasal colonization by adherent *Staphylococcus aureus* occurs in about 15% of persons. In these individuals, secondary staphylococcal infections are more likely prone to develop.

The adhesive capacity of certain bacteria results from specialized adhesion molecules that attach to host cell carbohydrates (e.g., glycoproteins, glycolipids). Adherent bacteria in the gut represent important causes of infection. In some of the exogenously acquired diarrhea-producing *Escherichia coli* (enterotoxigenic *E. coli* and enteropathogenic *E. coli*), the organisms possess specialized capsular structures that allow them to attach to receptors in the lining of the intestine. Other intestinal strains of *E. coli* possess different attachment fimbriae, which belong to a certain number of O-antigen serogroups and have a predilection for uroepithelium. These organisms are important causes of pyelonephritis. The fimbriae (pili) attach to a carbohydrate moiety of the P blood group substance on erythrocytes and uroepithelial cells. Persons who lack P blood group antigens have a natural resistance to infection by these strains.

Initial attachment of gonococci to mucosal surfaces also appears to be mediated by pili. Rapid phase shifts between piliated and nonpiliated variants allow the organism to first detach from infected mucosal surfaces and subsequently attach to mucosal surfaces of susceptible hosts.

RESISTANCE TO PHAGOCYTOSIS

Microbes that breach the epithelial surface barrier encounter many phagocytic cells. These cells require alteration of the surface of the organism by immunoglobulins (IgG and IgM) to coat, or opsonize, the surface of bacteria. This defense process is particularly important for the eradication of encapsulated organisms such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *N. meningitidis*. Persons who lack these immunoglobulins develop severe and recurrent infections by these organisms and by *S. aureus*. Patients who do not have a spleen (e.g., patients with sickle cell anemia or who have had splenectomy) also lack coating antibodies (i.e., opsonic activity is deficient) and may present with overwhelming infections by one of the encapsulated organisms, particularly *S. pneumoniae*.

During systemic bacterial infection, complement is activated through the classic pathway when stimulated by microbial antigens or through the alternate pathway as a result of stimulation by microbial lipopolysaccharide. Complement participates in the phagocytosis process through its opsonic properties, or it may participate in the direct lysis of certain organisms. A deficiency in plasma complement components C6, C7, or C8 can be found in one-third of patients with meningococcal meningitis, reflecting the importance of complement in the defense against this organism. Deficiency of the terminal components of complement also predispose patients to bacteremic *N. gonorrhoeae* disease.

Bacteria inhibit phagocytosis through various mechanisms. Some bacteria possess capsular structures that serve as armor, such as K1 antigen of *E. coli* in neonatal meningitis, M proteins of *Streptococcus pyogenes*, and the carbohydrate capsule of *S. pneumoniae*. As a result of previous exposure, the host may opsonize the invader, coating the organism and its antiphagocytic moiety with immunoglobulin and complement, allowing phagocytosis to occur. In the case of *S. pyogenes*, outer surface structures may mimic host tissues, helping to hide the organism from phagocytic cells. Other bacteria produce enzymes that lyse phagocytic cells (e.g., streptolysin produced by *S. pyogenes*, α -toxin elaborated by *Clostridium perfringens*) or inhibit leukocyte chemotaxis (e.g., protein A from metabolically active *S. aureus*).

EXOTOXINS, EXTRACELLULAR PROTEINS, SIDEROPHORES, AND ENDOTOXINS

Strains of *S. aureus* produce several exotoxins that are important in disease expression. One of these is toxic shock toxin-1, a relatively low-molecular-weight, single-peptide-chain protein, important in the pathogenesis of toxic shock syndrome. Other exotoxins produced by *S. aureus* are enterotoxins A through D (implicated in food poisoning). *S. aureus* strains may also produce exfoliative toxins A and B, which may cause severe systemic infection associated with the scalded skin syndrome in neonates and young children and other exfoliative reactions in adults.

In tetanus, neurotoxins produced by *Clostridium tetani* bind to neural cells to produce spastic paralysis in tetanus. Several enzymes, including streptolysin (produced by *S. pyogenes*) and α -toxin (produced by *C. perfringens*), are capable of lysing phagocytic cells. *S. pyogenes* strains produce other pyrogenic exotoxins and are virulent by their ability to multiply rapidly and to excrete a variety of extracellular products that facilitate spreading through tissues planes. *S. pyogenes* grows with a doubling time of 30 minutes in log phase and produces DNAses, hyaluronidase, streptokinase, and proteinases, all of which prevent the host inflammatory response from localizing the infection at the site of bacterial implantation. The propensity of *S. pyogenes* to spread through lymphatics, the subcutaneous tissues, and the bloodstream, resulting in cellulitis, lymphangitis, and bacteremia, appears to be related to these spreading factors.

S. aureus also is a rapidly growing organism with a generation time similar to group A β -hemolytic streptococci. However, *S. aureus* characteristically produces a localized abscess (a boil) as its primary disease manifestation, perhaps because of the elaborated enzyme, coagulase, which leads to capillary thrombosis in the adjacent tissue. The organism is able to avoid phagocytosis by anatomical separation from the circulating host cells.

All living forms require iron for growth. Because tissue iron is normally bound to body proteins, it is necessary for bacteria to compete for iron binding. Some bacteria have siderophores to bind to available iron, or the organisms may induce hemolysis to gain access to iron freed from host tissue.

Endotoxins are complexes of polysaccharide, protein, and lipid composing part of the cell wall structure of gram-negative bacilli and gram-negative cocci. Endotoxin participates in certain septicemic infections through its effects on host factors. In bacteremic disease, the lysis of gram-negative organisms (e.g., Enterobacteriaceae, *Pseudomonas* spp., *N. meningitidis*) releases endotoxin, leading to myriad host responses involving macrophage cytokines (e.g., tumor necrosis factor, interleukin-1), the complement cascade, the intrinsic coagulation system (e.g., Hageman factor), platelet-activating factor, arachidonic acid metabolites, the humoral defense system

(e.g., complement, kinins), vascular endothelium, and myocardium. If the responses are generalized and extreme, they result in shock and end-organ failure due to poor tissue perfusion by blood. The types of organ failure and tissue damage include the adult respiratory distress syndrome, renal failure, disseminated intravascular coagulation, altered sensorium, and death. The sequence of metabolic and vascular complications of endotoxemia is known as the *sepsis cascade*.

INVASIVENESS

All viruses must gain access to an intracellular environment to replicate. This also is true for several pathogenic bacteria, fungi, and protozoa. These organisms have developed mechanisms that facilitate attachment and internalization to enhance their chances for survival and replication within the intracellular milieu. Some microorganisms can benefit from binding to phagocytes and lymphocytes; the host cells transport the microbe from an extracellular location to a preferred intracellular environment. For example, the Epstein–Barr virus infects B lymphocytes by attachment to a B-cell–specific membrane protein, CR2. Similarly, HIV gains access to CD4 T lymphocytes by forming a complex between the viral envelop glycoprotein, gp120, and the surface of the T lymphocyte. Other intracellular pathogens such as *H. capsulatum* can bind to the CR3 immune receptor on phagocytic cells to gain access to a protective intracellular environment. *Plasmodium vivax* penetrates human red cells after first attaching to the Duffy blood group determinant by a nonimmune, lectin–carbohydrate interaction.

Once ingested by phagocytic cells, intracellular organisms can bypass host defenses by a variety of mechanisms. One such mechanism is inhibition of phagosome–lysosome fusion (e.g., *Legionella pneumophila*, *M. tuberculosis*, *Toxoplasma gondii*); another is escape from the phagosome into the cytoplasm of macrophages, which lack a specialized mechanism for killing microbial pathogens (e.g., *Trypanosoma cruzi*).

Other organisms, although remaining extracellular, have the capacity to penetrate host tissues as part of their pathogenic mechanisms. *Shigella* species possess the capacity to invade epithelial cells because of chromosomal genes and a large (120 to 140 Md) enteroinvasive plasmid. The plasmid is necessary for the expression of several outer membrane proteins and invasion plasmid antigens, which assist the bacteria in gaining entry into the enterocyte.

MICROBIAL ANTIGENIC PHASE SHIFTS

Pathogens such as *N. gonorrhoeae*, influenza virus, and HIV undergo shifts in their antigenic expression and are able to avoid immune clearance that depends on specific antibody production. For example, hemagglutinin is an antigen on the surface of the influenza virus used to adhere to cells before infection. Significant changes in the antigenicity of the hemagglutinin occur through swapping genetic material with different viruses in other hosts. When the accrued alterations in hemagglutinin are sufficient to render previous lines of immunity ineffective, a new influenza epidemic is inaugurated. Such microbial alterations add complexity to the concept of immunity.

MICROBIAL PERSISTENCE AND LATENCY

Certain organisms undergo metabolic changes and resist host phagocytic effects and antimicrobials while remaining susceptible in vitro to the antibiotics used. Microbial persistence is clinically relevant in chronic bacterial infections. In these cases, pathogens may be cultured from the sites of purulent or granulomatous inflammation even after prolonged therapy with bactericidal antibiotics. *S. aureus* and some species of *Mycobacterium* are examples of organisms that may persist under these conditions.

Many viruses, including herpesviruses, adenoviruses, hepadnaviruses, papillomaviruses, and retroviruses, characteristically undergo a condition of latency after the initial or primary infection. Within the herpesvirus family, cytomegalovirus and Epstein–Barr virus cause a primary mononucleosis syndrome, after which the viruses remain latent in lymphoid tissues. Primary infection by the varicella-zoster virus or by herpes simplex types 1 and 2 is followed by establishment of latency within sensory nerve ganglion cells. Clinically apparent reactivation of these viruses is manifested by vesicular skin eruptions in dermatome distribution (varicella-zoster) or in the oral (herpes simplex 1) or genital (herpes simplex 2) regions.

Factors that trigger reactivation of latent infections are emotional or physical stress and immunodeficiency secondary to underlying disease or to immunosuppressive therapy. Neither free virus nor viral antigens can be detected in tissues during latency. A virally encoded RNA of herpes simplex has been identified within latently infected neurons, although a protein product has not been detected. The precise function of this latency-associated gene has not been determined, but it is almost certainly related to the capacities of latency and reactivation. The propensity of an organism to establish a latent state may be related to its capacity to undergo malignant transformation through a prolonged relation between the virus and host cell.

HOST GENETICS AND INFECTIOUS DISEASES

Persons differ in terms of susceptibility to microbial infection. Studies of the attachment of enterotoxigenic *E. coli* (ETEC) in the natural porcine host has revealed that certain strains of pigs do not possess the intestinal membrane receptors specific for the organism's attachment fimbriae. These animals are naturally resistant to ETEC infection by the organism containing these adherence ligands. Undoubtedly, the same sort of genetic resistance occurs in humans.

Many infectious diseases are correlated with blood type. The antigenic association between the pathogen and the host erythrocyte membrane may facilitate the microorganism's escape from immune surveillance in persons possessing certain blood types. Alternatively, the association may result from the presence or absence of specific receptors important in the interaction of receptor and infectious agent in those with specific blood types.

The geographic distribution of blood groups appears to influence the susceptibility of populations to many epidemic infectious diseases, including cholera, smallpox, plague, tuberculosis, typhoid fever, bartonellosis, leprosy, hepatitis, and echinococcosis. Patients with blood group type O experience more severe cases of cholera in endemic areas. It seems likely that receptor structures on target cells are related in part to the blood group. Patients with genes of the human leukocyte antigen HLA-B27 may develop Reiter's syndrome (hypersensitivity reaction associated with reactive arthritis, conjunctivitis, and uveitis) after infection by certain pathogens such as *Shigella flexneri*, *Shigella dysenteriae*, and *Campylobacter jejuni*. Major histocompatibility complex molecules strongly influence resistance to a variety of parasitic infections, including malaria, trypanosomiasis, onchocerciasis, and tapeworm infestation. The important interplay between host genetics and the infectious organisms is just now being explored.

CLINICAL MANIFESTATIONS OF HOST–MICROBE INTERACTIONS

When a host is exposed to a microbe, several consequences are possible ([Table 18.3](#)). No interaction may occur after exposure if the organism fails to propagate or to become established in any fashion. Another possibility is that the organism colonizes host tissues and serves as a commensal, living off available substrate. The organism may provide benefits to the host in return for the use of space and substrate. For example, microbial production of vitamin K facilitates clotting, and colonization with hospitable flora prevents the acquisition of more hostile microbes. The agent may produce a covert infection in which an immune response can be elicited but there is no clinical illness.

Host-Parasite Interaction	Conditions
Colonization: transient	Being travel to international regions, hospitalization, and confinement in close quarters with multiple persons, the host may be colonized transiently with abnormal flora. During the resolution of certain infections and during convalescence from other infections, transient carriage of viable organisms occurs.
Colonization: chronic	Some infectious agents (e.g., typhoid, hepatitis B) produce chronic infection that may not be associated with symptoms.
Subclinical infection	Most infectious agents more commonly produce subclinical infection than overt illness. In these cases, studies of antibody development or cell-mediated immunity confirm an infection.
Clinical disease	Some organisms (e.g., smallpox, Shigella infection, brucellosis) commonly cause illness when infection occurs. The organisms that characteristically produce subclinical infection less commonly produce overt disease.
Persistence and latency	The herpesvirus family members (e.g., herpes simplex, cytomegalovirus, varicella-zoster virus, Epstein-Barr virus) cause persistent infection. Although there is no evidence of active infection after the primary infection has resolved, relapses or recurrences of illness occur, often with a change in immunity or other factors.

TABLE 18.3. CLINICAL ASPECTS OF HOST-MICROBE INTERACTIONS

Overt disease may result when the host is exposed to the organism. Certain potential pathogens (e.g., smallpox) characteristically produce clinical illness when a susceptible person is exposed to the agent, although the typical response is for most susceptible and exposed persons to develop subclinical infection, with only a minority becoming ill. Epstein–Barr virus infection is a good example of the more typical type of host–parasite response. Perhaps only 5 of 1,000 infected persons experience infectious mononucleosis. Most adults have been exposed to the virus and have serologic evidence of past infection. Microbial persistence and latency characterizes infection by one of the herpesviruses.

An important concept in the epidemiology of infectious diseases is organism carriage. Humans often represent the important reservoir and vehicle of transmission for subsequent infection. There are at least four types of carriers. The *inapparent carrier* has an asymptomatic infection; the infectious particles are shed without any clinical illness. The *incubatory carrier* is a person incubating an infectious disease who is transmitting the organism before experiencing symptomatic illness. The *convalescent carrier* has recovered from an infection and is shedding the organism, potentially to other susceptible persons. The *chronic carrier* is clinically well, but for prolonged periods (years to lifetime) is capable of transmitting the virulent organism.

Important examples associated with inapparent carriage include poliovirus and meningococcus; with incubatory carriage, chickenpox, measles, and hepatitis A; with convalescent carriage, diphtheria and hepatitis B; and with chronic carriage, *S. typhi* and hepatitis B.

IMMUNOPATHOLOGY AND IMMUNOSUPPRESSION DURING INFECTION

Many viruses that infect cells of the immune system exert direct immunosuppressive effects. These effects may be severe enough to render the host susceptible to opportunistic infection or malignant transformation of host cells. The measles virus may lead to a loss in delayed hypersensitivity to *M. tuberculosis* antigen during active infection. The loss of allergic reactivity, known as anergy, manifests a few days before onset of the rash and may persist for 6 weeks after recovery from measles. Disseminated *M. tuberculosis*, *Coccidioides immitis*, or *Mycobacterium leprae* infections are associated with anergy in a high percentage of cases. Except for leprosy, antimicrobial therapy of the disseminated infection usually reverses the anergy.

A striking impairment of immunity is seen in HIV infection. The virus causes numeric depletion and dysfunction of CD4 T lymphocytes. HIV also infects and damages macrophages, leading to reduced capacity of these cells to present antigens to T cells and to elaborate cytokines. HIV-infected persons experience infection by a variety of opportunistic pathogens, such as *Pneumocystis carinii*, a commensal of the normal lung.

Other infectious agents produce variable degrees of immunosuppression. Cytomegalovirus is commonly associated with immunosuppression, probably as a consequence of infection of lymphocytes by the virus. Influenza viruses primarily attack columnar epithelial cells of the respiratory tract, monocytes, and macrophages, leading to reduced bactericidal activity. This virus-induced impairment of macrophage function in influenza may contribute to the secondary pulmonary infection by bacteria, including *S. aureus*, *S. pneumoniae*, and *H. influenzae*.

CHAPTER 19: ETIOLOGY OF MALIGNANT DISEASE

WILLIAM A. BLATTNER

[Lifestyle Factors](#)
[Therapeutic Factors](#)
[Environmental Factors](#)
[Occupation](#)
[Infectious Agents](#)
[Host Factors](#)
[Conclusion](#)

Over the last 20 years, public awareness of environmental factors, personal habits and lifestyle, and genetic predisposition associated with heightened cancer risk has translated into increased activism reflected in legislation, litigation, and personal commitment to a prevention-oriented lifestyle. Following the lead of AIDS activists, the demand for increased research funding, legislation to improve worker conditions and the environment at large, the “tobacco settlement” for health-related outcomes of tobacco use, and increased attention to diet and exercise are manifestations of this activism. The practicing clinician and subspecialist are called on to be the arbiter of an informed and balanced perspective on these issues.

Recent advances in molecular biology have improved our understanding of the genetic basis of cancer as a complex series of diseases involving multiple steps and multiple pathways involving genes at the center of cell signaling, DNA repair, and other vital check points of cellular function. Beginning with an initiation event that renders a tissue premalignant, followed by a number of promotional steps that increase the potential for an initiated cell to become malignant, cancer is a multistage process. Opportunities for early detection have increased with the emergence of screening approaches such as prostate-specific antigen (PSA), improved imaging techniques, and less invasive sampling such as fine-needle biopsy. These and improved therapies have started to make an impact on the morbidity and mortality of some tumors. With 70% of all deaths caused by cancer and cardiovascular disease in persons over age 65, declines in deaths due to cardiovascular disease and stroke are occurring at a rate faster than those for cancer. With the specter that cancer will become the leading cause of death in this age group in the United States and other developed countries in the next 5 to 10 years, identification of preventable exposures and strategies to reduce or reverse the risk for cancer remains a high priority.

LIFESTYLE FACTORS

In their 1981 monograph, Doll and Peto estimated that at least 30% to 40% of all cancer deaths could be avoided by applying the knowledge we have of the known causes of cancer. Effecting behavioral changes to reduce cancer risk is complex ([Chapter 22](#)), although major national campaigns in the areas of diet, physical exercise, and antismoking have achieved some success in changing behavior among targeted populations.

TOBACCO

In the United States, tobacco use accounts for about 40% of all cancers among men and 20% of all cancers among women. Lung cancer is the major tobacco-associated cancer site, with 90% of cases among men and 79% of cases among women attributed to tobacco exposure. The epidemic of lung cancer in the United States emerged among men in the 1930s and among women in the mid-1960s—approximately 20 years after the widespread introduction of cigarette smoking in each of these groups. Since then, an overwhelming body of evidence has amassed that shows that cigarette smoking causes a variety of malignancies of the respiratory, gastrointestinal, and genitourinary systems. For lung cancer, the risk from heavy cigarette smoking (more than two packs per day) is 20 times higher than among nonsmokers. Filter-tipped cigarettes, which decrease the tar and nicotine levels, reduce the risk for smokers, but the rates are still much higher than among nonsmokers.

Nonsmokers exposed to environmental tobacco smoke, *passive smoking*, experience excess risk and present with patterns of tumors similar to that of smokers. Heavily exposed passive smokers have risk estimates similar to that of light smokers. Former smokers experience a reduction in risk compared with active smokers; this is detectable within a few years of cessation.

Other malignancies associated with cigarette smoking are by system: respiratory (lip, oral cavity, pharynx, larynx, trachea, bronchus, and lung); gastrointestinal (esophagus and pancreas); genitourinary (bladder, kidney, and ureter); reproductive (uterus, cervix); and hematologic (myelogenous leukemia). The risk of cancers of the lip, mouth, tongue, pharynx, larynx, and esophagus is further amplified by heavy alcohol consumption.

Smokeless tobacco usage, tobacco chewing, and particularly snuff dipping is of increasing concern, because the practice has become popular among teenagers and young adults. Rates of mouth and throat cancer are increased up to 50 times in long-time snuff users. In general, a dose-response relationship governs mouth and throat cancer; risks increase with the amount and duration of tobacco use.

ALCOHOL

Alcohol consumption synergistically enhances the risk for several tobacco-related neoplasms. Combined exposure to alcohol and smoking account for about 75% of all oral and pharyngeal cancers. Alcohol alone is estimated to contribute to about 3% of cancers and has been associated with colon cancer and colorectal adenomatous polyps and with esophageal, pancreatic, nasopharyngeal, prostate, and breast cancers. Ethanol is not carcinogenic in laboratory animal studies but may enhance carcinogenicity by making carcinogens more soluble or by facilitating tissue penetration. Alcohol is associated with heightened risk for liver cancer, and tissue injury resulting from cirrhosis may contribute to the carcinogenic process. Nutritional deficiencies among black men who are heavy drinkers have been linked to high rates of cancer of the esophagus. Several analyses suggest that even moderate use of alcohol enhances female breast cancer by a factor of 50%. Although the basis for this determination is unknown, effects on hormonal metabolism have been postulated.

DIET AND NUTRITION

Establishing clear links between diet and cancer is complicated by methodologic issues, such as differential recall bias and the long latency between putative dietary exposures and subsequent cancer risk. Observational studies, such as those among migrants from areas with low colon cancer risk who adopt a Western diet, thus heightening their risk for this tumor in their lifetime, demonstrate the importance of diet in cancer risk. Interventional studies, including one that used vitamin A supplementation to effect reversal of preneoplastic lesions of the esophagus in a high-risk Chinese population, mirror results in experimental animal studies in which supplemental vitamin administration reversed preneoplastic lesions. For cancers with a suspected dietary component, some have estimated that 35% of cancer has a dietary factor involved in the cause, but with a wide range for this attribution. Current public health guidelines suggest that a prudent diet, which emphasizes reduction in total animal fat consumption, increase in intake of fruits and vegetables, good food preservation and healthy preparation, moderation in alcohol consumption, and avoidance of obesity, may reduce cancer rates by as much as one-third while reducing risk of cardiovascular disease as well.

The mechanism or mechanisms by which diet may influence cancer risk—either by increasing or decreasing it, are complex, and it is difficult to distinguish which nutrients are the active agents and how much daily intake is required to have a desired effect. Obesity is strongly linked to risk of endometrial cancer and cancer of the biliary system, colon cancer in men, and possibly renal cell cancer. Higher mortality for breast cancer among obese postmenopausal women may result from delayed detection. However, high fat intake is associated with increased risk for breast cancer in correlational but less clearly in analytic studies. Prostate and colon cancers are more strongly associated with dietary fat and meat consumption, and some studies also suggest a role in ovarian cancer as well.

Sir Dennis Burkitt popularized consumption of high dietary grain fiber as a means of reducing colon cancer risk, but a recent study, while showing benefit of increased fiber intake for cardiovascular disease, did not make a favorable impact on colon cancer. However, high vegetable and fruit intake is beneficial, but the effect may result from vitamins or other nutrients (e.g., vitamin C, indoles, and other nutrients) in reducing cancer risk. Vitamin A, carotenoids, vitamin C, vitamin E, and selenium have been implicated in a variety of studies as having a beneficial effect in reducing cancer risk. These dietary adjuncts have been used in interventional studies in varying combinations or alone with mixed results, including the finding in one Finnish study in which men at high risk of lung cancer experienced increased rates of lung cancer when given vitamin A supplements. In this same trial, those receiving vitamin E did not experience an increased risk of lung cancer, but a modest

reduction in prostate cancer was observed.

In vitro studies of carcinogens and mutagens detected as a result of food preparation (e.g., high-temperature cooking) raised questions about the role of these factors in human cancers. But epidemiologic studies in human populations have not linked such factors, except for salt-preserved foods that may heighten risk for stomach cancer and nasopharyngeal cancer in China. Several natural products are themselves carcinogenic, such as aflatoxin, a carcinogenic metabolic product of the fungus *Aspergillus flavus*, which is associated with high rates of liver cancer.

Compelling data from many sources document that diet may modify cancer risk by years. As a fuller understanding of these complex interactions develops and accumulated supportive evidence increases, acceleration of educational campaigns on the health benefits derived from improved nutritional practices may lead to substantial reduction in cancer rates.

THERAPEUTIC FACTORS

The major classes of medically prescribed drugs linked to heightened risk for cancer are hormones, anticancer drugs, and immunosuppressive agents. Despite these associations, drugs are believed to account for less than 2% of all cancers.

EXOGENOUS HORMONES

In the late 1960s, an epidemic of vaginal and cervical adenocarcinoma in young women was linked to prior exposure in utero to diethylstilbestrol, which was used as an adjunct to preventing miscarriage. The use of synthetic conjugated estrogens alone for menopausal symptoms has been linked to the development of endometrial cancer, but low-dose estrogen replacement in combination with progesterone-containing hormonal replacement regimens is not associated with increased endometrial cancer risk. The relation of hormonal replacement therapy and risk for breast cancer is complex, with a number of studies conducted in the 1990s demonstrating modest increases in risk but with several studies suggesting that the associated subtype of breast cancer has a good prognosis. So the impact of such therapy on mortality is not known. Some have argued that the benefits of hormonal replacement outweigh the risks because of reduction in heart disease and osteoporosis. Decisions about hormonal replacement therapy depend on the individual circumstance of the patient and her medical needs as well as results of further studies that can help to refine our understanding of this complex paradigm.

There are conflicting data on oral contraceptives as a risk factor for breast cancer; early, prolonged use in persons with a predisposition is implicated. Other studies of oral contraceptives suggest that they may decrease the risk of ovarian and endometrial cancer, although an association with invasive cervical cancer was suggested in one study.

IMMUNOSUPPRESSIVE AGENTS

The concept of immunosurveillance in cause of cancer, first proposed in the early 1960s, suggested that cancer emerges because of a loss of immunologic recognition of tumor-associated antigens. Studies of immunodeficiency in various settings have documented a limited repertoire of tumor types. One of the first settings evaluated involved the study of tumors among patients receiving immunosuppressive therapies to suppress rejection of organ transplants. In this setting, non-Hodgkin's lymphomas, especially of the brain, are the most prominent manifestation. The emergence of such tumors within months of transplantation contrasts with the longer duration for cancer induction associated with environmental carcinogens. An infectious agent, Epstein-Barr virus (EBV) is linked to such transplant lymphomas.

Other cancers associated with immunosuppressive therapy include Kaposi's sarcoma and cervical, vulvar, and anal (all human papillomavirus-associated) cancers. Squamous cell carcinoma of the skin and malignant melanoma are also increased in this setting. This pattern of tumors has also been observed in acquired and congenital immunodeficiency, with some additional tumor types linked to specific congenital immunodeficiency states such as ovarian dysgerminomas, and stomach and liver cancers in ataxia telangiectasia, probably associated with this disorder's chromosomal changes. The stomach cancer observed in common variable immunodeficiency is probably a result of the common occurrence of achlorhydria in that disorder.

OTHER DRUGS

With the exception of hormones and several medicinal agents, most drugs as they are ordinarily used clinically pose no risk for cancer. Arsenicals are no longer used in clinical practice but are associated with some risk for skin cancer. Diphenylhydantoin is linked to a slightly increased risk for non-Hodgkin's lymphomas. Phenacetin used in high dosages is linked to renal cancer, whereas nonsteroidal anti-inflammatory drugs, including aspirin, have been shown to reduce the risk of colon cancer. Some anticancer drugs, particularly alkylating agents, which have radiation-like effects, are associated with increased cancer risk, particularly leukemia. However, their use is justified when treating otherwise incurable cancers. Studies of patients treated with alkylating agents for Hodgkin's and non-Hodgkin's lymphoma, multiple myeloma, and ovarian, gastric, and colorectal cancers have shown a 16- to several hundred-fold increase in risk for acute nonlymphocytic leukemia emerging after 3 to 5 years and peaking after 10 to 15 years.

ENVIRONMENTAL FACTORS

IONIZING RADIATION

Ionizing radiation produces its carcinogenic effects by direct damage to the genetic material of the cell. Radiogenic cancers are most prominent in the breast, brain, thyroid, and bone marrow, with excesses of some other tumors associated with particularly heavy local exposure to a particular site, such as with osteosarcomas and bone-seeking radionuclides.

Most data on the carcinogenic potential of ionizing radiation are derived from moderate to high exposure levels; extrapolations from these data suggest the importance of the cumulative effect of exposure. It is unlikely that a threshold dose exists below which there is no carcinogenic effect.

Radiogenic leukemia differs from most radiation-induced cancers in that the latent period is relatively short. Cases occur within a few years of exposure, peak at 6 to 8 years, and are followed by a decline to normal rates within 25 years. Radiogenic carcinomas have much longer latent periods. In the prospective follow-up of the children exposed to radiation after the atomic bomb blasts in Japan, prepubertal girls exposed to moderate doses were at high risk for breast cancers 20 to 30 years later. Even modest doses of prenatal radiation are associated with heightened risk for leukemia and other childhood cancers. Cancers have also developed in sites where radionuclides are concentrated. Some examples include osteosarcoma (radium 224), leukemia (phosphorus 32), and liver angiosarcoma (Thorotrast).

Although ionizing radiation appears to account for no more than 3% of all cancers, there is considerable public concern about this risk factor. Increased public awareness of radon in ground water and its potential for household contamination and the publicity surrounding the general population exposure from the nuclear accident in Chernobyl, intensify this concern.

ULTRAVIOLET RADIATION

Solar radiation causes up to 90% of nonmelanoma skin cancer, and its effects are linked to skin melanoma as well. The link between sunlight exposure and squamous and basal cell carcinomas was determined from the high rates among persons with outdoor occupations (e.g., sailors, farmers), among persons residing in southern latitudes, and among fair-skinned people with lower levels of protective melanin pigment.

Skin cancers tend to occur most prominently in sun-exposed areas. For nonmelanoma skin cancer, risk is related to annual cumulative lifetime ultraviolet-B exposure; for melanoma skin cancer, a history of repeated sunburn, especially in youth, is associated with heightened risk for subsequent skin melanoma years later. Behavioral modification, such as avoidance of excessive sunlight exposure and the use of readily available and highly protective sunscreens, could have a major preventive impact on cancers of the skin.

OCCUPATION

TABLE 19.1. MOLECULAR BASIS OF SELECTED CANCERS AND SYNDROMES

Over 200 single-gene disorders have been recognized, which confer a cancer-prone genetic predisposition. Studies of such high-risk patients with these predispositions have yielded important insights concerning the fundamental biology of cancer. Hereditary neoplasms are best exemplified by autosomal dominant gene disorders, which result in the development of specific neoplasms or constellations of tumors. Approximately 40% of all retinoblastomas occurring in childhood are of the hereditary type. A deletion involving the long arm of chromosome 13 has been recognized in some cases, and molecular analyses with genetic probes have identified a specific gene region called a *suppressor gene*, which acts by modulating specific cell-cycling regulators. The absence of this down-regulation results in increased and unregulated cell proliferation. Thus, mutations in such genes—and in the case of retinoblastoma a specific gene, *RB1*, a DNA-binding nuclear protein—confer a high risk for tumor formation. For such suppressor genes to lose activity, both alleles of the gene must be mutated. In the case of hereditary retinoblastoma, in which patients are also prone to osteosarcoma of the leg and radiogenic sarcoma of the orbit, susceptible patients are born with an inherited constitutional rearrangement or deletion of chromosome 13q14, where the *RB1* gene resides. A single mutation of the remaining intact *RB1* gene allele results in tumor formation.

Studies of sporadic oat cell carcinoma of the lung and renal carcinoma also suggest a mechanism similar to retinoblastoma that involves a gene on the long arm of chromosome 3. Other cancer genes are the targets of gene-mapping studies applied to a variety of cancer-prone disorders. [Table 19.1](#) lists some of the cancers for which studies of genetic or familial syndromes have contributed to understanding their molecular basis. The practice of oncology will be significantly influenced by these discoveries as these markers are applied to the diagnosis and staging of a wide range of common cancers.

A variety of preneoplastic states have been recognized. Hamartomatous syndromes are typified by autosomal dominant disorders in which faulty embryonic development results in localized abnormal growth in mixed component tissues and heightened risk for various cancers. The genodermatoses are autosomal recessive disorders linked primarily to skin cancers, particularly of sun-exposed areas. Defects in the repair of ultraviolet-induced DNA damage in xeroderma pigmentosum have provided insights into the types of metabolic pathways by which the body repairs solar radiation-induced damage.

The dysplastic nevus syndrome predisposes to malignant melanoma, and because it occurs as a heritable and sporadic condition, it is an important precancerous condition that practitioners are likely to see, diagnose, and cure.

Congenital immune deficiency states predispose to a variety of cancers, especially of the lymphoreticular system. Ataxia telangiectasia, an immune deficiency syndrome, also shares a defect in chromosome fragility. Tissue from these patients is usually susceptible to g-radiation exposure in vitro and in vivo. Patients with this autosomal recessive disorder are prone to lymphoma, lymphocytic leukemia, stomach cancer, and other cancers; heterozygous relatives are said to be at heightened risk for leukemia, lymphoma, and carcinoma of the biliary tract and a variety of other cancers.

The finding of cancer in close relatives is not unusual, and the risk for a particular cancer has been consistently reported to be about two- to threefold if a close family member has that tumor. Familial cancer family syndrome patients are often distinguished by a tendency for multiple primary cancers in the same person and often by a younger than usual age of onset. Site-specific familial cancer aggregations are the most common, with familial breast and colon clusters observed most frequently. In other instances, multiple types of cancer occur in the same family. Examples include the multiple adenocarcinoma syndrome (colon, endometrial and breast carcinoma); Turcot's syndrome (brain and colon cancer); and the Li-Fraumeni syndrome (bony and soft tissue sarcomas, breast, brain, lung, larynx and adrenocortical neoplasms, and leukemia).

CONCLUSION

Cancer is a complex disease involving multistep molecular and cellular processes. Because no single genetic factor is sufficient to predict risk, the ultimate goal of epidemiology is to understand the environmental factors, lifestyles, and individual risk profiles that can facilitate population-based and individually targeted prevention approaches.

Some cancers are already declining as a result of efforts to eliminate exposures such as cigarette smoking. Nonetheless, more research is needed to identify the risk factors for common cancers, particularly those that are increasing, such as breast cancers in young women and non-Hodgkin's lymphomas.

CHAPTER 20: MOLECULAR AND CELL BIOLOGY OF NEOPLASIA

PETER C. NOWELL

[Growth Regulation in Normal and Neoplastic Cells](#)
[Tumor Progression and Host Response](#)

It is now widely accepted that most tumors (neoplasms) are a cellular mass that represents the progeny of a single cell in which one or more mutations resulted in a growth and/or survival advantage over normal cells. It also appears that in most cases, a number of sequential mutations within the expanding cell clone are necessary for it to develop into a clinical neoplasm. If these mutations involve only a growth advantage and the tumor remains localized, it is termed *benign*. If additional changes occur in other genes that allow a subpopulation of the tumor to successfully invade adjacent tissues and metastasize to distant sites, the neoplasm is considered *malignant* (cancer). Typically, malignant tumors at this stage are also less well differentiated and grow more aggressively, but the ability to invade and to metastasize is the critical biologic and clinical difference between benign and malignant neoplasms.

Since the mid-1980s, much progress has been made in identifying the multiple genes and proteins involved in the pathways of normal growth regulation; there has also been the recognition that a wide variety of genes may be altered through somatic mutations or as inherited defects and that they contribute to the development of many kind of tumors. Similarly, numerous genes and proteins associated with invasiveness and metastasis are being identified, along with specific gene defects that confer instability on the tumor cell genome, thus increasing the frequency of further mutational events within such cells.

In some circumstances, these findings are already being applied usefully in clinical diagnosis and prognosis, and new therapies are beginning to be developed, targeting specific genetic alterations in particular neoplasms. At the same time, the enormous amount of new information about normal and abnormal growth regulation has made it clear that no single answer to cancer will be forthcoming and that our clinical progress in dealing with this disease will necessarily be incremental.

The following sections summarize the current state of knowledge about tumor molecular and cell biology.

GROWTH REGULATION IN NORMAL AND NEOPLASTIC CELLS

NORMAL GROWTH REGULATION

Many aspects of growth regulation in normal cells are summarized in [Chapter 4](#); however, before considering neoplastic growth, it is important to reiterate just how much has been learned about the complexity of normal growth-regulatory mechanisms. Although efforts continue to define common pathways, significant differences exist among various types of normal cells as well as a wide spectrum of alternative pathways and redundancies within every cell. We have characterized numerous stimulatory and inhibitory local growth factors, such as epidermal growth factor, platelet-derived growth factor, and transforming growth factor- β , and we continue to learn more about the growth-modulating effects of circulating hormones. Specific receptors have been identified for these various growth-regulatory molecules—many on the cell surface and some within the cytoplasm or nucleus. Researchers have also characterized a variety of kinases and other second messengers that transmit receptor-mediated signals from the cell surface to the nucleus, often through several intermediary proteins. Additional regulatory proteins have been identified in the nucleus, transcription factors that directly interact with DNA and other proteins that represent a further intermediary in the signaling pathway.

Besides the multiple steps involved in triggering a cell to enter the cell cycle and ultimately divide, and inhibitors of these signals, there are a variety of proteins that regulate progression through every phase of the cell cycle and significantly influence cellular proliferation in different organs. Moreover, within the broad context of maintaining homeostasis, considerable information has been developed about genes and proteins involved in signaling cells to enter pathways alternative to cell division, specifically terminal differentiation or programmed cell death (apoptosis). For example, retinoic acids play a key role in signaling certain cells to leave the cell cycle and terminally differentiate, and other proteins, such as *BCL2* and *P53*, are important regulators of apoptosis in many cell lineages.

ABNORMAL GROWTH REGULATION IN NEOPLASIA

Since the mid-1980s, molecular studies in many different human tumors have indicated that alteration in the function of growth-regulatory genes, with or without structural change in the gene, is the mechanism whereby nearly all tumors are initiated and by which their clonal expansion progresses. These genes may code for proteins involved in *growth-stimulatory pathways* (and in their altered state are often called *oncogenes*) or may act within *inhibitory pathways*, such that loss of function results in abnormal growth. The latter genes have been termed *tumor suppressor genes*.

A number of these stimulatory and inhibitory “cancer genes” have been identified in a variety of human tumors, and the proteins for which they code function at every level of the growth-regulatory pathways. There are several examples in human malignancies of genetic changes leading to altered production of a stimulatory or an inhibitory growth factor, with resultant effect on proliferation through autocrine mechanisms. Even more common are changes in the structure or expression of growth factor receptors as a result of mutation or amplification of genes, such as *EGFR* (previously designated *ERBE*) and *ERBB2*. Aberrant regulatory signals transmitted by these modified receptors appear to play an important role in the pathogenesis of many common epithelial malignancies, including those of the breast and lung.

Similarly, mutations in second messengers, such as the RAS family of proteins and the NF1 gene product, have been demonstrated in a significant proportion of human tumors, also contributing to their altered growth. Particularly within the nucleus, a large number of gene products that either bind directly to DNA or interact with such proteins have been shown to be altered either in structure or expression in many human malignancies. These include both stimulatory molecules, such as *MYC*, and those that have an important growth inhibitory function, such as *RB1* and *P53*.

A few of the better characterized human cancer genes are listed in [Table 20.1](#), with an indication of their function or functions and the associated tumors. Although a few of the genes known to be important in human cancer were originally identified from experimental studies with RNA tumor viruses (e.g., *MYC*, *RAS*, *ABL*, *EGFR*), nearly 100 additional human cancer genes have been recognized through other investigative approaches. Most of these previously unknown growth-regulatory loci are not shown in [Table 20.1](#), in part because their oncogenic effect is often limited to a specific cell type or stage of differentiation so that each is typically associated with only a very small subset of human malignancies.

Gene	Function	Tumor
<i>EGFR</i>	Growth factor receptor	Carcinomas
<i>ERBB2</i>	Growth factor receptor	Carcinomas
<i>RAS</i>	Cytoplasmic signaling	Diverse tumors
<i>NF1</i>	Cytoplasmic signaling	Neural tumors
<i>ABL</i>	Cytoplasmic signaling	Leukemia
<i>MYC</i>	Regulates transcription	Diverse tumors
<i>RB1</i>	Regulates transcription	Diverse tumors
<i>P53</i>	Multiple	Diverse tumors
<i>BRCA1</i>	Multiple	Breast carcinoma
<i>RARA</i>	Differentiation	Leukemia
<i>BCL2</i>	Apoptosis	Lymphoma
<i>MSH2</i>	DNA repair	Colon carcinoma

TABLE 20.1. SOME HUMAN CANCER GENES

Furthermore, in addition to this complexity, at least five to ten different oncogenes and tumor suppressor genes appear to be usually altered in every fully developed cancer, and there is also evidence that genes substantially involved in differentiation, such as the retinoic acid receptor- α (*RARA*), or in apoptosis, such as the *BCL2* gene family, are frequently defective in certain tumors and contribute to the expanding clonal mass. Also under investigation is telomerase activity in many tumors, which may be prolonging cell survival by preventing normal chromosome telomere shortening.

The mutagenic agents that mediate these critical genetic events in human tumor cells, such as ionizing and ultraviolet radiation as well as a variety of chemicals, are discussed in detail in other chapters. Similarly, the inherited gene defects that contribute to this process in a proportion of both childhood and adult tumors are covered elsewhere. It is worth noting, however, that we are increasingly aware that many of these mutations involved in human cancer do not necessarily represent the effects of genotoxic agents in the environment or of inherited genes. Often, particularly in older persons, they may simply represent the accumulation of spontaneous errors in DNA replication or repair that occur in all of our tissues throughout life. Also, inflammatory processes and other types of nonspecific injury that generate in our tissues both increased mitotic activity and endogenous mutagenic agents, such as oxygen radicals, may be important contributory factors.

The specific types of alterations that occur in our growth-regulatory genes and lead to tumor development are also variable. Where there is a structural change in the genome, involving gains or losses of all or part of a chromosome or translocations between chromosomes, many of these alterations are visible at the level of the light microscope. In hematopoietic tumors, for example, several dozen specific reciprocal translocations that characterize different subgroups of leukemias and lymphomas have been identified. Typically, these involve the translocation of a growth-regulatory gene into association with a gene on another chromosome, with resultant critical alteration in function. There may be a structural change in the growth-regulatory gene, as in the formation of a fused *BCR/ABL* locus from the translocation between chromosomes 9 and 22 that characterizes chronic myelogenous leukemia, or aberrant expression, as when an intact *MYC* gene is translocated next to a transcriptionally active immunoglobulin locus in the t(8:14) translocation of Burkitt's lymphoma.

In many of the common solid tumors, such as carcinomas of the lung, breast, and colon, there are frequently *deletions* of particular chromosomes, some of which have been shown to involve a loss of function of specific tumor suppressor genes, such as *RB1* or *P53*, within the tumor cell. In some neoplasms, amplification of a critical oncogene, such as *MYC* or *ERBB2*, in which the gene is duplicated many times with resultant overexpression, is also visible as a karyotypic abnormality.

Of course, many circumstances exist in which the alterations in cancer genes are submicroscopic. With the *RAS* gene family, for example, these usually involve point mutations, and this is also true in some circumstances as a mechanism for loss of function of *P53*. Submicroscopic deletions and other types of rearrangements have been demonstrated by molecular techniques, resulting in alteration of oncogene or suppressor gene function. In a few cases, some potentially reversible changes in gene function, resulting, for example, from altered methylation of particular DNA sequences, appears to play an important role in the multiple genetic events leading to the full development of colon cancer and other malignancies.

The introduction of foreign genetic material by a *tumor virus* is a relatively unimportant aspect of human carcinogenesis. The concept of oncogenes was first developed in experimental systems in which it was shown that an RNA tumor virus could introduce an altered mammalian or avian gene into a normal cell and initiate neoplasia. However, this mechanism does not appear to be a significant factor in human malignancy, and many of the important human growth-regulatory genes (e.g., *SRC*, *SIS*, *JUN*, *FOS*) originally identified in these viral studies appear to have little, if any, direct involvement in human tumors.

Most viruses associated with human cancer, such as the Epstein–Barr virus in B-cell tumors and the hepatitis B virus in liver cancer, act primarily by causing nonspecific cell damage, stimulating polyclonal hyperplasia of the target tissue. Only when other mechanisms lead to a specific mutation in one of these hyperplastic cells, such as the t(8:14) translocation in a B lymphocyte, does a clonal neoplasm develop. The papilloma family of DNA viruses does appear to initiate human genital tumors by introducing viral genes (e.g., *A6*, *A7*) into the recipient cells, but the products of these genes do not appear to act directly within a growth-stimulatory pathway, as with the classic RNA virus oncogenes, but rather by interacting with and down-regulating the function of the protein products of cellular tumor suppressor genes, specifically *RB1* and *P53*.

It is now clear that many different genes and mechanisms are involved in the specific growth-regulatory defects and related cellular alterations that ultimately lead to the development of an expanding clonal mass that we identify in humans as a neoplasm.

EFFECTS OF ALTERED GROWTH REGULATION

The actual rate at which a tumor enlarges, like every other aspect of neoplastic development, is the result of a number of different factors. First, the initial mutated cell must divide for its acquired growth advantage to be significant. If the mutated cell is in an actively proliferating population, this occurs promptly; but in a tissue such as the liver, kidney, or prostate, there may be a lengthy period before some nonspecific growth stimulus, such as injury, inflammation, or a hormonal change, triggers mitotic activity. This aspect of tumorigenesis, sometimes called *promotion*, is one factor in the long *latent period* frequently observed between exposure to a known carcinogen and the subsequent appearance of a clinical neoplasm.

After the tumor begins to grow, its rate of expansion is primarily determined by the proportion of cells that are in the cell cycle (“growth fraction”), rather than by any change in the length of the cycle itself. The growth fraction at any stage of tumor development is the result of the combined effects of the various specific genetic changes in that particular neoplastic clone.

Although it is common to refer to cancer as uncontrolled growth, most tumors, in fact, remain responsive to some degree to normal growth-regulatory mechanisms. For the clone to begin expanding, it requires only enough alteration in responsiveness to allow a slightly increased proportion of the cells to remain in the cycle and gain a selective growth advantage over adjacent normal cells. In early stages, this advantage may be small enough that local changes in growth factors or other regulators could lead to tumor regression. Later, with the acquisition of additional genetic changes over time within the clone, most neoplasms become decreasingly responsive to normal growth regulation, have an increasing growth fraction, and expand more rapidly.

Other variables also contribute, of course. In addition to a change in response to signals for cell cycling as such, altered signals for differentiation or for apoptosis may also help to determine the number of viable cells within the clone over time. In some circumstances, as in certain slow-growing lymphoid tumors, a lack of apoptosis, resulting from overexpression of the *BCL2* gene, appears to be a much more important factor in the slowly expanding neoplastic clone than an increase in cellular proliferation.

Another extremely important variable, and one that is extracellular, is the ability of the expanding tumor mass to stimulate an adequate blood supply. Tumors that successfully grow and metastasize often secrete increased amounts of various angiogenic factors (e.g., VEGF, bFGF) that stimulate the development of new microvasculature to provide sufficient oxygenation for the neoplasm. It is a common observation, in fact, that rapidly growing tumors outstrip their blood supply and may be largely a mass of dead and dying cells, except at the periphery. Just as with the genes and proteins involved in altered growth regulation, the actual rate at which a tumor mass expands either locally or at a metastatic site is typically the result of many variables.

TUMOR PROGRESSION AND HOST RESPONSE

Many tumors have a tendency to demonstrate much more aggressive growth over time, both locally and at distant sites. Histologically, this is frequently associated with greater loss of differentiation in the tumor cells, often accompanied by more mitotic activity and nuclear atypia. It has also been demonstrated that some tumors at this late stage of development show decreased antigenicity and evoke less of a host immune response.

Many of the clinical and biologic characteristics that commonly emerge during the course of human tumors have long been recognized and collectively termed *tumor progression*. Molecular studies since the mid-1980s have demonstrated that this phenomenon of progression results from *clonal evolution* within the neoplasm, with the accumulation of sequential genetic alterations and the selection of subpopulations with more and more aggressive characteristics ([Fig. 20.1](#)). Typically, a number of subclones continue to coexist in every advanced tumor, accounting for the *heterogeneity* of many properties that is commonly observed. The subclones that come to predominate in a particular patient represent the effect of those specific mutations that allow the cells to grow most effectively in that individual and to resist immunologic, therapeutic, and other inhibitory pressures that may be generated by the host and the physician.

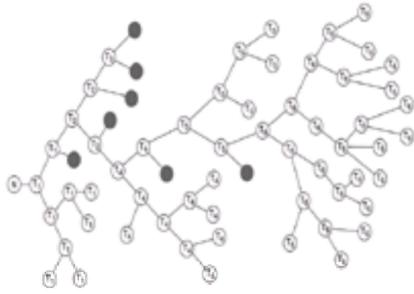

FIGURE 20.1. Model of clonal evolution in neoplasia. A normal cell (N) is converted to a tumor cell (T_1) by mutation in one or more growth-regulatory genes. As the resultant clone expands, additional mutations occur, some lethal (*solid circles*) and some generating subclones (T_2 – T_6) with more aggressive biologic and clinical properties. The fully developed malignancy is heterogeneous (coexisting subclones) and has multiple genetic changes in the predominant subclones.

Such a sequence of events in a common human cancer has been best documented in *adenocarcinoma of the colon*. In these tumors, using a combination of molecular and cytogenetic techniques, Vogelstein and others demonstrated a series of stepwise genetic alterations associated with the progression from benign colonic polyps to early and late stages of malignancy. For example, they found mutations in a *RAS* oncogene and deletion of a previously unknown tumor suppressor gene, called *APC*, often associated with early lesions, and then, in addition, deletions of two other suppressor genes, *P53* and a newly identified locus called *DCC*, in advanced carcinomas. Although even more genetic changes are usually present and still remain to be defined fully, these findings suggest that the *RAS* and *APC* alterations play an important role in the development of the benign adenomatous polyps, with the loss of *P53* and *DCC* contributing to the subsequent acquisition of more aggressive malignant properties, including the capacity to invade and to metastasize.

Similar sequences of events, involving some of the same genes as well as different genes, are being defined in other common cancers, such as those of the breast and lung. The most critical of the later alterations in terms of clinical significance are those that contribute to local invasion and to the development of distant metastases.

INVASION AND METASTASIS

Studies have indicated that more than half of solid tumors (excluding carcinomas of the skin) have metastasized by the time they are clinically apparent. This represents the most important aspect of tumor progression. Much has been learned concerning the biology and biochemistry of invasion and metastasis, and some of the specific genes directly involved in these phenomena in particular neoplasms are beginning to be identified.

From a variety of studies, it is possible to define rather precisely a sequence of events involved in those malignant properties. The first step involves separation of the neoplastic cells from the primary mass and, in the case of epithelial tumors, the successful invasion of the underlying basement membrane. The cells can then expand within the adjacent extracellular matrix and invade thin-walled vessels—both lymphatics and veins. In many tumors, these early steps involve alterations in cellular adhesion as the result of changes in a variety of membrane proteins (e.g., E-cadherins, laminin receptors, integrins) and the generation by the tumor cells of a spectrum of proteolytic enzymes (e.g., collagenases, cathepsin B) that permit them to move through cellular and matrix barriers. As with all of the changes associated with invasion and metastasis, such alterations do not represent gains or losses of proteins unique to tumor cells but simply quantitative differences in the amounts being produced, with resultant critical biologic effects. Some of the efforts to control cancer through dietary means have involved agents such as vitamin C and protease inhibitors, which might limit invasiveness by strengthening the extracellular matrix or blocking tumor proteases.

The next step in the systemic dissemination of tumor cells involves moving through circulatory pathways until arrested by a distant capillary bed or comparable microvasculature. There has been much debate over whether the location of metastases is simply a matter of mechanical distribution within the lymphatics and circulatory systems or if certain characteristics of the tumor cells and of the sites where tumor emboli are arrested determine whether metastasis is successful. Current knowledge indicates that both factors are important. Most tumor emboli lodge in lymph nodes or in the first capillary bed that they reach through the venous system. However, there is evidence that not only certain surface molecules but also clotting factors and local growth factors (e.g., insulin-like growth factors) that are associated with particular types of tumor cells and with certain capillary beds may play an important role in the arrest and establishment of a metastatic embolus at a particular location.

Fortunately, most tumor cells that enter the circulation appear to lack the additional characteristics necessary for survival and growth after they arrive at a distant site. Among the properties that have been identified as particularly important to the tumor embolus at this stage of metastasis is the secretion of one or more angiogenic factors (as already mentioned with respect to primary tumors), which are necessary for the local stimulation of endothelial proliferation and the development of new blood vessels to support the nascent metastasis. Also, as with the initial invasion adjacent to the primary tumor, the ability of the embolic tumor cells to grow effectively in their new location depends in part on the secretion of various proteolytic enzymes, such as type IV collagenase, to allow successful escape from the arresting microvasculature and movement into the parenchyma of the lung, liver, or other metastatic site.

A few specific genes that appear to contribute most substantially to this phenomenon of invasion and metastasis have been identified. One is *NM23*, a metastasis-suppressor gene that appears to regulate a number of other genes. Extensive additional studies are underway.

METABOLIC CHANGES IN TUMOR PROGRESSION

Despite repeated efforts, no specific metabolic alteration consistently associated with all cancers has been identified. This is no longer surprising in view of the large number of genes that have been identified as being involved in the development of many different kinds of malignancy. It has long been recognized, however, that as the process of progression occurs, with general reduction in the proportion of differentiated cells within the tumor mass, there does tend to be convergence in the metabolic characteristics of many different cancers. This reflects the metabolic pathways common to actively dividing cells, as opposed to the more variable patterns associated with differentiated populations.

It is true that some neoplasms retain a sufficient degree of differentiation to produce large quantities of specific cellular products (e.g., hormones, epinephrine), which can have clinical effects in the patient, but this is usually associated with relatively early tumors rather than with late-stage malignancies.

In the later stages of tumor progression, as both primary and metastatic tumors grow more aggressively, the tumors often outgrow their blood supply. Not surprisingly, clonal evolution under these circumstances results in the selection of viable subpopulations that are best able to survive in a low-oxygen environment, and increased anaerobic glycolysis is frequently a property of the cells of rapidly growing cancers. At one time, this was thought to represent a specific characteristic of the malignant state, but it is now recognized as another manifestation of the clonal evolution phenomenon.

The same is apparently true of the tendency of many tumors in the later stages of progression to develop drug resistance, particularly after exposure to various therapeutic agents. This also appears to result from the outgrowth of specific subpopulations within the neoplastic clone, in this case under the selective pressure of the particular chemotherapeutic agents being used. The resistant populations have been shown to overexpress one or another drug-resistance genes, often by gene amplification, and, through an effect on the transport or metabolism of particular chemotherapeutic agents, allow a subset of malignant cells to survive and regrow within the patient.

ANTIGENICITY AND THE HOST IMMUNE RESPONSE

A similar phenomenon also appears to prevail with respect to the immunogenicity of many advanced tumors. Since the mid-1950s, through studies in both human populations and experimental animals, it has been extensively demonstrated that neoplasms do evoke a specific immune response from the host and that, through a phenomenon of *immune surveillance*, many incipient tumors are presumably successfully eliminated in healthy persons. Conversely, when a person is in a depressed

immune state, either congenital or acquired, tumors grow more readily.

Although many details remain unclear, it appears that most so-called tumor antigens are also present on some normal cells and are only recognized by the host as foreign because of inappropriate location or quantity. A few unique tumor antigens may exist; these are protein products of specific genetic alterations limited to the neoplastic cells. Most tumor-associated antigens are cell-surface proteins, and the host response is similar to that generated against histologically incompatible foreign tissues.

The immune response directed against tumors is primarily T-cell-mediated, with relatively less effect from antitumor antibodies. There is also a subpopulation of small lymphocytes, the natural killer cells, which represent an additional means by which the host generates a cytotoxic effect on tumor cells—in this case one that is immunologically nonspecific. In these various complex pathways, other host cells (e.g., macrophages) and cell products (e.g., interferon, tumor necrosis factor) can also play a critical role.

Unfortunately, with tumor progression, the host's success in controlling the neoplasm through these immunologic mechanisms is frequently reduced. Often, this seems to reflect still another aspect of clonal evolution: the selection of subpopulations that have reduced antigenicity or inhibitory effects on the host response. Some of the difficulties encountered in attempting to develop successful therapeutic approaches to human cancer through immunologic techniques undoubtedly stem from this remarkable ability of the evolving tumor to select for subpopulations that can successfully evade the host's attempts at regulation.

GENETIC INSTABILITY IN TUMOR PROGRESSION

A final aspect of the molecular and cellular biology of neoplasia that plays an important role in the phenomenon of tumor progression is the apparent genetic instability of many neoplastic cell populations. The sequential acquisition of genetic alterations during tumor development seems, in many circumstances, to reflect an increased probability of mutational events in the neoplastic cells compared with normal cells. As with other aspects of tumorigenesis, this appears to result from multiple mechanisms. In the late stages of progression, it is not surprising that cells that have already acquired major cytogenetic alterations may frequently undergo further errors in the course of mitosis. In earlier stages, the mechanisms are not as readily apparent.

It has been postulated that, either as an inherited defect or as an acquired mutation early in tumor development, essentially every neoplastic clone has some abnormality in DNA synthesis, DNA repair, or some other aspect of DNA "housekeeping" that results in increased mutability. A number of candidate *mutator genes*, both inherited and acquired, have been identified in different human tumors. For many years, it has been recognized that the greatly increased risk of cancer associated with certain inherited disorders, such as xeroderma pigmentosum and various chromosomal fragility syndromes (e.g., ataxia telangiectasia, Bloom's syndrome, Fanconi's anemia) results from constitutional defects in various genes necessary for the maintenance of DNA integrity. This concept has now been extended to include a number of genes (e.g., *MSH2*, *MLH1*, *PMS1*, *PMS2*) involved in DNA "mismatch" repair that have been shown to be defective in families prone to hereditary nonpolyposis colorectal cancer. Mutations in several of these genes also have been demonstrated in a variety of sporadic epithelial malignancies, indicating that acquired inactivation of these loci probably represents a basis for the *mutator phenotype* in some nonfamilial human tumors.

Also important is the loss of *P53* gene function, which occurs commonly in almost all types of sporadic human malignancies and is associated, as an inherited defect, with multiple familial cancers in the rare inherited disorder called the Li-Fraumeni syndrome. One normal role of the p53 gene product is to prevent genetically damaged cells from progressing through the cell cycle, and in its absence, the accumulation of such errors is greatly enhanced.

There is still much to be learned about the variety of genes and mechanism that increase the probability of genetic errors occurring and being maintained in tumor cell populations, but enough information has been acquired to support the view that such mutator genes and their defects are of major importance in tumor progression.

Our knowledge is rapidly increasing concerning the complexity of normal growth regulation and how it can be altered in a variety of ways to contribute to the development of an expanding cell clone that we recognize clinically as a tumor. Information is also accumulating on the molecular alterations that lead to the biochemical and biologic changes that allow neoplastic cells to invade and to metastasize successfully, the most critical aspect of the malignant state. And we are beginning to learn more about the molecular mechanisms that make tumor cells more genetically unstable than their normal counterparts and so are more likely to acquire the spectrum of genetic alterations necessary for the full development of the malignant phenotype. All of this information is stimulating a wealth of new approaches to the prevention, diagnosis, monitoring, and specific therapy of human cancer, and a number of these encouraging developments are discussed in other chapters. It is also clear, however, from our current understanding of the biologic and molecular aspects of human cancer cells, that no single, simple answer to the ultimate control of this disease should be expected.

CHAPTER 21: EPIDEMIOLOGY OF MALIGNANT DISEASE

DAVID SCHOTTENFELD

[Magnitude of Cancer](#)
[Age at Diagnosis](#)
[Cancer and United States Racial and Ethnic Minority Groups](#)
[Social Inequalities and Cancer Patterns](#)
[Epidemiologic Perspective](#)

MAGNITUDE OF CANCER

Cancer is the second leading cause of death in the United States, accounting in 1994 for 534,000 deaths (280,465 in men and 253,845 in women). In 1973, cancer was certified as the underlying cause in 17.7% of all deaths. Although cardiovascular disease mortality continued to decline after 1973 as a competing cause of death, the proportion of all deaths attributed to cancer increased to 23.4% in 1994. An estimated 1,257,800 incident cancer cases occurred in 1997 (about 661,200 occurring in men and 596,600 in women), or a cancer case:death ratio that exceeded 2.0. The estimation of total annual incidence does not include the more than 1 million persons diagnosed with basal cell or squamous cell carcinoma of the skin. Four organ sites—lung and bronchus, colon and rectum, breast, and prostate—accounted for 56% of all incident cancer cases and 53% of all cancer deaths. Based on US mortality and incidence rates for 1992 to 1994, the lifetime probabilities of developing cancer have been estimated to be 46.6% in men and 38.0% in women; the lifetime probabilities of dying of cancer have been estimated at 23.9% in men and 20.6% in women.

Incidence measures the rate of occurrence of newly diagnosed cancer cases over a specified time interval, for example, in 1 year. Similarly, *mortality* is an incidence measure of cancer deaths occurring in a population over a specified time interval. *Prevalence* is a cross-sectional measure of frequency based on the number of existing cancer cases in patients diagnosed in the past and surviving to the point in time of interest. Prevalence is a useful indicator of the impact of cancer on the health care resources in a population. In a population-based survey of adults aged 18 years and older in the United States in 1987, the prevalence of cancer (excluding nonmelanoma skin cancers) in women was estimated to be 4,402 per 100,000 and in men, 1,930 per 100,000. From the sample survey, it was projected that in 1987 there were 5.7 million adults (3.3% of the adult population) who were cancer survivors. The survey also determined that in 1.6% of the adult population with a history of cancer, the cancer had been diagnosed in persons under 15 years of age; the percentage distribution of prevalent cases by age at diagnosis increased with increasing age so that 22% had been diagnosed at age 65 and over.

Increasing incidence rates of site-specific cancers or advances in cancer treatment will almost certainly increase future cancer prevalence rates. Based on cancer incidence and survival rates from the Connecticut Tumor Registry, the prevalence of cancer survivors in the United States was projected to be 8.25 million in 1998. Of this total, patients with breast (24.4%), colorectal (15.0%), and prostate (12.1%) cancers accounted for at least 50% of persons diagnosed and surviving with cancer.

From 1973 to 1990, cancer incidence and mortality rates in the United States for all sites combined have increased by approximately 1.1% and 0.4% per year, respectively. Over the 18-year interval, incidence increased 18.3% and mortality increased 6.7%. The all-cancer mortality rate peaked in 1990, after which it declined on average, from 1990 to 1995, at the rate of 0.6% per year. Forty percent of the decline in the cancer mortality rate was due to a reduction in lung cancer mortality.

AGE AT DIAGNOSIS

In 1994, the percentage of all deaths due to cancer in the US population under age 65 was 26%, which exceeded that attributed to heart disease (20%). For persons aged 65 and over, the proportion attributed to heart disease (37%) exceeded that due to cancer (23%). During the period 1973 to 1990, the average annual percent change in mortality due to cancer at all sites in persons 35 to 64 years decreased 0.6%; in the subsequent 5-year period (1990 to 1995), the average annual decrease was 1.6%. In the population of those 65 to 74 years of age, who currently experience 31% of cancer deaths (Fig. 21.1), the average annual percent change in cancer mortality was an increase of 0.8% during 1973 to 1990 and thereafter a decrease of 0.1% per year.

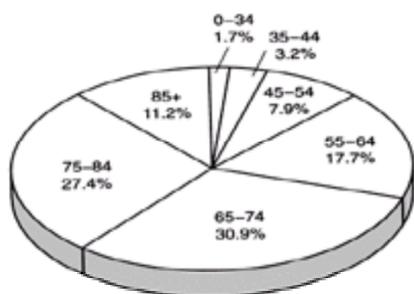

FIGURE 21.1. Percent of cancer deaths in the United States by age group, all sites, 1990–1994. (From SEER Cancer Statistics Review, 1973–1994, with permission.)

Major site-specific increases in cancer incidence in those under 65 years of age during 1973 to 1994 were due to prostate, melanoma, non-Hodgkin's lymphoma, lung (female), testis, liver (including intrahepatic bile duct), kidney and renal pelvis, and thyroid (female) cancer. Concurrently, there were significantly decreasing incidence trends for cancers of the larynx, stomach, pancreas, cervix uteri (invasive), and corpus uteri. For the subgroup 65 years and older, the significantly increasing cancer incidence trends were exhibited for melanoma, non-Hodgkin's lymphoma, and lung (females), prostate, brain, kidney and renal pelvis, liver (including intrahepatic bile duct), breast, thyroid, and esophagus cancer. Significantly decreasing trends were demonstrated for Hodgkin's lymphoma, stomach, and cervix uteri (invasive) cancer.

An estimated 8,000 children under 15 years of age, less than 1% of total cancer incidence, were diagnosed with cancer in the United States in 1994. The average annual incidence of all cancers in children in 1990 to 1994 was 13.8 per 100,000. The three most common types of cancer in infants under 1 year of age were neuroblastoma (27%), central nervous system tumors (15%), and leukemias (13%). The incidence among white children (14.3 per 100,000) exceeded that in black children (13.0). The most common cancers in children were the leukemias (3.8) and neoplasms of the brain and autonomic and peripheral nervous systems (3.3). This pattern was altered in the 15- to 19-year age group, in whom Hodgkin's disease (3.6) and testicular cancer (3.2) superseded neoplasms of the brain (2.1) as well as the leukemias (2.5). The age-adjusted incidence of primary malignant brain tumors in children increased by 35% during 1973 to 1994. The brain stem and cerebrum were the sites in which the reported incidence increased, in particular, for low-grade gliomas. The observed increase in incidence may have been due to changes in imaging detection practices after 1980. Childhood cancer mortality rates have declined substantially between 1973 (5.5 per 100,000) and 1994 (2.8 per 100,000), particularly for the leukemias, Hodgkin's and non-Hodgkin's lymphomas, and soft-tissue sarcomas. There were 1,571 cancer deaths certified among children in 1994, which represented 10.3% of total deaths; accidents were the leading cause (39.5% of total deaths).

CANCER AND UNITED STATES RACIAL AND ETHNIC MINORITY GROUPS

The average annual age-adjusted cancer incidence, including all sites combined, among African Americans was 11% higher than among whites from 1990 to 1994, but this was due to the 26% higher age-adjusted incidence in African American males. The age-adjusted incidence in African American females was slightly lower (3%) than that in white females. However, African American males and females experienced higher risks of dying of cancer, 49% and 20%, respectively. A major determinant of the elevated cancer mortality rate in African American women was that overall 5-year relative survival rate for persons diagnosed during 1986 to 1993 was significantly lower (47.9%) than that estimated for white women (62.3%). The increased mortality in African American men may be attributed to increased incidence density or risk and inferior survival. Individual sites that involved significant risks for the African Americans included cervix uteri, esophagus, larynx, liver

and intrahepatic bile duct, non–small cell lung, multiple myeloma, oral cavity and pharynx, pancreas, prostate, and stomach. It is also instructive to note those sites and cancer types for which African Americans had a significantly reduced risk: corpus uteri, melanoma, non-Hodgkin's lymphoma, ovary, testis, thyroid, and urinary bladder (Table 21.1).

Site	White	African American	Hispanic	Chinese	Japanese	Native American (New Mexico)
Men						
Prostate	18.7	90.6	89.0	46.0	88.0	32.5
Lung and bronchus	15.8	13.8	11.8	21.7	42.8	14.8
Colon and rectum	15.1	48.7	38.3	48.8	44.7	18.6
Urinary bladder	17.7	11.2	11.8	10.0	13.7	1
Non-Hodgkin's lymphoma	18.7	13.2	14.3	12.4	11.6	1
All sites combined	48.9	56.0	39.9	29.2	32.2	19.6
Women						
Breast	11.7	16.4	19.8	10.0	12.0	21.4
Lung and bronchus	11.8	44.2	19.8	21.1	11.2	1
Colon and rectum	11.2	45.5	28.7	30.8	28.5	11.8
Cervix uteri	11.8	14.4	11.7	11.8	14.5	11.7
Ovary	14.2	11.2	11.1	8.3	16.7	11.5
All sites combined	38.8	32.8	31.8	27.0	28.7	18.6

TABLE 21.1. COMPARISON OF FIVE MOST FREQUENTLY DIAGNOSED CANCER SITES IN UNITED STATES WHITES WITH INCIDENCE^a IN OTHER RACIAL AND ETHNIC GROUPS, 1988–1992

Variations in cancer incidence patterns by race or ethnicity are providing environmental and genetic clues for the epidemiologic and experimental pursuit of complex causal mechanisms. For men, overall cancer risks were highest among African Americans, followed by non-Hispanic whites, Hispanics, and Japanese Americans, whereas for females, the rates were highest for non-Hispanic whites and African Americans. Chinese Americans experienced elevated rates of cancers of the nasopharynx and liver, whereas Japanese Americans had a higher risk of cancers of the stomach and colon (comparable to the rate in non-Hispanic whites). Native Americans experienced about 50% of the overall cancer incidence of non-Hispanic whites but were distinguished by elevated rates of cancers of the liver and bile ducts, gallbladder, stomach, ovary, and cervix uteri.

SOCIAL INEQUALITIES AND CANCER PATTERNS

Poverty and social inequalities may confound patterns of cancer incidence and mortality attributed to racial or ethnic characteristics. Namely, social inequalities may influence access to or quality of medical care; knowledge, attitudes, and behavior with respect to screening and early detection practices; and the distribution of lifestyle risk factors. Studies of social class and health status in industrialized countries have demonstrated in general that persons in the lowest socioeconomic level, as measured by education, income, and occupation, when compared with those in the highest level, incur shorter average life expectancy, higher prevalence of comorbid conditions, and unfavorable distribution of cancer site-specific prognostic factors. The opportunity for providing cost-effective preventive services in the medical care setting appears to be achievable, but consideration is needed of the social context of health and illness and of how to overcome economic, cultural, and medical care systemic barriers.

Social class difference may determine cancer incidence patterns in that the prevalence of consumption of tobacco products and alcoholic beverages, dietary practices, and sexual and reproductive behavior may be highly correlated with socioeconomic status. For men in lower social strata, international studies have described excess risks for respiratory (larynx and lung) and upper digestive (including oral cavity, pharynx, stomach, and esophagus) cancers; for women in lower social strata, excess risks are for uterine cervical cancer. For persons in higher social strata, excess risks have been observed for cancers of the colon, brain, breast, endometrium, and ovary and for melanoma of the skin.

EPIDEMIOLOGIC PERSPECTIVE

The year 2000 objectives of the US National Cancer Institute are focused on cancer prevention and control that will achieve substantial reductions in cancer incidence, mortality, and morbidity. Total eradication of cancer by curative and preventive interventions would ultimately result in a gain of about 2.5 years in average life expectancy in the general population. However, for the approximately one in four adult Americans who would have died of cancer, the average gain in life expectancy would be approximately 15 years and would range from 9 years for patients dying of prostate cancer to 36 years for the young adult patients dying of testicular cancer (Fig. 21.2).

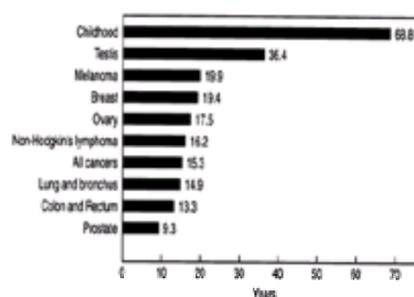

FIGURE 21.2. Average years of life lost from cancer by type of cancer, United States, based on 1990 life tables. (From SEER Cancer Statistics Review, 1973–1994, with permission.)

The discipline of cancer epidemiology provides the foundation for targeting and assessing cancer prevention and control priorities and practices. Compelling epidemiologic data indicate that a substantial proportion of cancer mortality and morbidity can be prevented, or postponed, by lifestyle choices such as avoiding tobacco products, limiting consumption of alcohol and exposure to ultraviolet radiation, consuming optimal amounts of fresh fruits and vegetables, and controlling dietary energy consumption while increasing physical activity. Globally, infectious agents, such as Epstein–Barr virus (lymphomas and nasopharyngeal carcinoma), hepatitis B and C, human papillomaviruses (anogenital tract cancers), HIV (Kaposi's sarcoma, non-Hodgkin's lymphoma), *Helicobacter pylori* (cofactor in stomach cancer), *Clonorchis sinensis* and other liver trematodes, and *Schistosoma haematobium* (urinary bladder cancer), probably account for 10% to 15% of cancer deaths, which eventually may be avoided by antimicrobial therapy or immunization, as well as targeted surveillance and early detection in high-risk populations. Although 5% to 10% of deaths due to cancer in industrial nations may result from exposures in the workplace, many of the chemical and physical agents currently viewed as environmental carcinogens were originally identified through epidemiologic studies in occupational settings. A relatively smaller proportion of cancers may be attributed to pharmaceutical agents, including sex steroidal hormones, but these established associations have generated important insights into mechanisms of cancer causation.

CHAPTER 22: PREVENTION OF NEOPLASIA

PETER GREENWALD

[Smoking and Cancer](#)
[Diet and Cancer](#)

Lifestyle factors such as tobacco use and diet are major contributors to cancer risk. Because these lifestyle factors can be controlled, they are a logical focus for cancer prevention strategies. Active participation in developing and carrying out such strategies by the medical community is critical to the success of cancer prevention. The involvement of physicians in recognizing emerging issues (e.g., the increased prevalence of youth smoking) and encouraging patients to undertake a healthier lifestyle (e.g., through adoption of a low-fat, high-fiber diet, decreased consumption of calories, and involvement in a regular exercise program) can result in clear benefits to the individual patient as well as to society.

SMOKING AND CANCER

Developing effective cancer prevention strategies aimed at reducing tobacco use is an enormous public health challenge. Although the total prevalence of smoking has declined in the United States over the past 30 years, tobacco use among adolescents is on the rise. Based on a 1995 survey, approximately 35% of all high school students smoke—an increase of 27% from 1991 through 1995. In the black community, the prevalence of teenage smoking doubled between 1991 (14%) and 1995 (28%). Cigarette smoking is responsible for about one-third of all cancer deaths in the United States. Lung cancer, attributable primarily to cigarette smoking, is the leading cause of cancer deaths among both men and women. Smoking also is a primary cause of cancers of the larynx, oral cavity, and esophagus and contributes to cancers of the pancreas, bladder, kidney, uterine cervix, and renal system. Moreover, consistent evidence indicates that household or occupational exposure of nonsmokers to environmental tobacco smoke (ETS) is associated with increased lung cancer risk. Although this increased risk is modest, the ubiquitous nature of ETS translates into a large number of persons at risk for lung cancer or other respiratory illnesses.

Recent studies indicate that smokers with specific polymorphisms of the *CYP1A1*, *CYP2D6*, *GSTM1*, or *Msp1* genes may have an increased risk of lung cancer compared with those without these genetic variants. Also, particular alleles of the D2 dopamine receptor (*DRD2*) may play a role in determining nicotine addiction and may thus predispose persons to smoke.

TOBACCO DEPENDENCE

More than 70% of smokers would like to quit, and 60% have tried seriously to do so. However, addiction to nicotine—present in all tobacco products—makes quitting difficult; 50% of smokers who have undergone major surgery for a tobacco-induced disease continue to smoke. Not all smokers exhibit the same degree of nicotine dependence. Increased physical dependence is indicated by a high number of cigarettes smoked per day; frequent smoking in the morning; and smoking while ill. Nicotine dependence must be given serious consideration when developing cancer prevention strategies related to tobacco use. Nicotine replacement therapies (NRTs) should be considered, along with adjuvant behavioral counseling, to facilitate smoking cessation. In an effort to make NRTs more accessible, the nicotine patch and nicotine gum were approved for over-the-counter (OTC) sale in 1996. The change from prescription to OTC use of NRTs resulted in more than twice as many persons attempting smoking cessation in 1997 as in 1995. In addition, nicotine nasal spray, a nicotine inhaler, and buprion hydrochloride are available as prescription medications to assist the smoker in quitting. All available pharmacotherapies appear equally effective; combining NRTs (e.g., patch and gum) may be more effective than either method alone.

ROLE OF PHYSICIAN IN SMOKING PREVENTION AND CESSATION

Smoking prevention and cessation may represent the best means of reducing the total cancer burden. The importance of the physician's role in these efforts cannot be overemphasized. At least 70% of smokers visit their primary health care provider at least once per year. A recent clinical practice guideline on smoking cessation recommends that every patient who smokes be provided smoking cessation treatment at every office visit. Indeed, patients who smoke expect their physician to inquire into their smoking habits and to advise them in cessation techniques. Studies indicate that 50% of all adult smokers started smoking by age 15, and 90% started by age 18. Thus, early intervention, focused on preteens and teenagers, is critical to reducing the prevalence of adult smoking. Physicians who care for children should anticipate the risk for tobacco use, ask about exposure to tobacco smoke and tobacco use, advise all smoking parents to stop smoking and all children not to use tobacco products, and assist children in resisting tobacco use.

The National Cancer Institute (NCI) has formulated recommendations for physicians, outlined in [Table 22.1](#), to help them institute smoking cessation techniques in their medical practices. These recommendations are discussed in a step-by-step handbook—*How to Help Your Patients Stop Smoking: A National Cancer Institute Manual for Physicians*—which includes resource lists, reprintable materials, and a special section, Clinical Intervention To Prevent Tobacco Use by Children and Adolescents. The handbook is available on the internet at http://rex.nci.nih.gov/PREV_AND_ERLYDETC/PREVED_MAIN_DOC.html. Additional information on smoking prevention, including items designed specifically for youth, is available at the Tobacco Information and Prevention Source (TIPS) Web page of the Centers for Disease Control and Prevention (CDC) at <http://www.cdc.gov/nccdphp/osh/>.

TABLE 22.1. SYNOPSIS FOR PHYSICIANS: HOW TO HELP YOUR PATIENTS STOP SMOKING

DIET AND CANCER

A considerable body of evidence supports the hypothesis that dietary factors play a major role in the determination of cancer risk. Illustrating this point are the significant international variations in the incidence of certain cancers as well as the increased risk observed when migrants from countries with a low-fat, high-fiber diet adopt a more Western (high-fat, low-fiber) diet. For colon cancer, the Western diet is associated with increased disease risk in both men and women, especially among those diagnosed before age 67 years. In contrast, consumption of the Mediterranean diet, which emphasizes vegetable, fruits, whole grains, fish, and olive oil (high in monounsaturated fatty acids [MUFAs]), is thought to be cancer-protective, particularly for the digestive and respiratory tracts.

Data from analytic and experimental studies also support a relation between increased intakes of vegetables and fruits, fiber and whole grains, and certain micronutrients and reduced cancer risk, whereas increased total caloric intake, body weight, and alcohol consumption are associated with greater risk. Overall risk of developing cancer, however, cannot be separated readily into individual contributions from specific components of diet and diet-related factors, such as body weight and exercise. All may interact to determine cancer risk. Individual genetic susceptibilities also may play an important role. To illustrate, among men who consumed more than one serving of red meat per day, those with rapid acetylator polymorphisms (*NAT1*, *NAT2*, or both) of the *N*-acetyltransferase gene were at increased risk

of colorectal cancer compared with men classified as nonrapid acetylators.

DIETARY FAT

Epidemiologic data suggest a relation between total fat intake or consumption of animal fat and increased cancer risk at several sites (e.g., endometrium, prostate, lung). The association between dietary fat and breast cancer risk is, however, uncertain. This is not surprising, considering that the effects of factors related to dietary fat, including caloric intake, weight gain, obesity, and physical activity, have a high probability of confounding the effect of dietary fat alone. Animal fat from red meat, particularly α -linolenic acid, is associated with an elevated risk of advanced prostate cancer, whereas consumption of polyunsaturated and vegetable fat may be protective. Red meat consumption, possibly independent of total or saturated fat intake, also may increase the risk of both colon and breast cancer. The production of carcinogenic heterocyclic amines in red meat is directly related to the amount of cooking. Data indicate that women consuming red meat at higher levels of doneness are at greater risk of breast cancer than women consuming red meat at lower levels of doneness.

Numerous studies indicate that the type of fat consumed is important to cancer risk. For example, polyunsaturated fats (corn oil, safflower oil, and others) rich in omega-6 fatty acids, primarily linoleic acid, act as tumor promoters in animals and have a direct association with postmenopausal breast cancer. *Trans* fatty acids also may increase breast cancer risk in postmenopausal women. Increasing evidence suggests that consumption of oleic acid—an MUFA that is a major component of olive oil—may decrease a woman's risk of breast cancer. The role of olive oil with regard to other cancers requires further research. Highly unsaturated omega-3 fatty acids, found primarily in fish oils, also may protect against certain types of cancer. The cancer-related effects of dietary fats may be linked to genetic factors. For example, increased consumption of MUFAs (as olive oil) is associated with a decreased frequency of *Ki-ras* wild-type colorectal tumors.

VEGETABLES, FRUITS, AND WHOLE GRAINS

The beneficial effects of vegetables, fruits, and whole grains may be a result of either individual or combined effects of constituents that include fiber, micronutrients, and nonnutritive phytochemicals. A review of more than 200 epidemiologic studies found that increased consumption of vegetables and fruits, particularly allium vegetables, carrots, green vegetables, cruciferous vegetables, tomatoes, total fruits, and citrus fruits, is protective for a variety of cancers. Furthermore, findings indicate that increased consumption of whole grains is associated with a decreased risk of colorectal, gastric, and endometrial cancers. Genetic factors also may influence the cancer-protective effects of plant foods. In one study, consumption of cruciferous vegetables exhibited significant protection against colorectal adenomas only in persons with a particular genetic variant of glutathione transferase.

FIBER

Epidemiologic studies generally endorse the cancer-protective properties of dietary fiber and fiber-rich foods, and some studies indicate that fiber may modulate the risk-enhancing effects of dietary fat. Dietary fiber consumption demonstrates a strong inverse correlation with colon cancer risk in most epidemiologic studies. Epidemiologic evidence regarding the protective effect of fiber consumption on breast cancer risk is mixed, but more rigorously designed studies indicate some beneficial effect, particularly at higher levels of intake.

The type of fiber consumed is important to cancer risk. In one study, the protective effect of fiber consumption against colorectal cancer was strongest for vegetable fiber and less strong for fruit fiber, with no benefit seen for grain fiber. Until more data are available, it is prudent to recommend consumption of a wide variety of vegetables, fruits, and whole grains.

MICRONUTRIENTS

Cancer-protective relations have been demonstrated for foods high in antioxidants (e.g., vitamin C, beta-carotene, vitamin E) as well as the micronutrients vitamin A, calcium, and folate. Epidemiologic studies consistently demonstrate a strong inverse relation between lung cancer risk and foods high in beta-carotene intake but this association could not be confirmed in large-scale clinical trials (discussed in Diet and Cancer Clinical Trials). Significant protective effects of foods containing vitamin C have been found for cancers of the stomach, esophagus, and oral cavity, and moderate protective effects have been found for cancers of the cervix, rectum, breast, and lung. Recent clinical trial data support a possible protective effect of vitamin E for colorectal and prostate cancer. Folate intake appears to be related to reduced risk of cervical and colon cancer, based on a limited number of studies. Although epidemiologic studies on selenium have been inconclusive regarding its potential cancer-protective effect, secondary end-point analyses in a recent clinical trial showed significant reductions in total cancer incidence and mortality as well as incidence of lung, colorectal, and prostate cancers for persons who received a daily 200 μ g supplement of selenium.

PHYTOCHEMICALS

Phytochemicals with demonstrated potential for inhibiting cancer include carotenoids, indoles, isothiocyanates, glucosinolates, dithiols, coumarins, terpenes, organosulfur compounds, plant sterols, flavonoids, protease inhibitors, and lignans. Although the exact mechanisms of action of many of these phytochemicals are not known, such inhibitors can be classified broadly as carcinogen-blocking compounds, compounds that suppress promotion, and antioxidants. For example, common vegetables and fruits contain approximately 50 carotenoids—a class of compounds that exhibits strong antioxidant activities. Lutein (a component of yellow and orange vegetables and fruits) and lycopene (a component of tomatoes and tomato-based foods) are exceptionally strong antioxidants. Findings from a large prospective epidemiologic study suggested that intake of lycopene and tomato-based foods may be particularly beneficial for reducing prostate cancer risk.

ALCOHOL

Alcohol intake is directly associated with cancers of the esophagus, oral cavity, pharynx, and larynx, in which alcohol acts synergistically with smoking to increase risk. Alcohol also may contribute to increased risk of cancer of the rectum and liver. A pooled analysis of cohort studies that examined incidence of alcohol consumption and breast cancer reported that risk increased linearly with increasing intake, for all types of alcoholic beverages consumed. For total alcohol intake of 30 to 60 g per day (two to five drinks per day), risk of breast cancer increased by an average of 40% compared with nondrinkers after adjustment for other known breast cancer risk factors.

BODY WEIGHT AND PHYSICAL ACTIVITY

A close relation exists between body weight and physical activity—the latter being one of the principal means of maintaining desirable weight. Excessive body weight increases risk for several cancers, including endometrial, renal, colon, and postmenopausal breast cancer. Physical activity reduces the likelihood of colon cancer, perhaps through stimulation of intestinal motility. Some data suggest a protective effect of physical activity on breast cancer. Physical activity, leading to loss of weight and body fat, helps reduce circulating levels of estrogen and progesterone and, thus, possibly breast cancer risk.

DIET AND CANCER CLINICAL TRIALS

Clinical trials are the best means for determining the effectiveness of dietary interventions for reducing cancer risk. Dietary factors being investigated in NCI-sponsored intervention trials include beta-carotene, vitamin E, vitamin C, retinol (vitamin A), folic acid, calcium, selenium, wheat bran, and omega-3 fatty acids. Results from several closed large-scale intervention trials are described here; long-term follow-up is continuing for these trials.

The Physicians' Health Study was conducted among 22,000 male physicians who received a 50-mg supplement of beta-carotene on alternate days. After approximately 12 years of treatment (1982 to December 1995), data showed no significant evidence of either benefit or harm from beta-carotene for either cancer or cardiovascular disease.

The Alpha-Tocopherol, Beta-Carotene Cancer Prevention Study (ATBC) and the Beta-Carotene and Retinol Efficacy Trial (CARET) were carried out in populations at high risk for lung cancer. The ATBC study investigated the efficacy of vitamin E alone, beta-carotene alone, or both on lung cancer among male cigarette smokers. Unexpectedly, this study showed a 16% higher incidence of lung cancer in the beta-carotene group. The adverse effects of beta-carotene were observed at the highest two quartiles of ethanol intake, indicating that alcohol consumption may enhance the actions of beta-carotene. Among men who received vitamin E, 16% fewer cases of colorectal cancer were diagnosed. Recent analysis of ATBC follow-up data found decreases in both prostate cancer incidence (36%) and mortality (41%) among men receiving vitamin E. CARET tested the efficacy of a combination of beta-carotene and retinol (as retinyl palmitate) in former and current heavy smokers and in men with extensive occupational asbestos exposure. This trial was terminated in January 1996 after 4 years of treatment when data showed an overall 28%

higher incidence of lung cancer in participants receiving the beta-carotene/retinyl palmitate combination. Participants with higher serum beta-carotene concentrations, which reflect total intake of vegetables and fruits, at entry into both the ATBC study and CARET developed fewer lung cancers, even among those who received beta-carotene supplements, reaffirming the importance of including an abundance of plant foods in our diets.

ROLE OF PHYSICIAN IN DIET MODIFICATION

An ever-increasing amount of evidence supports a relation between diet and cancer—the clear implication being that modification of behavior has considerable potential for reducing cancer risk. The NCI and various other scientific organizations have developed similar interim dietary guidelines directed at reducing cancer risk while research continues. The NCI's guidelines are outlined in [Table 22.2](#). In addition to reducing cancer risk, these guidelines are likely to benefit overall health. At present, average Americans consume too much fat (more than the 30% or less recommended), the wrong types of fat (too much saturated fat, too little monounsaturated fat), too little fiber, and too few vegetables, fruits, and whole grains. Physicians should take the lead in advising and encouraging patients to adhere to the dietary guidelines. Collaboration with nutritionists and registered dietitians to help patients in modifying their diets is essential.

- Reduce fat intake to ≤30% of calories.
- Increase fiber intake to 20–30 g/day, with an upper limit of 35 g.
- Include a variety of vegetables and fruits in the daily diet.
- Avoid obesity.
- Consume alcoholic beverages in moderation, if at all.
- Minimize consumption of salt-cured, salt-pickled, or smoked foods.

CHAPTER 23: TRANSPLANTATION IMMUNOLOGY

JUDITH A. SHIZURU

[Major Histocompatibility Complex](#)
[The Immune Response and Tissue Rejection](#)
[Hyperacute Rejection](#)
[Bone Marrow Transplantation](#)
[Pharmacologic Suppression of Rejection of Transplanted Tissues](#)
[Conclusions](#)

The transplantation of tissues to replace diseased organs has evolved over the last several decades to become an important therapeutic modality. Success has been possible in transplantation for two reasons: (a) an evolving understanding of how the immune response mediates the recognition and destruction of foreign organisms and (b) the development of multiple classes of drugs that can effectively suppress the immune response.

Although tissue transplantation has been practiced sporadically by a number of civilizations dating back to as early as 700 BC, not until the 1930s did biologists begin systematic study in animals that led to our current understanding of tissue rejection. The most crucial paradigm is that rejection of grafts has an immunologic basis mediated primarily by T cells. Studies of skin graft transplantation between inbred strains of mice revealed the basic rules of rejection: Grafts that are exchanged between different sites on the same animal or person (*autologous*) or exchanged between genetically identical people (twins) or inbred animal strains (*syngeneic*) are accepted 100% of the time. In contrast, when skin grafts are transplanted between genetically disparate humans or animals but within the same species, the graft is initially accepted, but subsequently rejected at about 2 weeks. This donor–recipient combination is termed *allogeneic*. Grafts exchanged between organisms of different species are called *xenografts*.

In the allogeneic and xenogeneic setting, if a second graft is placed from the same donor, but after the first graft is rejected, the tempo of rejection is accelerated, occurring at approximately 6 to 8 days. These responses are called first-set rejection and second-set rejection, respectively, and demonstrate that the reaction against the tissue is specific for antigens on the graft, because transplantation of skin from another unrelated donor results in a first-set rejection. There are special circumstances in which allografts or xenografts are rejected in a very rapid time frame; these are described in the section on hyperacute rejection.

T lymphocytes mediate the rejection of transplanted tissue. This is because T cells, particularly CD4⁺ T cells, are central to the induction and perpetuation of most antigen-specific immune responses. Experimentally, the role of T cells in tissue rejection was shown by transplantation of skin grafts onto strains of mice that genetically lack T cells. The mice were unable to reject an allogeneic skin graft unless T cells were transferred to them from a genetically matched mouse with a normal immune system.

MAJOR HISTOCOMPATIBILITY COMPLEX

Understanding of how tissues are recognized and rejected has occurred in parallel with knowledge of how the immune response functions. The skin graft studies between inbred mouse strains led investigators to discover a gene region that encodes for surface molecules that not only control organ rejection, but also control most T-cell responses. That gene region is generically termed the major histocompatibility complex (MHC) (Fig. 23.1). In mice, the MHC is designated H-2, and in humans it is called the human leukocyte antigen (HLA) complex and is located on the short arm of chromosome 6. The MHC is composed of a stretch of linked genes of three different classes. The class I and class II genes encode proteins that are expressed on the cell surface and whose function it is to bind peptides and present peptides for recognition by a T cell (Fig. 23.2). Thus, the ligand for a T-cell clone's receptor is a composite of an MHC class I or class II molecule plus peptide bound in its antigen-binding groove. The class III MHC–encoded proteins are structurally and functionally distinct from the class I and II molecules. These proteins include components of the complement system and certain cytokines, which play a less direct role in transplantation biology. They will not be further discussed as a group in this chapter.

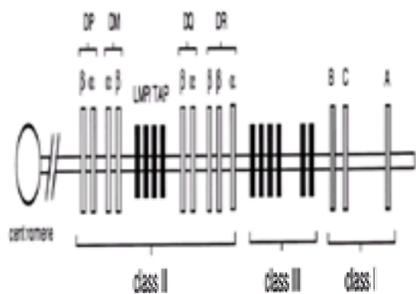

FIGURE 23.1. Genetic organization of the human major histocompatibility complex (MHC). There are separate regions of class I and class II genes, and class III genes are interspersed as indicated. The class I genes are HLA-A, HLA-B, and HLA-C. The class II genes are DR, DQ, and DP. DM genes are related to class II genes and function to catalyze peptide binding to class II MHC molecules. The LMP/TAP genes are class III genes that encode molecules involved in processing and transporting endogenous antigens. Other proteins encoded in the class III region are tumor necrosis factor α and β , and complement factors C2, C4, B, and F.

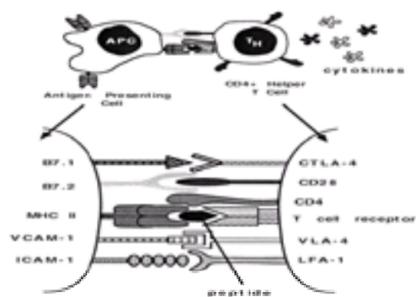

FIGURE 23.2. Schematic representation of the molecular interactions that lead to activation of T lymphocytes. Shown here is the activation of a CD4⁺ T cell by an antigen-presenting cell. The primary ligand for the antigen-specific T-cell receptor is an MHC class II molecule bound to a peptide antigen. The CD4 molecule stabilizes this interaction. Also shown are some of the known costimulatory and adhesion receptor–ligand pairs that participate in the cellular interaction. CD, cluster designation; VCAM-1, vascular adhesion molecule-1; VLA-4, very late activation antigen-4; ICAM-1, intercellular adhesion molecule-1; LFA-1, lymphocyte function-related antigen.

Both class I and class II MHC molecules are cell-surface glycoproteins that resemble one another but have slightly different structures. Class MHC I molecules are heterodimers composed of an α chain that is membrane spanning and is associated noncovalently with the molecule β_2 -microglobulin. β_2 -Microglobulin is not encoded within the MHC complex. Class II MHC molecules are composed of an α and a β chain; both chains are derived from the MHC and both span the plasma membrane. Class I MHC molecules are expressed on virtually all nucleated cells, but their level of expression depends on the cell type. In humans, there are three class I

molecules designated A, B, and C. Class I MHC molecules present peptides derived from cytosolic pathogens to CD8⁺ T cells. In contrast to class I molecules, tissue expression of class II molecules is restricted. The cells that express significant amounts of class II molecules include the professional antigen-presenting cells and epithelial cells in the thymus. Class II MHC molecules present peptides that come from pathogens that have been phagocytosed and are thus derived from exogenous antigens. Such antigens are presented by class II molecules primarily to CD4⁺ T cells. In humans, there are three class II molecules that are designated DR, DQ, and DP; in some human haplotypes, the DR region contains an extra b chain whose product can pair with the DR α chain. Thus, three sets of genes give rise to four types of class II MHC molecules. Most mouse strains express two class II molecules designated I-A and I-E.

ROLE OF MHC MOLECULES IN TRANSPLANTATION IMMUNOLOGY

An important feature of the class I and II MHC genes relevant to transplantation immunology is that they are highly polymorphic. Specifically, this means that among individuals in a population, there is great variation in the structure of the gene products encoded at MHC loci. The individual variants of the genes are *alleles*. There are more than 200 alleles of some of the class I and class II loci. Another salient feature of MHC genes is that they are codominantly expressed. Therefore, unlike genes in which only one parental gene is expressed, both paternal and maternal genes are expressed in MHC molecules. This means that an individual human cell can coexpress six class I and eight class II HLA molecules. Together, these variations make it highly unlikely that nonrelated individuals will express identical class I and class II MHC molecules. On the other hand, the likelihood that two siblings will express identical MHC molecules is one in four because molecules within the MHC are tightly linked. Thus, parental MHC molecules are inherited as a group, and the probability of matching at both loci is inherited in a mendelian fashion.

The function of MHC-encoded molecules is to present foreign peptides to T cells to eliminate foreign pathogens by inducing an immune response that results in activation of appropriate effector mechanisms (Fig. 23.2). During T-cell development, T-cell clones that recognize and bind to self-MHC molecules are eliminated. However, T cells that mature and circulate in the blood are capable of recognizing MHC molecules that differ from self-MHC molecules by as little as a single amino acid. Thus, within a population of T cells many clones are capable of recognizing the structural differences that occur between MHC molecules of one individual in contrast to another. It is known that the frequency of T cells that respond to a single peptide antigen is ~0.001%, whereas the number of T-cell clones that are capable of responding to foreign MHC molecules is between 1% and 10%. The higher frequency of MHC-reactive T-cell clones explains why rejection of foreign tissue elicits such a vigorous immune response.

Thus, it is optimal to attempt to match donor and recipient for MHC type to minimize rejection. But even among those who have identical MHC types, such as MHC-matched siblings, there is still the possibility that rejection can occur, because even siblings have differences in other gene products. The peptide-binding pocket of MHC molecules is often filled with peptides derived from self-antigens; thus, a transplanted organ from a sibling can contain peptides that differ slightly from the recipient, but enough to be recognized by recipient T cells. These other nonhistocompatibility antigens are *minor histocompatibility antigens*. As expected, there are many potential minor histocompatibility antigens, most of which have not been characterized.

THE IMMUNE RESPONSE AND TISSUE REJECTION

Conventional immune responses against bacterial and viral pathogens involve processing and presentation of the bacterial–viral antigens to T cells by professional antigen-presenting cells (APCs). Professional APCs include dendritic cells, macrophages, and B cells and have several important features: (a) They express high levels of class II MHC molecules on their surface and thus interact primarily with CD4⁺ T cells; (b) they synthesize and secrete several cell-activating cytokines such as interleukin-1 and interferon- γ (IFN- γ); and (c) they express cell-surface molecules called *costimulatory molecules* (Fig. 23.2). Among the most well studied of the costimulatory molecules are B71, B72, and the CD40 ligand (CD154). In a T-cell–APC interaction, the primary receptor–ligand pair are the antigen-specific T-cell receptor and the MHC molecule bound to a peptide. However, it is known that unless secondary costimulatory receptors are engaged, the T cell will not become activated and in fact may become refractory to stimulation through its receptor. In addition to the costimulatory molecules, professional APCs express adhesion molecules such as ICAM-1, ICAM-2, LFA-1, and LFA-3.

Activation of CD4⁺ T cells by APCs is a major pathway in the induction and perpetuation of immune responses. Once activated, CD4⁺ T cells stimulate other effector cells either by direct cell–cell contact or by the production and secretion of cytokines. Both antibody-mediated responses (*humoral immunity*) and cellular responses are activated in this way and include the conversion of pre-B cells into antibody-secreting plasma cells, the stimulation of precytotoxic T cells to become mature killer cells, and the activation of antigen-nonspecific inflammatory cells such as macrophages. The effector arms of the immune response ultimately lead to the destruction of the tissue graft.

The central role that CD4⁺ T cells play in rejection of tissue allografts was demonstrated experimentally in animal models. Treatment with monoclonal antibodies directed against the CD4 molecule in the peri-transplantation phase allows long-term organ graft acceptance without the need for further immunosuppression. The CD4⁺ T-cell subset can be subdivided into two functional subtypes, T_H1 and T_H2, which activate the cell-mediated versus the humoral arm of the immune response, respectively. Determination of whether a naive T cell becomes a T_H1 or a T_H2 cell is thought to be controlled by the cytokines present locally during the initial phase when a naive T cell is undergoing activation. In vitro experiments have shown that T cells stimulated in the presence of IL-12 and IFN- γ tend to differentiate into T_H1 cells, whereas T cells stimulated in the presence of IL-4 and IL-6 tend to differentiate into T_H2 cells. In addition, activated CD4⁺ T cells themselves secrete cytokines that further polarize the response so that one TH subtype dominates; T_H1 cells secrete IFN- γ , whereas T_H2 cells secrete IL-4 and IL-10. IFN- γ can prevent the activation of T_H2 cells, and IL-10 can inhibit the development of T_H1 cells.

In the setting of graft rejection, the T-cell subtype that dominates may have important consequences. It is thought that T_H1 responses are ultimately much more damaging to a transplanted organ, whereas T_H2 responses (with the exception of hyperacute rejection, described in the next section) may be protective.

HYPERACUTE REJECTION

For most solid organ transplantations, the rejection and graft destruction ultimately result from a combination of cellular and antibody-mediated effector mechanisms. However, there are special situations when rejection is aggressively mediated by antibodies and leads to a syndrome termed *hyperacute rejection*. This occurs when a recipient has preformed antibodies directed against the graft before its transplantation. The most common reason for this presence is exposure to different MHC alleles as a result of prior blood transfusions. Preformed antibodies can recognize and damage vascular structures. Thus, when anastomoses are made between donor and recipient vessels, a very brisk response ensues; antibody binding to the vascular endothelium of the graft activates the complement and clotting cascades, occluding blood flow to the graft and causing immediate death of the graft. To avoid hyperacute rejection, *cross-matching* is performed between donor and recipient. Cross-matching involves determining whether the recipient has circulating antibodies that react with the white blood cells of the donor. If found, such antibodies are a serious contraindication to transplantation because standard immunosuppressive treatments are ineffective against hyperacute rejection.

XENOGRAFTS

Another scenario in which preformed antibodies appear to play an important role is in transplantations between species (xenografts). Humans are known to naturally produce antibodies that can respond against the antigens on the vascular endothelium of other species and thus cause hyperacute rejection. The pig-to-primate model is perhaps the best-studied xenogeneic system in which the problem of hyperacute rejection has been shown to be further exacerbated because a group of proteins called *complement regulatory proteins* demonstrate species specificity. These regulatory proteins include CD59, decay-accelerating factor (DAF or CD55), and membrane cofactor protein (MCP or CD46); these normally function to protect endothelial cells from damage caused by inadvertent activation of the complement cascade. Because these regulatory proteins are species-specific, the DAF expressed on pig endothelium cannot protect the tissue from attack by primate complement. Recently, transgenic pigs expressing human DAF were produced in attempts to overcome the problems of hyperacute rejection in xenotransplantation.

BONE MARROW TRANSPLANTATION

Transplantation of allogeneic bone marrow (BM) differs from solid organ grafts in several ways. First, the biology of resistance (or rejection) to engraftment differs. From experiments in inbred mouse strains, it is clear that although the MHC molecules and T cells are important in controlling resistance to allogeneic BM, other genes and other immune cells (natural killer cells) also contribute significantly. Second, because BM is a heterogeneous population of cells that contain both mature immune cells and primitive hematopoietic stem cells, the immune cells in the graft have the potential to respond against antigens present on the recipient tissues and cause a syndrome called *graft-versus-host disease* (GVHD). GVHD is a life-threatening complication of allogeneic bone marrow transplantation (BMT); to prevent GVHD (and to prevent BM rejection), BMT patients receive immunosuppressive therapy in the post-transplantation period. Third, the major indications for allogeneic

BMTs are hematologic malignancies, and the presence of immune cells contained within the BM graft can have a favorable effect because donor immune cells have been shown to suppress tumor growth. Fourth, BM grafts are unique in that they appear to induce immune tolerance to themselves, as well as to other tissues derived from the BM donor. Thus, most patients who undergo an allogeneic BMT may be eventually tapered off all immunosuppressive therapy. The use of allogeneic BMT to induce tolerance to solid organ grafts is still in the experimental stages and not used clinically. This is because the risks associated with the BMT procedure limit its use primarily to the treatment of malignancies and BM failure states. However, more recently, promising advances have been made in reducing the severity of the BMT conditioning regimens that will likely lead to the more widespread use of BMT for clinical applications that include organ transplantation tolerance induction.

PHARMACOLOGIC SUPPRESSION OF REJECTION OF TRANSPLANTED TISSUES

A major reason why solid organ transplantation and BMT are successful is because pharmacologic agents can effectively suppress the immune system. The drugs currently used to suppress the immune system may be divided into five broad categories: (a) anti-inflammatory drugs of the glucocorticoid family; (b) cytotoxic drugs such as cyclophosphamide; (c) drugs that affect purine metabolism and synthesis required for DNA synthesis, including azathioprine and mycophenolate mofetil; (d) fungal and bacterial derivatives such as cyclosporin A (CSA), FK506, and rapamycin, which inhibit signaling events that occur within T lymphocytes; and (e) monoclonal agents directed against immune cell subsets such as anti-CD3 antibodies or anti-CD25 (anti-IL-2 receptor) antibodies. The current mainstay of immunosuppressive therapy is CSA or its related compounds, which are well tolerated and have powerful effects on T-cell function. These agents are generally used in combination with one or more of the drugs from the other classes. The goal of therapy is to taper the immunosuppressive agents to the lowest effective dose, but most patients who receive a solid organ transplantation remain on one or two of these drugs permanently. Most BMT patients, however, can be withdrawn completely from the immunosuppressive drugs (see above).

CONCLUSIONS

Understanding the way in which organ grafts are recognized and rejected continues to be an active area of research, and newer forms of immunosuppressive therapy are being developed. However, tissue transplantation still involves significant risks. These include infections due to chronic use of immunosuppression, secondary malignancies, metabolic bone disease, hypertension, and, in the case of BMT, GVHD. Additional problems involve the limited availability of organs for transplantation. Moreover, patients who have had prior exposure to alloantigens are at risk of hyperacute rejection, which is poorly treated with currently available immunosuppressive therapies. The ultimate goal still being pursued by transplantation biologists is the induction of immune tolerance. The experimental approaches to achieve this include rendering the grafts nonimmunogenic or alternatively designing recipient immunosuppressive regimens that can be tapered off over a relatively short time. Given the pace of new developments in in vitro and in vivo cellular manipulation, we can look forward to achieving the goal of tissue-specific immune tolerance in the near future.

CHAPTER 24: PERIODIC HEALTH EVALUATION

ALBERT G. MULLEY JR.

[Criteria for Screening](#)
[Recommendations for the Periodic Health Evaluation](#)

More Americans see their physicians for periodic health examinations than for any other reason. Many screening and other preventive measures (e.g., blood pressure measurement, breast examination, testing of stool for occult blood) are performed when patients present with symptoms that are unrelated to the condition that may be prevented or detected. This kind of clinical activity, referred to as *prescriptive screening* or *case finding*, carries with it an ethical imperative for the clinician, who must be certain that the patient is more likely to be helped than harmed by the initiative. The potential for harm and the pressure for cost containment force careful evaluation of the rationale for periodic health evaluation and for specific case-finding procedures.

Several groups, including professional societies and government-sponsored task forces, have examined evidence for and against specific preventive services. Because the evidence is incomplete, resulting recommendations must be made in the face of uncertainty, and they inevitably reflect value judgments about alternative uses of resources. Not surprisingly, such recommendations vary from group to group and change over time. The clinician must know what is recommended and by whom and must understand the rationale for evaluating screening and preventive services. Whether screening results in improved health outcome depends on characteristics of the disease in question and available therapy, characteristics of available screening tests, and characteristics of patients screened ([Table 24.1](#)).

Characteristics of the Disease
 Significant effect on the quality and length of life
 Prevalence sufficiently high
 Acceptable methods of treatment available
 Asymptomatic period during which detection and treatment significantly reduce morbidity or mortality
 Better therapeutic result with treatment in the asymptomatic phase than with treatment delayed until symptoms appear

Characteristics of the Test
 Sufficiently sensitive to detect disease during the asymptomatic period
 Sufficiently specific to provide acceptable positive predictive value
 Acceptable to patients

Characteristics of the Population Screened
 Sufficiently high disease prevalence
 Subsequent diagnostic tests and necessary therapy acceptable

TABLE 24.1. CRITERIA FOR SCREENING

CRITERIA FOR SCREENING

CHARACTERISTICS OF THE DISEASE

Screening or case finding is performed to identify a condition or disease in a person who is asymptomatic. Without screening, a diagnosis would not be made until and unless signs or symptoms occurred; the effect of screening is to advance the time of diagnosis. Earlier diagnosis is worthwhile when it provides prognostic information that is of value to the patient or when earlier therapeutic intervention produces a better health outcome than would later therapy. In the case of communicable diseases, screening may be warranted to protect potential contacts from infection, regardless of potential benefit to the person already infected.

The relation between natural history of disease and effectiveness of intervention that is critical to the screening decision is illustrated in [Figure 24.1](#). The horizontal line represents the natural history as a function of time, with the biologic onset of disease (e.g., malignant transformation of a cell, infection of a host) at the far left. At some variable point after disease onset, a diagnosis is possible if a screening test is carried out. After another variable period during which the patient remains asymptomatic, symptoms or signs occur that may prompt clinical presentation and subsequent diagnosis. Eventually, after appropriate therapeutic maneuvers, there is an identifiable clinical outcome that can range from cure and complete health to death. At some point in the natural history, the disease may become less amenable to available therapy; an *escape from cure* is said to occur.

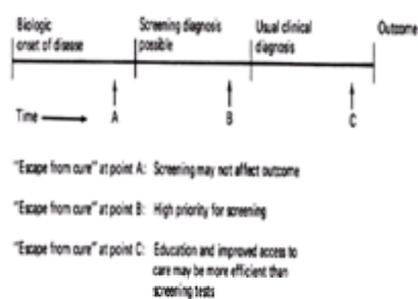

FIGURE 24.1. Relation between screening and natural history of disease. (From Mulley AG Jr. Health maintenance and the role of screening. In: Goroll AH, May LA, Mulley AG Jr, eds. *Primary care medicine: office evaluation and management of the adult patient*, third ed. Philadelphia: JB Lippincott, 1995, with permission.)

Much variability in the natural history of a disease exists among persons with the same disease. Nonetheless, some cautious generalizations about relations illustrated in [Figure 24.1](#) can be useful. If the escape from cure usually occurs before a screening diagnosis is possible (e.g., point A), the value of screening must be questioned; the value of prognostic information must be weighed against the effects of the patient receiving bad news sooner. If the escape from cure regularly occurs after symptoms or signs have pointed the way to a diagnosis (e.g., point C), education of patients or clinicians to ensure early presentation and prompt diagnostic evaluation may be more efficient than screening programs. Diseases for which the escape from cure commonly occur during the asymptomatic detectable period (e.g., point B) are the most promising targets for screening strategies.

[Figure 24.1](#) also is helpful in understanding two methodologic problems that sometimes affect interpretation of evaluations of screening studies: lead time and time-linked bias sampling. *Lead time* is the average time by which diagnosis is advanced by screening. If survival is the outcome measure used to compare screening and nonscreening strategies, longer survival may reflect earlier diagnosis rather than extended life. *Time-linked bias sampling* refers to the potential selection of more indolent cases of a particular disease by means of screening that can occur, because persons with a long asymptomatic detectable period have more opportunity to be detected earlier. Such variability in duration of the asymptomatic period must be kept in mind when screening intervals are chosen. The mean duration of asymptomatic detectable disease is not as important as the distribution of durations or, more specifically, the proportion of asymptomatic detectable periods that are shorter than the designated screening interval.

CHARACTERISTICS OF THE TEST

The validity of a test depends on its ability to differentiate patients with and without a disease or condition, measured by its sensitivity or true-positive rate and its specificity or true-negative rate. The predictive value of the test result depends on these characteristics of the test and on the prior probability of the disease or condition in question ([Chapter 42](#)). This relation is particularly important in the screening situation when prior probability of disease (i.e., prevalence in the population tested) is invariably low. Under these conditions, the positive predictive value is critically influenced by test specificity; even small false-positive rates can generate many false-positive results from the majority of those tested who do not have disease. However, generalizations about which is more important for a screening test—sensitivity or specificity—are hazardous. Any tradeoffs between sensitivity and specificity should be based on the relative value of a true-positive result and the cost of a false-negative result and, conversely, the value of a true-negative result and the cost of a false-positive result.

Before deciding about the appropriateness of a test for the screening situation based on reports of the test's sensitivity and specificity, the clinician should be certain that the reports were generated by studies relevant to the screening situation.

CHARACTERISTICS OF THE PATIENTS

Patients hold widely different views about disease prevention and health promotion activities. How do they feel about the morbidity of a test, whether it is simply a venipuncture or something worse? Given their current level of anxiety and knowledge, how will they respond to a true-positive or true-negative test result? What effect would a false-positive or false-negative result have? Would the patient accept indicated therapy or appropriately change behavior if a disease or condition were identified? The clinician should try to understand these differences and respect the patients' prerogatives.

RECOMMENDATIONS FOR THE PERIODIC HEALTH EVALUATION

When criteria such as these are systematically applied, relatively few preventive services are endorsed. The US Preventive Services Task Force examined evidence for and against use of more than 100 interventions, including screening tests, counseling interventions, and immunizations or chemoprophylaxis. The Task Force reports provide specific clinical guidelines, leaving discretion to the clinician when evidence does not justify a definitive judgment. Selectivity in the use of services, based on particular patients' risk factors, is emphasized. Overall, the early recommendations of the Task Force suggest a skepticism about the relative value of screening tests compared with the potential for physician counseling aimed at changing behavior to improve the health of patients. Discussion of specific examples, including some screening tests that should not be used widely but should be used in certain groups, can help clarify the rationale for preventive services.

COMMON CONDITIONS THAT WARRANT INCLUSION

Few conditions meet criteria for screening and are common enough to warrant attention in the periodic health examination of all patients of appropriate age and gender. These appear in [Table 24.2](#).

Disease	Comments
Hypertension	See Chapter 29, 30
Hyperlipidemia	See Chapter 12, 28
Breast cancer	See Chapter 22, 28, 220
Colon cancer	See Chapter 22, 28, 102, 116
Cervical cancer	See Chapter 22, 221
Smoking	See Chapter 33
Alcoholism	See Chapter 34

TABLE 24.2. CONDITIONS THAT WARRANT PERIODIC EVALUATION IN ALL PATIENTS OF APPROPRIATE AGE AND GENDER

Hypertension may be the most significant condition for the practitioner concerned about disease prevention and health promotion ([Chapter 29](#) and [Chapter 30](#)). The prevalence is staggering, and morbidity and mortality attributable to hypertension, as well as benefits of treatment, are well documented. Evidence for benefits derived from treatment of systolic hypertension has produced revisions in treatment guidelines.

Moderate elevations in cholesterol that confer risk are also exceedingly prevalent in most Western societies. Potential benefits to be derived from screening and subsequent treatment have been demonstrated in randomized, controlled trials. Patients younger than 65 years of age should be screened for hypercholesterolemia using total cholesterol and high-density lipoprotein levels. The age at which screening should begin is a matter of controversy. Screening every 5 years after starting at age 18 is the most common recommendation.

Smoking is a major risk factor for coronary and cerebrovascular disease as well as being the primary cause of lung cancer and chronic pulmonary disease and the single largest preventable cause of death in America. Evidence suggests that most clinicians underestimate the effectiveness of counseling and other smoking-cessation interventions. A patient should always be asked whether he or she smokes. Those who smoke must be apprised of the reasons for stopping and of available smoking-cessation resources.

Relatively few screening tests to detect cancer are recommended for patients with no symptoms and without specific risk factors. Annual stool guaiac testing and sigmoidoscopy every 3 to 5 years for men and women older than 50 years of age has been a controversial recommendation of the American Cancer Society and the American College of Physicians. Evidence from a randomized trial and a case-control study support the effectiveness of these interventions. Papanicolaou (Pap) smears of the uterine cervix every 3 years in women between the ages of 20 and 65 and known risk factors, including early sexual activity and a high number of sexual partners, are indications for screening at yearly intervals.

Annual mammograms in women older than 50 years of age are well supported by evidence and have been endorsed by many expert panels. The recommended age at which screening mammography should begin is controversial. Most professional organizations now advise beginning annual or biannual mammographic screening at age 40. Other groups including the US Task Force recommend starting at age 50, unless there is a history of premenopausal breast cancer in a first-degree relative that warrants mammography at an earlier age. Breast self-examination is complementary, and the technique should be emphasized if the woman is at high risk and has breasts that are suitable for effective self-examination. Physical examination by the physician is also important and should be performed at yearly intervals after the age of 40 or earlier if breast cancer occurred before menopause in a first-degree relative.

A controversial question in cancer screening for men is whether prostate-specific antigen (PSA) should be used to screen for prostate cancer. Prostate cancer is the most common cancer and the second leading cause of cancer death in men. However, most histologically confirmed prostate cancers, which are extremely common among older men, do not produce morbidity and mortality. Screening tests, including PSA, have limited sensitivity and specificity. It is not clear that outcome can be improved significantly for patients with cancers detected by screening. Recommendations vary. Even those most enthusiastic about screening do not advise PSA testing for men with a life expectancy of less than 10 years because it is unlikely that they will survive to see a benefit. PSA should be used only among men who understand and accept the potential harms including the significant morbidity of earlier diagnosis followed by treatment that may not alter outcome.

The rationale behind cancer-screening recommendations is discussed more fully in [Chapter 28](#).

CONDITIONS THAT SHOULD BE SELECTIVELY INCLUDED

CHAPTER 25: PREOPERATIVE MEDICAL EVALUATION

JUDI M. WOOLGER

[General Approach](#)
[Cardiac Evaluation](#)
[Other Considerations](#)

GENERAL APPROACH

As the mortality from general anesthesia continues to decline, the type of patient considered for surgical intervention has expanded to include both older and more medically challenging patients. With an increased willingness to offer surgery to a broader patient base, however, comes an increased need for the internist to be involved in the comprehensive care of the patient, both before and after the surgical procedure. This chapter focuses primarily on the preoperative assessment, although the obligation for care certainly does not end there.

In the preoperative evaluation, the internist is responsible for generating a comprehensive evaluation of all medical problems, with special attention to cardiovascular risk assessment and pulmonary evaluation. Because this may be the only contact the patient has with a generalist, however, it is also important to use this interaction to address preventive health issues and to facilitate follow-up for appropriate screening studies after the surgical issue has been addressed. Furthermore, and often most important, the preoperative evaluation is used to assess risk for specific types of surgical interventions and, when possible, to modify those risks before a patient proceeds to surgery. Recommendations for postoperative care are also made at this time.

Risk assessment is performed much the same as in any patient encounter, focusing on careful history-taking, directed physical examination, and judicious use of laboratory and radiographic evaluation. The medical history needs to focus not only on careful documentation of prior medical problems, but also on prior surgical history and outcomes of prior surgeries. Knowledge of previous complications (i.e., bleeding or reactions to anesthesia) are of paramount importance and dictates a directed search for causes. The review of systems is significant in defining an overall picture of the patient's general state of health and provides insight into potential postoperative issues, such as nutritional status and bowel or urologic issues. This is also the best time to evaluate medication usage of any kind; the surgical team should be aware of potential interactions of any prescription drugs and should recognize the risks for withdrawal in those who abuse alcohol or other nonprescription drugs.

During the physical examination, the physician should pay special attention to the cardiopulmonary system. Likewise, the need for preoperative testing is also directed by needs brought to light during the history and physical examination, still with a focus on the cardiopulmonary systems. Electrocardiograms are indicated for anyone over the age of 45 years or with two or more cardiac risk factors (hypertension, diabetes, hypercholesterolemia, tobacco use, or family history of accelerated coronary artery disease). Chest radiographs are indicated for any patient with significant respiratory complaints or history, as well as for patients scheduled for intrathoracic or intra-abdominal procedures. The basic laboratory evaluation includes a complete blood cell count and creatinine. Additional studies are based on the patient's overall medical condition, concurrent illnesses, and medications.

CARDIAC EVALUATION

Because of the high prevalence of coronary artery disease and the known cardiovascular stress associated with the induction of general anesthesia, much attention has been focused on the preoperative cardiac assessment of the patient going through noncardiac surgery. The American Heart Association (AHA), in conjunction with the American College of Cardiology (ACC), and the American College of Physicians (ACP) have outlined evidence-based approaches for determining which subset of at-risk patients for cardiac events needs additional cardiac risk modification before surgery. These algorithmic outlines are fairly similar, although the ACP guidelines place much less emphasis on the functional capacity.

The AHA/ACC approach uses three key components in the patient assessment: (a) cardiac risk factors, (b) exercise capacity, and (c) surgery-specific risk. The cardiac risk factors are divided into low, intermediate, and high risk, as shown in [Table 25.1](#). Exercise capacity is more difficult to quantify and requires careful questioning about both exercise and routine activities of daily living. Surgery-specific risk is based on very broad generalizations taken from historical data and may vary from institution to institution ([Table 25.2](#)).

High (Reported Cardiac Risk Often >5%)
Emergency major operations, particularly in the elderly
Aortic and other major vascular
Peripheral vascular
Anticipated prolonged surgical procedures associated with large
fluid shifts and/or blood loss

Intermediate (Reported Cardiac Risk ~5%)
Carotid endarterectomy
Head and neck
Intra-abdominal and intrathoracic
Orthopedic
Prostate

Low (Reported Cardiac Risk ~1%)^a
Endoscopic procedures
Superficial procedure
Cataract
Breast

^a Combined incidence of cardiac death and nonfatal myocardial infarction.
^b Generally no further preoperative cardiac testing required.
From Eagle KA, Herzig RH, Lugo JA, et al. Guidelines for perioperative cardiovascular evaluation for noncardiac surgery. Report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines, Committee on Perioperative Cardiovascular Evaluation for Noncardiac Surgery. *J Am Coll Cardiol* 1996;27:883-888, with permission.

TABLE 25.1. CLINICAL PREDICTORS OF CARDIOVASCULAR RISK^a

High (Reported Cardiac Risk Often >5%)
Emergency major operations, particularly in the elderly
Aortic and other major vascular
Peripheral vascular
Anticipated prolonged surgical procedures associated with large
fluid shifts and/or blood loss

Intermediate (Reported Cardiac Risk ~5%)
Carotid endarterectomy
Head and neck
Intra-abdominal and intrathoracic
Orthopedic
Prostate

Low (Reported Cardiac Risk ~1%)^a
Endoscopic procedures
Superficial procedure
Cataract
Breast

^a Combined incidence of cardiac death and nonfatal myocardial infarction.
^b Generally no further preoperative cardiac testing required.

TABLE 25.2. SURGERY-BASED CARDIAC RISK STRATIFICATION FOR NONCARDIAC PROCEDURES^a

OTHER CONSIDERATIONS

Beyond the cardiovascular assessment lies a myriad of issues in the internist's domain. These include pulmonary, renal, hematologic, and nutritional assessments. Complications are best avoided if potential problems are recognized and treated before the patient proceeds to surgery.

Another major area of attention is prevention of deep venous thrombosis, which is a major risk after many types of surgical intervention. It is appropriate to provide

recommendations for postoperative deep vein thrombosis prophylaxis, specific to the patient's concurrent illnesses, type of surgery, and risk of thrombotic event. Available treatments include early ambulation, sequential compression stockings, subcutaneous heparin, and low-molecular-weight heparin ([Chapter 378](#)).

Once care has been taken to thoroughly evaluate the patient preoperatively and to have modified any possible risk factors, it is of utmost importance to communicate directly with the surgical or anesthesia team or both. Concise, yet detailed recommendations about the patient need to be transmitted in a timely fashion, and appropriate arrangements should be made for postoperative medical care when warranted.

CHAPTER 26: IMMUNIZATIONS

THEODORE C. EICKHOFF

[General Principles of Immunization](#)
[Immunizations Routinely Recommended for Adults](#)
[Vaccines for Use in Adults Under Special Circumstances](#)

This chapter deals with immunization of adults, including both normally immunocompetent persons and persons with depressed immunocompetence. Immunizations recommended for all persons are considered first, followed by vaccines recommended under special circumstances. Immunizations to be considered only when international travel is contemplated are discussed in [Chapter 27](#).

GENERAL PRINCIPLES OF IMMUNIZATION

An up-to-date immunization history is critically important in determining the need for individual vaccines; this is just as important as any other aspect of a patient's health history and should be reviewed and updated at periodic intervals, for example, annually.

Indicated vaccines should be administered as soon as feasible. If there are contraindications, immunization may need to be deferred, or not given at all if there has been a previous significant adverse reaction to a vaccine. For example, a very small number of persons have true anaphylactic sensitivity to eggs; a number of commonly recommended vaccines, including measles, mumps, and influenza vaccines, are prepared in eggs or in chick embryo cell culture and should not be given to such persons. A significant intercurrent illness may be a sufficient reason to postpone an indicated immunization, but minor illnesses such as a "cold" or other upper respiratory illness, with or without low-grade fever, is not a significant contraindication. Similarly, a previous local reaction such as pain, tenderness, or warmth at the injection site lasting no more than several days is not a contraindication. Moreover, antimicrobial therapy, convalescence from recent illness, recent exposure to an infectious disease, household contact with a pregnant woman, and breast feeding are *not* contraindications.

The most important consideration in determining vaccine contraindication is the immunocompetence of the recipient. Fully immunocompetent persons should, with no other contraindications, receive all routine and special-purpose vaccines that may be indicated. Severely immunocompromised patients, including AIDS patients, on the other hand, should generally not be given live, attenuated vaccines, because such vaccines may pose a lethal risk. The live antigen products that are of concern are measles, mumps, rubella, oral poliomyelitis, varicella, yellow fever, BCG, and typhoid Ty21a vaccines. Killed vaccines may be safely given to such persons, of course, but the immune response may be suboptimal or negligible. Multiple repeated doses may be required to maintain some level of protection, and, with few exceptions, no direct assessments of protective efficacy are possible in immunocompromised patients. Recommendations may differ in persons with lesser degrees of immunocompromise; these issues are discussed in subsequent sections.

Manufacturer's recommendations or comprehensive guides such as the recommendations of the Advisory Committee on Immunization Practices (ACIP), those of the Centers for Disease Control and Prevention (CDC), or the American College of Physicians Guide for Adult Immunization (see [bibliography](#)) should be consulted for information on specific doses and schedules, route of administration, and possible adverse effects. Vaccine administration should be noted in the patient's record, including the dose, route of administration, manufacturer, and lot number. Significant adverse reactions that may occur after vaccination should be recorded and reported using the forms and instructions provided in the *FDA Drug Bulletin* or the *Physician's Desk Reference*.

Certain vaccines may be given combined or at the same time without any loss in immunizing effectiveness. For example, measles, mumps, and rubella vaccines are usually given simultaneously as a single product. Influenza and pneumococcal vaccines may be administered together, although at separate sites. Administration of immune globulin within the preceding 3-month interval is a relative contraindication to many live attenuated vaccines, because the passively administered antibody may prevent the attenuated infection that is the desired response to the vaccine. Under certain circumstances, for example, hepatitis B and rabies exposures, killed vaccine, and the corresponding hyperimmune globulin may be administered simultaneously to achieve immediate passive and prolonged active protection.

IMMUNIZATIONS ROUTINELY RECOMMENDED FOR ADULTS

The recommended overall schedule for immunization of adults is shown in [Table 26.1](#), and vaccines recommended for routine use are shown in [Table 26.2](#). Additional comments on each vaccine follow.

Age	Recommended Schedule of Vaccines
Teenagers/ young adults	Completion of all childhood primary immunizations Hepatitis B for those not immunized in childhood Td booster
50 years	Varicella vaccine for susceptible persons Completion of all primary immunizations Td booster Assess risk factors indicating need for pneumococcal vaccine and annual influenza vaccine
≥65 years	Varicella vaccine for susceptible high-risk adults Completion of all primary immunizations Annual influenza vaccine Pneumococcal vaccine

Td, tetanus–diphtheria toxoid.
 (Adapted from: Guide for adult immunization, third ed.
 Philadelphia: American College of Physicians, 1994.)

TABLE 26.1. RECOMMENDED IMMUNIZATION SCHEDULE FOR ADULTS

Vaccine	Recommendation
Pneumococcal	All adults ≥65 years; all younger adults with risk factors; reimmunize at age 65 if <6 years has elapsed since prior immunization
Influenza	Yearly for all adults ≥65 years; all younger adults with risk factors; all health care providers; may offer to anyone who wishes to prevent infection
Hepatitis B	Sexually active young adults; high-risk groups; assess serologic response in persons ≥30 years
Measles-mumps-rubella (MMR)	Adults born after 1956 without proof of immunity or documented immunization; two doses for special risk groups
Tetanus–diphtheria toxoids (Td)	Completion of primary (3 doses) immunization, followed by either Td boosters every 10 years or single boosters at about age 15 and again about age 50
Varicella vaccine	All susceptible adults should be vaccinated

(Adapted from Guide for adult immunization, third ed.
 Philadelphia: American College of Physicians, 1994.)

TABLE 26.2. VACCINES USED IN ROUTINE IMMUNIZATION OF ADULTS

PNEUMOCOCCAL VACCINE

Pneumococcal vaccine is indicated for all persons over 65 years and for those under 65 years with certain risk factors. Such risk factors are chronic cardiac or pulmonary disease, functional or anatomical asplenia, chronic liver disease, alcoholism, and diabetes mellitus. Patients with chronic renal failure and those on dialysis, patients with hematologic malignancies, those undergoing chemotherapy for carcinoma, and organ transplant recipients are also candidates for the vaccine,

but their immunologic response is likely to be diminished. Patients with HIV infection are also at risk and should be vaccinated as soon as possible after HIV seropositivity is recognized. Regardless of the age at which initially vaccinated, a second dose should be given at age 65 unless less than 6 years have elapsed since initial immunization.

Vaccine usage in the target population has been suboptimal, owing in part to concerns about efficacy. In the healthy elderly person, efficacy has varied from 67% to 75% and only from 40% to 60% in persons with significant underlying disease. Recent successes with a conjugate pneumococcal vaccine formulated for pediatric use provides hope for a more immunogenic vaccine for adult use in the future.

INFLUENZA VACCINE

Risk factors that indicate the need for annual influenza vaccination before age 65 are virtually identical with those that exist for early use of pneumococcal vaccine, except for asplenia. In addition, persons providing either home care or health care for persons at increased risk for complications of influenza should be vaccinated, because such caretakers could transmit the disease to those at high risk. During epidemic years, persons who provide essential community services should also be vaccinated. It may be prudent to vaccinate immunocompromised persons as well, although efficacy is likely to be lower than in immunocompetent persons.

There have been reports of transient increases in HIV viral loads in persons with AIDS after receipt of influenza vaccine. Such increases have been found after other infections and vaccines and appear to result from a variety of antigenic stimuli. The viral load increases have been transient and not associated with adverse outcomes. For this reason, most physicians caring for AIDS patients continue to provide annual influenza vaccine.

HEPATITIS B VACCINE

The policy goal for hepatitis B vaccine in the United States is universal immunization. Special effort should be made to ensure full immunization of young people as they enter their sexually active years. Older adults at increased risk include health care workers, heterosexual persons with multiple partners, homosexual males, injecting drug users, hemophiliacs and hemodialysis patients, and those with environmental risks, such as household or sexual contacts of hepatitis B surface antigen (HBsAg) carriers, prison inmates, and others. Vaccine response decreases with advancing age, and serologic testing of high-risk individuals over 30 years of age, such as health care workers, is recommended since the protocol for postexposure prophylaxis depends on knowledge of the preexposure immune status. There is no recommendation for booster doses of hepatitis B vaccine after primary immunization in immunocompetent persons, although some health care institutions are providing booster doses to high-risk staff at 7- to 10-year intervals.

MEASLES, MUMPS, AND RUBELLA VACCINE

A two-dose schedule of measles, mumps, and rubella (MMR) vaccine has been recommended since 1989, but until the cohort of children who has already been given two doses of MMR reaches young adulthood, physicians caring for young adults should ensure that a second dose of MMR is given. Although the need for a second dose of this product has been established only for measles, in almost all cases it is simplest to use the existing MMR vaccine, because there is little price advantage to using the monovalent product and there is no adverse effect in giving MMR to persons already immune to one or more of the antigens. It is especially important to ensure that adults born in 1957 and after who may be exposed to measles have received two doses; such persons include students and teachers in educational institutions, health care workers, and travelers to areas in which measles is endemic. Adults born in 1956 and earlier may be considered immune.

Measles has been a special threat in HIV-positive patients and a cause of fatal disseminated infection in susceptible patients with AIDS. Although the data are limited, experience to date suggests that measles vaccine, given as MMR, may be administered safely to patients with asymptomatic or even symptomatic HIV infection. Individual judgment should be exercised in the case of susceptible AIDS patients with extremely low CD4 cell counts (less than 50 per cubic millimeter), depending on the likelihood of exposure. Because vaccine efficacy under such circumstances has not been established, exposed patients with CDC-defined AIDS should be given immune globulin as soon as possible after exposure, even if they have previously received two doses of MMR.

TETANUS AND DIPHTHERIA TOXOIDS

The standard recommendation, after the primary immunization series with tetanus and diphtheria (Td or DTP) has been completed, has been for a booster dose of Td at 10-year intervals throughout the balance of the adult life span. In 1994, the ACP's Adult Immunization Task Force modified its recommendations. Booster doses every 10 years are still acceptable but may be unnecessary. Alternatively, it is recommended that once primarily immunized, a booster dose be given at adolescence (age 15) and again at age 50; further booster doses are not necessary. The ACIP, however, has not changed its recommendation for booster doses at 10-year intervals, owing to concerns about the adequacy of diphtheria immunity in light of recent outbreaks in Eastern Europe and Asia.

VARICELLA VACCINE

Varicella vaccine is a live, attenuated virus vaccine that has been approved for use since 1995. Since the disease may be severe and even life-threatening in adults, susceptible adults should be immunized. Most adults are immune as a result of childhood chickenpox infection. Adults with a reliable history of chickenpox may therefore be considered immune. Serologic testing may be cost-effective for those with an uncertain history.

The ACIP has defined several groups of adults as being at high risk of being exposed to varicella-zoster virus (VZV). These include (a) persons who live or work in environments where transmission of VZV may occur (e.g., teachers of young children, day care employees, those in institutional settings such as health care workers, college students, military personnel); (b) nonpregnant women of childbearing age; (c) adolescents and adults living in households with children; and (d) international travelers.

Although varicella is a live virus vaccine, it may be given to persons with impaired humoral immunity, but not to persons with severe cellular immunodeficiency. The vaccine has been safely given to patients with asymptomatic or mildly symptomatic HIV infection. It should not generally be given to persons with more advanced AIDS, to persons receiving immunosuppressive therapy, or to those receiving moderate or high-dose corticosteroid therapy.

In spite of years of prelicensure study, there is much yet to be learned about this vaccine and the epidemiologic consequences, if any, of its widespread use. Continuing postlicensure surveillance of varicella and herpes zoster are of critical importance. Whether administration of the vaccine to older adults will decrease the frequency or the severity of subsequent cases of herpes zoster is currently under investigation.

VACCINES FOR USE IN ADULTS UNDER SPECIAL CIRCUMSTANCES

Several vaccines are not recommended for routine use in adults, but are recommended for use in particular circumstances such as occupational risk, unusual epidemiologic circumstances, or exposures. These special-purpose vaccines are summarized in [Table 26.3](#) and include vaccines directed against hepatitis A, poliomyelitis, rabies, meningococcal infection, Lyme disease, typhoid fever, and tuberculosis. Certain other vaccines indicated only for international travel, that is, yellow fever, cholera, plague, and Japanese encephalitis vaccines, will not be discussed further here ([Chapter 27](#)).

Vaccine	Major Indications
Poliomyelitis (IPV only)	Travelers to endemic/epidemic areas; persons potentially occupationally exposed
Rabies	Postexposure prophylaxis; preexposure prophylaxis for persons with high risk of exposure
Meningococcal	Travelers to endemic areas; outbreak control; consider in certain immunocompromised patients (see text)
Typhoid BCG	Travelers to endemic areas; limited settings with unavoidable transmission of tuberculosis (see text)
Hepatitis A	International travelers; persons with occupational or lifestyle exposures; high-risk areas or populations; consider in food handlers
Lyme disease	Persons age 15-70 at high risk of exposure

BCG, Bacille Calmette-Guérin; IPV, inactivated polio vaccine.

TABLE 26.3. VACCINES FOR SPECIAL-PURPOSE IMMUNIZATION OF ADULTS

HEPATITIS A VACCINE

Hepatitis is an inactivated vaccine that has been approved for use since 1995. It is indicated for the following groups of persons:

- Persons traveling to or living in countries where the endemic incidence of hepatitis A is intermediate or high. In practical terms, this includes all destinations except North America, Western Europe, Japan, and Australia/New Zealand. Thus, any traveler who is a candidate for immune globulin may be considered a candidate for hepatitis A vaccine. For only a single trip of less than 3 months' duration, immune globulin prophylaxis is just as effective and at lower cost.
- Sexually active homosexual males.
- Illegal drug users.
- Persons who have occupational risks, such as workers in infected primate colonies or those working with hepatitis A virus in research settings.
- Persons in whom the consequences of hepatitis A infection might be especially adverse, such as patients with chronic liver disease, including hepatitis B or C, and persons with clotting factor disorders.

Food handlers should be considered for vaccination, depending on state and local circumstances. Restaurants and catering establishments may wish to immunize their employees. The vaccine has also proved useful in controlling several community-wide outbreaks.

Since this is an inactivated vaccine, it poses no risk for immunocompromised patients, although the immune response may be suboptimal.

POLIOMYELITIS VACCINES

Two types of polio vaccines are available: live oral polio vaccine (OPV) and inactivated polio vaccine (IPV). OPV has been until recently the most widely used product in the United States. There is an extremely low (approximately 1 out of 1 million doses) risk of paralytic disease caused by OPV; that fact, combined with the fact that the vaccine has been extremely effective in essentially eradicating natural poliomyelitis from the Western hemisphere, has resulted in the somewhat anomalous circumstance that all the paralytic poliomyelitis occurring in the United States for most of the past decade has been vaccine-induced. The ACIP is currently moving toward exclusive use of IPV in the United States.

After primary immunization has been completed, usually in childhood, the need for subsequent doses is limited to travelers to destinations where polio is occurring and to health care and virology laboratory personnel who, in the course of their occupational duties, may be exposed to wild polio virus. Given the absence of the natural disease from the United States, such circumstances are infrequent.

For primary immunization or booster doses in adults, IPV should be used exclusively. Immunocompromised persons should not be exposed to OPV or to excreted vaccine virus of OPV recipients.

RABIES VACCINE

Present rabies vaccines are inactivated products, prepared from rabies virus grown in human diploid cell culture. Recommended uses are for either preexposure or postexposure prophylaxis of rabies. Preexposure immunization should be considered for persons at high risk for exposure; such persons include veterinarians, animal handlers, those with occupations or hobbies resulting in unavoidable exposure to potentially rabid animals, and laboratory personnel working with wild rabies virus.

Postexposure prophylaxis always includes the use of rabies hyperimmune globulin in addition to the vaccine. Any decision to initiate postexposure prophylaxis should include consideration of the animal species involved, the nature of the bite or other exposure, the vaccination status of the exposed person, and the recent history of presence of rabies in the region. Local or state public health officials should always be consulted whenever questions arise about the need for rabies prophylaxis.

MENINGOCOCCAL VACCINE

The current vaccine is a quadrivalent product containing polysaccharides from serogroup A, C, Y, and W-135 meningococci. No antigen directed against serogroup B meningococci is yet available. Meningococcal vaccine is not recommended for routine use in adults, because the frequency of meningococcal infection in the United States is so low. It is recommended for the small number of high-risk persons who have terminal complement component deficiencies or are asplenic. Meningococcal vaccine is also recommended to be used for travelers to parts of the world where there is an increased frequency of meningococcal infection and for control of outbreaks caused by vaccine serogroup strains in closed or semiclosed populations, such as those on college campuses.

LYME DISEASE VACCINE

Lyme disease vaccine is a recombinant inactivated vaccine prepared from outer surface protein A (rOspA) of *Borrelia burgdorferi*. It was approved for use in the United States in early 1999. The mechanism of action is unique in that outer surface protein A of the bacterium is expressed only in the gut of the host tick; ingested blood from an immunized human, containing antibody to OspA inactivates the spirochete before it reaches its human host. Once inside humans, OspA is no longer expressed. Thus, the vaccine acts by eliciting antibodies that kill the spirochete in the tick gut, rather than by any direct microbicidal effect within the human host.

Lyme disease vaccine is recommended for persons age 15 to 70 years who are at increased risk of exposure to Lyme disease. The population at risk is thus limited to those who reside in or visit Lyme disease endemic areas and who engage in activities that result in frequent or prolonged exposure to tick-infested areas.

Many questions remain about this vaccine, which could not be addressed in the pivotal field trials leading to licensure. These include, among others, safety and efficacy in children under 15 years of age, safety issues in those with chronic arthritis or autoimmune states, and the need for booster doses. Continuing postlicensure surveillance of the disease and further studies of vaccine are of critical importance.

TYPHOID VACCINE

The administration of typhoid vaccine is not recommended for any persons living in the United States and is generally of no use in areas of natural disaster, such as floods or earthquakes. It is indicated only for travelers who are likely to be exposed in areas of the world in which typhoid fever is endemic.

Three vaccines are available, two inactivated and one live, oral product. Since good alternatives are available, the live attenuated vaccine should not be given to immunocompromised persons.

BACILLE CALMETTE-GUÉRIN VACCINE

Recommendations for the use of Bacille Calmette-Guérin (BCG) vaccine in the United States are extremely limited, in sharp contrast to many other countries where BCG is used widely or even universally in infants. Adults in the United States for whom BCG vaccine might be considered include susceptible adults who are unavoidably exposed and identifiable populations with an excessive rate of new tuberculosis infection (more than 1% per year) that cannot be controlled by the usual public health measures.

Some hospital staff populations in the United States have qualified as having an excessive rate of new tuberculosis infection, and recent hospital outbreaks of multidrug-resistant tuberculosis in AIDS and other immunocompromised patients and hospital staff have also raised questions about a possible role for BCG vaccine. These situations have usually been amenable to control by implementation of CDC's guidelines for prevention of tuberculosis transmission in health care settings. An expanded role for BCG vaccine, therefore, is not indicated. Furthermore, since it is a live, attenuated vaccine, it is contraindicated in all persons with AIDS as well as

in other immunocompromised patients; use in asymptomatic HIV-positive patients should probably be avoided also.

CHAPTER 27: INFECTIOUS DISEASE PREVENTION IN THE INTERNATIONAL TRAVELER

DAVID O. FREEDMAN

[Epidemiology](#)
[Preventive Measures and Risk Management](#)
[Immunization](#)
[Chemoprophylaxis](#)
[Self-Treatment of Infectious Diseases](#)

Infectious disease prevention in the international traveler should be based on risk management principles. Prevention strategies and medical interventions must be highly individualized according to both itinerary and traveler-dependent factors. The medical program for travelers to a particular country varies according to specific disease endemic zones visited within that country, urban versus rural travel, previous vaccination history, age, class of travel, duration of stay, and underlying medical history. Essentially all necessary preventive measures, aside from immunization, are behavioral and entirely within the patient's control. Unfortunately, these measures are to be initiated only much later at the destination, making clear printed instructions in lay language mandatory.

EPIDEMIOLOGY

Annually, 35 million people travel from industrialized to developing countries. Approximately 5% of US citizens travel by air to the developing world each year. The amount of travel to Central and South America taken together has begun to approach that to Asia. Fewer than 250,000 US citizens travel to Africa each year. A broad range of microbial pathogens present varying degrees of risk to the traveler ([Fig. 27.1](#)). Infectious agents account for significant morbidity among travelers but only for 1% of deaths.

FIGURE 27.1. Incidence (rate/month) of health problems during a stay in developing countries.

Although it is infrequently medically serious, the most common health problem during stays in countries with poor hygiene is traveler's diarrhea. Classic *traveler's diarrhea* is usually defined as three or more unformed stools per day together with one enteric sign such as abdominal cramps, fever, nausea, or vomiting. However, milder diarrheal illnesses can make a significant impact on the quality of daily life. The incidence varies from about 7% for travel to developed countries to about 20% in southern Europe, Israel, Japan, South Africa, and some Caribbean islands. In most of Asia, Latin America, Africa, and the Middle East the risk is 25% to 50% in the first 2 weeks abroad and subsides somewhat thereafter. Although there is some regional variation throughout the world, the most common causative agent of diarrhea is enterotoxigenic *Escherichia coli* (6% to 70%). Other types of *E. coli*, *Salmonella*, *Shigella*, and *Campylobacter* each account for about 5% to 15%. Parasites such as *Entamoeba histolytica*, *Giardia lamblia*, *Cryptosporidium*, and *Cyclospora* account for less than 2% each, and in adults Norwalk virus or rotavirus rarely may be detected.

About 30% of diarrheal episodes remain unexplained but many apparently are of bacterial origin, because they improve with antibacterial agents. *E. coli* and *Cyclospora* are more common during summer months, and *Campylobacter* is more common during cold months. *Campylobacter* and noncholera *Vibrios* are more common in Asia. Nonpediatric travelers showing an above-average incidence of traveler's diarrhea include those taking proton-pump inhibitor drugs (but not those on H₂ blockers), those who are naturally achlorhydric, as well as young adults between 20 and 29 years of age.

Traveler's diarrhea is usually mild and is rarely dehydrating. Only 25% of those affected have more than six bowel movements per day. Fifty percent of affected persons suffer abdominal cramps, and roughly 15% have nausea, vomiting, fever, or blood admixed in the stools. None of the clinical symptoms are pathognomonic for a specific agent. Untreated, the disease is self-limited with an average duration of 4 to 5 days. Persistent diarrhea, that is, diarrhea lasting more than 14 days, occurs in 1% to 2% of travelers and has a different spectrum of causes.

Malaria is the most important life-threatening risk for travelers going to endemic areas. Two-thirds of the world's cases occur in Africa, India, Brazil, Sri Lanka, Vietnam, the Solomon Islands, and Colombia. Belize, Nicaragua, and Guatemala have the highest incidence of malaria in Central America. Falciparum malaria has had a recent upsurge in the Amazon regions of Peru, Guyana, and Bolivia. Estimates of risk in travelers not taking chemoprophylaxis vary widely by destination but range from 24 of 1,000 travelers per month in West Africa to 3.5 of 1,000 per month on the Indian subcontinent to 0.5 of 1,000 per month in South America. Most cases of imported malaria in the United States and Europe occur in noncitizen immigrants visiting friends and relatives abroad. Malaria chemoprophylactic drugs are underused by these ethnic minority travelers.

For vaccine-preventable diseases, the monthly incidence in developing countries is most significant for symptomatic hepatitis A (3 of 1,000 travelers per month). The risk of symptomatic hepatitis B is most significant for long-stay travelers and expatriates (0.25 of 1,000 per month). Typhoid fever has a risk of 0.03 per 1,000 per month, but the risk on the Indian subcontinent is ten times higher. Epidemiologic data are scant on the risk of yellow fever, meningococcal meningitis, rabies, cholera, polio, measles, and Japanese encephalitis in travelers. Imported measles occurs with some regularity in nonimmune persons. The risk of the other infections previously listed is real but apparently exceedingly small even for travel to highly endemic areas. In 1996, a fatal case of yellow fever, the first case seen in the United States in over 50 years, occurred in an unvaccinated American traveler to Brazil.

Travel is a disinhibiting experience in itself, and alcohol consumption tends to increase during travel. Between 19% and 26% of all travelers report a new sexual contact during their last trip abroad. Risk factors include younger age, business travel, trip longer than 3 months, previous visits to the same destination, and infection with a sexually transmitted disease (STD) in the past 5 years. Condom use during casual travel sex is uniformly less than 25%, even in those who had received pretravel counseling.

PREVENTIVE MEASURES AND RISK MANAGEMENT

The risk of travelers' diarrhea can be reduced but not eliminated by educating the traveler to avoid dietary indiscretions. Nevertheless, increasing evidence suggests surprisingly small differences in the incidence of travelers' diarrhea in persons self-reporting meticulous compared with adventurous eating habits. Less than 3% of all travelers avoid all potentially risky food and drink items. The safest foods include those served steaming hot, fruits that can be peeled, and bread. Hot soup, coffee, or tea, as well as bottled carbonated beverages (preferably multinational brands), beer, and wine are generally safe. Clearly high-risk items include undercooked shellfish and meats, salads, creamy desserts, sauces sitting for long periods at room temperatures, and ice cubes made from contaminated sources. Wherever boiled, bottled, or other safe source of drinking water is not likely to be available, travelers should carry either halogen-based water purification tablets or an iodine resin-based filtration device.

Antimalarial chemoprophylactic drugs are less than 100% effective at many destinations. Efforts to minimize mosquito bites protect not only against malaria but also against dengue, filariasis, and a number of important arboviral diseases. Maximizing personal arthropod protection during *Anopheles* feeding hours (dusk to dawn) should include the following: cover up exposed skin areas with more than the thinnest of fabrics; apply DEET (diethyltoluamide)-containing repellent liberally on any remaining exposed skin; impregnate clothing with permethrin; if an air-conditioned or carefully screened room is unavailable, sleep under a permethrin-impregnated bed net; and use a knockdown insect spray right before bed. *Aedes* sp. and Culicine mosquitoes are usually day biters, so vigilance at all hours best protects against a full spectrum of arthropod-borne infectious agents.

Avoidance of casual travel sex will maximally protect against STDs and HIV. Education regarding the incidence of HIV and STDs among professional sex workers abroad, the usage of condoms, and the failure rate of condoms (3% to 5% breakage/slippage) should be given to each and every traveler, regardless of apparent circumstances.

A predeparture dental checkup reduces the risk of oral infections during travel. A predeparture baseline tuberculin skin test with annual retesting is indicated for long-stay travelers to developing countries. Aggressive treatment of skin-test converters prevents cases of active tuberculosis later. Travelers should carry a compact medical kit. Simple first-aid supplies such as bandages, gauze, antiseptic, antibiotic ointment, and splinter forceps allow early self-treatment of minor wounds before infection ensues. Travelers should be instructed on scrupulous avoidance of recreational (swimming, rafting, wading) or other exposure to fresh water in schistosomiasis endemic areas.

A significant risk of leptospirosis exists in fresh water throughout the developing world owing to excretion of the spirochetes (which can penetrate intact skin) in the urine of rodents and other animals. Walking barefoot in tropical areas predisposes to hookworm, strongyloides, cutaneous larva migrans, and tungiasis. Scabies and lice are prevented by close attention to personal hygiene and careful laundering of clothes. In Africa, all clothes dried outdoors should be ironed to avoid cutaneous myiasis due to the tumbu fly. Long-stay travelers should plug themselves into the local expatriate medical infrastructure immediately after arrival so as to be able to rapidly seek competent care for any ensuing infectious disease early in its course.

IMMUNIZATION

Vaccine selection depends on risk evaluation, but travelers differ in their tolerance of risk. Requests for immunization against infectious agents that have bad outcomes if acquired, but are of negligible risk to the traveler, are often difficult for the physician to refuse. Issues pertaining to children and special needs travelers with HIV infection, immunocompromising conditions, pregnancy, and chronic diseases are dealt with elsewhere. These patients are best referred to a specialized travel medicine clinic. Technical details of the vaccines to be discussed are provided in [Table 27.1](#).

Vaccine	Route	Regimen (Days)	Efficacy (%)	Effective from Day*	Duration of Protection
Cholera					
DTC (oral)	PO	2 (0-14)	85-95	14-21	3-5 yr

CHEMOPROPHYLAXIS

No single drug provides optimal protection against malaria in all parts of the world. Chemoprophylactic drug regimens must be individualized to the person's particular itinerary, the duration of travel, medical history, access to medical care abroad, and the traveler's personal tolerance for risk. Not all regions or cities within a malarious country are malarious. In general, malaria is a rural disease, with the cities of Africa and India as exceptions. For malaria prevention, mefloquine (250 mg once weekly) is the drug of choice with two exceptions: (a) the border areas of Thailand, where, because mefloquine resistance, doxycycline (100 mg daily) is indicated; and (b) Central America, Mexico, Haiti, and the Middle East, where chloroquine (500 mg base, once weekly) is still effective. If contraindications to mefloquine exist, daily doxycycline can be used. Chloroquine-resistant *Plasmodium vivax* occurs only in areas where mefloquine is already indicated for prophylaxis because of the concomitant presence of resistant *Plasmodium falciparum*. For long-term residents, a specialized travel clinic should be consulted. Travelers need to be reminded in writing that they should continue antimalarial drugs for 4 weeks after the last possible exposure, that malaria can still occur despite chemoprophylaxis, and that a malaria smear is mandatory for any febrile illness occurring within 3 months of travel. Malaria chemoprophylaxis recommendations are liable to change periodically. Physicians may check the Centers for Disease Control and Prevention Web Page (<http://www.cdc.gov/travel/malariadrugs2.htm>) or call the CDC physician malaria hotline (770-488-7788) for the latest advice.

Antibiotic prophylaxis for diarrhea is contraindicated for the typical traveler because of potential adverse drug effects while away from medical care and because effective rapid-onset therapy is available for diarrhea if it occurs. However, chemoprophylaxis can be considered for travelers with HIV infection, an underlying chronic medical problem that makes them more prone to adverse consequences from diarrhea and for those on a vital mission for a short period of time (less than 1 week) who cannot tolerate even a day of disability. Bismuth subsalicylate (two tablets four times per day) during travel and for 1 to 2 days after returning may reduce the incidence of diarrhea by up to 60%, but it is inconvenient to take. Antimicrobials are more effective, but they may have significant potential toxicity and may complicate therapy if breakthrough illness occurs. One of the quinolone antibiotics is recommended. These include norfloxacin (400 mg), ciprofloxacin (500 mg), ofloxacin (300 mg), or levofloxacin (500 mg) once daily during travel and for 1 to 3 days after returning home. Antibiotic prophylaxis should be used only for trips of 2 weeks or less. For longer trips, chemoprophylaxis is not advised.

SELF-TREATMENT OF INFECTIOUS DISEASES

All travelers to the developing world should be thoroughly educated in self-therapy for diarrheal disease. All travelers should carry in their medical kit loperamide and a quinolone antibiotic. Diarrhea that does not improve quickly (within a few hours) to loperamide can be treated with a 3-day course of a quinolone (see drugs and dosages above) while loperamide therapy is continued. Eighty percent of patients respond to this regimen within 24 hours. Slower responders may continue therapy for up to 5 days. Those with dysentery or who don't respond to 5 days of antibacterial agents should seek medical attention, if feasible. A significant increase in quinolone-resistant *Campylobacter* in Southeast Asia is emerging. Bismuth subsalicylate by itself is sometimes curative but is less effective than antibiotics. Traveler's diarrhea is not dehydrating, but those who are going to remote regions should carry packets of oral rehydration salts.

For stays in areas with very low transmission rates of malaria, some physicians, notably in Europe, may advise that only a standby drug be carried, which is to be taken if symptoms suggestive of malaria occur and if there is no access to a physician or facility that can perform a competent malaria smear within 6 to 12 hours. In areas with chloroquine-resistant *P. falciparum*, the drug of choice is mefloquine; 1,250 mg divided in two to three doses separated by an interval of 8 hours. In areas without chloroquine-resistant *P. falciparum*, chloroquine is the drug of choice. Even after a good response, the patient should consult a physician as soon as possible.

The travel medical kit may include an extended-spectrum quinolone, such as levofloxacin, or a macrolide, such as azithromycin, which will allow early self-treatment of respiratory or soft-tissue infections. Antifungal creams or powders alleviate mycotic infections prevalent in humid tropical environments. Travelers to high-risk areas should have a thermometer to document elevations in temperature to determine early the need for antimalarial or antimicrobial drugs or the need to seek medical attention.

CHAPTER 28: CANCER SCREENING AND EARLY DETECTION

JHON K. GOHAGAN, BARNETT S. KRAMER AND WILLIAM C. BLACK

[Principles of Cancer Screening](#)
[Screening for Specific Cancers](#)
[Assessment of Screening Effectiveness](#)

PRINCIPLES OF CANCER SCREENING

Several methods of cancer screening have proved effective in decreasing cancer mortality. Dramatic technological advances in imaging and molecular detection during the last two decades have greatly enhanced the opportunities for cancer screening in the future. However, there is much confusion about assessing effectiveness of early detection and the net benefit of specific screening strategies. Experience has shown that arguments for earlier cancer detection based on advances in detection technologies, disease risk, or treatment advances should be treated as plausible hypotheses to be tested with scientific rigor.

Early detection of cancer does not axiomatically confer benefit and may confer harm. For early detection by screening to be appropriate, two consequent conditions must be met:

- Treatment provided at the time of screen detection must be more effective in reducing cause-specific mortality than treatment provided at the usual time of clinical diagnosis.
- The benefits of earlier treatment must outweigh the harms derivative to screening.

The first condition is very difficult to determine. Survival measured in screen detected versus clinically detected cases overestimates effectiveness. The second condition is also very difficult to determine, and the potential for harm is often not recognized by screening advocates. False-positive screening tests often lead to invasive procedures to exclude malignancy. When early detection does not change the course of the disease, the patient suffers the effects of diagnosis and treatment for a longer period of time. This latter harm is particularly relevant to the detection of premalignant lesions and carcinoma *in situ*, many of which might never have become clinically significant.

Some organizations apply categorical quality levels to sources of evidence regarding screening effectiveness. The National Cancer Institute's Physician Data Query system uses a five-level categorization, in declining order of strength, similar to the one listed below. The US Preventive Services Task Force, the Canadian Task Force on the Periodic Health Examination, and the American College of Physicians use similar rating systems.

Randomized controlled trials
Internally controlled trials without randomization (e.g., allocation by birth date)
Cohort or case-control studies
Multiple-time series with or without intervention
Opinions of respected authorities based on clinical experience, descriptive studies, or reports of expert committees

Randomized controlled trials that correct for or eliminate several confounding biases provide the most compelling scientific evidence.

Selection bias can cause either under- or overestimation of screening effectiveness, depending on whether those at higher risk of the disease are more or less likely to undergo screening. *Lead-time bias* pertains to comparisons that are not adjusted for the timing of diagnosis. If screen-detected cases are diagnosed earlier, they will survive longer from the time of diagnosis even if their death is not delayed. *Length bias* pertains to comparisons that are not adjusted for the rate of disease progression. Cases detected by screening are more likely to be slowly progressive than those not detected by screening and ultimately presented clinically. *Overdiagnosis bias* pertains to comparisons that are not adjusted for the detection of pseudodisease, preclinical disease that would not have produced any signs or symptoms before the person would have died from other causes. Overdiagnosis bias, which can be considered an extreme form of length bias, can markedly inflate the survival and cure rates in screen-detected cases ([Fig. 28.1](#), [Fig. 28.2](#) and [Fig. 28.3](#)).

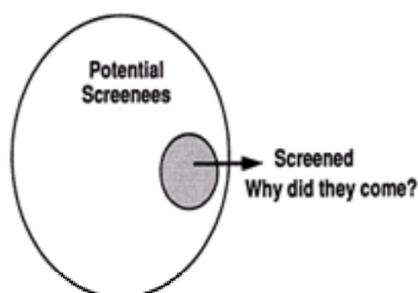

FIGURE 28.1. Selection bias results from the tendency of more health-conscious persons with mortality rates lower than expected to join screening programs. (From Kramer BK, et al. Prostate cancer screening. *Ann Intern Med* 1993;119:917, with permission.)

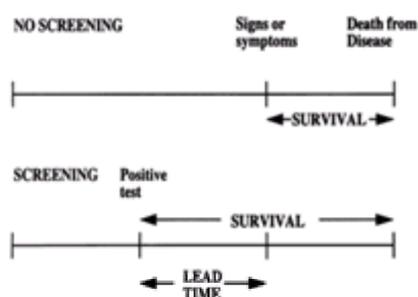

FIGURE 28.2. Lead time bias. Without screening, diagnosis occurs when clinical signs or symptoms develop. With screening, time of diagnosis is advanced by lead time provided by positive test result. If earlier diagnosis has no effect on time of death from disease, then survival with testing is equal to survival without testing plus lead time. (From Black WC, Welch HG. Screening for disease. *Am J Roentgenol* 1997;168[1]:3–11; www.arrs.org, with permission.)

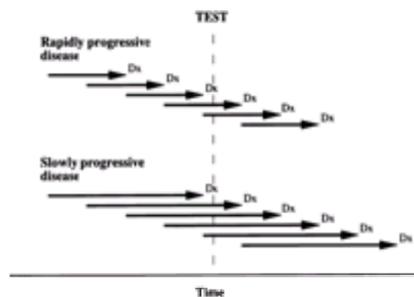

FIGURE 28.3. Length bias. Probability of detection is related to rate of disease progression. The length of each arrow represents length of detectable preclinical phase, from initial detectability to clinical diagnosis (D_x). Testing at a single moment in time detects four slowly progressive cases, but only two rapidly progressive cases (**bold arrows**). Cases not detected by test (*gray arrows*) are diagnosed clinically, either before or after time of testing. (From Black WC, Welch HG. Screening for disease. *Am J Roentgenol* 1997;168[1]:3–11;www.arrs.org, with permission.)

SCREENING FOR SPECIFIC CANCERS

BREAST CANCER

In 1999, an estimated 176,300 new cases of breast cancer will be detected in the United States. Incidence increased at an annual rate of 1% between 1940 and 1980 and has been increasing at a substantially higher rate since 1980 with the widespread application of screening mammography. Recent data suggest that incidence may be leveling off. In 1999, an estimated 43,700 breast cancer deaths are projected.

Data from the world's eight randomized breast cancer screening trials were reviewed and critiqued at the National Institutes of Health (NIH) Consensus Development Conference of January 21–23, 1997. The NIH Consensus Statement on Breast Cancer Screening for Women Ages 40–49 contained two reports. The Majority Report stated, "The Panel concludes that the data currently available do not warrant a universal recommendation for mammography for all women in their forties." Two panel members wrote a Minority Report in which they expressed an opinion that the risks of mammography were overstated by the majority and that current data supported screening mammography for all women ages 40 to 49.

One major concern of the NIH Consensus Panel was the detection of ductal carcinoma in situ (DCIS), which may progress to invasive cancer very slowly or not progress at all. DCIS constitutes about 50% of all mammographically detected malignancies in women 40 to 49 years of age, and the age-adjusted incidence of DCIS has increased more than threefold since 1983, along with the increased use of mammography.

Controversy continues regarding the appropriateness of periodic mammographic screening of women ages 40 to 49 years.

The Consensus Panel's report did not address the issues of screening mammography for women aged 50 and older. Previously, the National Cancer Institute's International Workshop on Screening for Breast Cancer (February 24–25, 1993) concluded that there is strong evidence from clinical trials that, "between 50 and 69 years of age, screening with mammography alone or in combination with clinical breast examination at 12- to 33-month intervals can reduce mortality by about 30%." The effectiveness of screening beyond 70 years of age is unknown.

PROSTATE CANCER

An estimated 179,300 new cases of prostate cancer and 37,000 prostate cancer-related deaths are projected for 1999 in the United States. It is projected that prostate cancer will account for 29% of all male cancers and 13% of male cancer deaths in the United States in 1999.

The rate of progression of prostate cancer is highly variable and unpredictable. Clinical prostate cancer is rare in men younger than 50 years of age, although occult cancer is common in autopsy series of men who died of causes unrelated to prostate cancer. Incidence rises rapidly after 50 years of age. Age-adjusted incidence among blacks (142.0 cases per 100,000 men) is substantially higher than among whites (108.3 cases per 100,000 men). Men with a family history of prostate cancer are thought to have an increased risk of the disease compared with men without this history.

Widespread prostate cancer screening in the United States has led to dramatic increases in prostate cancers detected in the United States compared with the United Kingdom where screening is less intense. However, prostate cancer mortality in the two countries is nearly identical.

Predictions of the effect of prostate cancer screening from mathematical models range from net benefit to net harm. Opinions based on clinical experience, descriptive studies, or reports of expert committees therefore vary from endorsement to specific recommendations against population screening. Randomized trials designed to ascertain the risk-to-benefit balance will not report results for several years.

COLORECTAL CANCER

Colorectal cancer is the second leading cause of death from cancer in the United States. Approximately 129,400 new cases and 56,600 deaths in the United States are projected for 1999. Incidence is higher among men than women. Both incidence and mortality rates in the United States are declining for reasons that may include dietary changes, improved treatment, and screening.

Screening for colorectal cancer represents a form of primary and secondary prevention, because it can lead to the identification and eradication of preneoplastic lesions such as adenomatous polyps.

Hereditary risk factors, such as familial polyposis, hereditary nonpolyposis syndrome, the cancer family syndrome (autosomal dominant), and hereditary site-specific colon cancer together may account for less than 10% of colorectal cancers. Other risk factors include a personal or first-degree family history of colorectal cancer or adenomas, inflammatory bowel disease (especially ulcerative colitis), and a personal history of ovarian, endometrial, or breast cancer. High-risk groups may account for as much as 23% of all colorectal cancers.

A large percentage of early cancers and precursor adenomas can be detected by screening asymptomatic persons older than 50 years of age using the fecal occult blood test and flexible sigmoidoscopy. It is hypothesized that removal of premalignant adenomatous polyps should decrease mortality, although direct evidence from a randomized clinical trial is not available. The discovery of polyps in the distal colon or rectum or the presence of occult blood mandates colonoscopy to search the entire colon.

Two case-control studies evaluated the association of screening sigmoidoscopy with a decrease in colorectal cancer mortality. One study evaluated rigid sigmoidoscopy; the other evaluated rigid and flexible sigmoidoscopy. Both studies suggested a significantly decreased risk (60% to 80%) of fatal cancer of the distal colon or rectum among persons with a history of one or more sigmoidoscopic examinations compared with nonscreened patients. The decrease in colorectal cancer associated with screening was restricted to cancers that occurred within the reach of a sigmoidoscope.

Several controlled clinical trials are evaluating the efficacy of screening using the fecal occult blood test (FOBT). The Minnesota trial demonstrated that annual FOBT using rehydrated samples decreased mortality from colorectal cancer by 33%; biennial FOBT yielded a 21% reduction. Randomized trials in Denmark and the United Kingdom also report mortality reductions with biennial FOBT screening.

CERVICAL CANCER

In 1999, more than 12,800 new cases of invasive cervical cancer are expected, with about 4,800 women dying of this disease. From 1950 to 1970, the incidence and mortality rates of invasive cervical cancer fell by more than 70%. Since the early 1980s, the rates for incidence and mortality appear to be decreasing more slowly. Mortality rates have actually risen slightly for young white women in recent years. A major aim of cervical cancer screening is to detect and eradicate preneoplastic lesions (carcinoma in situ), making it in large measure a primary prevention practice.

Rates for carcinoma in situ reach a peak for black and white women between 20 and 30 years of age. After the age of 25, however, the incidence of invasive cancer for black women increases rapidly with age, but it rises more slowly for white women. Mortality increases at dramatically different rates for blacks and whites with advancing age.

Substantial evidence exists from numerous observational studies that mortality from cervical cancer is reduced by screening using the Papanicolaou (Pap) test. Data from several large studies show sharp reductions in incidence and mortality rates after the initiation of organized screening programs. Mortality rates fell by 80% over 20 years in Iceland and by 50% and 34%, respectively, in Finland and Sweden. Similar reductions have been found in large populations in the United States and Canada. Reductions in incidence and mortality rates seem to be proportional to the intensity of screening efforts. However, screening every 2 to 3 years has not significantly increased the risk of invasive cervical cancer above the risk expected with annual screening. Cytologic screening of women who have not had a Pap test for several years, usually older women and often of lower socioeconomic status, offers the greatest benefit, because these women have a highest risk of dying of cervical cancer. Pap testing is of little or no value in women who have had a hysterectomy with surgical removal of the uterine cervix.

A randomized, controlled trial of Pap test screening is ruled out by falling cervical cancer mortality rates associated with widespread practice of periodic Pap testing, but the National Cancer Institute is conducting a randomized trial to determine the effectiveness of human papillomavirus testing to discriminate between low- and high-risk cervical intraepithelial lesions.

LUNG CANCER

Cancers of the lung and bronchus are expected to total 171,600 in 1999 and to account for 158,900 deaths. Prevention, especially smoking avoidance, rather than early detection is more likely to favorably affect these statistics. Four randomized lung cancer screening trials have been reported, and none shows any mortality benefit, even in a high-risk population of male smokers. The Memorial Sloan-Kettering Hospital and Johns Hopkins Hospital trials showed no benefit to the addition of sputum cytology to regular chest radiographs for evaluating male smokers. After a prevalence screen for lung cancer, the Mayo Lung Project randomized male smokers to receive regular chest radiographs plus sputum cytology versus routine medical care. However, there was substantial contamination by screening in the control group, which lowered the power of the trial to detect a benefit.

All three trials achieved a stage shift to earlier cancer detection (resulting in more thoracotomies with curative intent) in the screened arms. This was associated with longer survival after diagnosis of screened subjects but no decrease in lung cancer mortality rates. This discrepancy is probably mainly due to lead-time, length, and overdiagnosis biases. A fourth randomized trial in Czechoslovakia of semiannual screening by chest radiograph and sputum cytology versus screening at 3 year intervals also showed no mortality reduction.

However, the issue is not fully settled. Two of the trials screened both study arms with chest radiographs. None was large enough to reliably detect medically important mortality benefits of even 10% to 20%, because even the largest of the trials randomized fewer than 10,000 subjects. It is also important to see whether lung cancer screening with chest radiographs benefits women, who exhibit the most rapidly increasing rate of lung cancer in the United States. The potential for screening with spiral computed tomography and molecular marker is currently under investigation.

OTHER CANCERS

There is no information from clinical trials or even observational studies regarding mortality reduction from screening for other cancers.

ASSESSMENT OF SCREENING EFFECTIVENESS

The National Cancer Institute provides scientific statements through the Physician Data Query system on the state of knowledge regarding cancer screening. The US Agency for Health Care Policy and Research issues periodic organ-specific reviews and policy statements. Many professional organizations issue screening guidelines.

It is firmly established that screening reduces mortality from cervical cancer (Pap tests every few years), breast cancer (mammography with or without clinical breast examination every 1 to 2 years for women 50 to 69 years of age), and colon cancer (rehydrated FOBT annually after 50 years of age). Mortality benefits from flexible sigmoidoscopy (for colon), chest radiograph (lung), transvaginal sonography, and CA125 (ovary), and digital rectal examination and prostate-specific antigen (prostate) are being assessed in the US National Cancer Institute's Prostate, Lung, Colorectal, and Ovarian (PLCO) Cancer Screening Trial. Randomized trials for colon, ovary, and prostate are underway in Europe. Mammographic screening among women ages 40 to 49 years is being studied in the United Kingdom, and a multinational extension of that trial is under consideration elsewhere in Europe.

CHAPTER 29: EPIDEMIOLOGY AND PREVENTION OF CARDIOVASCULAR DISEASE

LORI MOSCA

[Epidemiology of Coronary Heart Disease](#)
[Risk Assessment](#)
[Comprehensive Preventive Cardiology](#)

Cardiovascular disease (CVD) has remained the leading cause of death and a major cause of disability in the United States for nearly a century. Although there has been a decline in the age-adjusted death rate of coronary heart disease (CHD) and stroke exceeding 50% since 1963, there has not been a similar decrease in the actual number of deaths due to CVD relative to the expansion and aging of the US population. For example, between 1986 and 1996, the overall death rate due to CVD decreased 21.3%, with a decline in the actual number of deaths of only 2%. Among women, the absolute number of deaths has increased because more women are living to older ages, when CVD is more common ([Fig. 29.1](#)). The decline in the CVD death rate has also been less for women than men and has been smaller for blacks than whites.

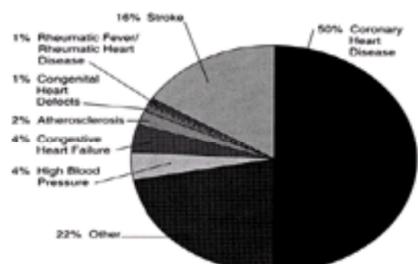

Source: CDC/NCHS and the American Heart Association.

FIGURE 29.1. Cardiovascular disease mortality trends for men and women in the United States, 1979 through 1996.

Each year, CVD claims nearly one million lives in the United States, accounting for 40% to 45% of all deaths. This rate is more than for the next seven leading causes of death combined and translates to an average of one death every 33 seconds. Approximately one-sixth of individuals who die from CVD are under age 65 years, and one-third die before the average life expectancy. It is estimated that if CVD were eliminated, the average life expectancy would increase by almost 10 years. CVD is also an important cause of disability. It ranks first among all disease categories in number of hospital discharges. Between 1979 and 1996 there was a 25% increase in discharges from short-stay hospitals, with CVD listed as the first diagnosis. It also accounts for a significant number of physician office visits, hospital outpatient visits, and emergency room visits. According to the American Heart Association, the direct and indirect costs of CVD exceeded \$250 billion in 1997. The sheer magnitude of the epidemic of CVD necessitates an emphasis on the prevention of the disease.

Several major forms of CVD, including CHD, stroke, hypertension, and lower-extremity arterial disease, are preventable and have many risk factors in common. CHD accounts for one-half of all CVD deaths and is the principal type of CVD discussed herein ([Fig. 29.2](#)). Other kinds of CVD, including rheumatic heart disease, congenital cardiovascular defects, and congestive heart failure, are discussed in subsequent chapters.

Source: CDC/NCHS and the American Heart Association.

FIGURE 29.2. Breakdown of US deaths from cardiovascular diseases in 1996.

EPIDEMIOLOGY OF CORONARY HEART DISEASE

CHD is the single leading cause of death in men and women in the United States. It accounts for nearly a half million deaths each year and an estimated one of every five deaths due to any cause. Approximately every 30 seconds someone suffers a coronary event, and every minute someone dies from one. On the basis of data from the Atherosclerosis Risk in Communities studies, sponsored by the National Heart, Lung, and Blood Institute (NHLBI), it has been estimated that myocardial infarction (MI) is fatal in one-third of the more than one million Americans who experience a new or recurrent episode of MI. A significant proportion of CHD deaths occur within 1 hour of the onset of symptoms and before patients reach the hospital. Over one-half of the men and nearly two-thirds of the women who die suddenly have never had symptoms. Moreover, 80% of CHD deaths in individuals less than 65 years old occur during an initial MI, highlighting the need for prevention of the first coronary event.

The risk of a heart attack is greatest among individuals with a history of MI. Approximately 21% of men and 33% of women have a recurrent heart attack within 6 years of an MI. Of these, 7% experience sudden death, a rate four- to sixfold higher than that of the general population. Another 20% to 30% are disabled with congestive heart failure. CHD accounts for 19% of disability allowances and is the leading cause of premature, permanent disability in the US labor force. Nevertheless, nearly 90% of patients surviving an MI under age 65 years are able to return to their usual work.

Age and gender have an important influence on the occurrence and outcome of CHD. At any given age, women have a lower rate of CHD compared with men. However, because women have a greater likelihood of survival to advanced ages, the number of actual deaths due to CHD is nearly equal in men and women. The onset of CHD is delayed approximately 10 years in women compared with men. The gender gap in the incidence of CHD may reflect the protective effects of endogenous hormones in premenopausal women but is more likely explained by declining levels of testosterone with age and a corresponding slowing of CHD death rates in men. The prognosis for women with CHD is consistently worse than it is for men, and this has been attributed to increased age and severity of initial disease as well as greater comorbidity among women.

Substantial ethnic differences exist in CHD prevalence and mortality rates. The age-adjusted death rate from CHD is nearly 70% higher for black women compared with white women aged 35 to 74 years. On the basis of the NHLBI Cardiovascular Health Study, the rate of new and recurrent MIs per 1,000 people aged 65 to 74 years is 26.3 for nonblack men, 16.3 for black men, 13.3 for black women, and 7.8 for nonblack women. In another study, the prevalence of CHD in adults over the age of 20 years was 7.5% for non-Hispanic whites, 6.9% for non-Hispanic blacks, and 5.6% for Mexican Americans. Among Native Americans aged 65 to 74 years, the rate (per 1,000) of new and recurrent MIs was 25.1 for men and 9.1 for women in the NHLBI Strong Heart Study. During a 19-year follow-up of the NHLBI Honolulu

Heart Program, the age-adjusted CHD mortality rate (per 1,000) for middle-aged Japanese-American men living in Hawaii declined from 4.7 to 2.9, which was similar to the decline observed for U.S. white men.

Rates of CHD vary dramatically by state, suggesting that environmental and sociocultural factors are important etiologic elements. The rates of CHD in such states as New Mexico and Hawaii are about one-half the rates in New York and Oklahoma. Patterns of CHD also differ among nations. European countries tend to have very high rates compared with those of Asian countries and several countries along the Mediterranean. The United States is in the middle of the range. CVD (more specifically, CHD) is the leading cause of death globally, with a majority of deaths occurring in developing nations. Even among those 30 to 69 years old, CVD death exceeds the number of deaths for infectious and parasitic diseases in all populations except those in sub-Saharan Africa, where the death rates are nearly equal. As we begin the new millennium, the rising epidemic of CVD will impart a tremendous burden in terms of death, disability, and health care costs. Fortunately, a substantial proportion of CVD and CHD is preventable through risk factor avoidance and modification.

RISK ASSESSMENT

Evaluation of CHD risk involves measurement and determination of both modifiable and nonmodifiable risk factors. Epidemiologic studies have established several major modifiable risk factors for CHD, including cigarette smoking, hypertension, dyslipidemia, diabetes mellitus, obesity, sedentary lifestyle, and improper nutrition. Age, male gender, and family history of CVD are also independent risk factors, but because they are not modifiable, they are considered more important for predicting risk than for targeted risk factor management.

Data from the Framingham Heart Study have shown that the risk associated with a given risk factor varies as a function of the number and level of other concurrent risk factors. Assessment of risk can involve calculation of the relative risk and/or absolute risk associated with a given factor. The relative risk is a ratio that compares the incidence of disease in a population of individuals with a certain characteristic to a population without the characteristic and is important in understanding causal factors for CHD. Absolute risk is the probability that the disease will develop in an individual with a certain characteristic or set of characteristics during a specified time interval. Quantitative global risk assessment is useful because information about a constellation of risk factors provides better prediction than that for a single factor. Moreover, it allows for identification of a small segment of the population who will experience a large percentage of CHD events. An example of an absolute risk assessment tool derived from Framingham data is shown in [Table 29.1](#). A related concept is attributable risk, which is derived by subtracting the incidence rate of disease in a population without the risk factor from the rate in a population with the risk factor. The attributable risk provides an estimate of how much CHD might be reduced if the risk factor were eliminated; this estimate is important for public health purposes and for prioritizing risk factors.

TABLE 29.1. CORONARY HEART DISEASE RISK FACTOR PREDICTION CHART^a

Assessment of family history of CHD provides valuable information for evaluating an individual's level of risk. Familial aggregation of CHD and antecedent risk factors is well established; contributing further to these risks are genetic influences and shared environmental and cultural factors. About one-half of the variability in quantitative risk factors for CHD are due to genetic factors. The risk of CHD is substantially higher among first-degree relatives of patients with premature heart disease, even when classic risk factors are similar to those of persons without a family history of early CVD. The magnitude of increased CHD risk is dependent upon the definition of premature disease. Persons with a positive family history of a coronary event or revascularization before the age of 55 years have between two and one-half and four times the risk of CHD compared with persons without such a family history. These data underscore the importance of taking a careful family history in evaluating CHD risk.

MAJOR RISK FACTORS

Cigarette Smoking

Cigarette smoking is a completely preventable cause of CHD and accounts for 30% to 40% of all CVD deaths. Smokers have a twofold increase in risk of CHD compared with nonsmokers and a two- to fourfold increase in risk of sudden death. Despite the well-established consequences of smoking, approximately 25% of adults are smokers. Smoking rates have declined 42% since 1965; however, the downward trend has leveled off, and rates are rising among adolescents. Exposure to passive smoke is also a risk factor, and 43% of American children aged 2 months to 11 years are exposed to environmental smoke in the home. Filtered or low-yield cigarettes do not eliminate risk. Cigar and pipe smoking without inhalation do not carry the same risk as cigarette smoking.

Factors proposed to explain the accelerated risk of CHD and precipitation of events among smokers include endothelial damage, dyslipidemia, elevation of blood pressure and heart rate, increased myocardial oxygen demand, reduced oxygen available to the myocardium, vasospasm, increased platelet activation, and increased reactive oxygen species. Smoking cessation has immediate benefits on the cardiovascular system, and after the initial year of cessation, risk drops dramatically. After 5 years of abstinence, risk is nearly equal to that of a nonsmoker. Counseling and nicotine replacement and other forms of pharmacotherapy should be provided in conjunction with behavioral therapy or a formal cessation program, as indicated.

Hypertension

Hypertension is considered a disease entity as well as a risk factor for CHD. High blood pressure is the most prevalent of all CVDs, afflicting 25% of adults. Hypertension is typically defined as systolic blood pressure ≥ 140 mm Hg or diastolic blood pressure ≥ 90 mm Hg or the need for treatment with antihypertensive therapy. The prevalence of high blood pressure is greater in blacks than whites. In hypertensive black men and women, 30% and 20%, respectively, of all deaths are attributable to hypertension. More men than women have high blood pressure until age 55 years, after which the rate in women exceeds that in men. After the age of 45 years, more than one-half of women have elevated blood pressure. Persons living in the southeastern United States also have a high prevalence of hypertension.

The risk of CHD and stroke increases continuously with rising systolic and diastolic blood pressure. For example, the rate of coronary events is doubled when the diastolic blood pressure is greater than 105 mm Hg. The sixth report of the Joint National Committee on Detection, Evaluation, and Treatment of High Blood Pressure (JNC VI) defines an optimal blood pressure as less than 120/80 mm Hg and provides a classification system and recommendations for follow-up based on blood pressure measurement ([Table 29.2](#)). Blood pressure is strongly influenced by genetics; however, there are many environmental and behavioral determinants. Important modifiable contributing factors are excess sodium intake among susceptible individuals, obesity, weight gain, alcohol intake, and sedentary lifestyle. A diet rich in fruits and vegetables has been shown to lower mild to moderately elevated blood pressure effectively.

as that for patients with established CVD (less than 100 mg per deciliter). Niacin is an effective therapy for patients with low HDL cholesterol and elevated triglycerides, a common pattern in diabetics; however, because niacin may be associated with a worsening of glucose tolerance, statins are often the preferred therapy. Proper nutrition, weight management, and regular exercise are the mainstay of treatment for diabetics, as is control of concomitant risk factors.

Obesity

The number of men and women who are obese is substantial and on the rise. Nearly 60% of white men and 45% of white women aged 20 to 74 years are overweight [body mass index (BMI) between 25 and 30 kg per square meter], and 20% and 22.4%, respectively, are obese (BMI \geq 30 kg per square meter). The prevalence of obesity is greater among blacks and is as high as 67% among Mexican Americans. There is a linear relationship between BMI and CHD. Central obesity (intra-abdominal fat) is a stronger predictor than peripherally deposited fat. Measurement of waist circumference is useful as a diagnostic aide. A substantial amount of the risk associated with obesity is mediated through high blood pressure, dyslipidemia, diabetes, and insulin resistance. Gradual (1 to 2 pounds per week) and sustained weight loss in persons whose weight exceeds the ideal for their height should be encouraged through caloric restriction and increased physical activity.

Sedentary Lifestyle

A sedentary lifestyle is associated with a doubling of CHD risk compared with a more active lifestyle, even when other factors are taken into consideration. About 25% of adults report no regular leisure-time activity. Physical inactivity is more common among women than men, greater among older than younger adults, and more prevalent among ethnic minorities and the less educated and less affluent. Physical inactivity increases the risk of high blood pressure 30% to 50%. In contrast, regular physical activity is associated with reduced cholesterol and increased HDL levels, lower triglycerides, enhanced fibrinolysis, improved insulin sensitivity, and a lower incidence of diabetes. Moreover, exercise may slow progression of atherosclerosis, improve myocardial oxygen delivery, enhance myocardial function, and reduce vulnerability to dysrhythmias.

The greatest differential in CHD risk appears to be between those who are completely sedentary and those who exercise moderately on a regular basis. Recent evidence suggests that regular activity of moderate intensity, including brisk walking, is associated with a significant reduction in CHD risk. These data support the 1995 federal exercise guidelines endorsing 30 minutes of moderately intense physical activity most days of the week, a safe and feasible strategy for most of the population. For patients who have experienced cardiovascular events or undergone revascularization procedures, participation in formal cardiac rehabilitation or a physician-guided home exercise program should be encouraged.

Dietary Factors

Diet is a major cause of CHD. Dietary intake of fat, especially saturated fat, and cholesterol is strongly correlated with cholesterol concentrations and CHD risk. Saturated fat intake is also associated with increased thrombogenicity. Intake of *trans* fatty acids has been linked to adverse lipid profiles and increased risk of CHD. Salt and alcohol intake influences blood pressure. Moderate alcohol intake (one to two glasses per day) is associated with increased HDL and reduced CHD risk, but it is not generally recommended as a prevention strategy because of the potential for abuse and increased CVD risk at higher intakes. Increased ingestion of fiber, whole grains, and fruits and vegetables is cardio-protective. Diets rich in antioxidant nutrients, such as vitamin E, ascorbic acid, and beta carotene, have been associated with a reduced risk of CHD in epidemiologic studies; however, clinical trials of antioxidant supplementation have been inconsistent. The American Heart Association has recommended that total fat intake not exceed 30%, that saturated fat intake be 8% to 10% of calories, and that cholesterol intake be less than 300 mg per day. Further reductions in saturated fat and cholesterol are indicated in those with CVD or lipid disorders ([Table 29.3](#) and [Table 29.4](#)). Total dietary fiber intake should be 25 to 30 g per day, salt intake should be limited to 6 g per day, alcohol should be limited to two glasses per day (one glass for women), and five or more servings of fruits and vegetables should be consumed daily.

Psychosocial Factors

Several psychosocial factors are associated with CHD risk, but there is a paucity of data to verify that improvements in psychosocial parameters lower risk. The type A personality is a good example, with hostility traits also emerging as a consistent factor. Social isolation and features that contribute to it, such as low education level, adverse economic circumstances, and lack of family and social networks, are associated with increased CHD risk. Depression, especially following MI, increases coronary risk. Chronic stress, particularly in situations of "high demand and low control," may double the risk of MI. Acute psychological stress may also trigger MI. Psychosocial risk factors are common and their assessment should be part of a routine screening evaluation for CHD. Intervention may improve quality of life and adherence to medical regimens and potentially lower mortality rates and recurrent CHD events.

New Risk Factors

Well over 200 risk factors have been described for CHD. Only a small fraction of them are classified as major risk factors, because they are not considered independent and causal, because they are modifiable or have a low prevalence, or because there is no reliable screening test or effective intervention. Recently, levels of small, dense LDL particles, insulin, lipoprotein(a), C-reactive protein, *Chlamydia pneumoniae* antibody titers, homocysteine, dehydroepiandrosterone sulfate, oxidative stress, fibrinogen, plasma viscosity, and a number of other thrombotic factors (plasminogen activator inhibitor type 1, tissue-type plasminogen activator antigen, von Willebrand's factor, factor VIIa) have been correlated with CHD risk. The current role of screening for these factors in practice is limited, owing to the reasons cited earlier. Moreover, the added value of measurement of new risk factors over traditional risk factors in identifying individuals at risk of CHD or in developing risk-reduction strategies is not established, but it is unlikely to be substantial. In certain clinical situations or in the case of unexplained or premature CHD, however, selective determination of novel risk factors may be useful to physicians and patients.

COMPREHENSIVE PREVENTIVE CARDIOLOGY

A shift in paradigms from a reactive approach to CVD and its side effects to prescribing prevention is necessary to reduce the burden of the disease. Several strategies for prevention are available to guide the physician in determining the type and aggressiveness of interventions in various patients. In healthy patients without known risk factors for CVD, an emphasis should be placed on developing and maintaining healthy lifestyle habits in an effort to prevent the evolution of such risk factors as high blood pressure and hypercholesterolemia. Primary prevention is the term applied to prevention among individuals free of clinical CVD who are susceptible to it because they have a risk factor. Lifestyle modification is also emphasized in this context, as is appropriate treatment of risk factors, especially among individuals with multiple risk factors ([Table 29.3](#)). Patients with established CVD (secondary prevention) are at greatest risk of a future event and therefore should be treated most aggressively ([Table 29.4](#)).

The risk/benefit ratio of aggressive risk factor management is most favorable among those with the highest level of baseline risk. An overlapping area of risk occurs in patients without clinical manifestations of CVD but with evidence of significant disease based on a screening procedure such as carotid ultrasound or ultrafast computed tomography scanning of the coronary arteries. Because the number of noninvasive tests to identify patients with CVD is increasing and because the predictive value of these tests is often not firmly established, interpretation of the results can present a challenge. Aggressive risk factor management has been shown to prevent the progression of atherosclerosis; therefore, it may be prudent to treat subclinical disease more aggressively than would occur in the context of primary prevention. Because one-third of coronary events are fatal, it is also important to prioritize risk factor management before an event occurs.

There is abundant evidence of missed opportunities to institute the consensus recommendations for the prevention of CVD outlined in [Table 29.3](#) and [Table 29.4](#). National data have shown that only a small proportion of patients receive counseling about lifestyle risk factors in ambulatory care settings. As described previously, there are adverse trends in several major risk factors for CHD, and many patients are not being treated to target risk factor levels. Only a small fraction of patients who qualify for cardiac rehabilitation are referred, despite a 25% improvement in survival rates associated with participation. Cardiac rehabilitation is a key step in initiating risk factor management and restoring functional capacity after an MI or revascularization procedure. It is a model for a comprehensive prevention program, yet the reasons for its underutilization are not fully understood. Barriers to the spectrum of prevention strategies may be related to patients, physicians, the lack of organizational structure, or societal factors. Communication, training, infrastructure, and reimbursement for preventive services will undoubtedly help patients achieve risk factor targets that have been shown to reduce the burden of CVD. A multidisciplinary team approach that includes nonphysician health care providers may be an especially cost-effective approach to the prevention of CVD.

CHAPTER 30: SYSTEMIC HYPERTENSION

MYRON H. WEINBERGER

[Consequences of Elevated Blood Pressure](#)
[Blood Pressure Measurement](#)
[Epidemiology of Hypertension](#)
[Mechanisms for Blood Pressure Control](#)
[Factors Contributing to Hypertension](#)
[Secondary Forms of Hypertension](#)
[Prevention](#)
[Management](#)

The definition of hypertension depends on the levels of blood pressure that are associated with vascular damage and increased cardiovascular morbidity and mortality. Actuarial data gathered by the Metropolitan Life Insurance Company confirm the concept that the relationship between blood pressure and life expectancy is continuous rather than dichotomous. Patients with systolic pressures between 130 and 139 mm Hg or with diastolic pressures between 85 and 89 mm Hg are classified as having “high normal” blood pressure levels, since current evidence indicates that fixed hypertension is more likely to develop in these patients with the passage of time; they also have increased morbidity and mortality rates when compared with individuals with lower blood pressure levels.

CONSEQUENCES OF ELEVATED BLOOD PRESSURE

The major effects of blood pressure elevation can be separated into those resulting directly from the increased pressure (cerebral hemorrhage, retinopathy, left ventricular hypertrophy, congestive heart failure, aneurysm, and vascular rupture), those resulting from atherosclerosis (increased coronary, cerebral, and renal vascular resistance), and those resulting from decreased blood flow and ischemia (myocardial infarction, cerebral thrombosis and infarction, renal nephrosclerosis). It has even been suggested that functional cerebral damage and senile dementia may be more common in hypertensive than normotensive persons. The benefits of blood pressure reduction are most immediately observed by a reduction in pressure-related complications, such as stroke, heart failure, retinopathy, and dissecting aneurysm. Those manifestations related to atherosclerosis and ischemia may be more difficult to reverse and thus provide a compelling rationale for primary prevention or for early treatment in the asymptomatic state. Multiple risk factors exist for cardiovascular disease, such as hyperlipidemia, diabetes, cigarette smoking, and left ventricular hypertrophy, and these factors in conjunction with blood pressure have a synergistic impact.

BLOOD PRESSURE MEASUREMENT

Blood pressure is usually measured in an indirect fashion. A standard sphygmomanometer cuff is used to compress the brachial artery from outside the arm by raising pressure to levels that occlude the artery. The examiner then listens carefully as the pressure decreases until the pulse is heard (systolic pressure). Careful auscultation continues during the decline of pressure until the sound completely disappears (Korotkoff's phase V), which is the conventional definition of diastolic pressure. True intra-arterial pressure correlates more closely with the fourth Korotkoff's sound (muffling of the pulse). A rate of cuff deflation of 2 to 4 mm Hg per heartbeat is optimal. The cuff must be wide enough to occlude the artery evenly, thus avoiding the artifact frequently observed when an obese person's blood pressure is measured using a standard-sized cuff. The arm should be at the same level as the heart to avoid artifact. Discrepancies in blood pressure between the right and left arm can be seen in persons with vascular anomalies or compressive lesions involving the aortic arch or distal structures. In addition, in coarctation of the aorta the blood pressure may be substantially lower in the legs than in the arms.

With extreme rigidity of the peripheral vascular system, as is occasionally seen in elderly persons, a phenomenon known as “pseudohypertension” may occur. A marked increase in the external cuff pressure is required to occlude the sclerotic vessel. Generally, such patients have palpably sclerotic peripheral vessels, a primary systolic elevation in pressure without an increase in diastolic pressure, failure of an observable blood pressure response to adequate doses of antihypertensive agents, and, frequently, a positive Osler's maneuver. This indicates that the sclerosis of the vascular wall permits continued palpation of the radial artery after occlusion of the brachial artery by the sphygmomanometer cuff during maximum inflation.

EPIDEMIOLOGY OF HYPERTENSION

In general, elevated blood pressure is more common in industrialized societies. The reasons include variations in levels of stress, nutrient intake, obesity, exercise, and nutritional status. The strongest association between lifestyle and blood pressure is the relationship between dietary intake of sodium and blood pressure. High levels of sodium intake have not always been found to be associated with increased blood pressure, and thus a genetic or physiologic sensitivity to sodium appears to be required for the expression of the effects of sodium on blood pressure. Less consistent inverse relations between blood pressure and the intake of potassium or calcium have also been observed.

Black Americans have an incidence of hypertension approaching 40%, but the incidence among white Americans is between 15% and 20%. Blood pressure also increases with age in acculturated societies, and more than 60% of persons over age 65 in the United States have increased blood pressure. An increased incidence of hypertension is often observed in first-degree relatives of hypertensive subjects. The familial and genetic role of hypertension has been well established.

MECHANISMS FOR BLOOD PRESSURE CONTROL

It is useful to view increased blood pressure as resulting from an alteration in one or more of four major components: extracellular fluid volume, renal function, vasoactive factors and peripheral resistance, and cardiac output. The control of extracellular fluid volume is determined by the intake of sodium, the excretory efficiency of the kidneys, the activity of factors influencing sodium and water metabolism, and the capacitance of the vascular system. Some normotensive persons, such as blacks, older persons, and those with hypertensive first-degree relatives, have a reduced renal excretory capacity for sodium when challenged with an intravenous saline load, which may predispose them to the development of sodium-induced blood pressure elevation. Similarly, enhanced activity of the renin–aldosterone system or an alteration in the renal responsiveness to vasopressin or to atrial natriuretic factor may also increase sodium or water conservation in some persons. Evidence suggests that insulin resistance is common in untreated hypertensives. It has been proposed that interactions among hyperinsulinemia, sodium retention, and increased sympathetic nervous system activity may all contribute to the pathogenesis of essential hypertension.

The kidney plays a pivotal role in the pathogenesis of hypertension. A genetically mediated or acquired abnormality in renal excretion of sodium can increase extracellular fluid volume and blood pressure. The kidney is a source of the enzyme renin, which generates the potent vasoconstrictor peptide angiotensin II. Vasopressin and atrial natriuretic factor can both influence sodium and water handling and may have independent pressor effects in accelerated or malignant forms of hypertension. Other peptides, such as bradykinin and dopamine, have important renal actions that influence blood pressure by various mechanisms of action, including alterations in hemodynamics and sodium handling. The kidney contains catecholamines and adrenergic receptors that influence renal blood flow and resistance as well as sodium reabsorption in the proximal tubule and its subsequent excretion.

Central or local sympathetic nervous system activation can induce constriction and raise resistance and thus blood pressure. An interaction between angiotensin II and norepinephrine release from sympathetic neurons has been identified, and renin release can be stimulated by a β_1 -adrenergic mechanism in the kidney. Although prostaglandins and the products of the kallikrein–kinin system are known to be active in promoting contraction and relaxation of vascular smooth muscle, it is likely that these substances act primarily at the local, rather than the systemic, level. Structural abnormalities, such as progressive narrowing of the vasculature or reduction of intraluminal surface area by atherosclerosis or by rarefaction of blood vessels, may also increase peripheral resistance.

Increased blood pressure affects the heart because it causes coronary artery disease by accelerating atherosclerosis, left ventricular hypertrophy, congestive heart failure, and cardiac dysrhythmias. In addition, the heart itself can raise blood pressure by amplifying cardiac output. This happens most often by virtue of an increase in heart rate, in stroke volume, or in the sympathetic responsiveness of the heart. It has also been suggested that there is a direct effect of angiotensin II in terms of increasing cardiac output.

FACTORS CONTRIBUTING TO HYPERTENSION

Current evidence suggests that genetic and environmental factors may interact to raise blood pressure. Other environmental factors, such as stress and alcohol consumption, can produce an acute transitory rise in blood pressure. Generally, the impact of stress is superimposed on a background of predisposition to hypertension and represents an exaggerated vascular response to sympathetic activation induced by stress. It is typically associated with increased cardiac output and intense vasoconstriction. Similarly, alcohol, which has a biphasic effect on blood pressure, can be viewed as producing a depressor effect when used in small doses (less than 2 oz of alcohol or its equivalent per day), which tends to induce peripheral vasodilatation and perhaps enhances the renal excretion of sodium and water. In larger amounts, alcohol acts much as stress does to enhance both sympathetic activity and cardiac output, thus raising blood pressure and increasing resistance.

EXOGENOUS PRESSOR AGENTS

Various agents can raise blood pressure and should be considered in evaluating a hypertensive patient. These include "recreational" drugs, such as amphetamines and cocaine, which can cause marked increases in sympathetic discharge, peripheral resistance, and cardiac output. Proprietary decongestant preparations, cold remedies, and appetite suppressants contain sympathomimetic agents that may raise blood pressure. Thyroid supplements, corticosteroids, and nonsteroidal anti-inflammatory drugs can all raise blood pressure or worsen existing hypertension. Oral contraceptives and conjugated estrogens used to treat menopausal symptoms or to prevent osteoporosis are also a common cause of hypertension in women. It is often necessary to withdraw these agents for 3 months or longer before their effects on blood pressure are seen. Licorice is a rare cause of volume-expansion hypertension.

SECONDARY FORMS OF HYPERTENSION

Occasionally, hypertension is caused by an underlying identifiable abnormality that, if discovered and corrected in a timely fashion, can lead to a cure of the hypertension and the prevention of its side effects (Table 30.1). Clues that can identify persons in whom such a source is likely include hypertension at a young age. This is particularly true if the blood pressure elevation is moderate or severe (diastolic pressure more than 100 mm Hg). When a patient has initial symptoms of severe hypertension in an accelerated or malignant phase, it often indicates a secondary form of hypertension. When blood pressure control is difficult to achieve despite the use of appropriate combination therapy and good patient compliance, a secondary form of hypertension should be sought. When physical examination of the hypertensive patient shows severe hypertensive retinopathy with grade III (hemorrhages, exudates) or grade IV (papilledema) retinal changes, a secondary form of hypertension manifesting in a marked increase in peripheral resistance should be considered (pheochromocytoma, renal vascular hypertension).

Disorder	Approximate Incidence (%)
Renal vascular hypertension	5-10
Estrogen-induced hypertension	3-5
Primary aldosteronism	3-5
Pheochromocytoma	<1
Drug-related (corticosteroids, sympathomimetics, "recreation")	<1
Cushing's syndrome	<0.5
Hyperthyroidism	<0.5
Vasculitis	<0.5

There are no definitive studies assessing the incidence of these secondary forms of hypertension in an unselected population of representative American hypertensive subjects. These estimates of incidence are derived from relative incidence data obtained from small, selected samples.

TABLE 30.1. SECONDARY FORMS OF HYPERTENSION

RENAL VASCULAR HYPERTENSION

Two forms of renal vascular hypertension are commonly recognized. One form, which occurs predominantly among older persons, is due to atherosclerotic narrowing of one or both renal arteries, reducing renal perfusion. The other form, more common in young persons with hypertension, is the result of fibromuscular dysplasia of the renal arteries. This type is more common in women and is typically found on the right side.

Renal vascular hypertension decreases renal perfusion, stimulating renin release by the involved kidney and raising peripheral resistance. In addition, angiotensin II stimulates aldosterone production, promoting reabsorption of sodium and water and the consequent expansion of the extracellular fluid volume. There is probably a further enhanced effect of angiotensin II on blood pressure in the face of increased total body sodium and fluid content. Suppression of renin secretion is typically seen in the contralateral, uninvolved kidney. Thus, total renin production is at a normal or elevated level in the context of expanded extracellular fluid volume, and a new steady state results, operating at an elevated blood pressure. The reduction in renin release by the contralateral kidney, if unaffected by the stenotic process, is a protective mechanism to prevent further excessive production of renin and reflects an appropriate response to the increase in volume and pressure.

Clues to renal vascular hypertension include grade III or IV hypertensive retinopathy and a mid-epigastric bruit with both systolic and diastolic characteristics. Some patients may have evidence of secondary aldosteronism caused by increased stimulation of the renin-aldosterone system with consequent potassium loss. Abnormalities of renal blood flow and function can be observed with rapid-sequence intravenous pyelography (films taken at 1, 2, and 3 minutes after dye injection as well as after 5 and 15 minutes) or arteriography. The more costly digital subtraction angiography, particularly if it is combined with rapid-sequence films, can provide information about the size and function of the kidney as well as a direct computer-assisted picture of the renal arteries.

The diagnosis of renal vascular hypertension depends on evidence of the functional significance of the renal arterial lesion and the consequent improvement of hypertension after repair of the obstructive lesion. The use of a competitive antagonist of angiotensin II, such as saralasin (Sarenin), and the blood pressure response to an angiotensin-converting enzyme (ACE) inhibitor that prevents the formation of angiotensin II, though helpful in identifying patients with renal vascular hypertension, are neither sensitive nor specific enough for routine screening purposes. Studies comparing the uptake and excretion of radioisotopes selectively delivered to and filtered by the kidney have been of some benefit in distinguishing renal vascular hypertension. They are generally dependent on cardiac output and can be influenced markedly by renal parenchymal disease as well as by the size of the kidneys and the magnitude of background isotopic uptake. Combining isotopic renography with administration of a short-acting ACE inhibitor (captopril) to enhance detection of significant lesions has proved to be an effective screening test.

A renal vein renin ratio of 1.5:1 or more of the involved over the uninvolved kidney or, in the case of bilateral stenosis, the more involved over the less involved side is helpful in pinpointing functionally significant lesions and predicting the benefit of intervention. More than 92% of such patients improve after effective intervention. Renal vein renin sampling is performed under stimulated conditions using both postural tilting and antihypertensive agents known to stimulate renin release (e.g., diuretics, ACE inhibitors). Furthermore, these observations require that the patient be removed from such drugs as β -adrenergic blockers and antisympathetic agents, which may lower renin production, particularly by the involved kidney. A period of 7 days or more of withdrawal of such renin-suppressing agents may be required to ensure the ability to identify a significant difference between renal vein renin concentrations.

Another valuable clue to the functional significance of a unilateral lesion is the observation that the concentration of renin in the contralateral kidney is equal to or less than that of the inferior vena cava below the level of the renal vein. This observation implies virtually complete suppression of renin release from the contralateral kidney, indicating that the involved kidney is the sole contributor of renin to the circulation. An additional advantage of performing arteriography or digital subtraction angiography before renal vein renin sampling is the identification of segmental renal vascular disease, permitting sampling of the venous drainage from the affected segment when obtaining renal venous samples for renin measurement.

ACE inhibitors, β -adrenergic blocking drugs, and calcium channel blockers have provided an effective array of antihypertensive agents with which to control blood pressure in even the most severe case of renal vascular hypertension. Several studies have suggested that antihypertensive therapy is not a desirable choice for renal vascular hypertension despite adequate blood pressure control, because of the likelihood of progression of renal impairment and the high incidence of diffuse

vascular disease seen in such patients.

Various new surgical techniques have expanded the options and approaches available for the repair or reconstruction of renal arterial lesions. The less invasive, less risky angioplastic procedure would appear to be the ideal choice for the patient at relatively high risk with atherosclerotic renal vascular hypertension. Unfortunately, the results of percutaneous angioplasty in such patients have been inconsistent. The atherosclerotic lesions are often located at the ostium of the renal artery, and for this reason, attempts at balloon dilatation may simply displace the plaque into the aortic lumen and may even cause embolization of atheromatous material. Even when angioplasty has been performed successfully in atherosclerotic renal vascular lesions, the recurrence rate has been found to be very high on long-term followup.

Our observations, as well as those of others, suggest that surgical intervention is the most desirable option. Among patients with fibromuscular renal vascular hypertension—typically healthy young women—percutaneous angioplasty has been as effective as surgical intervention in repairing the lesion and improving blood pressure control. Thus, this group often can be effectively treated by percutaneous angioplasty unless fibromuscular disease is present in the segmental branches of the renal artery beyond the reach of the angioplasty catheter.

PRIMARY ALDOSTERONISM

Primary aldosteronism is less common than renal vascular hypertension. Patients with this condition often have severely elevated blood pressure. One clue that a patient may have primary aldosteronism is the relative absence of severe hypertensive retinopathy (grade III or IV) in the context of marked blood pressure elevation of substantial duration. The mechanism of action by which aldosterone induces salt and water retention involves the loss of potassium and hydrogen ions in exchange for sodium by the distal tubule of the kidney. Thus, hypokalemic alkalosis is prevalent in patients with primary aldosteronism. The presence of a normal serum potassium level does not rule out the diagnosis, however. Moreover, hypokalemia in most hypertensive patients results from diuretic therapy or secondary aldosteronism. Because of increased aldosterone production and expanded intravascular volume, there is concomitant suppression of renin production by the kidneys to limit further stimulation of unneeded aldosterone. In the context of normal renal function, therefore, plasma renin activity is markedly suppressed in patients with primary aldosteronism and cannot be stimulated into the normal range with the usual maneuvers, such as diuretic administration and upright posture.

A useful screening test is the measurement of plasma renin activity and plasma aldosterone in a random blood sample obtained when the patient is not receiving drugs known to suppress the renin–aldosterone system (e.g., β -blockers and centrally acting antisympathetic agents). If the ratio of aldosterone (in nanograms per deciliter) to renin activity (in nanograms per milliliter per 3 hours) on a numeric basis exceeds 30, the diagnosis of primary aldosteronism can be made. The measurement of aldosterone excretion in a 24-hour urine sample is an older way to identify aldosterone excess. It is necessary, however, to administer a high-sodium diet or to provide a sodium load of some sort to differentiate the inappropriate excess of aldosterone excretion in patients with primary aldosteronism from other subjects. A rapid procedure is measurement of plasma aldosterone concentration before and after intravenous administration of 2 L of normal (0.9%) saline given over a 4-hour period in the morning. Normal subjects and patients with hypertension without primary aldosteronism exhibit suppression of plasma aldosterone after intravenous sodium loading to levels of less than 10 ng per deciliter, often to levels below 5 ng per deciliter. Patients with primary aldosteronism, however, fail to suppress their plasma aldosterone levels to that degree.

Once the diagnosis of primary aldosteronism has been made by evidence of nonsuppressible aldosterone production in conjunction with renin levels that cannot be stimulated, the differentiation of unilateral from bilateral forms is required, because surgical removal is usually helpful only when the disease is unilateral. An isotopic scan using I^{131} iodocholesterol has been reported to be useful by some investigators. The benefit of this approach is that it can identify adenomas larger than 1.5 cm in diameter; however, because most tumors producing excessive amounts of aldosterone are smaller than 1 cm in diameter, this approach is not usually effective.

The most useful localizing techniques are adrenal venography and adrenal venous blood sampling during administration of adrenocorticotrophic hormone (ACTH). The ratios of aldosterone to cortisol are then compared in venous blood from both adrenals and from the inferior vena cava, below the level of the adrenal veins. In normal subjects, when aldosterone is compared in blood obtained at 8 a.m., after recumbent posture, to that obtained after 4 hours of ambulation at noon, a significant increase in plasma aldosterone is seen. In patients with a unilateral source of hyperaldosteronism, typically from an adenoma, a fall in aldosterone may be seen. This may be related to the primary modulation of aldosterone production in such situations by ACTH. In normal persons as well as in persons with hypertension and in those with hyperaldosteronism due to bilateral adrenal hyperplasia, aldosterone production depends, at least in part, on angiotensin II. If the formation of angiotensin II is rapidly reduced by inhibition of ACE, this major stimulus to aldosterone production is removed, and plasma aldosterone levels decline markedly. In contrast, when primary aldosteronism results from an autonomous adrenal adenoma, the role of angiotensin II in the stimulation of aldosterone production is negligible and, therefore, administration of an ACE inhibitor has little discernible effect on aldosterone levels.

Another rare form of hyperaldosteronism is due to dexamethasone-suppressible hyperaldosteronism. This disorder is typically familial, and evidence of a hypertensive diathesis suggestive of primary aldosteronism with hypokalemia in two or more generations of the same family should be a strong clue to its presence. A trial of treatment with dexamethasone or another glucocorticoid may be useful in establishing this diagnosis. Alternatively, treatment with an aldosterone antagonist (spironolactone) or the use of thiazide diuretics with potassium-sparing components (amiloride or triamterene) may be effective in controlling blood pressure and conserving potassium in these patients. Rare causes of primary aldosteronism include adrenal carcinoma, renin-secreting tumors of the kidney, or an undifferentiated tumor producing various peptides.

PHEOCHROMOCYTOMA

Pheochromocytoma, another secondary form of hypertension, can be fatal if undetected. Hypertension results from enhanced production of catecholamines, usually norepinephrine, causing intense vasoconstriction and increased peripheral resistance in addition to stimulating the β -adrenergic receptors of the heart, intensifying cardiac output. The hypertension in patients with pheochromocytoma is usually sustained, but in 15% of cases it is intermittent. Less often, epinephrine production dominates, which allows localization of the tumor to the adrenal or the organ of Zuckerkandl. With excessive epinephrine production, orthostatic hypotension may occur. Other symptoms of pheochromocytoma include pallor, headache, and nausea. Physical findings may comprise manifestations of intense vasoconstriction, such as grade III or IV hypertensive retinopathy.

The diagnosis of pheochromocytoma depends on evidence of excessive catecholamine production, usually found by measuring the urinary excretion of catecholamines or their major metabolites. These tests can be influenced by various confounding elements. In general, all antihypertensive agents, except for centrally acting antisympathetic drugs (reserpine, clonidine, guanabenz, guanfacine, methyldopa) and ganglionic blocking agents (guanethidine, guanadrel) increase catecholamine excretion. The latter agents tend to lower sympathetic activity and excretion. If a hypertensive patient being treated with an agent that is known to increase catecholamine release is found to have normal values of catecholamines or their metabolites, it is unlikely that pheochromocytoma is present.

By obtaining urine for radioenzymatic measurement of norepinephrine during sleep, the physician can minimize the false-positive and false-negative responses that often accompany 24-hour urine collections. Using this technique, patients with pheochromocytoma can be distinguished from those with hypertension from other causes, including essential hypertension.

Plasma catecholamine levels also can be elevated in patients with hypertension due to pheochromocytoma as well as in those in whom elevated blood pressure results from sympathetic overactivity. The pharmacologic effects of centrally acting antisympathetic agents that suppress sympathetic outflow have been used to advantage in discriminating between hypertension due to sympathetic overactivity and that due to pheochromocytoma. In normal subjects and hypertensive patients without pheochromocytoma, the administration of clonidine (0.3 mg orally) is associated with at least a 50% decline in plasma catecholamine values within 3 hours. In patients with pheochromocytoma, this degree of suppression is not seen.

Once the diagnosis of pheochromocytoma has been made, it is necessary to provide adequate α -adrenergic receptor blockade before surgery to permit reexpansion of a relatively contracted intravascular volume. It is also important to pinpoint the site of the tumor to enable the surgeon to remove it with a minimum of manipulation. Localizing the tumor is often simplified in patients with pheochromocytoma because it is usually large (more than 3 cm). By obtaining cuts at 0.5-cm increments in both adrenal areas and the organ of Zuckerkandl, computed tomography often identifies these tumors. Intravenous pyelography may find tumors in the adrenal area because of displacement of the kidney. In the case of relatively large tumors, hemorrhagic necrosis and subsequent calcification occasionally permit their identification on a plain abdominal roentgenogram. Most recently, an isotopic scanning technique using a precursor to catecholamine production, meta-iodobenzylguanidine, has been found to be useful in localizing a pheochromocytoma. During surgery, rises in blood pressure induced by anesthesia or manipulation of the tumor can be controlled by intravenous phentolamine, and cardiac dysrhythmias resulting from increased catecholamine production can be

controlled by intravenous β -blockade or other antiarrhythmic agents.

CUSHING'S SYNDROME

A less common cause of secondary hypertension is Cushing's syndrome (see [Chapter 407](#)). In this condition, the adrenal gland generates excessive amounts of glucocorticoids, predominantly cortisol, either autonomously, because of the presence of an adrenal tumor (usually unilateral), or as the result of increased production of ACTH by pituitary hyperplasia or by an undifferentiated neoplasm producing ACTH-like peptides. In the latter situation, where Cushing's syndrome results from an increase in ACTH production, bilateral adrenal hyperplasia is noted. The hypertension associated with Cushing's syndrome appears to be predominantly the result of increased vasoconstriction and increased peripheral resistance, though cardiac output may also rise. Glucocorticoids can expand renin substrate concentration, thus generating higher levels of angiotensin II, which may contribute to vasoconstriction.

The patient with Cushing's syndrome usually has a characteristic appearance, including truncal obesity; a florid, round facial appearance; a "buffalo hump;" and prominent cervical fat pads. Violaceous striae, often found on the medial aspects of the thighs and knees as well as over the abdomen, also are evident. The diagnosis can be made through evidence of excessive cortisol production by measuring urinary free cortisol in a 24-hour urine sample. Urinary excretion of 17-hydroxysteroids and 17-keto-steroids are weight dependent and are substantially higher in obese persons than in those of normal body weight. Thus, when a patient suspected of having Cushing's syndrome is obese, this must be considered in interpreting 24-hour urinary excretion values. In addition, blood sampling may indicate the absence of the normal diurnal rhythmicity in plasma cortisol concentration, which typically is higher in the morning.

HYPERTHYROIDISM

Another form of secondary hypertension is due to hyperthyroidism (see [Chapter 406](#)). In this situation, increased production of thyroid hormone is associated with increased sympathetic nervous system activity, with its attendant peripheral vasoconstriction, enhanced resistance, and amplified cardiac output. The elevated blood pressure frequently resolves with effective treatment of the hyperthyroidism or administration of β -blocking drugs that reduce cardiac output.

ESTROGEN-INDUCED HYPERTENSION

Estrogens, given in the form of birth-control pills or as conjugated estrogen for menopausal symptoms or osteoporosis, can increase blood pressure. In most patients, the rise in blood pressure induced by estrogen therapy is mild and depends on the duration of therapy. In a few normotensive women, however, estrogen administration can be associated with precipitation of overt hypertension and, rarely, with more severe or accelerated forms of blood pressure elevation. Furthermore, when estrogens are given to a hypertensive woman, a further rise in blood pressure may ensue. When a hypertensive patient has a history of estrogen use, it is generally prudent to discontinue the agent and observe carefully for a decline in blood pressure. With oral contraceptives, it may take 6 to 8 weeks for maximum decline; with conjugated estrogens, many months may be required for the decrease in blood pressure to be observed.

MALIGNANT OR ACCELERATED HYPERTENSION

Although no specific numeric level of blood pressure elevation can be used to define malignant or accelerated hypertension, it is rarely encountered at levels below 160/110 mm Hg. The manifestations are directly related to the pressure-induced vascular damage of end-organ structures or to ischemic symptoms resulting from increased vascular resistance. In the brain, these may include severe headache, visual disturbances, changes in mental function or alertness, lethargy, or localizing neurologic features, such as hemiparesis or seizures. These manifestations are usually accompanied by evidence of severe central nervous system involvement by the elevated blood pressure, including grade III or IV hypertensive retinopathy, and, in particular, papilledema.

The presence of accelerated or malignant hypertension mandates rapid blood pressure reduction and simultaneous support of any end-organ dysfunction. When the affected organ is the heart, the manifestations may be acute pulmonary edema, congestive heart failure, or angina. Renal involvement with severe malignant hypertension may manifest as acute renal failure. Physical and laboratory assessments of the status of end-organ function, including chest roentgenogram, electrocardiogram, and evaluation of renal function and electrolyte status, are initiated immediately and followed by the use of antihypertensive agents that are likely to lower blood pressure rapidly and also maintain regional perfusion.

HYPERTENSION IN PREGNANCY

At least two blood pressure problems can be identified in some pregnant women. One is the situation of a hypertensive patient who becomes pregnant. Usually, the hypertension is known to be present before the pregnancy, and when the patient becomes pregnant it is often possible to reduce or eliminate antihypertensive therapy, at least during the first trimester, because of the natural decline in blood pressure that takes place early in gestation. It is desirable to discontinue medication as long as possible during pregnancy, to minimize potentially adverse effects.

Pregnancy-induced hypertension is a unique disorder. It is more common in young primigravidas, is rarely seen before the twenty-seventh week of pregnancy, and is identified by a rise in blood pressure to above 140/90 mm Hg after the twenty-seventh week of gestation in a patient known to be normotensive earlier in pregnancy and, ideally, whose normal blood pressure was documented before pregnancy. The American College of Obstetrics and Gynecology has also identified an increase in blood pressure exceeding 30/15 mm Hg after the first trimester as suggesting the diagnosis of pregnancy-induced hypertension. This syndrome is often associated with pedal edema and proteinuria during the last trimester.

The treatment strategy for hypertension in pregnancy is generally conservative. When hypertension is diagnosed, it is almost invariably the result of increased peripheral resistance and increased sympathetic nervous system activity. Therefore, drugs effective in altering these abnormalities are preferred. In the past, direct-acting vasodilating agents, such as hydralazine, were frequently used. Centrally acting antisympathetic drugs, such as clonidine, guanabenz, and methyl dopa, and β -adrenergic blocking drugs have also been used. However, β -blockers can have an effect on labor and can induce fetal and neonatal bradycardia; thus, when β -blockers are used, short-acting agents are preferred and should be eliminated during labor and delivery. The α -blockers (prazosin, terazosin, doxazosin) are also useful in the treatment of pregnancy-related hypertension. The safety and efficacy of calcium channel blockers in the treatment of hypertension in pregnancy has not been established. ACE inhibitors and angiotensin receptor blockers are contraindicated in pregnant women.

After delivery, the elevated blood pressure often declines, and a marked natriuresis is noted. On occasion, blood pressure remains elevated, and there may be no postpartum increase in sodium and water excretion unless diuretics are given. Occasionally, hypertension may occur de novo within 24 hours of delivery; it requires prompt recognition and treatment. Because labor and the fetal effects of drugs are no longer an issue after delivery, the choice of antihypertensive agents is wider, unless the mother is breast-feeding. Rarely, blood pressure elevation is very severe or cannot be adequately controlled with medications, and symptoms of increased neuromuscular irritability may ensue. In these situations, multiple drug therapy for the blood pressure elevation, combining such agents as α -blockers, centrally acting anti-sympathetic drugs, and β -blockers, may be required. Magnesium sulfate given by intramuscular injection is also effective in minimizing the neuromuscular symptoms.

HYPERTENSION AND CONGESTIVE HEART FAILURE

Hypertension and its cardiac side effects, which include left ventricular hypertrophy, are major contributing factors to the development of congestive heart failure (see [Chapter 66](#)). The increases in peripheral resistance and extracellular fluid volume often associated with hypertension also are factors aggravating congestive heart failure.

The current approach to the treatment of hypertension and heart failure is to use modest doses of agents that attack both volume and resistance and, preferably, to use indirect-acting vasodilators that reduce preload and afterload. Included in this category are ACE inhibitors, α -adrenergic blocking drugs, β -blockers, angiotensin receptor blockers (ARBs), and long-acting calcium channel blockers. ACE inhibitors can reduce peripheral resistance, limit expansion of intravascular volume, and increase renal blood flow and renal function. When using ACE inhibitors in patients with hypertension and heart failure who are also undergoing diuretic therapy, it is prudent to use a small dose to initiate therapy (see [Chapter 66](#)).

HYPERTENSION AND RENAL FAILURE

When choosing drugs to use in the treatment of hypertension associated with renal failure, consideration must be given to the agent's efficacy in the face of impaired

kidney function and to the impact of kidney function on its excretion and metabolism. When renal function is impaired, the traditional thiazide diuretics are often ineffective, and loop diuretics must be used. Sometimes these agents alone are inadequate to promote diuresis and natriuresis, and combinations of furosemide and metolazone may be more effective. When there is renal impairment, potassium excretion may also be affected. Thus, serum potassium levels must be monitored carefully, particularly when potassium-sparing agents, potassium supplements, or ACE inhibitors are given.

Many antihypertensive agents can have an adverse impact on renal function, so they should be used cautiously in patients with renal impairment. Some β -adrenergic blocking drugs (propranolol, timolol) not only lower cardiac output, thereby reducing renal blood flow, but may also increase renal vascular resistance. However, nadolol has been shown to enhance renal blood flow and thus may be a safe and effective β -blocker in patients with impaired renal function. Because nadolol is highly water soluble and has a long duration of action, and because the primary route of excretion is renal, it may be necessary to reduce the dose or the frequency of administration of the drug in patients with impaired kidney function.

The centrally acting antisympathetic agents, such as reserpine, methyl dopa, clonidine, and guanabenz, do not appear to have adverse effects on renal function, so they can be safely used in patients with renal impairment. Direct-acting vasodilators, such as hydralazine and minoxidil, because of their reflex sympathetic stimulation, may lead to a further increase in renal vascular resistance and a decrease in renal function. This is particularly likely to occur when β -blockers are combined with these agents to enhance blood pressure reduction and to blunt the effects of reflex sympathetic discharge on the heart. Sometimes only such agents as minoxidil are effective in hypertensive patients with renal failure, however; in such cases these agents may be required. The indirect-acting vasodilators, including α -blockers, ACE inhibitors, ARBs, and calcium channel blockers, appear to have a similar beneficial effect on blood pressure and renal function and for this reason are good drugs to use when hypertension is associated with renal impairment.

Hypertension and impaired renal function may be associated with diabetic nephropathy. ACE inhibitors and ARBs, which provide balanced glomerular arteriolar dilatation, appear to be helpful in reducing proteinuria and in limiting the rate of progression of renal impairment. When hypertension and renal impairment are caused by bilateral renal vascular hypertension or by renal vascular hypertension in a solitary functioning kidney, however, the use of ACE inhibitors or ARBs may not be wise because of adverse effects on renal function. In patients with renal impairment associated with collagen vascular disorders (systemic lupus erythematosus, scleroderma, periarteritis nodosa), administration of ACE inhibitors may result in hematologic abnormalities.

HYPERTENSION AND DIABETES

Hypertension and diabetes are both common chronic disorders, but they coexist with a greater frequency than would be predicted from the prevalence of either alone, and they may be pathogenetically related. Hypertension that develops in a previously normotensive diabetic patient is usually associated with a reduction in renal function. Recent observations suggest that hyperinsulinemia and insulin resistance producing carbohydrate intolerance may be pathogenetic features of essential hypertension. Diabetes may also develop in hypertensive patients as a manifestation of diuretic-induced hyperglycemia, perhaps related to potassium loss. The diuretic-associated hyperglycemia and alterations in carbohydrate tolerance can often be corrected by restoring serum potassium levels to normal.

The diagnosis of therapy-related hyperglycemia and diabetes should be suspected when an elevated blood glucose level is encountered in a hypertensive patient receiving diuretic therapy who also manifests hypokalemia. If renal function is normal, it is appropriate to institute a trial of potassium-sparing diuretic agents and reevaluate carbohydrate tolerance after hypokalemia has been corrected. In many of these patients, hyperglycemia remits when the potassium level returns to normal. Hyperglycemia also can be a manifestation of a secondary form of hypertension associated with impairment of carbohydrate tolerance, such as in primary aldosteronism, where the carbohydrate intolerance is often responsive to restoration of normal potassium levels. Hyperglycemia also can be a feature of pheochromocytoma and Cushing's syndrome. Diuretics and β -blockers reduce insulin sensitivity; α -blockers and ACE inhibitors improve it. If the blood glucose abnormality is not corrected after the potassium balance is restored to normal, and if the patient has no evidence of one of the secondary forms of hypertension occasionally associated with hyperglycemia, treatment of carbohydrate intolerance is justified.

If the serum creatinine value is less than 1.8 mg per deciliter, the thiazide diuretics are usually effective and are reasonable initial therapeutic choices. When renal function is more markedly impaired, the use of loop diuretics is often required. Because of carbohydrate intolerance, it is important to avoid hypokalemia when giving diuretics. If renal impairment is severe, potassium loss is often not observed with thiazide or loop diuretics. Furthermore, there is a risk of hyperkalemia with potassium supplementation, potassium-sparing agents, and ACE inhibitors in diabetics with renal impairment, particularly in older subjects with hyporeninemic hypoaldosteronism. Therapy in hypertensive diabetics should thus be initiated with small doses of thiazide or loop agents, and serum potassium levels should be monitored carefully, with supplementation or potassium-sparing agents added only when indicated. This is particularly important when ACE inhibitors are used. Diabetic hypertensive patients often also respond to vasodilators of the indirect-acting category, including α -adrenergic blocking drugs, ACE inhibitors, and calcium channel entry blockers. These agents appear not to have deleterious effects on blood glucose in diabetic subjects and may improve insulin sensitivity. Centrally acting antisympathetic agents also may be used in diabetic hypertensive patients; however, β -adrenergic blocking drugs are generally ineffective and often are relatively contraindicated, particularly in diabetics who require insulin. Recent evidence supports reduction of blood pressure to levels $\leq 130/85$ in diabetic subjects for preservation of renal function.

PREVENTION

Patients known to be at high risk of hypertension because of a high-normal blood pressure, a parental history of blood pressure elevation, black race, or elderly age may be able to reduce the likelihood of hypertension by adopting nutritional and behavioral habits to modify factors known to interact with the predisposition to hypertension. These habits include lowering sodium intake to less than 100 mEq of sodium (2.3 g) per day, adopting a diet low in sodium and high in fruits, vegetables, and low-fat dairy products, losing weight by caloric restriction and a systematic moderate exercise program, restricting alcohol intake to no more than 2 oz per day, quitting cigarette smoking, and avoiding foods high in saturated fat. Increased calcium intake may be of benefit in some susceptible patients: it appears to lower blood pressure in subgroups of normotensive and hypertensive patients. The benefit of increased potassium intake is less well established, but it seems to reduce cerebrovascular disease in hypertension and thus can be recommended as long as the potassium intake is not superimposed on a background of renal impairment that could precipitate dangerous hyperkalemia. The major difficulty with lifestyle modification is in ensuring long-term compliance.

MANAGEMENT

When hypertension is present and no immediate cause is found, the diagnosis of primary or essential hypertension is usually assumed. As previously described, genetic and environmental factors can contribute to blood pressure elevation; there is often a family history of hypertension. Primary hypertension typically begins with a subtle rise in blood pressure in the thirties and forties, progressing to definite and sustained blood pressure elevation in the fifties and older. The most recent recommendations by the Joint National Committee on High Blood Pressure are to use nonpharmacologic interventions when blood pressure reaches a persistent level of 140 mm Hg systolic or 85 mm Hg diastolic or higher. Nondrug therapy (weight loss, reduction of sodium and alcohol intake) is often used for mildly hypertensive patients (90 to 95 mm Hg) as sole therapy in the absence of target-organ disease, concurrent cardiovascular disease, or diabetes mellitus.

BIOFEEDBACK AND OTHER BEHAVIORAL MODIFICATION TECHNIQUES

Studies examining the usefulness of behavioral modification techniques, ranging from transcendental meditation to biofeedback, on blood pressure have verified that relaxation and stress avoidance can be associated with blood pressure reduction in both normotensive persons and hypertensive patients who are successful in achieving these goals. These techniques, which require active conditioning, are often ineffective in maintaining a lower blood pressure level when the patient is busily involved in his or her daily routine, however. There appears to be no holdover effect on blood pressure when these techniques are not being actively applied.

PHARMACOLOGIC THERAPY

Many antihypertensive drugs are available for the treatment of hypertension, and they can be conveniently separated into three general categories on the basis of their mechanism of action: diuretics, antisympathetic agents, and vasodilators.

Diuretics

The short-acting diuretics (furosemide, ethacrynic acid, bumetanide) all act primarily on the loop of Henle of the renal tubule. Their brief duration of action makes them generally unsuitable for routine use in uncomplicated cases of hypertension, because they must be given frequently (three or four times a day) to achieve adequate blood pressure control over a 24-hour period. Torsemide, a long-acting loop diuretic, is an exception. The loop diuretics are generally reserved for use in patients with

acute pulmonary edema, congestive heart failure, malignant or accelerated hypertension, or renal failure. For most uncomplicated cases of hypertension requiring diuretic therapy, hydrochlorothiazide can be given once a day because of its 10- to 14-hour duration of action.

Diuretics lower blood pressure primarily by reducing extracellular fluid volume, at the expense of stimulating sympathetic activity and renin activity, increasing heart rate, inducing peripheral and regional vasoconstriction, and increasing vascular resistance as well as raising blood viscosity. In addition, diuretics generally promote potassium and magnesium loss, increasing the risk for ventricular dysrhythmias and sudden death. Furthermore, they increase blood glucose and uric acid levels, catecholamine release, and cholesterol levels (particularly the low-density lipoprotein fraction and triglycerides). All these metabolic changes, which are significant and persist for the duration of diuretic therapy, may increase the risk of coronary artery disease. Long-acting diuretics (chlorthalidone, metolazone, indapamide) have a duration of action of 18 to 30 hours. They often cause nocturia, which may be a cause of noncompliance. In addition, they promote prolonged sodium-for-potassium exchange, causing greater potassium loss for an equivalent pressure-lowering effect than do the intermediate-acting thiazide diuretics.

Potassium-sparing agents (spironolactone, triamterene, amiloride) are generally ineffective in reducing blood pressure when given alone; they usually are administered in combination with thiazide diuretics. Diuretics can be associated with impotence in men, and this appears to be more common with Aldactazide (a combination of spironolactone and hydrochlorothiazide) than with the other potassium-sparing/thiazide combinations. The duration of action of spironolactone and triamterene is only about 60% of that of amiloride, and thus only Moduretic (a combination of hydrochlorothiazide and amiloride) is generally effective on a once-daily schedule. It is rarely necessary to exceed a dose of 50 mg per day of hydrochlorothiazide or its equivalent; often, therapy is initiated at 25 or even 12.5 mg per day, particularly in sodium-sensitive and elderly hypertensive patients.

Diuretics remain the drugs of first choice for the treatment of hypertension in sodium-sensitive patients, particularly the elderly, and in black patients. In the context of risk factors for coronary disease, such as left ventricular hypertrophy, diabetes, electrocardiogram abnormalities, gout, hyperuricemia, and hyperlipidemia, diuretics may not be ideal, and effective alternatives that do not increase the risk of cardiovascular disease may be preferable. When combined with other classes of antihypertensive agents, doses of hydrochlorothiazide as low as 6.25 mg per day have been shown to be efficacious. Thus, diuretics, in small doses, have a major role as added therapy when another class of first-step treatment does not lower blood pressure sufficiently.

Antisymphathetics

The centrally acting agents reserpine, α -methyldopa, clonidine, guanabenz, and guanfacine are not often used because of their central nervous system side effects, which range from dry mouth and stuffy nose to sleepiness, lethargy, fatigue, depression, and impotence. The β -adrenergic blocking drugs lower blood pressure primarily by diminishing cardiac output. Cardioselectivity is dose dependent and is minimal at higher doses. It appears that the nonselective β -blockers can lessen the likelihood of sudden death, particularly that seen during acute myocardial infarction, by blocking the β_2 -receptor. The cardioselective agents, unless used at high doses, do not provide this cardiac protection. Moreover, this cardioprotective effect of β -blockade is manifest early after myocardial infarction, and continued reduction of mortality rates after 1 year has not been consistently observed.

The combined α - and β -receptor antagonist labetalol lowers blood pressure by diminishing peripheral resistance through α -adrenergic blockade and through reducing cardiac output by β -blockade. Labetalol is very effective in the emergent treatment of hypertension and is efficacious in a broad spectrum of hypertensive patients, particularly those with relatively severe blood pressure elevations. The desirability of routine use of labetalol as initial therapy for mild to moderate hypertension remains to be extensively investigated.

Vasodilators

Direct-acting vasodilators, such as hydralazine and minoxidil, are potent in dilating the vasculature. They are generally reserved for third- or fourth-step antihypertensive therapy because of marked salt and water retention and sympathetic nervous system stimulation. When these direct-acting vasodilators are used, they are generally combined with diuretics and β -blocking agents, thus consigning them to the third or fourth step in the treatment of patients with severe, refractory hypertension. The calcium channel blockers provide peripheral vasodilatation and reduce vascular resistance without promoting expansion of extracellular fluid volume or stimulating reflex sympathetic discharge. The edema seen with some agents is not a reflection of salt and water retention and extracellular volume expansion but rather an effect of capillary dilatation. The increased risk of cardiovascular disease reported with these agents appears to be limited to the short-acting preparations.

Indirect-acting vasodilators include peripheral α -adrenergic blocking agents, such as prazosin, terazosin, and doxazosin; ACE inhibitors; and ARBs. They are effective antihypertensive agents that do not produce volume expansion or stimulate increased sympathetic nervous system activity. Another advantage of the indirect-acting agents is their neutral or beneficial effect on lipid levels and glucose.

ACE inhibitors lower blood pressure by preventing the formation of angiotensin II, the effective vasoconstrictor product of the renin-angiotensin system. ACE inhibitors may have other mechanisms of action involving kinin production and the synthesis of vasodilatory prostaglandins. ACE inhibitors are uniquely devoid of the adverse central nervous system side effects common with other antihypertensive drugs. When ACE inhibitors are given to volume-depleted patients, they may have a pronounced hypotensive action. They may frequently cause an annoying, nonproductive cough, sinusitis, and other respiratory symptoms. A new class of agents, the ARBs, hold the potential for antihypertensive efficacy without many of the side effects of ACE inhibitors, and they may have unique benefits, which are being evaluated in clinical trials currently.

ACE inhibitors have been used in combination with diuretics, calcium channel blockers, β -adrenergic blocking agents, and centrally acting antisymphathetic drugs. When combined with diuretics, they appear to blunt or prevent the reactive metabolic responses to diuretic therapy that seem to be related to diuretic-induced stimulation of the renin-angiotensin-aldosterone system. These responses include hyperuricemia, hypokalemia, hyperglycemia, and hypercholesterolemia. ACE inhibitors have also been shown to improve insulin sensitivity.

CHOOSING INITIAL ANTIHYPERTENSIVE THERAPY

When hypertension develops in white or young patients (less than 60 years of age), it is likely to be responsive to β -adrenergic blocking drugs, ACE inhibitors, or ARBs as initial therapeutic agents. Calcium channel entry blockers and α -blockers have a broader demographic efficacy than do diuretics, β -blockers, ACE inhibitors, or ARBs when used as sole therapy. In black patients, diuretics or calcium channel blockers are usually effective initial agents. In white patients over age 60, diuretics or calcium channel blockers are also good initial therapy. For these reasons, the initial therapy in hypertensives today (Fig. 30.1) is based on the likely pathophysiologic picture, the probability of blood pressure responsiveness to given therapeutic agents, the relative risk of cardiovascular disease, and the presence of other disorders (pulmonary disease, angina, diabetes, gout, hyperlipidemia, peripheral vascular disease). Also, because some side effects of antihypertensive agents are dose dependent, it is often wise to add a second drug before reaching the maximum dose of the initial agent to minimize the dose-dependent adverse effects.

FIGURE 30.1. Beginning antihypertensive therapy.

Combination therapy is most likely to be effective if drugs of different classes are used (e.g., diuretics, vasodilators, antisympathetics). Combinations shown to have additive effects include diuretics and b-blockers, diuretics and ACE inhibitors or ARBs, diuretics and a-blockers, diuretics and central sympatholytics, and ACE inhibitors and calcium channel blockers. The combination of a diuretic and a b-blocker produces additive effects on lipids (raising total cholesterol and low-density lipoproteins and lowering high-density lipoproteins) and raises glucose levels. The combination of an ACE inhibitor and a diuretic blunts or prevents the adverse metabolic effects of diuretic therapy on uric acid, potassium, glucose, and cholesterol. The a-blockers also reduce the adverse lipid effects of diuretics. There is little evidence for an additive antihypertensive effect when diuretics are combined with calcium channel entry blockers.

COMPLIANCE WITH ANTIHYPERTENSIVE THERAPY

Hypertension is generally an asymptomatic disease for decades until a cardiovascular complication occurs. Control of blood pressure in the asymptomatic phase significantly reduces overall cardiovascular morbidity and mortality rates. Even in elderly patients with isolated elevation of systolic pressure and normal diastolic pressure, systolic blood pressure reduction has been shown to lower mortality rates, particularly from stroke. Convincing an asymptomatic patient of the need for long-term medical therapy to control blood pressure elevation and to prevent the development of cardiovascular disease is a challenge, however. Thus, patient compliance has been and remains the major deterrent to long-term blood pressure control and prevention of cardiovascular complications. For this reason, it is important to educate the patient that side effects may occur with antihypertensive therapy and to encourage reporting them. It is equally important to be familiar with alternative therapeutic agents that are likely to be effective in a given patient.

Another major challenge in the treatment of the hypertensive patient is to recognize concomitant disorders that may also require treatment and that can complicate the efficacy, side effects, or safety of antihypertensive therapy. The wide variety of effective antihypertensive agents available today, when used alone or in combination with other agents, can provide excellent blood pressure control and can even improve quality of life for a hypertensive patient. The issues of patient well-being and subjective responses to antihypertensive therapy are assuming increasing importance in light of studies addressing this issue as well as the increased awareness of the lay population regarding the variety of agents available for treatment of hypertension.

The asymptomatic nature of uncomplicated hypertension requires a substantial amount of education of the patient regarding the need for continued antihypertensive therapy and periodic blood pressure assessment, end-organ evaluation, and routine laboratory studies. An office reminder system for periodic recall is helpful to maximize follow-up of patients. The issues of compliance with therapy and side effects can be improved by evaluating quality of life through direct questioning of the patient.

CHAPTER 31: APPROACHES TO HYPERCHOLESTEROLEMIA AND OTHER ABNORMAL LIPID PROFILES

DANIEL J. RADER

[Hypercholesterolemia](#)
[Hypertriglyceridemia](#)
[Hypoalphalipoproteinemia \(Decreased High-Density Lipoprotein Cholesterol\)](#)
[Hypolipidemia \(Decreased Cholesterol\)](#)

Elevated total cholesterol and low-density lipoprotein (LDL) cholesterol levels, elevated triglyceride levels, and reduced high-density lipoprotein (HDL) cholesterol levels are all independently associated with a higher risk of atherosclerotic cardiovascular disease. Markedly elevated triglyceride levels (more than 1,000 mg per deciliter) are associated with the risk of acute pancreatitis. The clinical evaluation and treatment of patients with lipid disorders are directed primarily toward preventing atherosclerotic cardiovascular disease (for most patients with lipoprotein disorders) or preventing acute pancreatitis (for patients with severe hypertriglyceridemia).

HYPERCHOLESTEROLEMIA

PRESENTATION

The most important clinical consequence of hypercholesterolemia is premature atherosclerotic cardiovascular disease, and any patient with cardiovascular disease should be tested for a potential lipoprotein disorder. In addition, routine screening of asymptomatic adults for potential lipid disorders is also recommended, as described below under “Laboratory Studies and Diagnostic Tests.” The subsequent approach to the evaluation and treatment of a patient with an abnormal lipid profile is strongly influenced by the presence of atherosclerotic cardiovascular disease and other risk factors. Treatment in patients with coronary heart disease (CHD) or other forms of atherosclerosis is known as secondary prevention; treatment in patients without CHD is known as primary prevention. A general approach to the screening, diagnosis, and management of hypercholesterolemia has been developed by the Adult Treatment Panel of the National Cholesterol Education Program. The guidelines suggest an approach to management the intensity of which takes into account the presence of CHD or other atherosclerotic cardiovascular disease as well as the presence of other cardiovascular risk factors.

PATHOPHYSIOLOGY

The pathophysiologic description of lipoprotein disorders is reviewed extensively in [Chapter 12](#).

HISTORY AND PHYSICAL EXAMINATION

A complete history should be obtained, including a history of atherosclerotic cardiovascular disease and a history of other cardiovascular risk factors ([Table 31.1](#)). The presence of established cardiovascular disease or other risk factors has a significant impact on subsequent evaluation and management. A history of known secondary causes of hyperlipidemia, including medications (see [Chapter 12](#)), also should be procured, along with a comprehensive family history of premature cardiovascular disease and hyperlipidemia. The physical examination should include a careful examination of the eyes for arcus corneae, the eyelids for xanthelasmas, the palms for palmar xanthomas, the knuckles and Achilles tendons for tendon xanthomas, and the elbows and knees for cutaneous and tuberous xanthomas. The thyroid should be palpated and major arteries should be examined for vascular bruits.

Positive risk factors	
Age, yr	Male ≥45
	Female ≥55 or premature menopause without estrogen replacement therapy
Family history of premature coronary heart disease (definite myocardial infarction or sudden death before 55 years of age in male first-degree or before 65 years of age in female first-degree relative)	
Current cigarette smoking	
Hypertension	
Diabetes mellitus	
Low HDL cholesterol (<35 mg/dL)	
Negative risk factors*	
	High HDL cholesterol (≥60 mg/dL)

HDL, high-density lipoprotein.
 * If the HDL cholesterol is ≥60 mg/dL, subtract one risk factor.
 (Adapted from the Summary of the second report of the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults [Adult Treatment Panel II], *JAMA*. 1998;279:1675–1685, with permission.)

TABLE 31.1. MAJOR CARDIOVASCULAR RISK FACTORS OTHER THAN LOW-DENSITY LIPOPROTEIN CHOLESTEROL TO CONSIDER IN THE EVALUATION AND TREATMENT OF HYPERCHOLESTEROLEMIA

LABORATORY STUDIES AND DIAGNOSTIC TESTS

All adults over age 20 should be screened for hypercholesterolemia. In adults without CHD, this screening should be performed by measuring total and HDL cholesterol in the nonfasting state. The initial classification, according to National Cholesterol Education Program guidelines, is described in [Table 31.2](#). A serum cholesterol level below 200 mg per deciliter is desirable and, if the HDL cholesterol level is above 35 mg per deciliter, requires no further evaluation. A serum cholesterol level of 200 to 239 mg per deciliter is borderline high, but if the HDL cholesterol is above 35 mg per deciliter and there is no more than one cardiovascular risk factor, no further evaluation is required. A cholesterol level of 200 to 239 mg per deciliter in the context of two or more risk factors should be evaluated further with a full fasting lipid profile. In addition, a serum cholesterol level above 240 mg per deciliter or an HDL cholesterol level below 35 mg per deciliter are indications for a full fasting lipid profile. Finally, a full fasting lipid profile should be undertaken for patients with established cardiovascular disease.

Initial Classification and Action Based on Total and HDL Cholesterol (Patients Without CHD Only)			
Total Cholesterol	Classification	Action	
<180 mg/dL	Desirable		
180–199 mg/dL		Repeat in 1 year	
200–239 mg/dL	Borderline high	Testing lipoproteins	
240–269 mg/dL			
270–359 mg/dL			
≥360 mg/dL			
200–239 mg/dL		Diets, information and repeat in 1 year	
200–239 mg/dL		Testing lipoproteins	
240–269 mg/dL		Testing lipoproteins	
≥270 mg/dL		Testing lipoproteins	

Treatment Decisions Based on LDL Cholesterol Level (All Patients)			
Patient Category	Initiate Dietary Therapy	Initiate Drug Therapy	LDL Goal
With CHD or other atherosclerosis	<100 mg/dL	<100 mg/dL	<100 mg/dL
Without CHD and with 2 risk factors	<100 mg/dL	<100 mg/dL	<100 mg/dL
Without CHD and with 1 risk factor	<160 mg/dL	<160 mg/dL	<160 mg/dL
Without CHD and without risk factors	<160 mg/dL	<160 mg/dL	<160 mg/dL

CHD, coronary heart disease; HDL, high-density lipoprotein; LDL, low-density lipoprotein.
 (Adapted from the Summary of the second report of the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults [Adult Treatment Panel II], *JAMA*. 1998;279:1675–1685, with permission.)

TABLE 31.2. INITIAL CLASSIFICATION BASED ON TOTAL AND HDL CHOLESTEROL AND TREATMENT DECISIONS BASED ON LDL CHOLESTEROL

The full fasting lipid profile includes measurement of the triglyceride, total cholesterol, and HDL cholesterol levels after an overnight fast of at least 12 hours. The LDL cholesterol is usually calculated using the following equation: LDL cholesterol = total cholesterol - (triglycerides/5) - HDL cholesterol. This formula is reasonably accurate if test results are obtained on fasting plasma and if the triglyceride level does not exceed 400 mg per deciliter. The determination of LDL cholesterol levels in patients with triglyceride levels above 400 mg per deciliter usually requires ultracentrifugal techniques in specialized laboratories, though direct assays for LDL measurement have now become available. All further evaluation and treatment should be based on the LDL cholesterol level, not the total cholesterol level. Once a lipoprotein disorder has been diagnosed, the laboratory should rule out potential secondary causes of hyperlipidemia. In practice, this assessment usually includes measurement of fasting glucose to rule out diabetes mellitus, serum thyroid-stimulating hormone (TSH) to rule out hypothyroidism, and serum albumin if the nephrotic syndrome is suspected and liver function tests to assess the possibility of obstructive liver disease.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of hypercholesterolemia includes primary and secondary causes. The major secondary causes of hypercholesterolemia are listed in [Table 31.3](#). Hypothyroidism should always be ruled out with measurement of the TSH, since this condition can often be subtle and is eminently treatable. Once secondary causes have been excluded, primary causes of elevated LDL cholesterol should be considered. The major inherited conditions that are sources of hypercholesterolemia (see [Chapter 12](#)) include familial hypercholesterolemia (FH), familial defective apoB-100 (FDB), familial combined hyperlipidemia (FCHL), familial dysbetalipoproteinemia (type III hyperlipidemia), and polygenic hypercholesterolemia. A few clinical clues and laboratory tests can assist in the diagnosis of these disorders. The presence of tendon xanthomas strongly supports the diagnosis of FH or FDB, though their absence does not rule out these diagnoses. FDB can be pinpointed by molecular screening in specialized laboratories, but heterozygous FH is diagnosed on the basis of clinical features. Elevated triglyceride levels are rarely seen in FH or FDB and are much more suggestive of FCHL.

Type of Dyslipidemia	Lipid Values	Phenotype	Primary Disorders	Secondary Disorders
Diets (II) (isolated HDL normal)	LDL >160 mg/dL TG <200 mg/dL	Ia	Familial hypercholesterolemia, familial defective apoB-100, polygenic hypercholesterolemia, familial combined hyperlipidemia	ApoE4, nephrotic syndrome, obstructive liver disease
HDL elevated	TG <200 mg/dL	Ib	Familial combined hyperlipidemia	Nephrotic syndrome, diabetes mellitus
Diets (remnant lipoproteins)	TG 200-800 mg/dL	II	Familial dysbetalipoproteinemia, hepatic lipase deficiency	Dyslipidemia
Diets (LDL)	TG 200-800 mg/dL	III	Familial hypertriglyceridemia	Diabetes mellitus, alcohol use, estrogen therapy, other drugs
Diets (dyslipidemia)	TG >1200 mg/dL	IV-V	Lipoprotein lipase deficiency, apoA-II deficiency, familial type V hyperlipidemia	Diabetes mellitus, alcohol use, estrogen therapy, other drugs

LDL, low-density lipoprotein; TG, triglycerides.

TABLE 31.3. DIAGNOSTIC CONSIDERATIONS IN PATIENTS WITH DYSLIPIDEMIA

A family history of hyperlipidemia in at least one first-degree relative is required to support the diagnosis of FCHL. This diagnosis can be established by the measurement of the plasma apoB level. In FCHL, the apoB level is high (usually more than 130 mg per deciliter) and is often elevated disproportionately to the LDL cholesterol level owing to the presence of increased amounts of small, “dense” LDL particles, a biochemical marker for FCHL that is difficult to measure directly. Therefore, a substantially elevated apoB level in the context of modestly elevated LDL and triglyceride levels strongly suggests FCHL.

Familial dysbetalipoproteinemia (type III hyperlipidemia) can masquerade as an apparent cause of elevated LDL cholesterol (based on the calculated level), but the true LDL cholesterol level is usually low; instead, the level of remnant lipoproteins is elevated. The formula for calculating LDL cholesterol is not accurate in this context because the 5:1 ratio of triglycerides to cholesterol in very low density lipoproteins (VLDLs) is not valid for remnant lipoproteins. Type III hyperlipidemia should be suspected when there is no family history of hyperlipidemia or a secondary cause of hyperlipidemia, when palmar or tuberoeruptive xanthomas are found, or when the total cholesterol and triglyceride levels are both substantially elevated to a similar degree. The diagnosis of type III hyperlipidemia often can be confirmed on laboratory tests. Traditionally, lipoprotein electrophoresis has been used, since the remnant lipoproteins run in the region between beta and prebeta, resulting in the “broad beta” band characteristic of this disorder. Ultracentrifugation has also been used in specialized laboratories to confirm this diagnosis. In many laboratories it is possible to screen for the apoE-2/2 genotype usually associated with this disorder. The finding of an apoE-2/2 genotype in a patient with clinically suspected type III hyperlipidemia confirms the diagnosis, but the absence of this genotype does not rule out rarer forms of type III hyperlipidemia associated with other mutations in apoE.

STRATEGIES FOR OPTIMAL CARE

Management

Secondary causes of hypercholesterolemia should be actively sought and treated. Obese persons should be encouraged to lose weight, sedentary persons to exercise, and those who drink alcohol to minimize their intake. Every attempt should be made to modify other cardiovascular risk factors as well. The decisions in the clinical treatment of patients with hypercholesterolemia are highly dependent on whether established atherosclerotic cardiovascular disease or other cardiovascular risk factors are present ([Table 31.2](#)). Aggressive treatment of hypercholesterolemia in patients with established CHD or other atherosclerotic disease (secondary prevention) is well supported by experimental data. Clinical trials have confirmed conclusively that lowering LDL cholesterol levels in patients with established atherosclerotic disease reduces the number of cardiovascular events and total mortality rates. Therefore, aggressive secondary prevention treatment to lower LDL cholesterol levels is clinically indicated and cost-effective. Nevertheless, it is estimated that up to 70% of patients with established CHD are not receiving adequate cholesterol-lowering therapy, according to current guidelines.

In primary prevention, several clinical trials have shown that lowering the total or LDL cholesterol level limits the number of cardiovascular events and mortality rates. Earlier trials were not designed with adequate power to assess the question of the effect on total mortality rates, but one trial has now verified a substantial reduction in total mortality. Therefore, LDL cholesterol lowering in the primary prevention of CHD is indicated for high-risk individuals. The generally accepted approach is that the more cardiovascular risk factors there are, and the higher the absolute LDL cholesterol level, the greater the potential benefit from drug therapy to lower the LDL cholesterol level. In persons considered to be at lower risk, the emphasis is more on dietary modification and less on drug therapy.

The National Cholesterol Education Program provides guidelines for the treatment of patients with elevated LDL cholesterol. A strategy for the management of elevated LDL cholesterol in the patient with established CHD or other atherosclerotic cardiovascular disease (ASCVD) is presented in [Figure 31.1](#). Because patients with diabetes mellitus are at similar very high risk, they should be treated in a similar fashion. The optimal LDL cholesterol level is 100 mg per deciliter or less for patients with established ASCVD or diabetes mellitus. Although dietary therapy should always be instituted as first-line therapy, most patients require drug therapy to reach the optimal LDL cholesterol level. The timing of drug therapy, when indicated, should not be delayed in the context of established CHD.

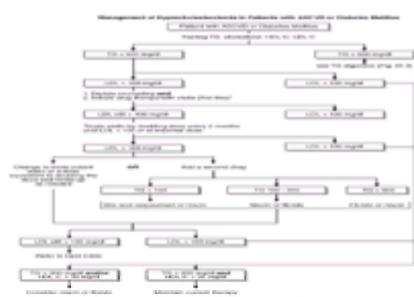

FIGURE 31.1. Strategy for the management of hypercholesterolemia in the secondary prevention of CHD in patients with established CHD.
EVIDENCE LEVEL: C. Expert Opinion.

Primary prevention often divides high-risk and low-risk patients, depending on the presence of other cardiovascular risk factors. A strategy for the management of elevated LDL cholesterol in the patient without CHD but who is at high risk owing to the presence of two or more cardiovascular risk factors is presented in [Fig. 31.2](#). Dietary therapy should be initiated for patients with LDL cholesterol levels above 130 mg per deciliter. It is important to stress weight reduction in overweight patients and increased physical activity in general. After a 3- to 6-month trial of diet therapy, the lipid panel should be repeated and the LDL cholesterol level determined. Drug therapy is indicated in patients with LDL cholesterol levels above 160 mg per deciliter. Patients with LDL cholesterol levels of 130 to 160 mg per deciliter are not usually candidates for drug therapy, but this decision must be individualized in high-risk patients and may be influenced by the HDL cholesterol level and perhaps other blood factors, such as apoB and lipoprotein(a) [Lp(a)].

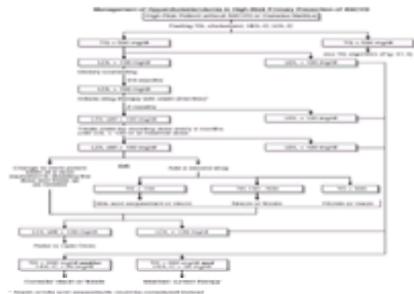

FIGURE 31.2. Strategy for the management of hypercholesterolemia in the primary prevention of CHD in patients with two or more risk factors for CHD.
EVIDENCE LEVEL: C. Expert Opinion.

For patients with no more than one cardiovascular risk factor, an LDL cholesterol level above 190 mg per deciliter is the recommended cutoff point for consideration of drug therapy. In patients at very low risk, with no other cardiovascular risk factors (e.g., men younger than 35 years old and premenopausal women), drug therapy can be reasonably delayed if the LDL cholesterol level is between 190 and 220 mg per deciliter ([Table 31.2](#)). All persons with LDL cholesterol levels above 220 mg per deciliter on an optimal dietary and exercise regimen are candidates for drug therapy.

It is often difficult to decide whether to initiate drug therapy in relatively low-risk patients without CHD who have LDL cholesterol levels in the borderline zone between 160 and 220 mg per deciliter. Although it is desirable to avoid drug treatment for patients in whom CHD is unlikely to develop, many patients with premature CHD have LDL cholesterol levels in this range. Therefore, factors that help predict cardiovascular risk may be useful in this population. One such test is the apoB level; if it is elevated, it can suggest the presence of dense LDL, an exceptionally atherogenic form of LDL. LDL particle size can also be determined using specialized gel electrophoresis or NMR methods. Another predictive blood test is the Lp(a) level, which cannot be measured by a standard lipid profile; if it is elevated, however, it points to an increased risk of CHD. Epidemiologic data strongly indicate that the apoE4 genotype is also predictive of increased cardiovascular risk independent of lipid levels. Therefore, these and other tests may assume increased importance in the treatment of patients with borderline LDL cholesterol levels.

Diet Therapy

The guidelines for dietary treatment of elevated LDL cholesterol levels are listed in [Table 31.4](#). To lower the LDL cholesterol level by diet modification, the intake of saturated fats must be restricted. Decreasing the intake of total fats and cholesterol is also useful, although less important than the intake of saturated fats. Low-fat, yet palatable diets have been developed; useful diet programs include those suggested by the American Heart Association and the National Cholesterol Education Program. The patient should be instructed in the diet by the physician or a qualified assistant. A second cholesterol measurement should be obtained at 6 weeks and a third at 3 months. If the diet has been successful, the patient can be monitored every 3 months for the first year and every 6 months thereafter. Periodic review of the diet may be needed to reinforce the need for its continued use. If therapeutic goals are not reached after 3 months, the patient should be referred to a registered dietitian for more detailed dietary instruction. The patient may be advanced to a step II diet, which further restricts total and saturated fat ([Table 31.4](#)). If the patient does not respond adequately to diet therapy after an additional 3 months and if the LDL cholesterol level remains above the cutoff for drug therapy, drug treatment should be considered ([Fig. 31.2](#)).

Dietary Constituent	Step I Diet	Step II Diet
Total fat	<30% of total calories	<30% of total calories
Saturated fatty acids	<10% of total calories	<7% of total calories
Polysaturated fatty acids	<10% of total calories	<10% of total calories
Monounsaturated fatty acids	10-15% of total calories	10-15% of total calories
Carbohydrates	50-60% of total calories	50-60% of total calories
Protein	10-20% of total calories	10-20% of total calories
Cholesterol	<300 mg/day	<200 mg/day
Total calories	To achieve and maintain desirable body weight	To achieve and maintain desirable body weight

(Adapted from the Summary of the second report of the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel II). JAMA 1993;269:351-352, with permission.)

TABLE 31.4. DIETARY GUIDELINES FOR THERAPY OF HYPERCHOLESTEROLEMIA

Patients with established atherosclerotic cardiovascular disease should be instructed concerning a step II diet by a registered dietitian. Diet is important in these high-risk patients, to maximize the chances of achieving the optimal LDL cholesterol level (less than 100 mg per deciliter). The period of observation on diet alone in these patients may be shorter than is the case with primary prevention, however, especially if the LDL cholesterol level is significantly elevated. Responses of total and LDL cholesterol to step I and step II diets vary widely and are greater in controlled studies on metabolic wards than they are among outpatients. In addition, most patients experience a decline in HDL cholesterol when they decrease the amount of total and saturated fats in their diet. It is important to inform patients of this possibility and to reassure them that the diet is nevertheless beneficial in terms of overall cardiovascular risk.

These recommendations do not always apply. For example, patients with significant hypercholesterolemia usually do not respond adequately to diet therapy alone. If the patient already has CHD, it is reasonable to start drug therapy after only 6 weeks of diet therapy or even immediately. In elderly patients with elevated LDL cholesterol levels, the need for dietary therapy should be balanced against the need for adequate nutrition. In pregnant women with hypercholesterolemia, previously initiated dietary therapy may be continued but should be reviewed to ensure adequate nutrient consumption. Pregnancy can be associated with hyperlipidemia in the third trimester, which generally requires no treatment.

Drug Therapy

When diet therapy alone fails to achieve therapeutic goals, drug therapy should be considered. The guidelines for initiating drug treatment based on LDL cholesterol

levels are listed in [Table 31.2](#). [Table 31.5](#) summarizes the major drugs used for treating hypercholesterolemia. When drug therapy is started, regular follow-up is necessary to gauge therapeutic effects, to reinforce the need for compliance, and to monitor for side effects. After drug therapy is started, lipids and transaminases should be obtained in 6 to 8 weeks and again in 4 months. If the patient is stable, long-term monitoring can be performed every 6 months. If the initial drug does not reduce LDL cholesterol to the therapeutic goal, a combination of drugs may be used. In these cases, it may be necessary to consult a specialist in lipid disorders. Most of the available lipid-lowering drugs are effective in combination, but patients must be monitored carefully because of the increased potential for complications.

Drug	Major Indications	Starting Dose	Maximal Dose	Mechanism	Common Side Effects
Bile acid sequestrants Cholestyramine Colestipol	Elevated LDL	4 g daily 5 g daily	8 g daily 18 g daily	Inhibit bile acid reabsorption and increase LDL receptor activity	Bloating, constipation, steatorrhea
Niacin and extended-release niacin	Elevated LDL, HDL, TG, apoB, apoA	100 mg 3 times daily after meals 125 mg 3 times daily	1 g 3 times daily 2,000 mg 3 times daily	Decreased VLDL synthesis	Cutaneous flushing, GI upset, elevated liver enzymes, headache, dizziness
Extended-release niacin (Elni)	Elevated LDL	100 mg 3 times daily	1,000 mg 3 times daily	Inhibit cholesterol synthesis, up-regulate LDL receptors	Bloating, constipation, GI upset, elevated liver enzymes, dizziness
Statins Lovastatin Pravastatin Simvastatin Fluvastatin Atorvastatin Rosuvastatin	Elevated LDL	20 mg daily 20 mg daily 20 mg daily 20 mg daily 20 mg daily 10 mg daily	80 mg daily 80 mg daily 80 mg daily 80 mg daily 80 mg daily 20 mg daily	Inhibit cholesterol synthesis, up-regulate LDL receptors	Myalgia, arthralgia, GI upset, elevated liver enzymes, dizziness
Fibrates and derivatives Gemfibrozil Fenofibrate Fenofibric acid	Elevated TG, elevated LDL	600 mg 3 times daily 200 mg 3 times daily	600 mg 3 times daily 200 mg 3 times daily	Increased lipoprotein lipase, decreased VLDL synthesis	Myalgia, GI upset, elevated liver enzymes, dizziness, headache, weight gain

TABLE 31.5. SUMMARY OF THE MAJOR DRUGS USED FOR THE TREATMENT OF HYPERLIPIDEMIA

HMG-CoA Reductase Inhibitors (Statins)

Inhibitors of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA reductase) include lovastatin, pravastatin, simvastatin, fluvastatin, atorvastatin, and cerivastatin. HMG-CoA reductase is the rate-limiting step in cholesterol biosynthesis; by reducing hepatic cholesterol biosynthesis, these drugs up-regulate hepatic LDL-receptor activity, leading to increased clearance of plasma LDL. They may also decrease hepatic production of VLDL in some circumstances.

Five major randomized controlled clinical trials of statin monotherapy reported in the 1990s (simvastatin, pravastatin, and lovastatin) found highly significant reductions in fatal and nonfatal myocardial infarction and, in some cases, in stroke and total mortality rates. Three of these trials (4S, CARE, and LIPID) were secondary prevention trials involving patients with established coronary artery disease, and two (WOSCOPS and AF/TexCAPS) were primary prevention trials in persons without known coronary artery disease. Many of the subjects treated in these trials had LDL cholesterol levels that would be considered average with respect to the general population.

The starting dose of each of the statins generally reduces LDL cholesterol by 20% to 30%, though response to the statins is highly variable, and some patients do not respond as well. Statins are generally titrated by doubling the dose, which produces a 6% to 7% further reduction in LDL cholesterol. Patients' acceptance of the statins is high, since they can be taken in tablet form once a day and are well tolerated. Levels of liver transaminases can rise, and they should be monitored during therapy, though the risk to the liver appears to be quite low overall. Other side effects can include muscle or joint pains, gastrointestinal upset, headaches, and sleep disturbance.

Nicotinic Acid (Niacin)

Nicotinic acid, also called niacin, belongs to the vitamin B complex. In doses well above those required as a vitamin, it is a potent lipid-lowering drug useful in the treatment of hypertriglyceridemia and hypercholesterolemia. Among the lipid-lowering drugs, nicotinic acid has the greatest effect in raising HDL cholesterol, and it is the only lipid-lowering drug that consistently lowers Lp(a) levels. Its mechanism of action is uncertain, but it probably reduces hepatic VLDL production. In the Coronary Drug Project, nicotinic acid reduced total mortality rates in patients with established CHD.

The starting dose of immediate-release niacin is 100 mg three times a day at the end of meals. Flushing is to be expected, but this effect improves with continued administration. After 4 to 7 days, the dose can be increased gradually by 100 mg per dose, eventually reaching 500 mg three times a day. After 1 month on this dose, lipids and pertinent blood chemistries should be measured, and, if necessary, the dose can be increased to 1,000 mg three times a day. Rarely, doses of up to 4,500 mg per day are used, but these are not generally recommended. Patients' acceptance of immediate-release nicotinic acid can be limited owing to the cutaneous flushing and pruritus it often causes. Proper education often permits the successful administration of immediate-release nicotinic acid. It may be necessary for some patients to take an aspirin 30 minutes before the dose of niacin, to prevent flushing.

The over-the-counter sustained-release forms of niacin are somewhat better tolerated but may be more likely to cause hepatotoxicity than the regular forms. A controlled-release form of prescription niacin called Niaspan is taken once daily at bedtime, is better tolerated than immediate-release niacin, and is probably safer than over-the-counter sustained-release niacin. Niaspan is titrated over 4 weeks to an initial maintenance dose of 1,000 mg daily at bedtime and can be increased subsequently to 2,000 mg daily.

Other side effects of nicotinic acid include hyperglycemia, hyperuricemia, elevated liver function test results, exacerbation of peptic ulcer disease, and acanthosis nigricans. Successful niacin therapy requires careful education of the patient as to its side effects. Its advantages are its low cost, long-term safety, ability to raise HDL cholesterol levels, and documented benefit in patients with established coronary artery disease. It is particularly useful in combination with statins in patients who cannot achieve LDL cholesterol goals on a statin alone, patients who have combined hyperlipidemia and persistently elevated triglycerides and/or low HDL cholesterol on statin therapy, and patients who require drug therapy to reduce LDL cholesterol but cannot tolerate statins.

Bile Acid Sequestrants (Resins)

Bile acid sequestrants, including cholestyramine and colestipol, interrupt the enterohepatic circulation of bile acids and accelerate the loss of bile acids in the stool. This change promotes increased hepatic conversion of cholesterol to bile acids, followed by stimulation of hepatic LDL-receptor activity and enhanced LDL clearance from the plasma. In the Lipid Research Clinics Coronary Primary Prevention Trial, cholestyramine reduced cardiovascular morbidity and mortality rates in patients without preexisting CHD.

Patients' acceptance of these drugs is limited because they are insoluble resins that must be suspended in liquid and are therefore often inconvenient and unpleasant to take. Colestipol is available in large tablets, which some patients prefer. Because these drugs are not systemically absorbed, major side effects are limited to the gastrointestinal tract (bloating, constipation) but are often dose-limiting. These agents bind many other drugs (digoxin, warfarin) and interfere with their absorption, and for this reason other medications must be taken 1 hour before or 4 hours after the bile acid sequestrants.

These agents are often drugs of first choice because of their safety. They are a particularly good choice for the young, well-motivated patient with mild hypercholesterolemia, but education of patients is critical for acceptance and successful therapy. They should not be prescribed for patients with triglyceride levels above 400 mg per deciliter, because they aggravate hypertriglyceridemia. Bile acid sequestrants are especially effective in combination therapy, and they have an increasingly important clinical role in combination with nicotinic acid or HMG-CoA reductase inhibitors.

Fibric Acid Derivatives (Fibrates)

Fibric acid derivatives include clofibrate, gemfibrozil, and fenofibrate. Fibrates are peroxisome proliferator activated receptor a (PPARa) agonists, and through this action they stimulate lipoprotein lipase (LPL) activity and may restrict hepatic VLDL production. They lower triglyceride levels effectively and generally raise HDL cholesterol levels modestly, but they have limited ability to lower LDL cholesterol levels. In the World Health Organization study, clofibrate lowered rates of cardiovascular mortality, but the drug was associated on longer follow-up with an increase in total mortality rates. In the Helsinki Heart Study, gemfibrozil reduced the number of major coronary events but had no effect on total mortality rates. Micronized fenofibrate is available for use in the United States and has a somewhat greater

LDL cholesterol–reducing effect than gemfibrozil.

Fibrates are generally well tolerated; side effects include gastrointestinal upset and muscle pains. Liver function test results are elevated on rare occasions and should be monitored during therapy. Fibrates potentiate the effect of warfarin and increase the lithogenicity of bile. Fibrates are primarily administered for reduction of triglyceride levels, and their major use is in patients with moderate to severe hypertriglyceridemia.

Combination Drug Therapy

Some patients with severe hypercholesterolemia may require therapy with two and sometimes even three drugs to achieve therapeutic goals. This is especially true in secondary prevention, in which the LDL cholesterol goal of 100 mg per deciliter can be difficult to achieve in many patients. Bile acid sequestrants can be combined successfully with HMG-CoA reductase inhibitors in patients with normal triglyceride levels. Nicotinic acid can be very effective in combination with statins in patients with FH as well as combined hyperlipidemia. Fibrates and statins can be used together successfully in patients with moderate to severe hypertriglyceridemia who also require further LDL cholesterol reduction. This combination should be used with caution, because the risk of myopathy is increased. Patients should be told about the potential for muscle pain. Patients with severe hyperlipidemia requiring combination therapy should be referred to a specialized lipid center.

Low-density Lipoprotein Apheresis

Patients who remain significantly hypercholesterolemic despite combination drug therapy are at high risk of progressive atherosclerotic cardiovascular disease. Patients with drug-refractory hypercholesterolemia who have established CHD or who are high risk should be considered for LDL apheresis. This procedure involves the selective removal of LDL by physically passing plasma over columns containing dextran sulfate or heparin, which binds the LDL; the LDL-depleted plasma is then returned to the patient. LDL apheresis is performed using an automated instrument on a repetitive basis, usually every 2 weeks, because the LDL cholesterol levels rebound over time. This method does not result in HDL lowering and is generally well tolerated. Several studies have indicated that LDL apheresis can retard progression or cause regression of atherosclerosis in patients with severe, drug-resistant hypercholesterolemia. LDL apheresis is the treatment of choice, when possible, for patients with homozygous FH, who respond poorly to drug therapy. Other patients with resistant hypercholesterolemia and CHD are potential candidates for this treatment as well. Patients must be referred to a specialized lipid center for evaluation for LDL apheresis. When LDL apheresis is not available, plasma exchange can be considered. A large volume of plasma is removed and replaced with an albumin/saline solution. This effectively lowers the LDL cholesterol level acutely but also removes many other plasma constituents, including HDL cholesterol. It is generally less well tolerated than selective LDL apheresis.

Partial Ileal Bypass

The partial ileal bypass procedure lowers LDL cholesterol levels by 30% to 40% in reported studies. Its mechanism of action is similar to that of bile acid sequestrants: the enterohepatic circulation of bile acids is interrupted, and the hepatic LDL receptor is up-regulated. One controlled trial of partial ileal bypass in patients with moderate hypercholesterolemia and established CHD showed significantly diminished cardiovascular morbidity and mortality rates in the treated group compared with the control group, which received no lipid-lowering therapy. However, diarrhea is a relatively common side effect, and the incidence of kidney stones, gallstones, and intestinal obstruction is also high. The procedure is relatively ineffective in persons with homozygous FH and in many other patients with severe, drug-refractory hypercholesterolemia. Therefore, its clinical utility is currently limited to those patients with severe hypercholesterolemia with established CHD who cannot tolerate standard lipid-lowering medications and do not have access to LDL apheresis.

Experimental Therapies

Novel therapies for severe, drug-refractory hypercholesterolemia are being developed actively. New molecular targets for the development of lipid-lowering small molecules include the microsomal transfer protein, which is required for assembly and secretion of apoB-containing lipoproteins. Gene therapy is also a consideration for severe conditions, such as homozygous FH. In a pilot study, five patients with homozygous FH were treated in a protocol involving ex vivo retroviral transfer of the LDL receptor gene into autologous hepatocytes, with subsequent reimplantation. LDL cholesterol levels declined modestly in three of five patients. As gene therapy vectors improve, homozygous FH and other conditions of severe, drug-refractory hypercholesterolemia will undoubtedly be targets for the development of gene therapeutic protocols. Patients with severe, resistant hypercholesterolemia should be referred to specialized centers so that they may benefit from experimental therapeutic protocols.

Indications for REFERRAL

Indications for referral to a lipid clinic include the following: inability to reach the LDL cholesterol goal, inability to reduce severely elevated triglyceride levels with a fibrate, intolerance of lipid-lowering medication, abnormal baseline liver transaminase (ALT and/or AST) levels in a patient who requires lipid-lowering drug therapy, increase in liver transaminase levels of greater than three times the upper limit of normal on drug therapy, consideration of LDL apheresis, persistently low HDL cholesterol in a high-risk patient, uncertainty about the need to institute lipid-lowering drug therapy, and suspected rare genetic disorders, such as familial chylomicronemia syndrome, homozygous FH, and abetalipoproteinemia.

COST-EFFECTIVENESS

Drug therapy to reduce LDL cholesterol in secondary prevention is highly cost-effective. The cost-effectiveness of drug therapy in primary prevention is determined by the level of risk of the patient to be treated. The higher the risk, the more cost-effective primary prevention becomes. One rationale for improving methods of risk assessment is to better identify persons who are candidates for lipid lowering in the context of primary prevention and make this intervention more cost-effective.

HYPERTRIGLYCERIDEMIA

PRESENTATION

The most important clinical consequence of severe hypertriglyceridemia is acute pancreatitis. In addition, moderate hypertriglyceridemia is frequently, but not invariably, associated with an increased risk of premature atherosclerotic cardiovascular disease. Therefore, any patient with acute pancreatitis or cardiovascular disease should be tested for triglycerides. In contrast to hypercholesterolemia, there are no formal guidelines for the classification and treatment of patients with hypertriglyceridemia. Patients with severe fasting hypertriglyceridemia (triglyceride levels more than 1,000 mg per deciliter) should be treated actively to reduce the risk of acute pancreatitis. For patients with mild to moderate hypertriglyceridemia, treatment should be directed primarily toward the assessment of cardiovascular risk and prevention of atherosclerosis. In general, if LDL cholesterol levels can be determined reliably, patients should be evaluated and treated based on the LDL cholesterol level, as described earlier. A significantly elevated triglyceride level (more than 400 mg per deciliter), however, often makes it difficult to assess the LDL cholesterol level accurately and requires a somewhat different approach to diagnosis and therapy.

PATHOPHYSIOLOGY

The pathophysiologic description of lipoprotein disorders is reviewed extensively in [Chapter 12](#).

HISTORY AND PHYSICAL EXAMINATION

A complete history should be taken, including any record of pancreatitis or recurrent abdominal pain, atherosclerotic cardiovascular disease, other cardiovascular risk factors ([Table 31.1](#)), and known secondary causes of hyperlipidemia, including medications (see [Chapter 12](#)). A comprehensive family history of pancreatitis, premature cardiovascular disease, and hyperlipidemia should be obtained. The physical examination should include a search of the eyes for arcus corneae and lipemia retinalis, the eyelids for xanthelasma, the palms for palmar xanthomas, the elbows and knees for tuberous xanthomas, and the back and buttocks for eruptive xanthomas. The thyroid should be palpated, and major arteries should be examined for vascular bruits. Patients with very high triglyceride levels are at risk of acute pancreatitis.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

Evaluation of triglycerides requires a fasting lipid profile. For assessment purposes, patients with elevated triglyceride levels are often divided into those with borderline high (200 to 400 mg per deciliter), high (400 to 1,000 mg per deciliter), and very high (more than 1,000 mg per deciliter) triglyceride levels. The major concern in patients with borderline and high triglyceride levels is the presence of dyslipidemia, which may increase the risk of CHD. Patients with very high triglycerides are at risk of acute pancreatitis. Once hypertriglyceridemia has been diagnosed, the laboratory should rule out potential secondary causes. In practice, this evaluation usually includes measurement of fasting glucose to eliminate the possibility of diabetes mellitus and measurement of serum albumin if the nephrotic syndrome is suspected. Liver function tests also are undertaken if obstructive liver disease is suspected.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of hypertriglyceridemia includes primary and secondary causes. Most patients with severe hypertriglyceridemia (more than 1,000 mg per deciliter) probably have an underlying genetic predisposition, which in many cases is exacerbated by another medical condition or a hormonal or environmental factor. Primary genetic causes of severe hypertriglyceridemia (see [Chapter 12](#)) include LPL deficiency, apoC-II deficiency, lipodystrophy, type I glycogen storage disease, and familial type V hyperlipidemia (of unknown origin). LPL deficiency can be diagnosed in specialized laboratories by measuring LPL in plasma obtained after the patient has been given a small dose of heparin, but it is unlikely to appear for the first time in an adult. It is much more common for a secondary cause to contribute to severe hypertriglyceridemia (poorly controlled diabetes mellitus, the nephrotic syndrome, heavy alcohol use, or the use of estrogens, isotretinoin, etretinate, or HIV protease inhibitors). In most cases, the secondary cause is probably superimposed on an underlying genetic predisposition to hypertriglyceridemia. Although familial dysbetalipoproteinemia alone normally does not produce triglyceride levels above 1,000 mg per deciliter, when a secondary cause of hypertriglyceridemia is superimposed on the apoE-2/2 genotype, triglyceride levels can be very elevated. Therefore, consideration should be given to determining the apoE genotype in all patients with severe hypertriglyceridemia.

Primary causes of less severely elevated triglycerides (see [Chapter 12](#)) include familial hypertriglyceridemia, FCHL, and familial dysbetalipoproteinemia (type III hyperlipidemia). A few clinical clues and laboratory tests can assist in the diagnosis of these disorders. A family history of hyperlipidemia in at least one first-degree relative is required to support the diagnosis of FCHL. This diagnosis can be corroborated by the measurement of the plasma apoB level. In FCHL, the apoB level is increased (usually more than 130 mg per deciliter) and is often elevated disproportionately to the LDL cholesterol level owing to the presence of increased amounts of small, dense LDL particles, a biochemical marker for FCHL. Therefore, a substantially elevated apoB level in the context of modestly elevated LDL and triglyceride levels strongly suggests FCHL. Familial dysbetalipoproteinemia (type III hyperlipidemia) should be suspected when there is no family history of hyperlipidemia or a secondary cause of hyperlipidemia, when palmar or tuberoeruptive xanthomas are found, or when the total cholesterol and triglyceride levels are both substantially elevated to a similar degree. The diagnosis of type III hyperlipidemia can usually be confirmed by lipoprotein ultracentrifugation or apoE genotyping. The finding of a ratio of VLDL cholesterol to total triglycerides of more than 0.3 or an apoE-2/2 genotype in a patient with clinically suspected type III hyperlipidemia confirms the diagnosis.

STRATEGIES FOR OPTIMAL CARE

Management

Secondary causes of hypertriglyceridemia should be treated. In general, dietary measures are useful in improving hypertriglyceridemia. Alcohol should be avoided. Obese persons should lose weight by restricting caloric intake. Physical exercise can often have a significant impact on triglyceride levels. Restriction of total dietary fat can be effective for patients with severe hypertriglyceridemia. Diabetes should be optimally controlled. Women taking estrogens should consider discontinuing them, especially if the triglyceride level is very high (more than 1,000 mg per deciliter). An algorithm for the management of hypertriglyceridemia is presented in [Figure 31.3](#).

[Figure 31.3](#).

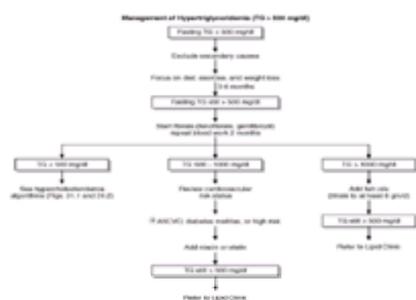

FIGURE 31.3. Strategy for the management of hypertriglyceridemia.

EVIDENCE LEVEL: C. Expert Opinion.

When fasting triglyceride levels remain above 1,000 mg per deciliter despite appropriate dietary and lifestyle measures, drug therapy should be instituted to lessen the risk of acute pancreatitis. There are three major classes of drugs used to lower very high triglyceride levels: fibric acid derivatives, nicotinic acid, and fish oils. The choice must be individualized to the patient. Nicotinic acid and fish oils worsen glucose intolerance, and for this reason fibrates are preferred in patients with diabetes mellitus. Sometimes combinations, particularly a fibrate with fish oils, are necessary for adequate control. When triglyceride levels cannot be reduced to levels below 1,000 mg per deciliter, patients should be referred to a lipid clinic.

Drug therapy also should be considered in the effort to lower triglyceride levels in the patient with established CHD who has a triglyceride level above 400 mg per deciliter. In this context, lowering the triglyceride level is essential for optimal management of the LDL cholesterol level (which is often difficult to assess when the triglyceride level is more than 400 mg per deciliter). Fibrates and nicotinic acid are the major choices. For triglycerides closer to the 1,000 mg per deciliter range, fish oils can be useful adjunct therapy. For triglycerides closer to the 400 mg per deciliter range in patients who also have elevated LDL cholesterol levels, statins may be helpful in reducing these levels, especially at higher doses. Triglyceride levels in the 200 to 400 mg per deciliter range are associated with increased cardiovascular risk, but little data exist that show that reduction of triglycerides in this range lowers risk. Nevertheless, in patients with established CHD, borderline high triglycerides could be considered a secondary target for intervention after the LDL cholesterol has been lowered to a desirable range. Fibrates and fish oils can cause the LDL cholesterol level to increase; for this reason, nicotinic acid may be preferred in patients with moderate triglyceride elevations and elevated LDL cholesterol levels.

Patients with type III hyperlipoproteinemia respond well to fibrates, but they also respond to nicotinic acid and statins. Type III hyperlipoproteinemia is one of the few hypertriglyceridemic conditions that responds favorably to estrogen replacement therapy.

HYPOALPHALIPOPROTEINEMIA (DECREASED HIGH-DENSITY LIPOPROTEIN CHOLESTEROL)

PRESENTATION

Given the current recommendations for screening of both HDL cholesterol and total cholesterol in all adults, many persons are now being diagnosed with low HDL cholesterol levels. There are no formal guidelines for the classification and treatment of patients with low levels of HDL cholesterol, however, except as an additional risk factor in the management of elevated LDL cholesterol. Many patients with low HDL cholesterol levels have associated hyperlipidemia, in which case they should be evaluated and treated based on the type of hyperlipidemia, as described earlier. Some persons, however, have isolated hypoalphalipoproteinemia (HDL cholesterol level in the bottom tenth percentile) with relatively normal cholesterol and triglyceride levels.

PATHOPHYSIOLOGY

The pathophysiologic description of low HDL cholesterol is reviewed extensively in [Chapter 12](#).

HISTORY AND PHYSICAL EXAMINATION

A complete history should be taken, including any record of atherosclerotic cardiovascular disease, other cardiovascular risk factors ([Table 31.1](#)), and known secondary causes of low HDL cholesterol, for example, medications (see [Chapter 12](#)). A comprehensive family history of premature cardiovascular disease and lipid disorders should be obtained. The physical examination should include a search of the eyes for arcus corneae. The thyroid should be palpated, and major arteries should be examined for vascular bruits.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

Evaluation of HDL cholesterol can be performed without fasting, but a full evaluation requires a fasting lipid profile. The laboratory should rule out potential secondary causes of low HDL cholesterol.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis and management of isolated low HDL cholesterol levels must distinguish patients with moderately decreased HDL cholesterol levels (15 to 35 mg per deciliter) and those with severely decreased HDL levels (less than 15 mg per deciliter). The major known causes of decreased HDL cholesterol levels are listed in [Chapter 12](#).

Moderately low HDL cholesterol levels often are associated with modestly elevated LDL cholesterol or triglyceride levels. In this context, the low HDL cholesterol level is used in clinical practice as an additional independent cardiovascular risk factor, but it is rarely appropriate to embark on a diagnostic evaluation of the low HDL cholesterol level itself. If the LDL cholesterol and triglyceride levels are relatively normal, the apoB level should be measured. The apoB level is often elevated in patients with moderately low HDL cholesterol levels; this suggests the presence of a form of FCHL often referred to as hyperapobetalipoproteinemia. The syndrome of low HDL cholesterol without accompanying hyperlipidemia has been referred to as primary hypoalphalipoproteinemia. Patients with this disorder may be at high risk of premature cardiovascular disease. There is no diagnostic test, though a low level of apoA-I can help confirm the low level of HDL cholesterol and supports the diagnosis. Secondary causes of a moderately decreased HDL cholesterol level include smoking, type II diabetes mellitus, obesity, and a sedentary lifestyle.

Severely decreased HDL levels (less than 20 mg per deciliter) often are seen in patients with markedly elevated triglyceride levels (usually more than 1,000 mg per deciliter). When HDL cholesterol levels are in this range in the context of normal to only moderately elevated triglyceride levels, a rare genetic source is virtually always the cause. The major known genetic causes of severely low HDL cholesterol levels (see [Chapter 12](#)) include mutations in apoA-I, lecithin:cholesterol acyltransferase, and ATP-binding cassette protein 1 (ATP1; Tangier disease). A patient suspected of having one of these disorders should be referred to a specialized lipid center for further evaluation.

STRATEGIES FOR OPTIMAL CARE

Management

There are no formal guidelines for the treatment of patients with isolated low HDL cholesterol levels. Diabetes should be optimally controlled, smoking should be discontinued, obese persons should lose weight, and sedentary persons should exercise. Postmenopausal women should consider estrogen replacement therapy, which results in a modest increase in HDL cholesterol. Nicotinic acid is the most effective pharmacologic method for raising HDL cholesterol, and fibrates have modest effects, particularly in patients who also have elevated triglycerides. However, there are few clinical data to suggest that raising the HDL cholesterol level protects against the development or progression of atherosclerotic cardiovascular disease. The Veterans Administration HDL Intervention Trial (VA-HIT) trial indicated the benefit of gemfibrozil therapy (which raised HDL cholesterol levels and reduced triglycerides but did not change LDL cholesterol levels) in men with CHD and low HDL cholesterol levels. In practice, in patients with established CHD and low HDL cholesterol levels, LDL cholesterol should be controlled first. If the HDL cholesterol remains low, however, additional consideration may be given to the use of nicotinic acid to raise the HDL level further. In primary prevention it is difficult to recommend drug therapy specifically to raise HDL cholesterol levels, though an individual at very high risk with an isolated low HDL cholesterol level might consider taking niacin despite the absence of clinical trial data. Firm clinical recommendations must await clinical trials designed to address this question.

HYPOLIPIDEMIA (DECREASED CHOLESTEROL)

Disorders causing clinically significant low levels of cholesterol are rare. In general, a total cholesterol level above 80 mg per deciliter is not associated with any known clinical signs or symptoms. The two major clinically important disorders of low cholesterol are abetalipoproteinemia and homozygous hypobetalipoproteinemia. Their clinical symptoms include spinocerebellar degeneration, pigmented retinopathy, fat malabsorption, and acanthocytosis (see [Chapter 12](#)). They should be suspected only if the total cholesterol level is below 80 mg per deciliter, in which case a full lipid profile should be performed along with quantitation of apoB. The diagnosis is confirmed by extremely low to undetectable levels of LDL cholesterol and apoB.

These disorders are differentiated from each other primarily by family history. Abetalipoproteinemia is autosomal recessive, and obligate heterozygotes (such as the parents) have normal cholesterol levels. Hypobetalipoproteinemia is autosomal codominant, and heterozygotes have about half the normal levels of cholesterol. Patients with either of these disorders should be referred to a specialized center for definitive diagnosis and appropriate therapy. Despite therapy, many patients have slowly progressive neurologic and retinal disease.

CHAPTER 32: APPROACH TO THE PATIENT WITH CHEST PAIN (CARDIAC AND NONCARDIAC)

ALBERTO A. MITRANI AND MARK MULTACH

[Cardiac Chest Pain](#)
[Noncardiac Chest Pain](#)
[Strategies for Optimal Cost-Effective Care](#)

The patient with chest pain may suffer from symptoms as trivial as indigestion or have a significant risk of sudden death within minutes. Physicians must be prepared to initiate an evaluation expediently, first differentiating the likelihood of myocardial ischemia or other life-threatening disease from less urgent situations. A rapid assessment is essential to identify the patient who may have an acute coronary syndrome and hence be at risk of sudden cardiac death.

CARDIAC CHEST PAIN

PAIN DUE TO ISCHEMIA

The initial concern is always the possibility of myocardial ischemia. Acute coronary syndromes include myocardial infarction (MI) and the various patterns of unstable angina. The latter is defined as new-onset angina, rest angina, or crescendo-pattern angina (more frequent, prolonged, or severe episodes in a patient with known angina pectoris). Any sustained episode of acute angina should be considered a potential evolving infarction until proved otherwise. These entities should be identified quickly so that immediate treatment to prevent MI or salvage myocardium can be initiated.

Chronic stable angina may stem from coronary artery disease, aortic stenosis, left ventricular hypertrophy, or pulmonary hypertension. The pattern of chest pain is usually related to effort and may become unstable. Owing to the high risk of sudden death with hemodynamically significant aortic stenosis, this diagnosis should be suspected in the patient with concomitant dyspnea or fatigue, transient loss of consciousness, and confirmatory examination results. Prinzmetal's angina typically occurs at rest but may also accompany exertion and other vasospastic phenomena. Aside from its occurrence at rest, the characteristics and associations are similar to those of classic angina.

PAIN NOT DUE TO ISCHEMIA

Pericardial pain results from inflammation and frequently has a pleuritic or positional component, in that it can be relieved in the sitting position. From time to time it is indistinguishable from ischemic pain. Pulmonary embolism (PE) should be suspected when a patient with risk factors for thromboembolism describes pleuritic chest pain. Evaluation with ventilation perfusion lung scanning, pulmonary angiography, or venous imaging of the lower extremities is necessary, since a diagnosis made on purely clinical grounds is unreliable. The pain of aortic dissection is usually sudden in onset, with radiation to the back. It may be described as an intense or a "tearing" sensation. Rapid confirmation by aortography, computerized tomography, magnetic resonance imaging, or transesophageal echocardiography is crucial for a favorable outcome.

HISTORY AND PHYSICAL EXAMINATION

A careful history is the single best initial diagnostic tool available in assessing chest pain ([Table 32.1](#)). In describing symptoms, patients may not refer to their complaint as pain. Any number of descriptive terms can be expected, including tightness, squeezing, crushing, pressure, aching, burning, and "heartburn." Since classic (typical) angina is effort related, any of the previously described sensations that have a consistent association with effort should raise the suspicion of ischemia. Morning episodes of discomfort are more frequent with ischemia. A sensation that radiates to the arms, neck, or shoulder may also be more common in cardiac ischemia. The association of pain with nausea or vomiting and diaphoresis should heighten the suspicion of ischemia. Symptoms occurring at rest or those related to meals, movement, stress, and respiratory pattern are more likely to be from a noncardiac cause. A sensation described as stabbing or fleeting is also less likely to be ischemic. Certain characteristics of symptoms are highly indicative of noncardiac chest pain, including respiratory "tics," obvious sighs, gasping respiration, and short breath-holding time.

Condition	Duration	Quality	Precipitation	Relief	Location
Stable angina	1-10 min	Myocardial pressure	Effort, emotion	Rest, nitroglycerin	Substernal, variable
Rest angina	5-15 min	Myocardial pressure	Serotonergic	Rest, nitroglycerin	Substernal, variable
Myocardial infarction	Minutes to hours	Myocardial pressure	Serotonergic to adrenergic	Time	Left anterior
Esophageal reflux	10-60 min	Myocardial	Refluxing acid	Food, antacid, upright position	Substernal, variable
Esophageal spasm	5-60 min	Myocardial	Serotonergic, cold liquids, emotion	Rest, nitroglycerin	Substernal, variable
Aortic dissection	Hours	Myocardial, tearing	Upper back, left arm	Rest, nitroglycerin	Upper, anterior
Widespread	Hours	Myocardial, aching	Serotonergic, cold	Time, analgesics	Upper, anterior, variable
Costal chondritis	Variable	Superficial	Respiratory, movement	Time, analgesics	Chest
Musculoskeletal pain	Variable	Superficial	Respiratory, movement	Time, analgesics	Multiple
Pulmonary	10-15 min	Myocardial, pressure	Other symptoms	Rest, time, bronchodilator	Multiple

MI, myocardial infarction; nitroglycerin, nitroglycerin; rest, rest; time, time; analgesics, analgesics; cold, cold; upright, upright; position, position; variable, variable; anterior, anterior; chest, chest; multiple, multiple.

TABLE 32.1. CHARACTERISTICS OF COMMON CAUSES OF CHEST PAIN

A detailed cardiovascular examination can provide vital clues to a cardiac cause, though normal examination results do not rule out a life-threatening process. The detection of a murmur of papillary muscle insufficiency, third or fourth heart sound, loud pulmonic valve component, abnormal precordial impulse, jugular venous distention, rales, or lower-extremity edema is associated with organic heart disease and may indicate ischemia or infarction. A diminished aortic closure sound, with a crescendo-decrescendo systolic murmur peaking late in systole and accompanied by a decreased carotid upstroke, suggests hemodynamically significant aortic stenosis. Unequal pulses or blood pressures should be a warning of possible aortic dissection. Pericardial friction rub (a rough, leathery sound), tachycardia, and pulsus paradoxus suggest pericarditis and possible tamponade. The presence of a pleural friction rub, evidence of consolidation, absence of or abnormal breath sounds, or Hamman's sign (a crunching sound heard in the precordium) may indicate a pulmonary source. Persistent sinus tachycardia with tachypnea, a pleural rub, and localized wheezing, can reflect pulmonary embolization. Atypical pain that is reproducible with cervical motion is likely due to a C6-7 radiculopathy.

DIAGNOSTIC TESTS

Electrocardiography (ECG) is essential in the evaluation of chest pain. Some 50% to 60% of patients with acute MI will show ECG changes suggesting the diagnosis. The actual percentage will be influenced by the previous or baseline ECG result, the timing of the study in relation to the onset of pain, the coronary distribution involved, and the specific criteria used. Depending on the diagnostic criteria for MI, sensitivity and specificity of the ECG will vary ([Table 32.2](#)). A normal ECG result makes the diagnosis of MI less likely but does not exclude the possibility. The presence of a left bundle-branch block (new or old) is a poor prognostic indicator.

TABLE 32.5. DIFFERENTIAL DIAGNOSIS OF CHEST PAIN

GASTROESOPHAGEAL REFLUX DISEASE

Up to 50% of patients with noncardiac chest pain have an esophageal abnormality that is acid related. Cardiac pain may be indistinguishable from pain of esophageal origin. Nocturnal and/or positional pain is more likely with gastroesophageal reflux disease (GERD). The presence of dysphagia, dyspepsia, or heartburn also suggests GERD. The diagnosis is frequently made on clinical grounds, justifying a trial of proton pump inhibitor or H₂-antagonist therapy. If symptoms do not resolve, diagnostic testing should be pursued. If dysphagia is an initial complaint, imaging with barium swallow or esophagogastrosocopy will best identify the stricture, esophagitis, or mass that is most likely to be found in such a patient. In the patient with symptoms suggestive of GERD, evaluation can be individualized and includes barium swallow, pH monitoring, esophageal manometry, motility studies, provocative testing, and esophagogastrosocopy.

UNEXPLAINED CHEST PAIN AND PANIC DISORDER

Patients with chest pain and normal coronary angiography have a 30% to 50% likelihood of meeting criteria for panic disorder. Panic attacks are required to establish a diagnosis of panic disorder and frequently include chest pain ([Table 32.6](#)). These patients have an excellent cardiac prognosis but continue to seek medical care for recurrent chest pain. Since the patient does not tend to seek psychiatric help, examining physicians must be sensitive to the possibility of panic disorder. The implications of high utilization of limited health care resources in these patients are obvious, and the economic impact is not trivial—a significant proportion of patients with panic disorder will visit an emergency department at least annually complaining of chest pain. The pathophysiologic explanation is not known, but abnormal metabolic activity in the anterior limbic structures has been noted in these patients. A trial of imipramine, other tricyclic antidepressants, or serotonin re-uptake inhibitors is warranted; if not successful, such treatment should be followed by referral to a mental health specialist.

A discrete period of intense fear or discomfort in which at least four of the following symptoms develop abruptly.
 Chest pain or discomfort
 Palpitations, cardiac awareness, or accelerated heart rate
 Sweating
 Trembling or shaking
 Sensation of shortness of breath or smothering
 Feeling of choking
 Nausea or abdominal distress
 Feeling dizzy, unsteady, lightheaded, or faint
 Feelings of unreality or detachment from oneself
 Fear of losing control or going crazy
 Fear of dying
 Numbness or tingling sensations
 Chills or hot flashes

TABLE 32.6. CRITERIA FOR PANIC ATTACK^a

STRATEGIES FOR OPTIMAL COST-EFFECTIVE CARE

The evaluation of patients with chest pain should begin with the initial history, physical examination, and ECG for immediate and appropriate risk stratification. [Figure 32.1](#) categorizes patients by these findings and suggests appropriate contexts for cost-effective evaluation and treatment. Future advances in biochemical markers and imaging techniques may help to distinguish patients with life-threatening conditions requiring hospitalization. The organization and implementation of regional chest pain centers will be studied for their potential to provide high-quality cost-effective care.

CHAPTER 33: SMOKING AND SMOKING CESSATION

ALFRED MUNZER

[Magnitude of the Smoking Problem](#)
[Biologic Basis for Nicotine Addiction](#)
[Stages in Tobacco Use and Smoking Cessation](#)
[Evaluating the Smoker](#)
[Smoking-Cessation Methods](#)
[Conclusions](#)

Smoking causes dysfunction and disease in virtually every organ of the human body. It is also a source of frustration to the physician, who feels powerless in the face of a habit that is deeply ingrained in the patient and that, despite a massive and largely successful public health campaign, is still condoned and even enshrined by segments of society. This chapter is designed to give an overview of the dimensions of the problem of smoking, to convey an understanding of the nature of tobacco and nicotine, and to provide the foundations for a clinical approach to the smoker.

MAGNITUDE OF THE SMOKING PROBLEM

Smoking remains the most common preventable cause of death in the United States. Smoking claims 450,000 lives annually, as many deaths as are caused by alcohol, cocaine, heroin, suicide, homicide, motor vehicle accidents, fire, and AIDS combined. Smoking doubles the overall mortality rate and is responsible for 30% of all deaths in the United States, including 90% of deaths due to lung cancer, 35% of all cancer deaths, 21% of deaths due to coronary heart disease, and 90% of deaths due to chronic obstructive lung disease. Smoking and the use of smokeless tobacco are also the major cause of cancer of the oral cavity and cancer of the esophagus, and they contribute to the deaths from cancer of the pancreas, cancer of the urinary tract, peripheral vascular disease, and cerebrovascular disease. Smoking also plays a significant role in the development of peptic ulcer disease and infectious respiratory disease and compounds the complications associated with diabetes.

Because women started smoking in large numbers more recently than men, their death rate from smoking has been lower, but the rate is catching up to that of men. Whereas the age-adjusted mortality rate from smoking rose 18% for men from 1973 to 1989, it rose 118% for women. Smoking exposes women to the same risks as men and also increases their risk of cancer of the cervix and osteoporosis. Smoking advances the age of menopause, causes premature aging of the skin, and increases the incidence of complications of stroke associated with the use of oral contraceptives. Smoking in pregnancy leads to postmature births, stillbirths, and heavy-birth-weight babies.

Smoking causes death, disease, and disability not only in smokers but also in those exposed to environmental tobacco smoke. Parental smoking, for example, provokes pneumonia, bronchitis, and middle-ear effusions in children, reduces their lung function, and places them at increased risk of asthma. Smoking by spouses increases the incidence of lung cancer in nonsmoking partners. Environmental tobacco smoke has been estimated to lead to 50,000 deaths due to cancer and coronary heart disease annually in the United States. The direct medical costs associated with smoking have been estimated conservatively at \$53 billion annually. The total cost of smoking probably exceeds \$100 billion annually.

Despite a massive campaign to inform the public of the hazards of smoking and despite increasing restrictions on smoking in the workplace and in public places, 47 million Americans, or 27.0% of men and 22.6% of women, were still smoking in 1995. In 1965, however, 42.4% of the population smoked, and 50% of all adults who have ever smoked have quit, a success unparalleled in the annals of public health. Furthermore, 70% of smokers responding to a 1994 survey of the Centers for Disease Control and Prevention expressed a desire to quit and have made at least one serious attempt to quit. Unfortunately, the addictive nature of nicotine, the strength of a habit reinforced by a million puffs taken over the career of a smoker, intense marketing by the tobacco industry, and the ready availability of tobacco products conspire to allow only 2.5% of smokers to succeed in quitting in any given year. Even the simplest intervention by the physician can double the success rate. Seventy percent of smokers consult their physicians at least yearly, but 30% of those who consult their physicians are not even advised to stop smoking, and only a few smokers receive the sustained, organized, and appropriately intense counseling and support their devastating habit deserves.

BIOLOGIC BASIS FOR NICOTINE ADDICTION

TOBACCO

The psychoactive properties of tobacco were an important part of the rituals and healing practices of the peoples indigenous to the Americas for millennia. Ancient Mayan manuscripts vividly depict an underworld populated by gods smoking tobacco rolled into cones resembling cigars. Acute intoxication was deemed to have a transcendental purpose and was achieved not only through smoking but also through chewing, drinking, licking, and purging. European discoverers turned tobacco into an important commodity that shaped the economy of the American colonies and laid the foundation for today's giant transnational tobacco companies. The use of tobacco, however, was condemned and even banned for religious and esthetic reasons as early as the sixteenth century.

The advent of the cigarette-making machine in 1884, the invention of the safety match, and the creation of a positive, healthful image associated with smoking broadly popularized the use of tobacco. Acute intoxication was replaced with the problems of long-term addiction and chronic disease. In 1930, lung cancer was listed for the first time as a cause of death in the vital statistics of the United States. Tobacco has undergone many changes. It has been bred into many different varieties that make each specifically suitable to a particular taste or mode of administration. Tobacco is predominantly smoked as cigarettes, but it is also smoked as cigars or in pipes. There has been a resurgence of the use of smokeless, or chewing, tobacco, especially by adolescents.

There are four commonly used types of tobacco: flue-cured, light air-cured, dark, and oriental. Flue-cured tobacco has a high sugar and a low nitrogen content and produces an acidic smoke that prevents the absorption of nicotine in the oral cavity and makes more nicotine available for absorption through the lung. It is therefore a major ingredient of cigarettes. Light air-cured tobacco has a cellular structure that facilitates the absorption of various fillers and flavorings. For this reason it is used as a carrier of additives in cigarettes. Dark tobacco is fermented and thus has a low sugar and a high nitrogen content and produces an alkaline smoke that favors the absorption of nicotine in the oral cavity. Dark tobacco is preferred in pipes and cigars, which are puffed rather than inhaled, and in smokeless tobacco, which is chewed. Oriental tobacco is prized for its aroma.

Tobacco contains an estimated 4,000 compounds, including many that are pharmacologically active, toxic, mutagenic, and carcinogenic. There are several pharmacologically active alkaloids in tobacco, but nicotine is the most important. Among the toxic substances found in tobacco smoke are carbon monoxide, hydrogen cyanide, and ammonia. Forty-three definite carcinogens have been identified in tobacco smoke, including polynuclear aromatic hydrocarbons, *N*-nitrosamines, and inorganic compounds, such as arsenic and chromium. The carcinogens are targeted to the oral cavity when tobacco is chewed, to the oral cavity and the esophagus when pipes or cigars are puffed, and to the lung and remote organs when cigarette smoke is inhaled.

During the manufacture of cigarettes, cigars, and pipe and chewing tobacco, numerous ingredients are added to the tobacco leaf. These include sugars and licorice, which alter the flavor of the cigarette; glycerol and diethylene glycol, which retain moisture; menthol to reduce throat irritation; inorganic salts, which change the burning characteristics of the tobacco; and several oils to enhance the aroma. As a result, there are hundreds of tobacco products on the market targeted to every segment of the population. But all are ultimately designed to deliver nicotine into the system and to reinforce the addictive properties of nicotine.

PSYCHOPHARMACOLOGIC PROPERTIES OF NICOTINE

In the early 1800s, Cerioli and Vauquelin isolated an oily essence of tobacco; they named it "nicotianine" after Jean Nicot, who sent tobacco seeds from Portugal to the French court at the end of the sixteenth century. Nicotine is by far the major, but not the only, psychoactive alkaloid found in tobacco. It is a tertiary amine composed of a pyridine and a pyrrolidine ring. It is a weak base with a pKa of 8.0. In its pure form, it is a clear, volatile, alkaline liquid that has the smell of tobacco and turns brown when exposed to air. The concentration of nicotine varies in different types of tobacco leaves, but after the manufacturing process, the nicotine content of different brands of cigarettes is remarkably constant (about 8.4 mg). The level of nicotine delivered to the smoker, however, varies from 0.1 to 1.9 mg per

cigarette, depending on the density of the tobacco in the cigarette and the presence of filters and designs that favor dilution of the smoke that is inhaled.

The temperature at the tip of a burning cigarette is 884°C, allowing for the distillation of nicotine along with other components into a vapor that is easily inhaled and rapidly absorbed across the alveolar surface. After absorption, nicotine is taken up rapidly by the brain and slowly distributed to other tissues. Nicotine is metabolized primarily in the liver to cotinine and nicotine oxide. Nicotine and its metabolites are excreted through the kidney. The half-life of nicotine in blood after tissue uptake is about 120 minutes. This means that during regular smoking, nicotine levels rise over 6 to 8 hours before reaching equilibrium and persist for 8 hours after cessation.

The effects of nicotine felt by the smoker are mediated through both the central and peripheral nervous systems. Nicotine, for example, affects various components of the neuroendocrine system and stimulates the release of anterior and posterior pituitary hormones. It binds to specific receptors in the brain and stimulates the release of acetylcholine in the cerebral cortex. It also causes the release of catecholamines from the adrenal medulla and from sympathetic nerve endings and of acetylcholine in the myenteric plexus of the gastrointestinal tract.

Nicotine, like heroin and cocaine, and far more often than ethanol, causes dependence. Criteria for dependence are the compulsive use of a substance, even when the harmful effects are known; the presence of psychoactive effects; the potential for reinforcement of behavior leading to use of the substance; the presence of physical signs of dependence manifested through withdrawal symptoms; and the development of tolerance indicated through the increasing use of the substance to achieve a desired end point. Nicotine meets all these criteria. It is psychoactive because it has effects on mental function and mood. At blood levels most commonly found in smokers, it acts as a euphoriant, an anxiolytic, and a stimulant. More important, nicotine acts as a positive reinforcer, making one dose of nicotine, or one puff, or one cigarette, lead to the next. Abstinence from nicotine leads to a constellation of withdrawal symptoms that together constitute a craving for nicotine. Nicotine, like other psychoactive drugs, produces tolerance. The typical new smoker, therefore, gradually increases cigarette consumption over several years before reaching a plateau.

It was long thought that smokers regulated their smoking to maintain a set level of nicotine in the blood and brain. The basic impetus for maintaining that level was believed to be the avoidance of symptoms of nicotine withdrawal. It is now thought, however, that nicotine use is also governed by a far more complex process of learning and conditioning. A smoker, in other words, learns to smoke in response to specific stimuli, initially because of a perceived benefit and then merely as a conditioned response. These stimuli may be general, such as stress or boredom, or specific, such as the ringing of a telephone, sexual arousal, or completion of a meal. The resulting stereotypical pattern of tobacco use is another important marker of dependence. Treatment of nicotine addiction must be directed to both physical dependence and conditioning.

STAGES IN TOBACCO USE AND SMOKING CESSATION

Tobacco use is often thought of as a career that typically spans decades and runs a circuitous route from experimentation to quitting. No single factor governs the career of tobacco use: it is determined by the complex interaction of the psychopharmacologic properties of nicotine, the psychological makeup of the smoker, and, perhaps most important, the surrounding cultural, social, and economic setting. Several stages have been described in the smoking career: experimentation, initiation, and regular or habitual use. Smoking typically begins during childhood or adolescence. Regular or habitual smoking usually starts during the transition from adolescence to adulthood. Of those who experiment, one-third to one-half go on to smoke habitually. Contrary to the popular belief that early experimentation is merely a rite of passage, it is more likely to lead to habitual smoking than later experimentation. Habitual smoking is more common among persons who are impulsive, extroverted, and subject to depression. Smoking is also more common among those who have a low level of academic achievement and among those whose parents and peers smoke. A higher degree of concordance for smoking status among monozygotic than among heterozygotic twins suggests that there also may be genetic factors involved in establishing the smoking habit.

Tobacco marketing may also be a major influence on smoking initiation and habitual use. The tobacco industry spends an estimated \$3.25 billion yearly on advertising and marketing, generally targeted to specific groups. The Joe Camel character, for example, is readily recognized by children. Marlboro cigarettes are the choice of adolescent boys and girls. Virginia Slims, on the other hand, are targeted to young women, many of whom smoke as a means of avoiding weight gain. Much advertising also appears to be directed at those who have quit smoking by emphasizing previous triggers of smoking. Smoking behavior is further complicated by social factors that enhance or deter smoking.

Recent rises in the excise tax on tobacco have shown that the cost of tobacco may be an important deterrent in the use of tobacco, particularly by children and teenagers. Like the development of the smoking habit, it is useful to think of smoking cessation not just as a single event but as a cyclic process with five stages: precontemplation, contemplation, action, maintenance, and relapse. In precontemplation, the smoker is not yet thinking of quitting; he or she may be unwilling, unaware, or discouraged from considering smoking cessation and may be defensive about smoking. Contemplation occurs as the smoker actively considers smoking cessation. At this stage, he or she seeks information and is typically concerned about smoking. Action occurs when the smoker takes steps to stop smoking. The smoker typically develops various strategies to prevent or overcome the temptation to smoke. Maintenance involves ongoing efforts to refrain from smoking after the smoker has achieved abstinence for about 6 months. Relapse, unfortunately the norm in smoking cessation, occurs when the smoker fails to maintain abstinence after quitting. Because smokers typically make many attempts at cessation before succeeding permanently, they may find themselves in various parts of the cycle several times during their smoking careers. Identifying the stages is useful because each requires a different intervention by the health care provider.

EVALUATING THE SMOKER

Because of the devastating impact of smoking on health, determining the smoking status should be as routine a part of every contact with a patient as measuring the vital signs. A more detailed evaluation geared to prescribing a specific smoking-cessation method should include measurement of the duration and severity of the smoking habit, identification of any symptoms or illnesses exhibited by the smoker that may be attributable to smoking, assessment of the smoker's readiness to quit, a history of previous attempts to quit, and identification of personality variables and other internal or external factors that can facilitate or hinder quitting and not relapsing.

DURATION AND SEVERITY OF SMOKING HABIT

The longer and the more packs of cigarettes per day a smoker has smoked, the greater the impact on health, the need for smoking cessation, the likely resistance to quitting and not relapsing, and the necessity for intensive support during cessation. The Fagerstrom Tolerance Questionnaire (Fig. 33.1) is a simple, useful measure of the severity of physical dependence to nicotine. An urgent need to smoke within 30 minutes of waking up appears to be the most important indicator of severe physical dependence.

1. How many cigarettes a day do you smoke? 0-10 11-20 21-30

2. What brand do you smoke? 0 = Low nicotine 1 = Moderate nicotine 2 = High nicotine

3. Do you inhale? 0 = Never 1 = Sometimes 2 = Always

4. Do you smoke more during the morning than during the rest of the day? 0 = No 1 = Yes

5. Have you ever after you wake up do you smoke your first cigarette? 0 = Within 30 minutes 1 = After 30 minutes

6. Which cigarette would you hate to give up? 0 = The first cigarette in the morning

7. Do you find it difficult to refrain from smoking in places where it is forbidden, eg. church, work, theater, library? 0 = No 1 = Yes

8. Do you smoke if you are so ill that you are in bed most of the day? 0 = No 1 = Yes

Score: 0 = Minimal physical dependence
11 = Maximal physical dependence

FIGURE 33.1. Questionnaire for identifying the addicted smoker. (Modified from Fagerstrom K-O. Measuring degree of physical dependence to tobacco with reference to individualization of treatment. *Addict Behav* 1978;3:235, with permission.)

SYMPTOMS AND ILLNESSES ATTRIBUTABLE TO SMOKING

Evidence of heart disease, in particular, and of other diseases attributable to smoking to a lesser extent are among the most potent motivators for smoking cessation.

READINESS TO QUIT

All smokers should be advised to stop smoking, and all smokers should be told clearly of any adverse effects that smoking has had on their health. Otherwise, it is best to tailor advice to the specific stage the smoker is in. Those in the precontemplation stage, for example, should be given information about the effects of smoking on health, which may motivate them to move to the next stage. They should be asked to read these materials carefully and should be questioned about them at a follow-up visit. Smokers in the contemplation stage should be given information about specific cessation methods and should be encouraged to set a "quit date." Smokers in the action stage should be given maximal support in the form of behavioral techniques and pharmacologic agents to help them withstand the urge to smoke.

Personality Variables and Internal Factors

Rebelliousness, impulsiveness, and "identity assertion" in adolescence and adulthood have traditionally been viewed as major determinants of smoking. They are now seen as modifiers of other forces that favor change. Self-confidence and a sense that one's actions can be effective, or the attribution of success to oneself rather than to others, are important predictors of success in smoking cessation that should be nurtured. A negative attitude or depression may be an obstacle to permanent abstinence from smoking, particularly if the euphoriant properties of nicotine have been used to combat depression.

Fear of weight gain is an important obstacle to smoking cessation and continued abstinence for many smokers. Appetite and hunger are common withdrawal symptoms after smoking cessation. Six months after cessation, men will typically have gained 9 pounds and women 10 pounds; greater weight gains are occasionally encountered. It is important to anticipate changes in weight and to develop appropriate strategies to prevent relapse of smoking. It should be stressed to the patient that the health benefits of smoking cessation far outweigh the risks associated with the usual weight gain.

External Factors

The presence of a nonsmoking environment, beginning in the physician's office and also at home and work and during leisure activities, is an important contributor to success in smoking cessation. Conversely, continued smoking by family and peers can be major obstacles that require specific, predetermined coping strategies.

SMOKING-CESSATION METHODS

Most smokers who have quit have done so without any obvious outside intervention. As the number of smokers in the population declines, however, an increasing number will be highly addicted to nicotine; these are the ones most in need of more intensive support and more specific cessation methods. Smoking-cessation methods can be classified on the basis of the intensity of the intervention and whether pharmacologic agents are used. Every smoker should be individually evaluated to determine the most appropriate smoking-cessation method. The patient's preference and his or her experience of previous attempts at quitting play a key role in choosing a specific cessation method.

MINIMAL INTERVENTION

Helping patients to quit smoking on their own may be the most cost-effective cessation strategy. Only 10% to 15% are likely to remain abstinent from cigarettes at 1 year, but 60% will succeed after repeated attempts. Minimal intervention typically includes providing self-help materials, such as the American Lung Association's Freedom from Smoking self-help manuals; setting a specific quit date; and offering brief counseling and follow-up to identify and deal with any obvious obstacles to smoking cessation.

BEHAVIOR MODIFICATION

More intensive smoking-cessation programs are indicated for smokers who want added support, those who have previously tried to quit and have been unsuccessful, those whose dependence on nicotine and smoking seem more intense, and those who lack sufficient self-confidence and external support. Intensive smoking-cessation programs may take the form of clinics organized by such voluntary health agencies as the American Lung Association, local hospitals, or employers; for-profit smoking-cessation programs; or individual therapy with physicians or other health-care professionals. In addition to providing health information that can motivate the smoker to quit, virtually all rely on behavior-modification techniques, such as the following.

1. Temptation management: careful identification of the time, place, and reason for smoking each cigarette and the development of avoidance and mitigation strategies to reduce the temptation to smoke
2. Cue extinction: deconditioning by purposefully avoiding smoking during exposure to cues that would normally lead to smoking
3. Contingency management: designation of concrete rewards to be earned for achieving specified goals or reaching specified landmarks during the action stage of smoking cessation

Aversive techniques, used in some research and commercial smoking-cessation programs, typically consist of rapid smoking of a series of cigarettes with frequent inhaling and with holding of smoke in the mouth to produce dizziness and nausea. Aversive techniques are effective but are infrequently used because of a fear, probably unfounded, of adverse health effects. In the past, electric shock has been used as an aversive stimulus, but it is applied rarely today. Hypnosis has been the subject of controversy and may or may not be effective. There is also little scientific evidence to support acupuncture as an adjunct to smoking cessation.

PHARMACOLOGIC AGENTS

Pharmacologic agents have been used in the treatment of various forms of substance abuse because they can provide relief of withdrawal symptoms, serve as blockers or replacements, and produce aversion to the ingestion of a substance. Pharmacologic agents increase the likelihood of success in smoking cessation when used in combination with an organized behavior-modification program and should readily be offered to all but very light smokers.

Nicotine substitution in the form of nicotine polacrilex (gum), transdermal nicotine (patch), nicotine inhalers, or nicotine sprays is effective as an adjunct to a behavior-modification program, particularly for smokers who show a high degree of physical dependence to nicotine (as measured, for example, by the Fagerstrom Tolerance Questionnaire). Nicotine gum requires careful instruction in proper use, such as the need to avoid acidic beverages that can prevent absorption of nicotine and a proper way of chewing. Transdermal nicotine has the advantage of once-daily dosing, greater social acceptability than chewing gum, and the availability of various doses that can be tailored to each patient. The nicotine inhaler is said to have the advantage of reproducing the hand-to-mouth ritual of smoking. All forms of nicotine replacement have the potential of causing further nicotine dependence, but the benefits of smoking cessation far outweigh that risk.

Bupropion is an antidepressant that has been shown to decrease the desire for cigarettes. It is an effective alternative to nicotine substitution therapy. Clonidine is effective for the short-term relief of symptoms of nicotine withdrawal. Lobeline is a chemical analogue of nicotine, but its effectiveness as a form of replacement therapy remains unproved. Mecamylamine is a noncompetitive nicotine antagonist that has been tried as an agent to prevent the reinforcing effects of nicotine. Side effects at the high doses that have been used, however, have proved prohibitive. Silver nitrate mixes with a smoker's saliva to produce an unpleasant taste, but it has not been proved effective as a form of aversion therapy in supporting abstinence.

CONCLUSIONS

Smoking has a devastating impact on health. Smoking cessation is difficult because of the addictive nature of nicotine and the continued social acceptance of smoking. The use of behavior-modification techniques and pharmacologic agents greatly increases the likelihood of success in quitting. If every physician and other health care practitioner were familiar with these tools and used them, the number of smokers who quit every year could double.

CHAPTER 34: APPROACH TO THE PROBLEM OF ALCOHOL ABUSE AND DEPENDENCE

CHARLES P. O'BRIEN

[Definition](#)
[Incidence and Epidemiology](#)
[Etiology](#)
[Pathogenesis](#)
[Clinical Findings](#)
[Optimal Treatment](#)

DEFINITION

The use of ethyl alcohol as a beverage began before recorded history, and most persons in Western societies at least experiment with this substance at some time in their lives. Alcohol is a sedative drug, and a high proportion of users find its effects to be quite pleasant. The attractiveness of this beverage leads to excessive use and severe medical problems in about 14% of consumers. Alcohol abuse and alcohol dependence (i.e., alcoholism) are behavioral syndromes that exist along a continuum from minimal use to abuse to addictive use. Alcoholism is a pattern of alcohol use that continues despite significant problems produced by alcohol. There is no specific quantity that is diagnostic of alcoholism, and some alcoholics use ethanol episodically rather than daily. There is no source of alcohol that is more or less toxic than others. One beer (12 ounces) equals approximately one glass of wine (5 ounces), which equals 1.5 ounces of 80-proof liquor ([Table 34.1](#)).

Regularly consuming more than originally intended
Desire to reduce or regulate use and failure at these attempts
Spending a great deal of time obtaining, consuming, or recovering from the effects of the drug
Important social, occupational, or recreational activities given up or curtailed because of use of the drug
Continuing use despite evidence that the drug is contributing to psychological or physical problems
Tolerance, the need for greatly increased amounts of the drug to achieve the desired effect
Physical dependence, as manifested by a withdrawal syndrome or by the use of more of the drug to prevent the development of withdrawal symptoms

TABLE 34.1. SIGNS OF DEPENDENCE ON ALCOHOL OR ANOTHER DRUG

As with other sedating drugs, drinkers acquire tolerance to the effects of alcohol. This reduced sensitivity to alcohol is the consequence of an adaptive process that occurs when homeostatic mechanisms are repeatedly perturbed by the stress of alcohol. If alcohol use is discontinued, a rebound occurs as the homeostatic mechanisms adapt to the absence of alcohol. This rebound is seen with many drugs and results in symptoms that are opposite in direction to the effects of the drug itself. This rebound is called a withdrawal syndrome. The state of adaptation to the repeated effects of a drug is called physical dependence, and its presence is determined by the appearance of withdrawal symptoms when the drug is abruptly stopped.

Evidence of increased tolerance and symptoms of withdrawal are frequently found in alcoholics, but neither tolerance nor withdrawal is necessary or sufficient for a diagnosis of alcoholism. Early diagnosis is important, because early treatment is more effective. Unfortunately, at an early stage, alcoholics convincingly deny their excessive drinking, and the physician must obtain a history from family members and look for physical and laboratory evidence to support a clinical suspicion of alcoholism.

An active alcoholic may appear to be a normal and productive person. Too often, physicians fail to recognize alcoholism in prosperous, employed individuals because of the stereotype of the homeless alcoholic who has been unemployed for years. A skilled diagnostician can recognize the signs of early alcoholism and make a referral to a treatment expert. Untreated alcoholism is a progressive disorder, with a downhill course that varies in rate.

INCIDENCE AND EPIDEMIOLOGY

Approximately 70% of American adults consume alcohol occasionally. A US probability sample of noninstitutionalized adults (15 to 54 years of age) conducted from 1990 to 1991 found that about 14% had experienced alcohol dependence at some time in their lives, and approximately 7% met criteria for alcoholism in the past year. This disorder is seen in all socioeconomic groups, including persons who are still gainfully employed.

ETIOLOGY

The development of alcohol abuse and dependence is influenced by a combination of hereditary and environmental factors. Children of alcoholics show an increased likelihood of becoming alcoholics, even when they are adopted at birth and raised by nonalcoholic parents. The studies of genetic influences in this disorder show only an increased risk of alcoholism, not 100% determinism, and this is consistent with the features of a polygenic disorder that has multiple determinants. Even identical twins, who share the same genetic endowment, do not have 100% concordance when one twin is alcoholic. The concordance rate for identical twins, however, is much higher than that of fraternal twins, who share the same environment but have a different genotype.

One of the inherited factors that seems to influence the development of alcoholism is tolerance to alcohol. Although tolerance can be acquired by repeated experience with alcohol, persons vary in the innate tolerance manifested when they first consume alcohol. The sons of alcoholics have reduced sensitivity (i.e., more tolerance) to alcohol than other young men of the same age (22 years) and drinking histories. When reexamined 10 years later, those who tolerated alcohol as young men were the most likely to have become alcoholics during the time since they were first tested. These data suggest that tolerance is partly inherited and that inherited tolerance can increase the probability of developing alcoholism. Having an innate tolerance to alcohol does not make a person an alcoholic, but it seems to enhance significantly the probability that alcoholism will develop.

The opposite influence, a kind of "antialcoholism," also can be inherited. Ethanol is metabolized by alcohol dehydrogenase, producing acetaldehyde, which is itself metabolized by a mitochondrial aldehyde dehydrogenase known as ALDH2. A common mutation occurs in the gene for ALDH2, resulting in a less effective aldehyde dehydrogenase. This allele has a high prevalence in Asian populations and results in excess production of acetaldehyde after the ingestion of alcohol. A person with this allele experiences a very unpleasant facial flushing reaction 5 to 10 minutes after ingesting alcohol. The probability of becoming alcohol dependent is reduced for persons with this heredity pattern, but the risk is not eliminated. Those who are strongly motivated to consume alcoholic beverages can endure the flushing to achieve the other effects of alcohol. There are likely multiple genetic factors that can influence the probability of becoming an alcoholic, but no single factor is determinant. Those who inherit a tolerance to alcohol may avoid alcohol and never become alcoholic. Conversely, those who inherit the gene for a less effective aldehyde dehydrogenase may drink excessively despite the flushing reaction.

PATHOGENESIS

Ethanol is classed as a depressant because it produces sedation and sleep. Nonetheless, the initial effects of alcohol, particularly at lower doses, are often perceived as stimulation and are thought to result from suppression of brain inhibitory systems. The course of alcohol intoxication varies. Early in the drinking period, when blood alcohol levels are rising, reports of expansive mood, increased verbalization, and more assertiveness are common, but the sedative symptoms are dominant for some individuals even at an early stage. Some impairment of psychomotor function is measurable at levels as low as 35 to 50 mg per deciliter, well below the level considered to be legal intoxication in this country. This impairment is not perceptible to the average drinker. With increasing dose, the individual is likely to become

progressively more depressed, withdrawn, and cognitively impaired. At very high blood alcohol levels (200 to 300 mg per deciliter), a nontolerant individual is likely to fall asleep and enter the first stage of anesthesia. Higher blood alcohol levels (in excess of 300 to 400 mg per deciliter) can inhibit respiration and pulse and can cause death in nontolerant individuals.

The duration of intoxication depends on how much alcohol was consumed over a given period. In general, the body is able to metabolize approximately one drink per hour, and the blood alcohol level generally declines at a rate of 15 to 20 mg per deciliter per hour. Experience with alcohol can produce greater tolerance (i.e., acquired tolerance) such that extremely high blood levels (300 to 400 mg per deciliter) can be found in alcoholics who do not appear to be grossly sedated. In these cases, the lethal dose does not increase proportionate to the sedating dose, and the margin of safety (i.e., therapeutic index) is dangerously low.

Heavy consumers of alcohol acquire tolerance, and they inevitably develop a state of physical dependence on alcohol. This often leads to drinking in the morning to restore alcohol blood levels diminished during the night. Eventually, alcoholics may awaken during the night and take a drink to avoid the restlessness produced by falling alcohol levels. The withdrawal syndrome generally depends on the size of the average daily dose, and it is usually “treated” by resumption of alcohol ingestion. Withdrawal symptoms are experienced frequently, but they are usually not severe or life-threatening until they occur in conjunction with other medical problems.

Depending on its concentration in tissues, alcohol has effects on brain physiology, varying from specific receptor actions to nonspecific membrane changes. Ethanol enhances the actions of the inhibitory neurotransmitter γ -aminobutyric acid (GABA) at a subpopulation of GABA receptors. One of the effects of ethanol is increased activity of the dopaminergic pathway from the ventral tegmental area (VTA) to the nucleus accumbens (NAc). This activation can be mediated by the effect on GABA receptors through suppression of inhibitory interneurons, but VTA activation results in an increase in extracellular dopamine in the NAc region. This effect can be learned; rats trained to self-administer alcohol begin to show an increase in NAc dopamine levels as soon as they are placed in the chamber where they have previously obtained alcohol. Other drugs of abuse, such as cocaine and heroin, also raise levels of the neurotransmitter dopamine in this brain area.

There is evidence from animal studies that the endogenous opioid system plays a part in alcohol reinforcement, because alcohol self-administration in animals is diminished by opiate receptor antagonists. In human volunteers, alcohol ingestion in the laboratory produced significant increases in peripheral β -endorphin levels in those with a family history of alcoholism, but the levels were not raised in those without such a family history. For alcoholics, data show that the opiate receptor antagonist naltrexone reduces or blocks the ability of alcohol to produce euphoria. Double-blind, placebo-controlled studies have shown that the relapse rate is lower when alcoholics are given naltrexone (50 mg daily) during the rehabilitation process.

CLINICAL FINDINGS

Taking an adequate history from a suspected alcoholic requires diligence and experience. Alcohol abusers typically underestimate the quantity of alcohol they have ingested, but they more often respond truthfully to indirect questions about the effects of their drinking. The CAGE questionnaire ([Table 34.2](#)) has been found to be a useful addition to the standard medical history.

Have you felt that you should Cut down on your drinking?
Have you felt Annoyed by people criticizing your drinking?
Have you ever felt Guilty about your drinking?
Do you require an “Eye-opener” in the morning to steady yourself or get rid of a hangover?

^a A score of two or more positive answers to this screening test correlates highly with alcohol abuse or dependence.

EVIDENCE LEVEL: B. Reference: Bisson J, Nadeau L, Demers A. The validity of the CAGE scale to screen for heavy drinking and drinking problems in a general population survey. *Addiction* 1999;94:715–722.

TABLE 34.2. CAGE QUESTIONNAIRE^a

Alcohol impairs recent memory and, in high doses, produces the phenomenon of blackouts, after which the drinker has no memory of his or her behavior while intoxicated. The mechanism of the acute memory effects is unclear, but the evidence suggests that reports from patients about their reasons for drinking and their behavior during a binge are not reliable. Alcohol-dependent persons often say that they drink to relieve anxiety or depression. When allowed to drink under observation, however, alcoholics typically become more dysphoric as drinking continues, contradicting the explanation that they drink to relieve tension. The long-term use of alcohol and other sedatives is associated with the development of depression, and the risk of suicide among alcoholics is one of the highest of any diagnostic category.

Cognitive deficits have been reported in alcoholics tested while sober. These usually improve after weeks to months of abstinence. More severe recent memory impairment is associated with specific brain damage caused by nutritional deficiencies common in alcoholics (see later discussion of Wernicke–Korsakoff syndrome). Contrary to the notions of many physicians, alcohol is not a good treatment for insomnia. Physicians should not recommend a bedtime alcoholic drink as a treatment for complaints of insomnia, because drinking alcohol in the late evening actually impairs sleep. Alcohol ingestion can result in stimulation or sedation, depending on the dose and the experience and metabolism of the individual. When sleep is induced, it tends to be a deep, drugged sleep with disruption of sleep stages and suppression of rapid eye movement sleep. Later in the night, a rebound produces lighter sleep and potential awakenings.

MULTIORGAN SYSTEM EFFECTS OF ALCOHOL

Alcohol is toxic to many organ systems, including the liver, pancreas, hematopoietic system, nervous system, heart, gastrointestinal tract, endocrine glands, and bone. Alcohol may produce mild, otherwise unexplained abnormalities that are noticed on routine laboratory testing. Common findings include signs of hepatotoxicity and hematologic abnormalities ([Table 34.3](#)). Although none of these findings is diagnostic of alcoholism, they should alert the clinician to take a more careful history of alcohol intake and look for other signs that would support this diagnosis.

Increased mean corpuscular volume
Increased γ -glutamyltransferase
Increased aspartate aminotransferase
Increased alkaline phosphatase
Increased triglycerides
Increased low-density lipoprotein cholesterol
Increased aspartate amino acid transferase
Increased blood pressure

TABLE 34.3. LABORATORY FINDINGS INDICATING ALCOHOL USE

Alcohol is an important cause of treatable hypertension. Physicians should always take a careful history of alcohol intake when evaluating a hypertensive patient. Drinking does not have to be heavy enough to qualify as alcohol abuse or dependence in order to increase blood pressure. Often simply reducing or stopping alcohol

will bring the blood pressure of a person with mild hypertension into the normal range, obviating the need for antihypertensive medication.

The gastrointestinal effects of alcohol, including hepatic toxicity, are covered in [Chapter 121](#). Alcoholism also has been associated with an increased rate of cancer of the esophagus, stomach, and other parts of the gastrointestinal tract. Many of the symptoms and physical findings associated with alcoholism are a consequence of the multiorgan toxicity of this drug. Examples are the dyspepsia, nausea, and bloating that accompany gastritis and the hepatomegaly, esophageal varices, and hemorrhoids associated with alcohol-induced changes in the liver. Other physical signs include tremor, unsteady gait, insomnia, and erectile dysfunction. Individuals with chronic alcoholism may exhibit decreased testicular size and feminizing effects, such as the gynecomastia associated with reduced testosterone levels caused by the endocrine effects of alcohol.

Severe, repeated alcohol intoxication may also suppress immune mechanisms and increase the risk of infections. Meningitis, especially tuberculous meningitis, is greatly overrepresented among alcoholics. Alcohol also impairs judgment and increases the likelihood of unprotected sex. Sexually transmitted infections, such as human immunodeficiency virus infection, syphilis, and gonorrhea, are linked to alcohol use. Spontaneous abortion and fetal alcohol syndrome have been associated with heavy drinking during pregnancy. Alcohol drinking during pregnancy is one of the most common preventable causes of mental retardation. Although the data show a correlation between heavy drinking and fetal alcohol syndrome, it is not clear whether small amounts of alcohol produce any increased risk. Because data from animal models and clinical studies are ambiguous on this point, many physicians advocate complete abstinence from alcohol during pregnancy.

NEUROLOGIC AND OTHER COMPLICATIONS OF ALCOHOL

Alcohol Overdose

Coma due to an overdose of alcohol is a medical emergency. It can occur in someone who rapidly drinks large quantities of alcohol, resulting in a high blood alcohol level. In most overdoses, alcohol is combined with another drug, such as a benzodiazepine. Benzodiazepines are widely prescribed for anxiety, insomnia, and muscle relaxation. Although this class of medication is not dangerous when taken alone, when combined with alcohol, accidental overdoses are common. Blood levels of alcohol and commonly used medications should be obtained when evaluating a comatose patient in the emergency room. For recent ingestion, gastric aspiration can prevent further absorption of toxic agents. Treatment consists mainly of support of vital functions. If opiates are involved, the opiate receptor antagonist naloxone can block opiate effects, but it has no effect on overdose from alcohol or other drugs.

Violence

The potential for violence and antisocial behavior is increased by alcohol. Intoxicated individuals tend to get into fights and commit crimes. Family violence, including spouse abuse and child abuse, is strongly linked to alcohol use.

Trauma

Alcohol is associated with about 50% of all traffic fatalities in the United States each year. Alcohol intoxication may result in falls and accidents that can cause fractures, subdural hematomas, and other forms of brain trauma. Individuals with histories of epilepsy or severe head trauma are more likely to experience alcohol-related seizures.

Alcoholic Blackouts

Alcohol intoxication seriously impairs the storage of memories, and it is not surprising that alcohol abusers and alcoholics frequently have periods of amnesia concerning events that occurred during bouts of heavy drinking. This amnesia facilitates the denial of drinking problems expressed by most alcoholics when confronted by a physician or family member. Even when the patient exhibited outrageous behavior that ordinarily would have been embarrassing, there is no memory of the events, and denial by the patient is facilitated.

Severe Alcoholism and Nutritional Deficiencies

The neurotoxic role of alcohol itself in directly producing chronic neurologic dysfunction is unclear. The neurologic syndromes of alcoholism are seen in a context of chronic nutritional deficiency in heavy drinkers who consume empty calories in the form of ethyl alcohol.

Wernicke–Korsakoff Syndrome

The Wernicke–Korsakoff syndrome is produced by severe nutritional deficiency, especially a lack of thiamine. It consists of a persistent inability to encode new memories and specific neurologic signs, including nystagmus, ophthalmoplegia, and ataxia. Wernicke–Korsakoff syndrome usually develops over days and weeks and then suddenly becomes dramatically apparent during a period of stress caused by infection or trauma. The lack of memory often produces confabulation, as patients try to “fill in the gaps.” This disorder was called Korsakoff’s psychosis, but it was discovered later that confabulation was a behavioral response to the underlying neurologic deficit, known as Wernicke’s syndrome. Hemorrhagic lesions of the mamillary bodies, a part of the brain known to be involved in the encoding of recent memories, have been described in cases examined at autopsy. High doses of thiamine partially reverse these deficits, and thiamine should always be given during the acute treatment of alcoholism. Although the Wernicke–Korsakoff syndrome is most often seen in alcoholics, it can be produced by severe nutritional deficiency in the absence of alcohol, as in cases of gastric carcinoma.

Peripheral Neuropathy

Alcoholics have many problems that can lead to peripheral nerve damage, and this is confirmed by reports of a 45% incidence in some alcoholic populations. Pressure palsies, especially affecting the radial or peroneal nerves and sometimes even the brachial plexus (called park bench neuropathy), arise when alcohol produces a deep sleep without the normal position shifts that protect peripheral nerves. Malnutrition probably accounts for most of the neuropathies seen in alcoholics, including those affecting sensorimotor and autonomic nerves. Rare neurologic complications of alcoholism that stem from extreme malnutrition have been described. These include Marchiafava–Bignami syndrome, a primary degeneration of the corpus callosum, and central pontine myelinolysis, which is associated with chronic hyponatremia.

OPTIMAL TREATMENT

DETOXIFICATION

A patient who is seen in a medical setting with an alcohol withdrawal syndrome should be considered to have a potentially lethal condition. Although most mild cases of alcohol withdrawal never come to medical attention, severe cases require general evaluation; attention to hydration and electrolytes; vitamin supplementation, especially high-dose thiamine (100 mg, given intramuscularly daily for 7 days); and a sedating medication that has cross-tolerance with alcohol. Because of the likelihood of liver impairment, a short-acting benzodiazepine, such as oxazepam, can be given at doses sufficient to block or diminish the alcohol withdrawal symptoms described in [Table 34.4](#). A typical alcoholic requires 15 to 30 mg every 6 hours for 48 hours, decreasing the dose by 10% to 20% per day over the next several days. After medical evaluation, uncomplicated alcohol withdrawal can be effectively treated on an outpatient basis. Hospitalization is required for all unstable patients or when there is a history of seizures. The likelihood of alcohol withdrawal seizures is increased by repeated attempts at withdrawal. Adequate treatment of withdrawal symptoms is important for preventing the development of seizures in the current episode of withdrawal and reducing the potential for seizures in the future.

Alcohol craving
Tremor, irritability
Nausea
Sleep disturbance
Tachycardia, hypertension
Sweating
Perceptual distortion
Seizures (12–48 h after last drink)
Delirium tremens (rare in uncomplicated withdrawal)
Severe agitation
Confusion
Visual hallucinations
Fever, tachycardia, profuse sweating, dilated pupils
Nausea, diarrhea

TABLE 34.4. ALCOHOL WITHDRAWAL SYNDROME

RELAPSE PREVENTION

Detoxification is only the first step of treatment. Complete abstinence is the objective of long-term treatment, and this is accomplished mainly by behavioral approaches. Self-help groups, such as Alcoholics Anonymous (AA), are a mainstay of the rehabilitation of alcoholics. Physicians should learn about the AA groups in their community and make appropriate referrals. AA is a movement rather than an institution, and each group is different, though they all follow a similar set of principles, called the twelve steps. AA can be an important ally of the physician in the care of alcoholics.

Medications that aid in the rehabilitation process are being sought. Disulfiram blocks the metabolism of alcohol, resulting in the accumulation of acetaldehyde, which produces an unpleasant flushing reaction when alcohol is ingested. This drug has been useful in some programs that focus on behavioral efforts to ensure that the patient ingests the medication. Knowledge of this unpleasant reaction helps the patient resist taking a drink. Although it is pharmacologically quite effective, disulfiram has not been found to be practical in controlled clinical trials, because so many patients have failed to ingest the medication regularly.

Naltrexone is another medication used as an adjunct in the treatment of alcoholism. This opiate antagonist appears to block some of the reinforcing properties of alcohol and has resulted in a decreased rate of relapse to alcohol drinking in double-blind clinical trials. Naltrexone was approved by the Food and Drug Administration for the treatment of opiate dependence in 1983, and in 1995 it received approval for the treatment of alcoholism. Naltrexone has not been shown to be effective when given alone, but in the context of a comprehensive treatment program for alcoholism, it increases the probability of a successful outcome.

LONG-TERM TREATMENT OF ALCOHOLISM

Alcoholism is a chronic, recurring disorder that requires long-term care. Physicians tend to see treatment of addictive disorders as unsuccessful because of their chronic nature. In reality, the course of alcoholism and other addictions is similar to that of hypertension, diabetes, asthma, and other chronic medical conditions. The patient initially responds to fairly intensive intervention, but some type of maintenance treatment is necessary to deal with recurrences and prevent their becoming severe. In this context, the prognosis for alcoholics in treatment is good because their function improves, but complete “cures” are unlikely.

CHAPTER 35: APPROACH TO THE PROBLEM OF SUBSTANCE ABUSE

CHARLES P. O'BRIEN

[Opioids](#)
[Prescription Sedatives](#)
[Cannabis: Marijuana and Hashish](#)
[Hallucinogenic Drugs](#)

The most important addicting drugs from the perspective of morbidity and mortality are clearly nicotine (see [Chapter 33](#)) and alcohol (see [Chapter 34](#)). This chapter addresses other substances that are frequently abused. The definitions of abuse and dependence are consistent across drug categories, and the reader is referred to [Chapter 34](#) on alcoholism for a discussion of terms. It is particularly important that all physicians have a clear understanding of the difference between physical dependence and addiction. Many of the medications that we prescribe produce changes in the body's homeostatic mechanisms; this alteration, in turn, produces an adaptive response to the changes. If the patient abruptly stops taking the drug, the adaptation is unopposed, and there is a rebound, called a withdrawal syndrome. This means that the patient was physically dependent on the drug, but it does not imply that the patient is or was an addict. The diagnosis of addiction (i.e., "substance dependence," as defined in the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders*, published by the American Psychiatric Association) is mainly a behavioral diagnosis. It is applied when persons engage in drug-seeking behavior that interferes with normal activities and when compulsive drug use continues despite serious social or medical consequences.

Abuse of drugs other than alcohol or nicotine occurs in all socioeconomic groups; general population studies find a lifetime prevalence around 6%. Thus, physicians are likely to encounter such patients in their practice. In some cases involving prescription sedatives and stimulants, the abuse is inadvertent and may be the result of the prescribing physician's ignorance of certain drug effects. In evaluating a patient with substance abuse, a physician should integrate information from all available sources, including the patient's history and information from relatives and the employer, if possible. The physical examination may provide some clues ([Table 35.1](#)). Laboratory testing of blood or urine can be useful, but the results require interpretation. The tests, when properly done and confirmed, indicate use within a specific period of time, depending on the drug and its dose ([Table 35.2](#)). Such tests give no information about abuse or dependence and must be interpreted in the light of all clinical information.

Scarred veins: "needle tracks"
Abscesses or scars from healed abscesses
Nasal septal lesions
Edematous hands or feet
Frequent injuries from falls
Hepatitis
Endocarditis
Respiratory infections

TABLE 35.1. CLINICAL HINTS REGARDING SUBSTANCE ABUSE

Drug	Specimen	Metabolite	Duration
Heroin	Urine	Morphine	12-24 hr
Methadone	Urine	Methadone	1-2 d
Cocaine	Urine	Benzoyllecgonine	3-15 d (10 d after heavy use)
Amphetamine	Urine	Amphetamine	1-2 d
Cannabinoids	Urine	Cannabinoids	2-8 d (14-50 d for long-term use)
Phencyclidine	Urine	Phencyclidine	2-8 d

TABLE 35.2. DRUG SCREENING TESTS

OPIOIDS

CLINICAL FEATURES

Derivatives of the opium poppy have been used for the treatment of pain, diarrhea, anxiety, and other indications dating back to the third century B.C. Heroin, morphine, and codeine are produced from opium. Synthetic drugs and endogenous peptides that also act at opiate receptors are called opioids. Heroin, the most abused drug in the opiate category, is widely available on the illicit market. During the 1990s, the purity of heroin purchased on the street reached an all-time high, and the price per gram was greatly reduced. In the past it was necessary to take heroin via intravenous injections because its potency was so low. In contrast, heroin in a relatively pure state can be smoked, and enough drug survives the heat to be absorbed through the lungs and produce significant pharmacologic effects. It is estimated that there are between 750,000 and one million heroin addicts in the United States.

Heroin produces a calming effect, contentment, and, if the dose is high enough, intense euphoria. The effects wear off in 3 to 5 hours, and heroin addicts may administer the drug two to four times per day. Because of heroin's rapid metabolism, addicts are constantly going in and out of the withdrawal phase, and this creates perturbations of endocrine systems modulated by opiate receptors. Male heroin addicts report many sexual performance problems, and women have irregular menses. Mood varies according to the dose of heroin. Addicts are anxious and irritable during withdrawal and content during periods of adequate heroin effects. Heroin addiction often coexists with a variety of psychiatric disorders, especially depression.

The daily injections of heroin are usually carried out without sterile technique and often with needles previously used by other addicts. The rates of such infections as hepatitis, endocarditis, and human immunodeficiency virus are very high. Intravenous drug abuse, mainly with heroin, has become a major source of new cases of AIDS (see [Chapter 349](#)). Heroin addicts become very tolerant to the respiratory effects of opioids, but overdose is still possible when a concentrated supply of heroin unexpectedly becomes available or when street heroin is mixed with a very potent opioid, such as fentanyl ([Table 35.3](#)).

Symptoms	Signs
Restlessness, irritability	Sweating, fever
Cramps, diarrhea	Pupillary dilatation
Nausea, vomiting	Piloerection ("gooseflesh")
Anxiety, insomnia	Yawning
Craving for opioids	Increased blood pressure

TABLE 35.3. OPIOID WITHDRAWAL

TREATMENT

Detoxification refers to the transition from the drug-dependent to the drug-free state. A withdrawal syndrome occurs—although it is unpleasant, opioid withdrawal is rarely life-threatening. Symptoms begin 6 to 12 hours after the last dose of a short-acting opioid such as heroin. Withdrawal symptoms can be treated by giving a long-acting opioid, such as methadone, in a single daily dose or twice daily ([Table 35.4](#)). The dose is tailored to the degree of physical dependence. An initial test dose of 20 mg is recommended; if that does not relieve the withdrawal symptoms in 30 minutes, an additional 20 mg can be administered. Higher doses are necessary when the patient has a high degree of physical dependence. After the symptoms are relieved, the dose is gradually reduced over 5 to 10 days. If opioid medication is not available, clonidine, an antihypertensive medication, can be used to block the adrenergic signs of withdrawal. Clonidine is given orally at a dose of 0.1 mg every 6 hours, as needed, depending on the severity of withdrawal signs. Blood pressure must be monitored, because hypotension is a limiting side effect of this treatment. Detoxification on an inpatient basis is usually successful, but it is simply the beginning of treatment. The most difficult aspect of treatment is the prevention of relapse to heroin use.

Drug	Class	Use
Methadone	Agonist	Analgesia, withdrawal, maintenance
L-methadyl (LAAM)	Agonist (ultra-long-acting)	Maintenance
Buprenorphine*	Partial agonist	Maintenance
Naltrexone	Antagonist	Maintenance
Naloxone	Antagonist (short-acting)	Overdose, diagnosis
Clonidine	α_2 -Adrenergic agonist (autoreceptor)	Withdrawal

* Not yet approved for this indication by the Food and Drug Administration.

TABLE 35.4. MEDICATIONS HELPFUL IN THE TREATMENT OF OPIOID ADDICTION

Because addiction is basically a behavioral disorder, all treatments require counseling or psychotherapy to assist the patient with psychosocial problems. Complete abstinence from opioids is the ultimate goal of treatment, but most drug-free former addicts relapse when they return to neighborhoods where drugs are plentiful. Long-term (months to years) treatment in a therapeutic community can help selected patients remain drug-free, but such treatment is not readily available. The best and most practical treatment is maintenance on methadone.

Daily methadone stabilizes heroin addicts socially and physiologically. Methadone blocks withdrawal and craving while leaving the patient alert and able to work. With this treatment, most patients are able to organize their lives rather than think only of the next dose of heroin. With the help of counseling in a rehabilitation program and, when necessary, psychoactive medication to treat depression or other psychiatric disorders, patients are able to return to employment or school. After months or years without using heroin, patients can be detoxified slowly from methadone.

Another medication that can be used for maintenance is L- alpha-acetyl methadol (LAAM), a long-acting opioid with active metabolites. LAAM can provide good stabilization for 72 hours, thereby requiring administration only three times per week. Both methadone and LAAM are full opiate agonists. Buprenorphine, a partial agonist, is in the final stages of approval for both detoxification and maintenance treatment of heroin addiction. Each medication has advantages and disadvantages, and the clinician can choose based on an individual patient's characteristics. A different approach utilizes naltrexone, an opiate receptor antagonist that prevents relapse by blocking opiate receptors. Naltrexone works well with highly motivated opiate addicts, especially physicians and other medical workers. It has no agonist effects, so it does not relieve anxiety and drug craving and it can be stopped with no withdrawal syndrome.

STIMULANTS

COCAINE

Clinical Features

Cocaine is the most important of the abused stimulants. It is widely available at low prices (\$3 to \$5 per dose in the northeastern United States). Cocaine hydrochloride can be administered in a powdered form through the nasal mucosa, called snorting, or taken intravenously. The alkaloid form, called freebase or crack, can be inhaled after heating. The use of cocaine peaked in the 1980s. Although the number of new users declined during the 1990s, at the turn of the century there are still about 1.3 million Americans who use cocaine.

Cocaine is a short-acting drug that produces intense euphoria, but it may leave the user wanting more cocaine after 20 to 30 minutes. Cocaine can be acutely toxic, even in those who suffered no ill effects from previous use. Acute toxicity is characterized by sympathomimetic effects, including hypertension, tachycardia, hyperthermia, and cardiac arrhythmias. Vasculitis in the cerebral vessels has been observed in persons dying after cocaine ingestion. Clinically, one sees seizures, stroke, coma, and cardiorespiratory collapse as complications of a cocaine binge.

Regular users of cocaine often undergo personality changes, becoming more irritable and suspicious. Continued use and higher doses can produce persecutory delusions and hallucinations. Prolonged psychotic episodes can be provoked in susceptible individuals. Alcohol, sedatives, opioids, and marijuana are often taken to combat the anxiety and irritability experienced by cocaine users. The "crash" after a period of heavy cocaine use constitutes a kind of withdrawal syndrome, reflecting changes in brain chemistry and blood flow. Anxiety and irritability give way to tiredness, sleepiness, lack of energy, and depressive symptoms. This syndrome usually resolves spontaneously over several days. If depression persists, antidepressant medication is indicated.

Treatment

Cocaine-induced psychotic reactions are usually self-limited, but in some cases a neuroleptic, such as haloperidol, may be required for emergency management. When necessary, low-dose, short-term haloperidol (5 to 10 mg daily taken intramuscularly or orally) can be administered. The anxiety reactions and irritability produced by cocaine can be treated with a brief course of benzodiazepines, such as diazepam (5 to 20 mg daily).

As is the case with other addictions, cocaine dependence requires long-term rehabilitation. Counseling and behavioral treatments aimed at reducing the likelihood of

return to cocaine use are indicated for at least 1 to 2 years. When a slip occurs, the treatment becomes more intense, and most patients respond. At follow-up, 7 to 12 months after starting treatment, studies found 60% to 70% of former cocaine addicts to be cocaine free and functioning well, though many experienced some slips. No medication consistently improves the psychosocial treatment of cocaine dependence.

OTHER STIMULANTS

Methamphetamine has become an important drug of abuse in the western United States. It can be made in amateur clandestine laboratories, and ephedrine, found in many over-the-counter cold medicines, is often used as starting material. Methamphetamine, which can be smoked, snorted, or taken intravenously, is more neurotoxic than cocaine and has a longer duration of action. Whereas cocaine blocks reuptake of monoamine neurotransmitters, resulting in increased activity of dopamine as well as other transmitters, amphetamine and methamphetamine cause greatly increased neurotransmitter release. Clinical reports suggest that the incidence of psychotic reactions is greater than with cocaine and that psychological deterioration is more rapid.

Prescription stimulants, such as dextroamphetamine and methylphenidate, are used for a variety of conditions, including weight reduction, narcolepsy, and attention deficit hyperactivity disorder in children. For weight reduction, amphetamines have a short-term effect and should be used, if at all, only in conjunction with behavioral interventions. Prescription stimulants have less abuse potential than cocaine, but in susceptible individuals, abuse and dependence occur. Treatment is similar to that for cocaine addiction.

PRESCRIPTION SEDATIVES

Sleeping pills and minor tranquilizers can be misused inadvertently because of ignorance of their long-term effects. For example, the symptom of insomnia should not be treated by simply prescribing a sleeping pill. Recurrent insomnia usually signals an underlying problem, such as depression or a primary disorder of sleep physiology. Administration of a sedative produces new problems that begin with changes in sleep patterns and may involve dependence on the medication. A few patients gradually increase their dose, leading to an addiction syndrome.

Benzodiazepines are a large class of drugs referred to as minor tranquilizers. They are a great improvement in terms of safety and efficacy over the medications that they replaced, but tolerance and physical dependence develop when they are used over the long term. Deliberate abuse of benzodiazepines is relatively uncommon and is seen mostly in alcoholics and polydrug abusers. It is common for any patient to show signs of physical dependence when benzodiazepines are prescribed for a long period of time. For example, 20 mg of diazepam daily or the equivalent amount of other benzodiazepines produces physical dependence in about 40% of patients after 4 months of treatment. Physical dependence at even lower doses has been reported in patients receiving benzodiazepines daily for longer periods. For clear-cut indications, such as anxiety disorders, these medications permit the patient to function normally, and long-term use may be justified. The decision to prescribe a benzodiazepine for more than 6 weeks should be considered carefully. Cessation of the medication after it has been taken for several months requires slow detoxification.

CANNABIS: MARIJUANA AND HASHISH

Marijuana, the most commonly used illegal drug, is actually a complex preparation containing many biologically active chemicals. The chemical D-9-tetrahydrocannabinol (D-9-THC) accounts for most of the psychoactive effects reported by marijuana users. These include a dreamy, so-called stoned feeling and enhanced perceptions of colors, sounds, and tastes. Learning is impaired, and coordination is poor for several hours after the high feeling wears off. The physiologic effects of cannabis are dose related and include tachycardia, conjunctival vascular congestion, decreased intraocular pressure, bronchodilation, increased airway conductance, and peripheral vasodilation. Overdose may produce orthostatic hypotension, fine tremors, ataxia, nystagmus, nausea, and vomiting. Acute panic, paranoid reactions, and frightening distortions of body image are sometimes experienced by marijuana users, especially when a higher dose than expected is taken. Although marijuana is capable of impairing learning and social adjustment in adolescents, few toxic effects have been demonstrated at average use levels. Dependence defined by compulsive frequent use of marijuana occurs in less than 10% of users.

Marijuana is sometimes recommended for its medicinal value in several conditions, including glaucoma, muscle spasm, weight loss of chronic disease, and the nausea produced by cancer chemotherapy. Marijuana as medicine is limited by psychoactive side effects and by the toxic effects of smoking as a means of ingestion. The effects of cannabinoid receptors in the brain, however are just beginning to be understood. These receptors are widespread, and already one endogenous ligand—anandamide—has been isolated. It is likely that useful and specific medications will be developed that interact with this system.

HALLUCINOGENIC DRUGS

CLINICAL FEATURES

Hallucinogenic drugs reliably produce distortions in perception or thinking as a primary effect, even at low doses. They are ingested for the purpose of inducing hallucinations or because users believe that they will enhance self-understanding. The popularity of this class of drugs has varied from high in the 1960s to low in the 1980s. Surveys among adults in the late 1990s indicated that about 15% of adults have used these drugs during their lifetime.

The main categories of hallucinogens are listed in [Table 35.5](#). Indoles and phenethylamines have high affinity for serotonin receptors and presumably interfere with normal serotonergic transmission. Lysergic acid diethylamide (LSD) is one of the most potent drugs known, in that it produces major changes in visual perception with a total dose as low as 25 to 50 µg. Other signs include pupillary dilation, increased pulse and blood pressure, flushing, salivation, lacrimation, and hyperreflexia. A major factor in the morbidity caused by these drugs is that samples purchased on the illicit market are mislabeled. The dose may be far higher than expected, and phencyclidine (PCP, also called “angel dust”) may be sold in place of one of the less dangerous hallucinogens. PCP produces analgesia and amphetamine-like stimulation in addition to hallucinations.

Phenethylamines
Mescaline
Dimethoxymethylamphetamine (DOM)
Methylenedioxyamphetamine (MDA)
5-Methoxy-3,4-methylenedioxyamphetamine (MDM, or “ectasy”)
Anticholinergics
Atropine
Benztropine
Hyoscyamine
Scopolamine
Indoleamines
Lysergic acid diethylamide (LSD)
Psilocybin
Dimethyltryptamine (DMT)
Phencyclidine (PCP, or “Angel Dust”)

TABLE 35.5. HALLUCINOGENS

MANAGEMENT

Tolerance develops to some of the effects of LSD, but dependence is not seen. Physicians may be asked to treat the unexpected effects of these drugs, including psychotic episodes, accidental injuries, and suicide attempts during a “trip.” Because medications can worsen the situation, counseling and reduction of stimulation are important. For severe agitation, intramuscular lorazepam (2 to 4 mg) or haloperidol (5 to 10 mg) can be helpful. Brief reappearance of the hallucinations or perceptual distortions experienced during the period of acute ingestion that occur days or weeks after the last trip are called “flashbacks.” These episodes usually cease without treatment, but in some cases they have persisted for years.

Hallucinogenic drugs tend to be used intermittently rather than on a daily basis. PCP is an exception. Compulsive, frequent use of PCP qualifies as addiction in some

users. Overdose with PCP can progress rapidly from aggressive or psychotic behavior to coma with dilated pupils, muscular rigidity, arrhythmias, elevated blood pressure, and seizures. Support of vital signs, gastric lavage with activated charcoal, and acidification of the urine are part of the acute treatment. Hallucinogenic drugs purchased on the street may contain anticholinergic substances, such as scopolamine. At high doses, these drugs produce visual or tactile hallucinations, acute toxic delirium with confusion, and amnesia for the episode.

INHALANTS

Substances that are volatile at room temperatures may be inhaled to produce changes in mental state. Common substances include toluene (airplane glue), kerosene, gasoline, carbon tetrachloride, amyl nitrite, and nitrous oxide. Solvents found in cleaning fluids, such as aerosol sprays, may be sought for their psychic effects. Frequent use of solvents may result in toxicity affecting the bone marrow, brain, liver, kidney, heart, and peripheral nerves. Fatalities have been reported, probably from cardiac arrhythmias accompanying upper-airway obstruction or exercise. Amyl nitrite causes relaxation of smooth muscle and has been used to treat angina. Adverse effects include postural hypotension, palpitations, and headache progressing to loss of consciousness. Nitrous oxide and halothane are anesthetic gases sometimes used by medical personnel as intoxicants. Specific acute treatments for inhalant intoxication are generally unnecessary. When inhalants are used long term or are associated with other psychiatric diagnoses, specific psychiatric treatment is indicated.

ILLICIT SYNTHETIC DRUGS

Drugs manufactured in illegal laboratories, sometimes called designer drugs, are inherently dangerous, because they vary in composition and purity. Analogs of the potent opioid fentanyl have been synthesized and have resulted in many overdose deaths. Some attempts at synthesis of opioids have produced such toxic compounds as MPTP. This analog of meperidine is a neurotoxin to the substantia nigra of the brain and results in irreversible Parkinson's syndrome.

CHAPTER 36: OBESITY

ALBERT J. STUNKARD AND THOMAS A. WADDEN

- [Definition](#)
- [Incidence and Epidemiology](#)
- [Etiology](#)
- [Clinical Findings](#)
- [Physical Examination and Laboratory Findings](#)
- [Optimal Treatment](#)

DEFINITION

Obesity is a condition characterized by excessive accumulation of fat in the body. In clinical practice, overweight (weight corrected for height) is used as a surrogate for body fat. This practice is reasonable because body weight and fat are highly correlated, especially at greater degrees of overweight. Traditionally, overweight has been defined in terms of tables of ideal or desirable body weight. It is now defined in terms of the body mass index (BMI = weight in kilograms divided by height in meters squared), with overweight defined as a BMI of greater than 25 and obesity as a BMI greater than 30. [Table 36.1](#) shows the BMI values for different heights and weights in inches and pounds, and [Table 36.2](#) depicts the World Health Organization's classification of obesity. Unlike many "real" diseases and like hypertension, obesity represents one arm of a distribution curve of body weight, with no physiologically defined cutoff point. In the future, diagnosis may be based on newer methods of measuring body fat. Until then, for most practical purposes, the eyeball test is sufficient: if a person looks fat, the person is fat.

Body Mass Index				
Height (in)	Body Weight (lb)			
	20	25	30	40
58	95	119	163	191
59	99	124	169	198
60	102	127	173	204
61	106	132	179	212
62	109	136	183	217
63	113	141	189	226
64	117	146	196	234
65	120	150	199	240
66	124	156	207	249
67	127	159	211	255
68	132	165	218	264
69	135	169	223	270
70	140	175	230	279
71	143	179	234	286
72	148	185	241	295
73	151	189	246	302
74	156	195	254	312
75	159	199	259	318
76	164	205	266	328

TABLE 36.1. BODY MASS INDEX

Classifications	BMI
Underweight	<18.50
Normal weight	18.50–24.99
Grade I overweight	25.00–29.99
Grade II overweight	30.00–39.99
Grade III overweight	≥40.00

TABLE 36.2. MODIFIED WHO CLASSIFICATION OF OVERWEIGHT AND OBESITY

INCIDENCE AND EPIDEMIOLOGY

Obesity is one of the most pervasive public health problems in the United States today. One-third of all adults are overweight, and this high prevalence occurs in all ethnic and racial groups at all ages and in both sexes. It is even higher among persons with lower levels of education and certain ethnic or racial groups. [Figure 36.1](#) shows the prevalence of overweight among three racial or ethnic groups by age, separately for men and women. A striking finding is the very high prevalence (almost 60%) among middle-aged African-American and Mexican-American women; the value for white women is 33.5%.

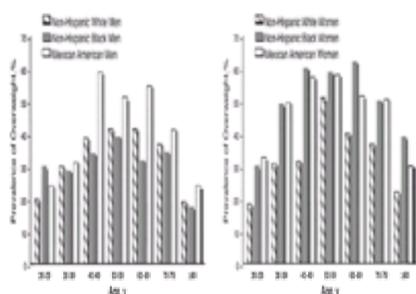

FIGURE 36.1. Prevalence of obesity by gender, age, and ethnic status according to the former criteria of a body mass index greater than 27.8 for men and 27.3 for women. (From Kuczmarski RJ, Flegal KM, Campbell SM, et al. Increasing prevalence of overweight among US adults: the national health and nutrition examination surveys, 1960–1991. *JAMA* 1994;272:205, with permission.)

For men and women, the prevalence of overweight increases with each 10-year increment of age until 50 to 59 years of age, when it begins to fall progressively at older ages. Overweight is also highly correlated with socioeconomic status; increasing body weight is associated with decreasing socioeconomic status, particularly among women. The high prevalence of overweight in the United States is compounded by a striking 30% increase in the past decade. The problem extends across the entire spectrum of body weight. During the past decade, the average American gained 3.6 kg, and the proportion of persons with healthier, lighter weights decreased significantly. Even children have not been spared the rapid increase in body weight; 25% of American children are overweight.

ETIOLOGY

What causes obesity? In one sense, the answer is simple—consuming more calories than are expended as energy. In another sense, the answer is most elusive. The

causes of obesity are to be found in the regulation of body weight (which is primarily the regulation of body fat), and we still have only an imperfect understanding of how this regulation is achieved. We do know that weight is regulated with great precision. During a lifetime, the average person consumes at least 60 million kcal. A gain or loss of 20 lb, or 72,000 kcal, would represent an error of no more than 0.001%. The determinants of obesity or, as we have suggested, an elevated body weight set point can be divided into genetic, environmental, and regulatory factors.

GENETIC DETERMINANTS

The existence of numerous forms of genetic obesity in experimental animals and the ease with which adiposity can be produced by the selective breeding of farm animals suggest that genetic factors can play an important role in human obesity. The stunning advances in our knowledge during the past decade have made it clear that genetic factors do play an important role in human obesity. The first studies, using the classic twin method, estimated very high levels of heritability; the percentage of the variance in body weight accounted for by genetic influences was about 80%. Even studies of identical twins separated at birth, a method that avoided some of the bias in classic twin studies, estimated heritability at 66%. These studies are still widely cited, but there is a growing consensus that they overestimate the influence of heredity.

The results of adoption studies and complex segregation analysis agree on a heritability of BMI of about 33%, a value now viewed as a more reasonable estimate than that of the twin studies. Genetic influences may play a more important part in the determination of regional fat distribution than of total body fat, with a particularly strong influence on the critical visceral fat depot.

Obesity has been considered to be a polygenic disorder. This belief has been challenged by the discovery of major genes responsible for five forms of genetic obesity in mice, and an active search is under way to determine if they participate in human obesity. This dramatic entry of molecular biology into research on the genetics of human obesity will undoubtedly make a major contribution to our understanding of this disorder.

SOCIAL DETERMINANTS

The fact that genetic influences account for only one-third of the variation in body weight means that the environment exerts an enormous influence. One measure of the extent of this influence is the dramatic increase in the prevalence of obesity during the past decade. One surprising aspect of the nature of environmental influences has become clear. Adoption studies have revealed that the early home environment, in which children learn their eating habits and which had been blamed for the origins of obesity, plays no role in determining obesity in adult life. The environment in which a person is living, however, makes a profound contribution to body weight.

Some of the most systematic studies of the environmental determinants of obesity are those of socioeconomic status. There is a strong inverse correlation between socioeconomic status and obesity, particularly among women, with lower socioeconomic status apparently favoring the development of obesity. Longitudinal studies on both sides of the Atlantic have shown that growing up in a lower-class environment is a powerful risk factor for the development of obesity, particularly for females.

The social influences on obesity involve energy intake and energy expenditure. Increased food intake plays a major role. After years of uncertainty about the contribution of food intake to the development of obesity, the introduction of doubly labeled water to measure energy expenditure, and so energy intake, has made it clear that obesity is associated with increased food intake. An increase in the fat content of the diet, from 32% in 1910 to 43% in 1985, has mirrored the increase in obesity in the United States. Dietary fat promotes obesity in at least four ways: the greater caloric density of fat (9 kcal versus 4 kcal for carbohydrate and protein); the high palatability of dietary fat; the 25% greater efficiency (compared with carbohydrate and protein) with which dietary fat is converted into body fat; and the likelihood that, unlike carbohydrate and protein, dietary fat is not regulated. Excessive intake of fat at one meal is not followed by decreased intake at the next meal, as is the case with carbohydrate and protein.

The second environmental factor promoting obesity is the sedentary lifestyle so prevalent in the United States today. A decline in physical activity has paralleled the increase in obesity, which is far more prevalent today than it was at the turn of the century. This increase in prevalence has occurred despite a substantial decrease in average food intake. The major drop in energy expenditure reflects a decline in physical activity.

This diminished physical activity has resulted from the proliferation of labor-saving devices that have transformed the nature of work and of leisure activities. It is the rare person today who puts in long hours at heavy labor, and even the home presents fewer opportunities for physical activity. The Bell Telephone Company has estimated that, in the course of a year, an extension phone saves a person 70 miles of walking, the energy equivalent of 2 lb of fat. For genetically predisposed persons, decreased physical activity means increased body weight.

Obese persons are considerably less active than are persons of normal weight. Programs that increase physical activity also decrease body weight, but because some of the decline in body weight in these programs is probably a result of diminished food intake, animal studies provide more direct evidence of the influence of physical activity. As in humans, physical activity is limited in most forms of experimental obesity, and intensifying this activity helps control the obesity. When the tendency toward obesity is strong, as in the obese hyperglycemic mouse (*ob/ob*) and the Zucker obese rat (*fa/fa*), exercise can mitigate, but not prevent, the development of obesity. When the tendency toward obesity is weaker, as in the yellow obese mouse (*AY*) or in rats with small lesions in the ventromedial hypothalamus, exercise can prevent the development of obesity in some cases.

GENES AND ENVIRONMENT

Genetic and environmental determinants of obesity are not in conflict. Neither acts alone to determine a clinical outcome. This outcome is determined instead by the combination of genetic vulnerability and adverse environmental events. This combination is diagrammed in [Fig. 36.2](#), in which the small inner circle represents persons who are genetically predisposed to a disorder. The wedge represents adverse environmental conditions to which these individuals may be exposed. The model indicates that only those genetically predisposed persons who are exposed to adverse environmental conditions are clinically affected.

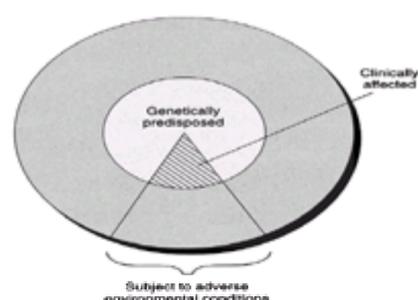

FIGURE 36.2. Model for the interaction of genetic vulnerability and environmental challenge. (From Stunkard AJ. Genetic contributions to human obesity. In: McHugh PR, McKusick VA, eds. *Genes, brain, and behavior*. New York: Raven Press, 1991:205, with permission.)

REGULATORY DETERMINANTS

Four determinants of obesity can be classified by their effect on the regulation of body weight: adipose tissue, brain damage, medication, and psychological factors.

Adipose Tissue

Adipose tissue is the organ primarily affected in obesity. Adults of average weight have approximately 25 billion fat cells, and weight gain is associated with an increase in the size of these cells (i.e., hypertrophy) but not in their number (i.e., hyperplasia). Persons who have been obese since childhood usually have

hyperplastic and hypertrophic obesity; in those who are 100% or more overweight, the cell number may exceed 150 billion. When weight is lost, it is solely by a decrease in fat cell size; fat cell number appears to be irreversible. As a result, when cell size in hyperplastic obesity is reduced to normal levels by dieting, persons may still have two to five times more fat cells than persons of average weight and, accordingly, a fat mass that is increased by the same amount. This hypercellularity is a major determinant of the elevated body weight (fat) set point of hyperplastic obese persons.

Brain Damage

A small number of persons become obese as a result of brain damage, particularly from tumors (e.g., pharyngeomas), even when they are successfully removed, and from infections (e.g., viral infections). These lesions exert their influence through two broad anatomic systems that mediate hunger and satiety, the former with representation in the lateral hypothalamus and related structures and the latter in the ventromedial hypothalamus. Damage to the ventromedial hypothalamus and its related structures results in impaired satiety, increased food intake, and gain in body weight.

Medication

Some medications, such as steroid hormones, contribute to obesity and even to altered body fat distribution. The widespread use of psychotropic medication has significantly increased the prevalence of iatrogenic obesity. Three major classes of drugs are responsible: tricyclic and heterocyclic antidepressants, lithium, and antipsychotic medication.

As many as one-half of all patients on tricyclic antidepressants discontinue desperately needed treatment because of weight gain, which may reach 2 kg per month. A major reason for the popularity of the selective serotonin reuptake inhibitors is that they are associated with far less weight gain. Weight gain with lithium is particularly troublesome, because lithium is usually prescribed for bipolar (manic-depressive) patients on a long-term basis, and weight gains of 10 kg have been reported over 2 to 6 years. Traditional antipsychotic medication also often produces weight gain, and the newer "atypical" neuroleptics may cause even larger weight gains. Since many of these medications are given on a long-term basis, weight gain is a very serious problem. A list of the psychotropic agents that promote weight gain is shown in [Table 36.3](#).

ANTIDEPRESSANT DRUGS AND BODY WEIGHT		
Tendency to increase appetite and body weight		
Greater	Imipramine	Desipramine
Ameliorate	Nortriptyline	Doxepin
	Paroxetine (SSRI inhibitor)	Sertraline (SSRI inhibitor)
May decrease appetite and facilitate weight loss		
Rucapar		
Fluoxetine		
ANTIPSYCHOTIC DRUGS AND BODY WEIGHT		
Tendency to increase appetite and body weight		
Greater	Haloperidol	Haloperidol
Chlorpromazine	Schizopazine	Haloperidol
Molindone	Pegaspazine	Haloperidol
Thioridazine	Thioridazine	Haloperidol
May decrease appetite and facilitate weight loss		
Molindone

TABLE 36.3. ANTIDEPRESSANT AND ANIPSYCHOTIC DRUGS AND BODY WEIGHT

Psychological Factors

Obesity has traditionally been viewed as a disorder with strong psychological determinants, but such determinants are confined to two specific eating disorders, binge-eating disorder and the night-eating syndrome. Binge-eating disorder is characterized by the consumption of large amounts of food in a short period, together with a subjective sense of loss of control during the binge and distress after it. Unlike patients with bulimia nervosa, these patients do not engage in compensatory behaviors, such as vomiting or laxative abuse, to prevent the weight gain after a binge, and the binge accordingly contributes to excessive caloric intake. The disorder is a source of distress, and as many as 50% of obese binge eaters suffer from depression, compared with 5% of obese persons who do not binge. Binge-eating disorder increases in prevalence with increasing body weight and afflicts about 10% to 20% of persons entering treatment programs for obesity. It may interfere with efforts at weight control and be an indication for treatment over and above that for obesity.

The night-eating syndrome, characterized by morning anorexia, evening hyperphagia, and insomnia, appears to be a manifestation of an altered circadian rhythm, precipitated by stressful life circumstances. It increases in prevalence with increasing body weight and may afflict as many as 10% of persons entering treatment programs for obesity.

CLINICAL FINDINGS

Obesity has been classified on the basis of the nature of the predominant type of adipose tissue as hypertrophic, hyperplastic, or both, and this classification is still recognized. Another classification is based on the age at onset: childhood-onset obesity is characterized by a greater genetic contribution, greater adipose tissue hyperplasia, and a greater body weight than adult-onset obesity.

Body fat distribution has become the basis for a generally accepted classification of obesity. This interest was aroused in the early 1980s by the finding that persons whose fat was located primarily in the upper part of the body suffered far higher mortality and morbidity from ischemic heart disease than persons whose fat was located primarily in the lower part of the body. Body fat distribution has been estimated by the waist-hip ratio, calculated from the waist circumference halfway between the lower rib margin and the iliac crest and the hip circumference at the level of the greater trochanter. Upper-body obesity is defined as a waist-hip ratio of more than 1.0 for men and 0.8 for women. More recently, waist circumference alone has been used, with a value of greater than 100 cm considered to represent upper-body obesity. Risk, however, is directly proportional to the extent of upper-body fat, independent of gender; the mortality and morbidity rates of men are a function of their greater upper-body obesity.

Although the waist circumference is now the most widely used clinical measure of body fat distribution, a major refinement has been introduced by imaging techniques, which have shown that essentially all of the risk of upper-body obesity is conveyed by the visceral fat depot within the abdominal wall. This finding has greatly expanded our understanding of the complications of obesity and has provided a rationale for the metabolic cascade that mediates many of these complications. This rationale suggests that visceral fat, particularly under the influence of steroid hormones, gives rise to an increased free-fatty-acid flux, which leads to decreased hepatic insulin clearance, hyperinsulinemia, insulin resistance, hyperlipidemia, hypertension, and, eventually, cardiovascular disease.

The serious health hazards of obesity have received increasing attention as part of the movement to view obesity as a disease rather than as a biologic variant. McGinnis and Foege estimated that 280,000 deaths per year in the United States are attributable to "overnutrition," making it second only to smoking as a cause of death. Some of the disorders through which this influence is exerted are described in the following sections.

DIABETES

Non-insulin-dependent diabetes (type II) is strongly associated with obesity; 70% of all type II diabetics are overweight or obese, and the prevalence of diabetes increases with advancing age and greater body weight. It occurs in fewer than 1% of young persons of normal weight, rising to 9% of older obese men and 13% of older obese women and to even higher rates in persons with more severe forms of obesity. Risk of diabetes is also amplified by a family history of the disorder and by upper-body-fat distribution. The good news is the remarkable improvement in insulin sensitivity and related abnormalities that is produced by weight reduction.

CORONARY HEART DISEASE

Obesity is responsible for several coronary risk factors and is an independent risk factor for coronary heart disease; compared with other risk factors, however, it is

not a particularly strong one. Upper-body obesity is a strong risk factor for coronary heart disease, independent of the overall level of obesity.

HYPERTENSION

Hypertension is one of the indirect measures by which obesity contributes to coronary heart disease. The prevalence of hypertension increases with greater body weight gains, with upper-body-fat distribution, and with advancing age. Weight reduction controls the disorder; the blood pressure values of most obese hypertensive patients fall to normal levels with weight losses of 10 kg. Such weight losses also permit a large percentage of obese hypertensive patients who are receiving antihypertensive medication to cut down or discontinue this medication.

ENDOCRINE ABNORMALITIES

Thyroid problems, which have been invoked in the past as contributing to obesity, are rarely significant. Adrenocortical hyperactivity, which gives rise to the characteristic fat distribution of Cushing's syndrome, is usually readily recognized. Excessive amounts of estrogen, converted from androstenedione and testosterone in adipose tissue, give rise to menstrual irregularities, dysfunctional uterine bleeding, and endometrial carcinoma.

SLEEP APNEA AND THE PICKWICKIAN SYNDROME

Sleep apnea is a greatly underdiagnosed disorder that is characterized by brief periods during sleep when breathing ceases, occurring as often as hundreds of times each night. The resulting impairment in sleep gives rise to daytime somnolence, automobile accidents, cardiovascular mortality and morbidity, and premature death.

Obesity is the most important cause of sleep apnea, and weight reduction is a highly effective therapy. Recognition of sleep apnea requires first becoming aware of the possibility and then enlisting the help of someone who sleeps with the patient. Alerted to the possibility, anyone sleeping with the patient has little difficulty in making a provisional diagnosis that can readily be confirmed by study in a sleep laboratory. The severity of this disorder, the ease of diagnosis, and the effectiveness of treatment cry out for vigorous inquiry into the possibility of sleep apnea in all obese patients.

The obesity-hyperventilation syndrome, also called the pickwickian syndrome, is a sleep-related disorder of greater severity, which is characterized by daytime hypercapnia and cor pulmonale and by a greater risk of premature death.

GALLBLADDER DISEASE

Gallstones occur in about 30% of obese women, compared with 10% of nonobese women. Unlike other obesity-related disorders, weight reduction can exacerbate the problem, presumably because of supersaturation of the bile with cholesterol.

OSTEOARTHRITIS

Obesity is strongly associated with joint symptoms; arthritis of one knee is six times more common and arthritis of both knees is 15 times more common among obese than among nonobese persons. In addition to its association with arthritis of the weight-bearing joints, obesity is also associated with arthritis of non-weight-bearing joints, such as the fingers. Weight loss is remarkably effective in controlling symptoms and in significantly lowering the risk of osteoarthritis.

PSYCHOLOGICAL DISORDERS

Although obesity has been viewed as a result of deep psychological problems, such problems of obese persons are now understood to be a consequence of obesity and of the stigma with which it is associated. In addition to the eating disorders described previously, an emotional problem specific to obesity is disparagement of the body image. Persons with this disturbance feel that their bodies are grotesque and loathsome. The problem most commonly affects middle-class white women, among whom the prevalence of obesity is low and the sanctions against it very high. It is confined to those who have been obese since childhood, in whom neurosis is closely related to their obesity.

PHYSICAL EXAMINATION AND LABORATORY FINDINGS

Before weight reduction, significantly obese individuals should undergo a physical examination and routine blood tests (biochemical profile) to rule out the neuroendocrine and other abnormalities described previously. Decreases in medications, such as antihypertensive and antidiabetic agents, that are anticipated with weight loss should be reviewed.

With significantly obese individuals, it is not necessary to assess the body composition with specialized techniques, such as hydrostatic weighing, skinfold measurement, and bioelectric impedance. The patients can be presumed to have excess fat. Such assessment may be useful with athletic, mildly overweight individuals, who may have a surfeit of lean rather than fat tissue. Body composition assessment is commonly available at health clubs and sports medicine clinics.

The resting metabolic rate should be measured for individuals who report weight gain on low-energy intakes. Objective confirmation of low-energy requirements is often reassuring to patients and indicates the desirability of increasing physical activity rather than severely restricting caloric intake. Repudiating the reported low-energy requirements may reveal problems of distortion and denial. The composition of the patient's diet should be assessed by a 3-day food diary, recorded just before the office visit. The objective is to determine the fat content of the diet, the extent to which the patient eats at regular times, and the presence of binge eating.

OPTIMAL TREATMENT

After completing the medical evaluation, the physician should summarize the findings for the patient and then invite questions. They should then discuss the need for weight loss and the goals and methods of treatment.

NEED FOR WEIGHT LOSS

Independent of the degree of obesity, the need for weight loss is greater in overweight persons who have upper-body obesity (particularly increased visceral fat), persons who have one or more obesity-related complications (hypertension, diabetes, hyperlipidemia), those who are younger (20 to 45 years of age), males, and individuals with a family history of an obesity-related illness. The greater the number of these risk factors, the more pressing the need for weight reduction. The absence of these factors minimizes the need for treatment. A goal of weight stability, rather than weight reduction, would seem appropriate for a 60-year-old woman with lower-body obesity who is 15 kg overweight but otherwise in excellent health.

GOALS OF TREATMENT

Persons with health complications from obesity should be encouraged to lose weight—but how much weight loss is necessary? Historically, overweight individuals have been told to reduce to “ideal” weight, as defined by height-weight tables. Obese individuals, however, cannot reach this goal, which has been superseded by a weight-loss goal of as little as 5% to 10% of their initial weight. Reductions of this magnitude are sufficient to improve or control weight-related complications, including hypertension, diabetes, and hyperlipidemia.

METHODS OF TREATMENT

The review by the Institute of Medicine of the National Academy of Sciences divided methods of treatment into three categories: do-it-yourself programs that include diet books and self-help approaches, such as Overeaters Anonymous; nonclinical (commercial) programs, such as Weight Watchers and Jenny Craig; and clinical programs that provide medical care and more aggressive measures, such as very low calorie diets (VLCDs) and drug therapy.

A primary task of physicians is to manage the health complications of their obese patients. They may also choose to manage their patients' weight-control efforts.

Such efforts are most successful with highly motivated, mildly obese individuals who have become obese as adults. Significantly obese persons usually require greater structure and support. The physician should help such patients evaluate the many available treatments and select the most appropriate one. Thereafter, the physician's task is to monitor changes in patients' health and to encourage them to attend treatment sessions and improve their eating and exercise habits.

An overview of current treatments for obesity is provided in [Fig. 36.3](#). The model combines a classification based on body weight with a stepped-care approach and efforts to identify the patient's specific treatment needs. The more obese the individual, the more structured and possibly aggressive is the therapy required. We think all significantly obese individuals should be treated initially by a 1,200 to 1,800 kcal/day diet of conventional foods combined with a program of behavior modification. Such treatment is provided by Weight Watchers to over two million people a week, at a cost of as little as \$12 a week. More intensive and costly versions of this behavioral approach are frequently offered, with better results, by hospital- and university-based programs. If the patient has already received this kind of treatment, the next intervention in the stepped-care model should be considered. The following sections describe behavior therapy, VLCDs, pharmacotherapy, and surgery. Results of nonclinical (commercial and residential) programs are not discussed, because of a lack of adequate data.

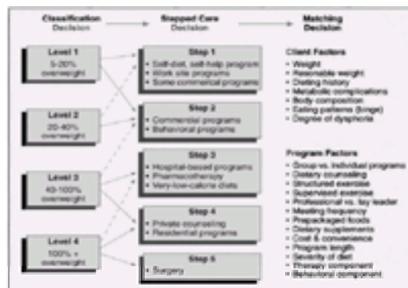

FIGURE 36.3. A conceptual scheme showing a three-stage process for selecting treatment. The first step, the classification decision, divides individuals into four levels, according to their percentage of overweight. These levels dictate which of the five steps would be reasonable in the second stage, the stepped-care decision, which indicates that the least intensive, costly, and risky approach will be selected from among the options. The third stage, the matching decision, is used to make the final selection of a program and is based on client and program variables. The dashed lines with arrows between the classification and stepped-care stages show the lowest level of beneficial treatment, but more intensive treatment is usually necessary for persons at the specified weight level. (From Brownell KD, Wadden TA. The heterogeneity of obesity: fitting treatment to individuals. *Behav Ther* 1991;22:162, with permission.)

Behavior Therapy

As applied to obesity, behavior therapy refers to a set of principles and techniques for the modification of eating and exercise habits. This approach is goal oriented; the objectives and methods of treatment are clearly specified in weekly homework assignments that patients discuss with their counselors each week. The techniques are used to facilitate patients' adherence to any one of a number of dietary regimens. Patients are usually asked to consume their customary foods but to reduce their caloric intake by 500 to 700 kcal/day and their consumption of fat to no more than 30% of total calories. In the initial weeks, patients keep daily records of the types and amounts of foods that they eat. Later, record keeping is expanded to include information about times, places, and feelings associated with eating.

Patients are asked to increase their physical activity by a variety of changes in lifestyle, such as walking more, using stairs rather than escalators, and reducing their dependence on energy-saving devices, for example, extension phones and remote-control devices. Most patients also adopt a structured exercise program, such as walking or swimming, but are cautioned not to make the program heroic or punishing. The behavioral approach is most effective when delivered in groups of 10 to 12 persons in which participants discuss their weekly homework assignments. Individual treatment may also yield adequate weight loss, although it does not usually provide the emotional support of group care. A favorable outcome is facilitated in either case by the use of a structured treatment manual, such as Brownell's *LEARN Program for Weight Control*.

Patients treated by group behavior therapy lose an average of 8 kg in 15 to 20 weeks, equal to a loss of 0.5 kg (1 lb) a week. Longer therapy produces larger losses, but they rarely exceed 15 kg, even when treatment lasts as long as 52 weeks. When patients stop treatment, they regain approximately one-third of their weight loss in the year after therapy, with increasing regain over time. Weight regain can be minimized, if not prevented, if patients maintain frequent, regular contact with their providers after weight loss. Contact can take the form of group meetings, telephone calls, or postcards. Increased physical activity is also a key component of long-term weight control. Persons who engage in regular physical activity for approximately 2 to 3 hours a week are the most likely to maintain reduced weights.

Very Low Calorie Diets

VLCDs, providing 400 to 800 kcal daily, are reserved for patients 30% or more overweight who have failed to lose weight satisfactorily with conventional methods. Candidates for VLCDs should be referred to multidisciplinary centers that provide medical supervision and a comprehensive program of behavior change. In such programs, patients lose an average of 20 to 25 kg and maintain approximately 60% of the weight loss 1 year later. Better results are achieved by combining the diet with a sound exercise program.

Pharmacotherapy

We stand at the threshold of a major new emphasis on the treatment of obesity with medication. This development arises in part out of the growing awareness of limitations of the behavioral programs and in part out of a radical revision of our views on medication that had led to its virtual abandonment in recent years. These views had two sources. The first was the revelation, two decades ago, of the serious abuses of amphetamines by unscrupulous so-called diet doctors. The result was the banning of amphetamines and a concurrent disinclination on the part of physicians to use other safe and effective medications. The second cause for the abandonment of medication was the widespread and mistaken belief that tolerance develops to the effects of appetite-suppressant medication. As a result, state medical boards proscribed their use for periods of longer than 3 months.

This belief was mistaken; appetite-suppressant medication maintains its effectiveness for as long as it is used. As soon as it is discontinued, however, weight, which had been kept down by its use, rapidly rebounds to pretreatment levels. These newer findings reverse the old rationale for treatment and suggest that appetite-suppressant medication should be used on a long-term basis or not at all. Clinical trials have strongly supported this rationale. They have produced weight losses of 10% of body weight within 6 months, and these losses have been generally well maintained for as long as medication is continued; when it is discontinued, weight is promptly regained. Changes in the regulations for use of appetite-suppressant medication are already under way, and it seems likely that long-term use will become standard practice. Other, older medications have proved safe and effective. These agents and their dosages are listed in [Table 36.4](#). Most are noradrenergic, and one of them, phenylpropanolamine, is available over the counter.

Medication Name and Its Mechanism of Action	DEA Schedule	Trade Name	Dosage Size (mg)	Daily Dose Range (mg)
Neuroleptic agents				
Risperidone	II	Risperidone	25, 50	25-50
Prochlorperazine	II	Compazine	5	10-20
Sibutramine	II	Meridia, Alli	25, 50 (slow release)	25
Mefenorex	II	Mefenorex	1, 2	1-2
Phenamine	II	Phenamine	15, 30	15-30
Phenpropionolamine	II	Phenpropionolamine	25	18-25
Phenpropionolamine	II	Phenpropionolamine	30	30
Phenpropionolamine	Over-the-counter	Phenpropionolamine	25, 30	25-30
Phenpropionolamine	II	Meridia	1, 1.5	1-1.5

* All medications except Sibutramine are approved for short-term use only (2 months or less). Sibutramine has been approved for long-term use.

TABLE 36.4. WEIGHT LOSS MEDICATIONS CURRENTLY APPROVED BY THE FOOD AND DRUG ADMINISTRATION^a

In 1997 the most popular medications, fenfluramine and its congener, d-fenfluramine, were removed from the market because of reports of valvular heart disease in a large number of persons who took this agent, usually in combination with phen- termine. Since then, sibutramine (Meridia), a noradrenergic and serotonin reuptake inhibitor, has been approved by the FDA, and it is increasingly widely used. Orlistat (Xenecal), a lipase inhibitor that reduces the absorption of fat from the intestine, will probably be approved by the time this volume is published. Its different method of action suggests that it may prove useful in combination therapy. The clinical trials employed diet and exercise; pharmacotherapy was an adjunct to this treatment rather than a replacement for it.

Surgery

Surgery is the treatment of choice for severely obese persons—those more than 100 lb or 100% overweight or with a BMI of more than 40 kg per square meter. Surgery may also be indicated for patients with lesser degrees of obesity—those with a BMI between 35 and 40—if they suffer from comorbid conditions. The first widely used operation, jejunioileal bypass, has been replaced by two gastric restriction procedures. In vertical-banded gastroplasty, a small (15 to 30 ml) pouch with a narrow stoma (10 mm in diameter) to the remainder of the stomach is created, which radically reduces the amount of food that can be eaten at any one time. In the gastric bypass, a larger pouch that empties into the jejunum is created. Nutrients bypass much of the stomach and the duodenum. A frequent result is a dumping syndrome, characterized by gastrointestinal distress and other symptoms caused by too-rapid absorption of carbohydrates from the jejunum. Gastric bypass produces somewhat greater weight losses than the vertical banded gastroplasty and is particularly effective with sweets eaters, presumably because of the greater dumping that they experience.

Weight losses after surgery are highly correlated with the extent of overweight and consist of about 50% of the excess weight, usually 40 to 80 kg. Weight loss reaches a nadir at about 2 years, and this loss is reasonably well maintained for another 2 to 3 years. Surgery is surprisingly well tolerated, even by extremely obese persons. In centers that specialize in this treatment, perioperative mortality rates are no more than 1%, and morbidity rates are less than 10%.

Surgery is associated with a striking reduction in physical and psychological complications of obesity. There is a marked decrease in non-insulin-dependent diabetes, hypertension, hyperlipidemia, respiratory distress, and almost all complications of obesity. The most striking indication of improvement is the enhanced life expectancy of operated patients, which approaches actuarial standards of the general population. The psychological benefits of surgery are comparable, with marked improvement in psychosocial functioning, mood, and quality of life. One note of caution is warranted. Surgery should be undertaken only in programs that specialize in this treatment and that have demonstrable records of safety and efficacy.

COMPASSIONATE CARE

One of the most important services that the physician can provide obese individuals is an opportunity to discuss their feelings of sadness and frustration concerning their weight. Moreover, practitioners should be aware that overweight individuals are very sensitive to criticism about their weight, whether from family and friends, passing strangers, or their doctors. It is imperative that the physician, through words and deeds, help patients maintain self-esteem as they struggle with the challenge of weight control.

CHAPTER 37: ANOREXIA NERVOSA and EATING DISORDERS

PAUL M. COPELAND

[Definition](#)
[Incidence and Epidemiology](#)
[Etiology and Pathogenesis](#)
[Clinical and Laboratory Findings](#)
[Optimal Management](#)

DEFINITION

The major eating disorders of anorexia nervosa and bulimia nervosa represent a spectrum of abnormalities with overlapping clinical features. Both disorders are characterized by preoccupation with weight, and about one-half of patients with anorexia nervosa exhibit bulimic behavior. The American Psychiatric Association specifies criteria for the diagnosis of anorexia nervosa that may be summarized as a refusal to maintain weight above 85% of ideal body weight; fear of obesity; distorted body image; and, in females, amenorrhea for at least 3 months. Patients with anorexia nervosa who engage in repeated binge-eating or purging behavior are subcategorized as binge-eating/purging types, and others are classified as restricting types.

Criteria for bulimia nervosa require an average of at least two binge-eating episodes each week for at least 3 months about which the person feels a lack of control. The person has a persistent overconcern with body shape and weight and regularly engages in self-induced vomiting; use of diuretics, laxatives, or enemas; strict dieting or fasting; or vigorous exercise to prevent weight gain. "Eating disorder not otherwise specified" is a category for patients who do not meet full criteria for anorexia nervosa or bulimia nervosa. Amenorrhea, in particular, has been the subject of controversy as a criterion for anorexia nervosa, since the degree of psychopathologic behavior may be as severe in patients who menstruate. Binge-eating disorder, a newly designated diagnosis, shares many characteristics with bulimia nervosa, but patients do not regularly purge or compensate by fasting or excessive exercise. Diagnostic criteria include binge eating at least 2 days per week, on average, for a period of at least 6 months.

INCIDENCE AND EPIDEMIOLOGY

The lifetime prevalence of anorexia nervosa is about 0.5%. Most surveys show a greater preponderance among upper-socioeconomic classes, but later studies suggest that this gap is narrowing. There is a bimodal peak age at onset at 14 and 18 years. Only 4% to 10% of patients are males. Bulimia nervosa occurs in about 1% of young adults; males make up fewer than 10% of the patients. More individuals occasionally engage in bulimic behavior, but do not meet the frequency and duration criteria for bulimia nervosa. About 10% to 19% of young women binge eat and purge. Certain groups are especially vulnerable: eating disorders are more common in women with a history of obesity or diabetes mellitus, models, ballet students, or those in professions that demand high achievement and among men who are homosexual. Binge-eating disorder has a prevalence rate of 0.7% to 4%. Among obese individuals in weight-control programs, the typical prevalence is 30%; females are approximately 1.5 times more likely than males to have this eating pattern.

ETIOLOGY AND PATHOGENESIS

The factors that initiate or perpetuate anorexia nervosa are unknown. Theories include developmental, familial, sociocultural, and biochemical factors. Typically, the person with anorexia nervosa is a perfectionist and may perceive that parents are more concerned with achievements than feelings. Crisp maintained that weight loss also becomes a means of avoiding the characteristics of sexual and psychological maturity. The etiologic importance of a history of sexual abuse is debatable. Fasting has long been associated with asceticism and purity. Although medical reports of anorexia nervosa date to the seventeenth century, the modern societal thin ideal influences choices about weight control. Many patients with anorexia nervosa begin their diets after being teased about the need to lose weight.

Concordance rates of approximately 55% for monozygotic as opposed to 5% for dizygotic twins have suggested a genetic predisposition to anorexia nervosa. Some biochemical theories for the origin of anorexia nervosa have focused on neurotransmitters that affect control of appetite. Defects in central nervous system norepinephrine and serotonin (5-hydroxytryptamine, 5-HT) metabolism have been verified in acutely ill and recovered patients. One difficulty with biochemical theories related to appetite is that anorexia nervosa is not characterized by true anorexia but rather by a willful avoidance of eating, at least in the initial stages. Other genetic data may relate to the behavioral trait of perfectionism; both anorexia nervosa and the frequent comorbid condition of obsessive-compulsive disorder have been associated with polymorphism in the promoter region of the 5-HT_{2A}-receptor gene.

The cause of bulimia nervosa is also unknown, but it typically begins during a diet. The binges often occur during times of stress or depressed mood. Patients describe an initial soothing, albeit frenetic, quality to food ingestion, followed by feelings of guilt and then resolution of the guilt by purging. One-half of those with anorexia nervosa develop bulimic behavior. The stress of chronic dieting may create a breakthrough of binge eating. Keys and co-workers' study of conscientious objectors who volunteered to undergo 6 months of semistarvation toward the end of World War II revealed experiences of uncontrollable binge eating reminiscent of bulimia when the subjects were subsequently allowed unrestricted access to food. As in bulimia nervosa, some patients with binge-eating disorder report episodes triggered by dysphoric moods. Others report binge eating to relieve tension or describe a dissociative "numb" state during episodes.

CLINICAL AND LABORATORY FINDINGS

The behavioral features of anorexia nervosa are most notable for obsessive pursuit of thinness, body image disturbance, and denial of illness. Even those who superficially agree that a problem exists may still not be able to change their behavior. Other characteristic features are hyperactivity, social isolation, food rituals, and hoarding of food that may then be disposed of or eaten in private in small amounts or in binges. Patients with bulimic behavior tend to be more outgoing, more impulsive and more sexually active and have a higher prevalence of alcohol and other drug use than those who purely restrict food intake. Depression is common among patients with anorexia nervosa or bulimia nervosa.

The clinical manifestations of anorexia nervosa are consequences of starvation plus any of the associated behaviors, such as binge eating, vomiting, or abuse of laxatives, diuretics, or ipecac (Table 37.1). Some patients with bulimia nervosa manifest milder consequences of intermittent starvation. Food restriction is typical between binge-eating episodes. Estrogen deficiency and amenorrhea are consequences of diminished hypothalamic gonadotropin-releasing hormone (GnRH) secretion. Leptin deficiency at low weights may lead to decreased GnRH secretion. Gonadotropin secretion is also reduced in males with anorexia nervosa, and low serum testosterone levels may contribute to symptoms of impotence and loss of libido.

TABLE 37.1. IMPORTANT CLINICAL AND LABORATORY ABNORMALITIES IN PATIENTS WITH EATING DISORDERS

About 20% of patients with bulimia nervosa also have amenorrhea, and another 20% to 40% of patients have oligomenorrhea. Reduced luteinizing hormone secretion has been correlated with weight reductions of less than 85% of past high weights. Osteoporosis in anorexia nervosa may lead to vertebral compression fractures and stress fractures. Although osteoporosis is related to the duration of amenorrhea, a lack of estrogen may not be the sole cause. Increased cortisol production rates are correlated with bone loss. Nutritional depletion and resultant low levels of insulin-like growth factor I may also be responsible for bone loss.

Thyroid function in anorexia nervosa resembles that of the euthyroid sick syndrome. Peripheral conversion of thyroxine to triiodothyronine (T_3) is decreased. Bradycardia, hypothermia, cold intolerance, dry skin and hair, slowed relaxation of deep tendon reflexes, and hypercarotenemia may result in part from low T_3 concentrations. Diminished norepinephrine turnover may also contribute to some of these features of slowed metabolic rate.

Low serum glucose concentrations are usually well tolerated in fasting; however, hypoglycemia has been associated with coma and death in several patients with anorexia nervosa. Some of these patients had the added stress of an infection, which may have further diminished the gluconeogenic capacity of the liver. Among young women with type 1 diabetes mellitus, approximately 30% intentionally omit insulin to achieve weight control; 8% omit it frequently. Frequent omission is associated with poorer glycemic control and a higher risk of diabetic retinopathy.

Excessive caffeine or water ingestion may cause polyuria. Patients with anorexia nervosa also have diminished or erratic secretion of vasopressin in response to an osmotic challenge. Some patients manifest partial diabetes insipidus. Renal abnormalities largely reflect dehydration and a reduced glomerular filtration rate. Laxative abuse and self-induced vomiting can contribute to hypokalemia, volume depletion, and renal failure. Diuretic abuse can cause hypokalemia and, if coupled with water ingestion and vomiting, hyponatremia. During treatment of severe hyponatremia, too-rapid restoration of serum sodium has led to central pontine myelinolysis.

Patients with anorexia nervosa manifest low blood pressure and diminished cardiac output. Arrhythmia may be lethal. Retrospectively, cardiac deaths have been associated with QT prolongation. Repeated use of ipecac to induce vomiting can cause fatal cardiomyopathy. Hypomagnesemia has been associated with congestive heart failure.

Gastrointestinal changes in anorexia nervosa include decreased gastric emptying and intestinal motility, which are associated with an exaggerated sense of stomach fullness, abdominal pain, and constipation. Metoclopramide and cisapride have been used to enhance gastric emptying. Hepatic transaminases may be elevated in anorexia nervosa because of fatty infiltration of the liver. Vomiting often elevates levels of salivary amylase, and starvation may raise levels of pancreatic amylase. Vomiting during a state of decreased consciousness (with alcohol or other drug use) has resulted in aspiration pneumonia. Low neutrophil counts (less than 1,500 cells per microliter) in patients with anorexia nervosa have been associated with increased risk of infection. A mild elevation of serum creatine phosphokinase and electromyographic changes consistent with myopathy also can be found in patients with anorexia nervosa.

OPTIMAL MANAGEMENT

Outcome studies of anorexia nervosa find that 50% of patients totally recover, 30% of patients improve, and 20% remain chronically ill. Studies with up to 20 years of follow-up observation show a 15% mortality rate. Suicide and medical complications each account for one-half of disorder-related deaths. With weight restoration, there may be various degrees of psychological and physical recovery. Most physical manifestations reverse with weight gain, but menstrual disturbances are prone to continue among patients with anxiety disorders or with persistent abnormal eating attitudes. To help improve bone formation, the patient should have a calcium intake of at least 1,500 mg/day and take a vitamin supplement containing 400 IU of vitamin D. Hormone replacement therapy has improved bone density in patients with ideal body weight less than 70%.

Psychiatric treatment of anorexia nervosa consists of combinations of individual, group, and family therapy. Recovered patients have emphasized the value of a relationship with a therapist or friend. Nutritional counseling and medical follow-up is important. Hospitalization is required for severe cardiovascular or metabolic disturbances, continued or rapid weight loss, or other psychiatric crises. Regular food is given, starting with intakes of 30 to 40 kcal per kilogram per day. Intake may increase up to 70 to 100 kcal per kilogram per day during weight gain and can require as much as 40 to 60 kcal per kilogram per day during weight maintenance. Tube feeding or parenteral hyperalimentation is rarely required and usually should be avoided. Serious volume depletion can be treated with intravenous fluids. Serum phosphorus levels should be assessed.

The course of bulimia nervosa has been less well studied. About 30% to 60% of patients recover. Up to another 20% experience anorexia nervosa. In addition to cognitive-behavioral therapy (also effective in binge-eating disorder) and individual psychotherapy, pharmacotherapy with antidepressant drugs has met with some success. Tricyclic antidepressants, monoamine oxidase inhibitors, and antidepressants that more selectively inhibit serotonin reuptake have reduced binge-eating episodes in double-blind clinical trials. Fluoxetine has been approved for use in cases of bulimia nervosa. The dose of fluoxetine is generally titrated upward from 20 to 60 mg per day.

CHAPTER 38: APPROACH TO THE PATIENT WITH UNINTENTIONAL WEIGHT LOSS

DANIEL M. LICHTSTEIN AND ROBERT L. HERNANDEZ

[Etiology](#)
[Approach To Unintentional Weight Loss](#)
[Conclusion](#)

Unintentional or involuntary weight loss is a common initial complaint among patients who see primary care physicians, particularly those caring for the elderly. Significant weight loss is generally felt to be a loss of 5 kg or more, or more than 5% of one's usual weight, over a period of 6 months to 1 year. In one study, involuntary weight loss was associated with a 1-year mortality rate of 25%. It has been estimated that in approximately one-half of patients claiming to have lost weight in the recent past, there is no evidence of such weight loss when previous records are reviewed. Therefore, the physician should try to corroborate and accurately quantify weight loss whenever possible. Comparison of the patient's current weight with recordings from previous office visits or with old records from other physicians' offices is the best method of validating weight loss. If this information is not available, speaking with family members of the patient and documenting a change in belt or clothing size can provide evidence of weight loss. Screening for unintentional weight loss, especially in the elderly, should be considered, in light of one study's finding that only one-third of patients found to have significant weight loss related this loss as a chief complaint to the physician.

ETIOLOGY

There have been several published studies examining the origins of unintentional weight loss. Psychiatric illness (depression), malignancy, and benign gastrointestinal diseases are the most common causes of weight loss in these studies. Lung and gastrointestinal tract malignancies are the most common cancers, and esophageal disorders and peptic ulcer disease are typical benign reasons for loss of weight. Despite investigative studies and follow-up, no definitive cause of weight loss could be determined in 25% of the patients studied. There are a large number of causes of unintentional weight loss ([Table 38.1](#)). They can be broadly divided into two main categories: those associated with decreased caloric intake and those associated with increased caloric expenditures. Some conditions, such as malignancies and malabsorption, can be related to both.

TABLE 38.1. DIFFERENTIAL DIAGNOSIS OF UNINTENTIONAL WEIGHT LOSS

DECREASED CALORIC INTAKE

Decreases in caloric intake can be due to conditions causing difficulty eating, anorexia, or malabsorption. Difficulty eating may be caused by oral (poor dentition), oropharyngeal (transfer dysphagia), or gastrointestinal (gastroesophageal reflux) conditions. Anorexia is associated with a wide variety of psychological conditions, including depression, eating disorders, and substance abuse. Social problems, such as poverty and isolation may also lead to a decrease in caloric intake. Appetite can also be suppressed by a large number of acute and chronic medical conditions. The mechanisms of appetite suppression and weight loss are incompletely understood. Circulating tumor-derived factors (tissue necrosis factor), increases in systemic inflammation, chronic activation of the immune system, and decreases in circulating growth factors are some of the mechanisms that have been proposed to explain cancer-related weight loss. Malabsorption syndromes, such as pancreatic exocrine insufficiency and Crohn's disease may cause a decrease in caloric intake, even when the patient ingests a normal amount of calories.

INCREASED CALORIC EXPENDITURES

Weight loss due to increased caloric expenditures may stem from metabolic diseases, such as hyperthyroidism, diabetes, and Addison's disease. Patients with hyperthyroidism may have typical signs and symptoms of the disease, but in the elderly, weight loss and tachycardia may be the only clinical manifestations. The initial signs of poorly controlled or unrecognized diabetes mellitus may be unexplained weight loss and a normal or increased appetite. Loss of calories may occur as a consequence of persistent fever, vomiting, or diarrhea. Some conditions, such as malabsorption, malignancy, and medication side effects, can lead to weight loss in several ways. Malignancies, for example, can suppress appetite while increasing caloric expenditures. Weight loss caused by medications may be the result of vomiting, dysgeusia, gastrointestinal tract involvement, or anorexia.

APPROACH TO UNINTENTIONAL WEIGHT LOSS

A detailed history and thorough physical examination should be the cornerstones of the initial evaluation of a patient with unintentional weight loss and will identify most organic causes. Questioning should include a psychosocial history, assessment of alcohol use, and a careful review of all medications. Oropharyngeal symptoms, dysphagia, early satiety, change in bowel pattern, fever, cough, polydipsia, and polyuria should be carefully evaluated. Additional history from family members or caregivers may prove to be valuable.

The physical examination should be comprehensive, starting with observations of the patient's general appearance and mood. A diligent search for lymphadenopathy, thyroid abnormalities, cardiac or pulmonary disease, hepatomegaly, abdominal masses, occult blood in the stool, and neurologic abnormalities (including mental status) should be undertaken. The prostate and genitalia should be examined in men, and a breast and pelvic exam should be performed in women.

Initial laboratory studies should comprise the complete blood count, including platelet count; urinalysis; chemistry panel, including liver function tests, calcium, and serum protein levels; ultrasensitive thyroid-stimulating hormone; stool for occult blood; and chest radiography. If risk factors are present for human immunodeficiency virus, appropriate consent for testing should be requested. If the history, physical examination, and laboratory studies yield normal results, it is unlikely that serious organic disease is present. However, cancer screening tests appropriate for the age of the patient should be performed as well (mammography, flexible sigmoidoscopy).

If no source for weight loss is found after the initial evaluation, careful follow-up is indicated. This is preferable to expensive nonfocused laboratory, radiographic, or endoscopic testing. Short-term follow-up allows for confirmation of continued weight loss or the lack of it. In addition, nutritional and psychosocial issues may be pursued further. It can be helpful to have the patient keep a daily record of all food eaten over a period of time to assess true caloric intake. Psychosocial issues, such as depression, alcoholism, and substance abuse may be explored in more depth at follow-up visits. Asking the patient what he or she believes is at the root of the weight loss can be helpful. Some organic diseases provoking unintentional weight loss may show no abnormal findings on history, physical examination, and initial laboratory testing. Pancreatic cancer, Addison's disease, and lymphoma are examples of these conditions. In the absence of symptoms suggestive of such disorders, however, extensive testing of all patients is not justified.

CONCLUSION

In summary, the cause of unintentional weight loss usually can be determined after a detailed history, thorough physical examination, and initial laboratory evaluation. More extensive testing should be guided by signs or symptoms or by new information or findings at follow-up visits. Despite appropriate evaluation and close follow-up, no source is established in a significant percentage of patients with unintentional weight loss.

CHAPTER 39: DEPRESSION, ANXIETY, AND OTHER PSYCHIATRIC DISORDERS

MARIA D. LLORENTE

[Definition](#)
[Mood Disorders](#)
[Anxiety Disorders](#)
[Schizophrenia](#)

In 1994 alone, psychotropic drugs were prescribed during the course of more than 45 million outpatient visits. Primary care physicians (PCPs) were seen for 55% of antianxiety, 41% of antidepressant, and 30.5% of antipsychotic drug visits. Most unexplained physical symptoms in primary care patients are not associated with organic disease but do correlate with anxiety and depressive disorders. Despite the significant prevalence of mental disorders ([Table 39.1](#)), 54% of patients are treated exclusively by generalists. As many as 50% of these disorders, however, are misdiagnosed or inadequately treated. This chapter reviews adult mental disorders commonly seen in primary care practice.

TABLE 39.1. TOTAL LIFETIME AND 12-MO PREVALENCE OF DSM-III-R PSYCHIATRIC DISORDERS PER 100 PERSONS

DEFINITION

Psychiatric disorders are classified according to the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV). These disorders have characteristic signs and symptoms that lead to impairment in occupational, social, and leisure functioning.

MOOD DISORDERS

INCIDENCE AND EPIDEMIOLOGY

Mood disorders include both depressive (unipolar) and manic-depressive (bipolar) conditions. These disorders represent abnormal clinical syndromes and are not simply normal reactions to stressful situations. The incidence rates of depression and mania are 1% and 1.2% in men and 3% and 1.8% in women, respectively. Age at first episode of major depression has steadily declined in industrialized countries, with mean age at onset of 40 years for men and women. Age at onset for bipolar disorder is 30 years. The majority of patients with depression experience more than one episode in their lifetime. Bipolar disorder is a chronic recurrent illness.

Persons with any mood disorder are 2.6 times more likely than nonaffected individuals to have a comorbid alcohol or substance abuse problem; for example, 56% of bipolar patients have a comorbid substance abuse problem. Additionally, 34% of patients with mood disorders also have anxiety disorders. Seven percent of these patients have mood, anxiety, and substance abuse disorders.

Depressed patients use medical services frequently, with prevalence rates of major depression approaching 8% in outpatient settings and 14.6% on medical inpatient units. Depression is consistently associated with poorer outcomes from coronary artery disease. Patients who have experienced myocardial infarction and who are depressed are 3.5 times more likely to die immediately after a myocardial infarction than nondepressed patients. Depression also has been found to be an independent risk factor for coronary artery disease. While it is still speculative, reasons for this association include altered (decreased) heart rate variability in depressed patients; increased platelet aggregation in depressed, nonmedicated patients; and poor compliance with medical treatment among depressed patients.

The current suicide rate in the United States is twelve per 100,000 persons. Up to 15% of depressed individuals and 19% of patients with bipolar disorder die by suicide. Women are three to four times more likely than men to make a suicide attempt, but men are three times more likely to be successful; white men older than 65 are at greatest risk. Most persons who commit suicide see their primary care physicians within 1 month of their deaths. Suicide risk factors include psychosis, lack of social support, no spouse, chronic medical illness, substance abuse (particularly alcohol), and an organized plan with little chance of rescue.

ETIOLOGY AND PATHOGENESIS

Family, twin, and adoption studies have consistently found rates of mood disorders to be two to three times higher and 10 times higher in first-degree relatives of unipolar depressed and bipolar patients, respectively. While no cause for these disorders is known, several biologic theories have been postulated: excessive activity of the hypothalamic-pituitary-adrenal axis, disturbed functioning of catecholamines, sleep and circadian rhythm disruptions, and left frontal hypometabolism in depression. Whether the relationship between mood disorders and comorbid psychiatric conditions is causal or secondary remains to be determined.

CLINICAL AND LABORATORY FINDINGS

Four questions are useful in screening for depression and the possibility of suicide:

Has there ever been a period of 2 weeks or more when you

- had trouble falling or staying asleep, woke up too early, or slept too much?
- felt sad, depressed, or lost interest in things you usually care about or enjoy?
- felt worthless, sinful, or guilty?
- felt that life was hopeless?

An affirmative response to any question is followed by a diagnostic clinical interview.

Major depression is characterized by at least 2 weeks of either a sad mood or loss of interest. Moreover, the patient must have four of the following symptoms (remembered with the mnemonic SIG E CAPS): sleep disturbance, classically early morning awakening; loss of interest; feelings of guilt or worthlessness; energy loss; impaired concentration; appetite change, usually decreased; psychomotor agitation or retardation; and suicidal or death wishes. Depressed patients may report irritability, deny sadness, or have vague somatic symptoms. They may also be more anxious than sad, but when the cited symptoms are sought, the symptom criteria for major depression are met.

Major depression can be subcategorized into the following classifications: depression manifesting as atypical hypersomnia, appetite increase, hypersensitivity to

rejection, and mood reactivity; depression with psychosis (presence of auditory hallucinations and delusions); postpartum depression (within 4 weeks of delivery, possibly accompanied by psychotic delusions involving the newborn that could lead to infanticide, severe anxiety, initial insomnia, and disinterest in the child); and pseudodementia, represented by abrupt cognitive decline associated with depressive symptoms, primarily in older patients.

Dysthymic disorder is similar to major depression, but symptoms are less severe and are intermittently present for 2 or more years. Approximately one-third of patients with dysthymic disorder experience a superimposed major depressive episode, known as double depression. In adjustment disorder, depressive or anxiety symptoms develop following an identifiable precipitating stressor. These symptoms impair functionality but typically disappear when the stressor is gone.

Bipolar I disorder is characterized by one or more manic episodes. These episodes consist of an elevated, expansive, or irritable mood and three or four of the following features: grandiosity, decreased sleep, excessive talking, racing thoughts, distractibility, or excessive involvement in pleasurable activities that have a high potential for negative consequences (for example, spending sprees). Rapid-cycling patients will experience four or more mood swings in 1 year, are likely to be female (4:1), and have a poorer prognosis. Patients with bipolar II disorder experience major depression and at least one lifetime hypomanic episode (similar symptoms to mania but without marked functional impairment). Bipolar II patients are more likely to be female and have a higher risk of recurrence in the postpartum period.

Seasonal affective disorder (SAD) is characterized by development of depressive symptoms in fall or winter, with a return to baseline or even hypomanic symptoms in spring and summer. SAD shares features with atypical depression (carbohydrate craving with increased appetite, excessive sleep, and hypersensitivity to rejection), is more common in females, and responds to light therapy (2 to 6 hours per day).

When there is clinical evidence that a mood disturbance is due to the physiologic effect of a medical condition, a diagnosis of "mood disorder due to general medical condition" is made. Medical conditions associated with mood disorders and suicide include Parkinson's disease, Huntington's chorea, multiple sclerosis, Alzheimer's disease, hepatitis, pancreatic cancer, HIV, the belief that one has cancer, and pain.

No laboratory tests exist to confirm the diagnosis of any affective disorder. Laboratory abnormalities that have been reported lack sensitivity and specificity. Sleep studies show frequent awakenings with decreased total sleep time in patients with mania. In depression, patients exhibit less stage 4 sleep, diminished rapid eye movement (REM) latency, increased REM density in the first half of sleep, and overall increased REM time. Low levels of serotonin and its metabolite, 5-hydroxyindoleacetic acid, are consistently reported in the brain stem and cerebrospinal fluid of patients who commit suicide.

OPTIMAL MANAGEMENT

The goals of treatment are elimination of disabling symptoms, restoration of functioning, and prevention of relapse/recurrence. Suicidal risk must be assessed in all affective disorders. Antidepressants are equally effective, with response rates averaging 70%. The choice of antidepressant drug is based on history (previous response by patient or blood relative), side-effect profile, or potential drug–drug interactions. The selective serotonin reuptake inhibitors (SSRIs) are currently the first-line choice for most patients. Patients must be informed that antidepressants are not immediately effective and require daily intake for at least 2 to 3 weeks before symptoms improve. [Table 39.2](#) lists dosage ranges for the newer antidepressants and how they affect the cytochrome P450 isoenzyme system.

Drug	Start Dose (mg)	Max Daily Dose (mg)	Cytochrome P450 Inhibited ^a			
			1A2	2C	2D6	3A4
Fluoxetine	20	40	W	M	S	W
Sertraline	50	200	W	M	S	W
Paroxetine	20	40	W	W	S	W
Fluvoxamine	25	300	S	S	W	S
Mirtazapine	15	45	0	0	W	0
Bupropion	150	450	0	0	0	0
Venlafaxine	75	375	0	0	W	0
Citalopram	20	40	W	0	W	0
Nefazodone	50-300	600	0	0	W	S

W, no data; 0, no or negligible inhibition; W, weak inhibitor; M, moderate inhibitor; S, significant inhibitor.
^a Examples of drugs metabolized by P450 isoenzymes: 1A2—antiarrhythmics, theophylline, tacrolimus; 2C—phenytoin, mefenamic acid, imipramine, 2D6—β-blockers, cocaine, 1C—antibiotics; 3A4—carbamazepine, lidocaine, terfenadine, erythromycin, quinidine, amoxicillin, clozapine.

TABLE 39.2. DOSAGE RANGES FOR NEWER ANTIDEPRESSANTS AND THEIR INHIBITORY EFFECTS ON CYTOCHROME P450 HEPATIC ISOENZYMES

For patients who have not responded to maximum dosages after 4 to 6 weeks, treatment alternatives include augmentation with lithium or thyroid hormone, change to a different agent, consultation with a psychiatrist, or electroconvulsive therapy, which remains the most effective treatment for major depression. Once a patient's symptoms have responded to treatment, antidepressants should be continued for 4 to 9 months at the same dose. Maintenance treatment for several years or longer is indicated for patients with age at onset younger than 20 years and a family history of bipolar disease, two previous severe episodes with early recurrence, or three or more previous depressive episodes.

Pharmacologic treatments for bipolar disorder include lithium carbonate, sodium valproate, and carbamazepine. Gabapentin and lamotrigine also have mood-stabilizing properties. Psychiatric consultations are helpful for patients who may need psychiatric hospitalization, who are potentially suicidal, or who are experiencing psychotic symptoms.

ANXIETY DISORDERS

INCIDENCE AND EPIDEMIOLOGY

Anxiety disorders have a high prevalence in medical inpatients (5% to 20%) and outpatients (4% to 14%). Females are two times more likely to suffer from all anxiety disorders except obsessive-compulsive disorder (OCD), for which the risk is the same for men and women. The onset of anxiety disorders, particularly social and simple phobias, is in adolescence, and in those individuals with comorbid depression, it precedes the onset of depression. One-fourth of patients with any anxiety disorder will also have a mood disorder, and 15% will have a substance use disorder. The highest prevalence rates for substance use disorders, however, are among patients with panic disorder (36%) and OCD (33%).

ETIOLOGY AND PATHOGENESIS

Biologic theories postulate excessive or inappropriate autonomic discharges, particularly in the locus coeruleus, a noradrenergic center in the brain. Learning theory explains anxiety disorders as learned through identification and imitation of societal patterns or as a conditioned response to a stressful situation. Family studies have found fivefold higher prevalence rates of anxiety disorders among affected first-degree relatives of patients with panic, generalized anxiety disorder (GAD), and OCD. Twin studies have found 80% to 90% and 10% to 15% concordance for GAD in monozygotic and dizygotic twins, respectively. There are several medical conditions and drugs that can mimic or produce anxiety symptoms, including hyperthyroidism, hypoglycemia, mitral valve prolapse, carcinoid, Cushing's disease, pheochromocytoma, caffeine use, cocaine use, and alcohol withdrawal.

CLINICAL AND LABORATORY FINDINGS

Panic disorder is characterized by the sudden onset of a discrete episode of intense fear that occurs out of the blue. The symptoms peak within 10 minutes of onset and include at least four of the following symptoms: dizziness, tachycardia, dyspnea, sweating, trembling, choking, nausea/abdominal discomfort, depersonalization, paresthesias, flushes or chills, chest pain/discomfort, and fear of dying/going crazy or losing control. The attacks are recurrent, may awaken the person from sleep, and are associated with anticipatory anxiety regarding another attack. Patients frequently go to emergency rooms. Approximately 40% will also experience agoraphobia, an avoidance of situations where escape may be difficult or where help may not be available in case of a panic attack. Travel may be severely restricted to the point of being housebound, or patients may leave home only with a companion. A typical panic attack can be induced in 50% to 75% of panic patients, but not in normal controls, with intravenous infusions of sodium lactate. In the case of social phobia, the person is afraid that he or she will do or say something that will cause

humiliation or embarrassment and thus avoids social situations.

GAD is marked by insidious onset of daily, persistent, and excessive worry that is unrealistic. Symptoms fluctuate over the course of years. GAD is associated with motor tension, restlessness, fatigability, autonomic hyperactivity, vague somatic symptoms, irritability, difficulty sleeping/concentrating, exaggerated startle response, and feeling on edge.

Patients with OCD experience recurrent intrusive thoughts (obsessions) and actions (compulsions) that are repetitive, purposeful, and need to be performed according to set rules or in a stereotyped fashion. These thoughts and behaviors cause marked distress, are time-consuming, and significantly interfere with an individual's routine.

Posttraumatic stress disorder results from exposure to an event that is outside the range of usual human experience and is typically life threatening. The event is reexperienced through recurrent dreams, flashbacks, intrusive memories, and so-called anniversary reactions. Thoughts or feelings associated with the trauma or reminders of them are avoided. Patients experience emotional numbing and distancing from relatives and friends and persistent symptoms of arousal, including insomnia, startle response, irritability, and hypervigilance.

OPTIMAL MANAGEMENT

Other psychiatric disorders, such as depression, must be ruled out. Anxiety symptoms that stem from a medical illness often improve when the medical illness is treated. Similarly, eliminating caffeine or making medication adjustments can improve associated anxiety symptoms. Panic disorder responds to SSRIs, tricyclic antidepressants, or monoamine oxidase inhibitors and, for immediate symptom relief, alprazolam. Cognitive-behavioral psychotherapy has been found to be effective, particularly in those panic patients who may not want to take medication. Social phobia responds to antidepressants—chiefly monoamine oxidase inhibitors—and b-blockers. OCD symptoms respond best to a combination of cognitive-behavioral psychotherapy and clomipramine or SSRIs. GAD responds to supportive psychotherapy and relaxation techniques. Short-half-life benzodiazepines are helpful for brief durations, and antidepressants are indicated for comorbid depressive symptoms. Posttraumatic stress disorder may be difficult to treat. A psychiatric consultation is often helpful in defining comorbid conditions, in initiating administration of an appropriate pharmacologic agent, and in providing psychotherapy.

SCHIZOPHRENIA

INCIDENCE AND EPIDEMIOLOGY

Two million Americans suffer from schizophrenia. Higher incidence rates occur in winter and early spring. The prevalence, severity, and morbidity are greater in urban areas and industrialized nations and in lower socioeconomic groups (downward drift). Age at onset is in the teens or early twenties—50% of patients show initial signs before age 25. The odds of these patients having an alcohol or substance abuse disorder is almost five times higher than for the general population. Approximately 47% of schizophrenics will meet criteria for substance abuse/dependence (33.7% alcohol and 27.5% another drug).

ETIOLOGY AND PATHOGENESIS

No etiologic factor has been identified. Genetic studies indicate a ten- to 12-fold higher risk of schizophrenia in first-degree relatives, with monozygotic concordance of 45% to 50%. Many schizophrenic symptoms are associated with excessive dopaminergic activity. High levels of expressed emotion in the families of schizophrenic patients is associated with higher relapse rates.

CLINICAL AND LABORATORY FINDINGS

The prodromal and residual phases of the illness are similar and are marked by social withdrawal, peculiar behavior (such as hoarding), poor personal hygiene, marked lack of initiative, vague/digressive speech, and magical thinking. The active phase consists of grossly impaired functioning with psychotic symptoms (auditory hallucinations and bizarre delusions), incoherent speech, thought disorganization, and flat or grossly inappropriate affect. Schizophrenia may be further categorized by subtype based on predominant symptoms. *Catatonia* is characterized by elective mutism, stupor, negativism, rigidity, or excitability that can lead to exhaustion and death. *Paranoia* has a later onset, the best prognosis, and the highest functioning of the subtypes; delusions are prominent. *Disorganized* schizophrenia is marked by a flat/silly affect, loose associations, and no systematized delusions. The *undifferentiated* type is represented by delusions, hallucinations, and disorganized behavior not meeting the criteria of the other subtypes. Symptoms can be characterized as positive (delusions, hallucinations, hostility) or negative (apathy, inattentiveness, ambivalence, flat affect). Negative symptoms are associated with a poorer prognosis, enlarged lateral ventricles, and cortical atrophy (frontal) on computed tomography scan and with soft neurologic signs, including frontal release and dysidiadochokinesia.

OPTIMAL MANAGEMENT

Owing to the severity of symptoms and impairment that may require psychiatric hospitalization, acute phases of schizophrenia are best managed by psychiatrists. A significant proportion of noncompliant patients will benefit from intramuscular long-acting depot neuroleptics, either haloperidol (50 to 100 mg every 4 weeks) or fluphenazine decanoate (12.5 to 25 mg every 2 to 3 weeks). The new, "atypical" antipsychotics clozapine, risperidone, olanzapine, and quetiapine improve positive and negative symptoms and cause fewer extrapyramidal side effects. Clozapine can cause agranulocytosis in 1% to 2% of patients and requires weekly complete blood counts for the first 6 months and biweekly counts thereafter. Comorbid substance abuse disorders complicate treatment but need to be addressed.

CHAPTER 40: CARE OF THE DYING PATIENT

JOANNE LYNN AND BETTY FERRELL

[Prognosis and the Timing of Palliation](#)
[Promises to Patients](#)
[Common Problems at the End of Life](#)
[Perspective](#)

All of us, physician and patient alike, will die. Even with optimal medical care, most of the illnesses described in this text will contribute to patients' deaths. Just a few generations ago, people died rapidly—of infections, accidents, and untreatable illness. Now, most people will die of heart and lung failure, malignancy, stroke, dementia, or the multifaceted frailty associated with advanced age. These conditions often allow both a full and meaningful life, despite disabilities, and a meaningful closure to life, if patients and families receive competent care and impending death is accepted rather than denied. Indeed, patients, families, and caregivers are all discovering extraordinary opportunities for human growth and activity at the end of life, which are denied to those who experience sudden, unpredicted death, and they are adopting new patterns of practice to encourage comfort and life completion during advanced illness.

PROGNOSIS AND THE TIMING OF PALLIATION

Patients, family members, hospice programs, and insurers expect physicians to predict the survival of seriously ill patients. Many people feel that life span is indefinite and that death is largely irrelevant until one becomes a “dying” person, and they look to physicians to declare that status at the right time. Once a person is declared to be dying, social practices allow farewells, attention to spiritual issues, and emphasis on symptom control. Before that designation, these matters are largely avoided.

This view of how physicians can provide prognoses is seriously misleading. Some people, especially those with cancer, do have a distinct terminal phase of decline at the end of life, when they lose weight, restrict food intake, spend most of the time in bed, and predictably die within a few weeks. Similarly, a rapid and obvious decline allows identification and then overt labeling of intensive care patients whose organ systems are going to be overwhelmed within a few hours. Most people with serious chronic illness, however, have a quite ambiguous prognosis until near the very end. Within a week of death, the most accurate statement possible is usually that the patient is likely to live for at least a few months. The most common course is rather rapid death in the context of serious, established chronic disease. ([Fig. 40.1](#)).

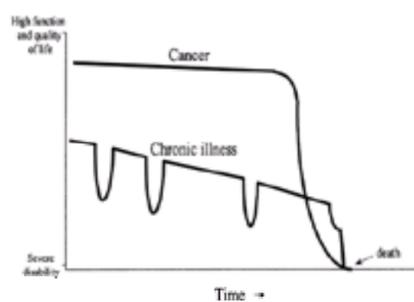

FIGURE 40.1. The time course of the end of life with cancer, in which a “terminal” phase is often evident, and with chronic illness with periodic exacerbations, in which death often seems sudden and its timing unpredictable.

Clinicians would do well to help patients and families prepare for the dying that they are likely to face. Most will not be served best by a transition model, with a shift from a focus on life prolongation to a focus on living comfortably, which is only declared at the time when the final decline becomes evident. Instead, a combination of palliative measures and life-prolonging measures will best serve most patients. This approach requires thoughtful engagement of a physician and, usually, an interdisciplinary team throughout the course of serious illness. Honest and empathetic communication among all parties concerned allows tailoring of care to the patient's needs and possibilities. One simple way for physicians to identify patients who would benefit from special attention to end-of-life issues is to ask: “Is this patient sick enough that I would not be surprised to find that he or she died in the next few months?” Keeping this question in mind allows earlier identification of patients and families who would benefit from special attention to comfort and to life closure, thereby avoiding the unfortunate tendency to attend to dying only at the brink of death, when little can be done.

PROMISES TO PATIENTS

Discontinuity, overwhelming symptoms, confusion about goals, family exhaustion, and mistrust often undermine quality in care at the end of life. Patients and families need skills and reliability in their professional caregivers—enduring commitment, sensitive understanding, and appropriate treatments. The clinician counseling a person who faces an eventually fatal illness will be most effective when he or she is able to promise that the care system serving the patient will reliably deliver the following services.

1. Medical and nursing care will be of the highest quality, in accord with *evidence-based standards*.
2. *Symptoms* of pain and discomfort will be prevented and treated quickly and will never be overwhelming.
3. *No gaps* in care will arise—services will be comprehensive and continuous.
4. Specific *plans will be made* to limit the impact of likely complications.
5. Patient and family can *customize care* to meet their values, dreams, and fears.
6. The use of *patient and family resources* will be decided collaboratively.
7. All caregivers will aim to help patients *make the most of every day*.

Most clinicians do not work in systems that can deliver on these promises. Pervasive shortcomings precipitate distress for patients and families, both from the experience and the anticipatory anxiety. Dying patients and their families are often exhausted and cannot advocate for their own needs. Clinicians working with the dying must shoulder the obligation to improve the reliability and quality of end-of-life care. Doing so will require collaboration across disciplines and across programs providing care. The burdens of facing the end of life sometimes lead patients and families to consider or to seek help in suicide or euthanasia. Practitioners should develop a thoughtful approach to these issues, consistent with the law and the opportunities for care in their localities as well as their own philosophy and beliefs.

COMMON PROBLEMS AT THE END OF LIFE

PAIN

Pain is often feared but fortunately can be relieved in most situations. Clinicians should understand the nature, precipitants, responses, and meaning of each patient's pain. The clinical pharmacology of analgesia is treated more fully in [Chapter 56](#). Here we note only that patients near death should be assured of pain relief, even if high doses of opioids are needed or if clouded consciousness or sedation is unavoidable. Respiratory depression is uncommon and can usually be avoided by careful titration of medications. Moreover, once a patient is using opioid drugs for a few days, respiratory depression as a result of their use is quite rare. Usually, cancer pain that is worsening requires escalation of doses to 1.5 times the previous stable dose. Neuropathic pain, however, necessitates anticonvulsants or antidepressant medications in addition to opioids. Patients with difficult pain problems should be referred to palliative care or pain specialists, since a number of new medication

regimens and advanced techniques have become available in recent years.

DYSPNEA

Dying from suffocation is a particularly grim passing and should be avoided if at all possible. If a patient faces death from emphysema, ventilator withdrawal, or another condition predisposing to ventilatory failure, the physician and care team must be willing to provide sedation sufficient to assure that the patient does not experience suffocation. This requires using opioids, anesthetic agents, or sedatives. For patients with serious illness who are placed on ventilators, consideration should be given early and often to how to withdraw the ventilator, and protocols for ventilator withdrawal should be clearly understood and rehearsed by staff in those contexts (see [Chapter 390](#)). Patients coming to the end of life often experience chronic dyspnea, and oral opioids typically offer enough relief to allow restful sleep or enjoyment of substantial parts of the day (see [Chapter 351](#)).

DEPRESSION

Clinicians, patients, and family often discount the patient's sadness and fatigue, attributing such symptoms to the fatal illness. Patients who are seriously withdrawn, anhedonic, uncommunicative, hopeless, or sleepless often benefit greatly from antidepressants (see [Chapter 39](#)). Moreover, response comes more quickly and from lower doses than in healthier patients. Amphetamines have rapid onset and elimination, offering advantages when time and therapeutic margins are slim.

INABILITY TO EAT OR DRINK

Patients very near death usually have little appetite. Families can be frightened by this development and feel helpless. They need to understand that reduced intake is natural and does not cause symptoms or distress. Sometimes a small amount of food and drink that has meaning to the patient and family is quite satisfying to all. For some patients, the loss of interest in food or the inability to swallow is part of the eventually fatal condition. This is especially true of dementing illnesses. Tube feeding requires careful consideration. If it is used, plans for discontinuation should be made at initiation and reviewed periodically. Long-term artificial feeding has not been shown to prolong life or improve function in patients with serious chronic illness, including dementia and cancer. The restraints and other complications of nasal routes for tube feeding usually make it necessary to switch to percutaneous gastric routes if artificial feeding is to continue for long. Bowel obstruction in a patient near death usually should not be treated surgically. Ondansetron and other drugs often effectively suppress nausea and emesis, and cramping responds to opioids and other drugs (see [Chapter 96](#) and [Chapter 98](#)).

DELIRIUM

Metabolic abnormalities, altered sleep, hypoxia, and multiple drugs probably contribute to the commonplace occurrence of delirium in dying persons. Occasionally, a meaningful spiritual experience, such as seeing dead family members or hearing the voice of God, has the features of delirium. The best course is usually to observe for any signs of distress or fear rather than to disrupt a spiritual experience for patient and family. Delirium may have features of terror or bewilderment, or a spiritual experience may become anguished in these ways. Often, in these very sick patients, other measures to relieve delirium must be accompanied by administration of a major tranquilizer, such as haloperidol. Very low doses are often sufficient to restore calm and appropriate behavior.

RESUSCITATION

Any patient who is sick enough that death within a year would not be surprising is a patient who deserves the chance to avoid cardiopulmonary resuscitation (CPR). The care system is primed to respond to any cardiopulmonary collapse with CPR, but persons with serious chronic illnesses are exceedingly unlikely to revive, and even "successful" CPR yields substantial additional disabilities. CPR at the end of life virtually guarantees that death will not be peaceful or supportive to family members. Discussion and decision making about the merits of CPR should begin with the onset of serious and eventually fatal illness and should be repeated as long as needed. CPR or the decision against trying CPR often symbolizes hopefulness or an acceptance of dying, respectively. Clinical teams often need to explore those meanings and possible alternatives.

OTHER PHYSICAL SYMPTOMS

The end of life often entails constipation, skin breakdown, muscle aches, dysphagia, fatigue, fevers, and incontinence. The clinical team must institute routines that prevent most of these complications and treat them early and aggressively. Hospice and palliative care services or consultation are valuable resources.

CAREGIVER SUPPORT AND BEREAVEMENT

Care for a dying loved one is simultaneously one of the most exhausting and most rewarding aspects of life. Clinical teams need to support family caregivers with flexible and thoughtful care plans, opportunities for respite, and emotional support. Grieving starts long before death for most illnesses, and the afflicted family often needs emotional and practical support. After death, many will have unresolved fears and misunderstandings as well as their own grief. Clinical teams should routinely communicate with family shortly after the patient's death and again near the anniversary date, to offer condolences, to answer remaining questions, and to evaluate for complicated grief.

HOSPICE, NURSING FACILITY, HOME CARE, AND OTHER SERVICES

The average duration of disability before death is now more than 3 years. Most people will need the support of services at home or will need to move into a nursing facility. Clinical care teams need to be effective in these settings and know how to utilize the patchwork of community resources. Although hospice programs have dramatically different eligibility requirements, their services are always worth considering, since that is one way to find continuity, comprehensiveness, and skilled symptom management in an affordable package.

QUALITY OF CARE

Patients and families need to be able to choose their care providers on the basis of reliable service quality, and providers need to engage in improvement of quality. The growing array of measurement instruments and experience with quality improvement allows for implementation of improved practices and standards.

ISSUES AT THE TIME OF DEATH

The health care team must ensure prompt pronouncement of death and certification of its cause. Families are often quite unfamiliar with the emotional, religious, and administrative issues that confront them at the time of death, and physicians often must make certain that families have support and guidance. Many patients and families are interested in providing organ or tissue donation, and all suitable patients or families should be offered that opportunity. One particularly important quality measure, especially for home care and nursing facility deaths, is routinely examining a reasonable rate of random autopsies, and clinical teams should ensure that autopsy is available.

PERSPECTIVE

Dying is not primarily a physiological failure of a biochemical system; it is the closing of a human life. Reliable, high-quality health care at the end of life would allow us all to focus on issues of meaningfulness, relationships, and the completion of life's goals rather than being overwhelmed by symptoms and bedeviled by fears. Competent health care is an essential prerequisite to comfortable and meaningful living in the shadow of death.

CHAPTER 41: THE CLINICAL APPROACH TO THE PATIENT

JAMES O. WOOLLISCROFT

[Patient's Perspective](#)
[Therapeutic Relationship](#)
[Clinician's Perspective](#)
[Conclusion](#)

The patient–physician interaction is the foundation for clinical medicine. For the physician making a diagnosis, monitoring the progression of chronic disease, determining the patient's response to therapy, or assessing and enhancing the patient's health status, the information obtained during the interview and physical examination is often sufficient for an accurate assessment of the patient in the majority of encounters. If needed, it provides the physician direction for subsequent diagnostic and therapeutic interventions. For the patient and physician, it serves as the basis upon which the therapeutic relationship is built and maintained. It also is the forum where treatment plans are discussed and agreed upon and education of the patient is accomplished.

Because accurate information gathering and its interpretation are essential to clinical function, physicians must consider how the clinical interaction is influenced by the patient's expectations for the encounter, by the perceived intrusion of employers and health plans, by cultural norms, and by similar nonmedical issues. Clinicians sometimes forget that the patient's view of this interaction is quite different. Understanding the underpinnings of the clinical encounter and how to optimize the encounter can enhance clinical acumen.

PATIENT'S PERSPECTIVE

For our patients, the language of medicine is often unfamiliar. Consider traditional expressions of risk or outcome in clinical medicine. Physicians tell patients that a procedure has a “low risk” or that the prognosis carries a “75% 10-year survival rate.” For the patient, however, the risk or chance of survival is 0% or 100%. Asking the patient his or her understanding of what was said or to repeat instructions or plans provides the opportunity to clarify areas of misunderstanding.

Our increasingly heterogeneous population, with physicians and providers coming from different cultural backgrounds, increases the likelihood of serious miscommunication. Too frequently, physicians assume that their culturally based communication norms are universal, but such is not the case. For example, a distance of 3 to 5 feet between the patient and the physician may be a very comfortable and mutually respectful distance for conversing for many Americans, but patients from different cultural backgrounds may interpret this as aloofness or disinterest. Such unintentional violations of cultural communication norms may inhibit or destroy rapport and prevent the development of a therapeutic relationship.

The expectations of the patient for the physician are in large part culturally determined. Unless specific attention is given to these expectations, the physician may unwittingly try to relate to the patient in a manner that the patient finds unacceptable. For example, some Asian, African, and other peoples view diet as very important when they are ill. If the physician does not address diet in his or her therapeutic instructions, the patient may consider the physician incompetent and not heed the advice. Physicians who do not understand the cultural background of their patients may violate norms for physician behavior, leading to a breakdown in the physician–patient relationship.

The patient's interpretation of symptoms and response to illness is also set in a cultural context. Illness may be viewed as an opportunity to atone for past wrongdoing, and the patient may believe that it is good to suffer. Attempts by the physician to intervene and shorten the suffering may be viewed as contrary to God's will. If the patient is from a different cultural background, the physician should strive to learn about their views of illness and healing and tailor the clinical approach accordingly. The potential for misinterpretation and communication problems increases when patient and physician come from different cultural backgrounds. In all clinical encounters, however, it is important to clarify the patient's understanding and perspective, which will enhance the physician's clinical problem-solving abilities as well as the therapeutic value of the patient–physician interaction.

Patients at different stages of life and illness may ask their physicians to play different roles in their care. Patients who have been very active in their care and decision making may ask their physicians to assume greater responsibility for making important care decisions as an illness progresses. These role changes in an ongoing patient–physician relationship are often signaled in subtle ways. We must be alert and respond to such requests, determine that this is the patient's desire, and then respect the request.

THERAPEUTIC RELATIONSHIP

Patients usually visit physicians for diagnosis of a problem, for continuing care of a known condition, for reassurance, to obtain information, and for disease prevention. Studies of patient–physician interactions show that the patient's satisfaction is enhanced if the physician ascertains the patient's expectations for the interaction and explicitly addresses these expectations. Patients' satisfaction is directly correlated with compliance with recommendations and desirable clinical outcomes, including enhanced control of chronic illnesses. Despite studies documenting the effect of physicians' questioning and communication styles on the interview as an information-gathering tool and as a means to establish rapport and enhance the patient's satisfaction, too frequently clinicians do not use optimal communication techniques. Using a nondirective “patient-centered” approach to establish the patient's reason for seeking care or his or her health status since the last visit allows the patient to establish the agenda for the visit. Once this is accomplished, using a more directed “doctor-centered” approach allows the physician to rapidly concentrate on eliciting the data that are pertinent at that particular interaction. Studies show, however, that physicians often do not allow their patients to complete their opening statements of concerns or symptoms and rapidly apply a directive interview style. This truncates the information elicited from the patient and may prevent the clinician from addressing the patient's concerns.

Of equal importance to verbal communication is nonverbal communication. Through nonverbal communication, the patient is communicating to the physician and the physician to the patient such information as expectations for the encounter, roles to be played by the patient and physician, respect, and the relative power of the participants. It behooves the physician to consider actively the communication that is occurring in the nonverbal realm. Are the patient's words consistent with her or his nonverbal language? Are you conveying a congruent verbal and nonverbal message?

The growth of electronic communication has the potential to change rapidly the dynamic of the patient–physician interaction. Electronic communication with patients has the promise of increased access to care, better education of patients, easy monitoring of chronic disease, and reminders to encourage patient's adherence to therapeutic regimens. Issues of confidentiality, fewer in-person opportunities to assess patients, and erosion of the therapeutic value of the relationship are potential negatives. Choosing the appropriate communication mode for different patients and different situations requires data from studies that are just beginning. While the efficiencies gained through increased reliance on electronic communication are apparent, the costs are often hidden.

The ready availability of medical information on the World Wide Web, ranging from peer-reviewed scientific journals to fallacious claims for therapy, is introducing further complexity into the patient–physician encounter. Increasingly, physicians are asked to comment on information that a patient has found on the Web. This can result in an empowered patient partner, but it can also lead to confusion. Careful explanations are required as to why a given finding or therapy is or is not applicable to the patient bringing you the information.

CLINICIAN'S PERSPECTIVE

From the clinician's perspective, the focus during the clinical encounter is problem solving. Physicians generate hypotheses early during a patient–physician interaction, on the basis of limited information. The physician's problem formulation and the accuracy or quality of the initial set of hypotheses largely determines the accuracy of the final diagnosis. If the clinician frames the problem incorrectly at the outset, it is virtually impossible for him or her to arrive at the right answer.

Although most research has focused on diagnosis, clinicians deal with a wide variety of situations. Healthy persons visit physicians for health maintenance

examinations, previously healthy persons come with new signs or symptoms, patients with chronic diseases are seen periodically to monitor disease status and the effect of therapy, and patients with chronic conditions are examined for new signs or symptoms. The expert clinician rapidly switches from one clinical problem to another without consciously recognizing that different issues are addressed and different data are used in the problem-solving process. Patients' data that are potentially important to the physician can be divided into at least three major domains: information required to make a diagnosis, information applied to determine risk of disease, and information to assess the person with the disease.

DIAGNOSIS

When confronted with a patient who has new signs or symptoms, the clinical interaction is designed to elicit information from the patient that facilitates diagnosis and the appropriate diagnostic and therapeutic interventions. Because the clinical approach to diagnosing and treating disease states is the focus for most of this textbook and most teaching and training, I do not consider it further in this chapter.

RISK OF DISEASE

The clinician should consider each patient's risk of disease and whether current diseases, ongoing therapy, or past therapy puts the patient at higher risk of complications or other diseases. The focus for risk determination should be limited to those conditions that it is possible to prevent or those diseases for which early detection methods are available and therapy at an early stage can alter favorably the natural history. The following guidelines provide a framework for risk assessment. The patient's sex and age determine which conditions he or she is most likely to experience. Risks for adolescents are different from risks for the elderly. There are also genetic risks. Are there diseases that run in the patient's family that can be prevented or detected at an early stage? As genetic screening becomes widespread, this will become an increasingly powerful and specific tool. Although environmental risks are usually considered for industrial or work site exposures, they may also be associated with leisure-time activities. Lifestyle and behavioral risks must be assessed. Certain patterns, such as cigarette smoking and alcohol and drug abuse, are independent risk factors that also can magnify environmental risks. Physicians should consider the risk that one disease imposes for the development of other diseases. Is the patient at risk because of current or past therapy? Many therapeutic interventions have side effects that predispose patients to further problems. Appropriate monitoring may reduce this risk.

PERSON WITH THE DISEASE

The third information domain defines the person with the disease. What are the unique attributes of your patient? This question encompasses psychological and social components, including their life experiences, spiritual dimensions, and social support systems. Studies are increasingly emphasizing the importance of this domain to patients. Many physicians, however, infrequently consider this information.

CONCLUSION

A broad knowledge base is insufficient to function as a physician. It is necessary to have the ability to obtain appropriate information from the patient to guide the application of knowledge to each patient's situation. The patient-physician interaction is arguably the most important diagnostic and therapeutic tool clinicians possess, and the approach to the patient can enhance or hinder this tool. Physicians must periodically assess their performances to ensure that the desired outcomes for each patient interaction are being achieved.

CHAPTER 42: PRINCIPLES OF CLINICAL EPIDEMIOLOGY

JAY M. SOSENKO

[Types of Studies](#)
[Epidemiologic Measures](#)
[Bias](#)
[Confounding](#)
[Diagnostic Test Interpretation](#)

This chapter is designed to familiarize the reader with certain aspects of clinical epidemiology. Although the field of clinical epidemiology cannot be fully covered here, selected topics are presented that are relevant to research, clinical practice, and the assessment of the medical literature. The reader who desires a broader discussion of clinical epidemiology or more in-depth information regarding the topics presented is referred to texts on epidemiology and clinical epidemiology in the bibliography.

Clinical epidemiology involves applying epidemiologic methods to the investigation of aspects of clinical medicine. Whereas the overall field of epidemiology commonly studies the general population for factors that affect disease occurrence, research in clinical epidemiology pertains mostly to patients. The clinical epidemiologist may also study disease etiology and prevention, but there is an emphasis on matters concerning the care of patients, including treatment response, cost-effectiveness analysis, and quality of life. Investigations of such patient care outcomes is commonly termed outcomes research. Clinical epidemiology, including outcomes research, uses standard epidemiologic methodology and study designs, which are discussed herein.

TYPES OF STUDIES

CLINICAL TRIALS

In these studies, an intervention—usually a potential treatment or preventive measure—is tested on research participants. Typically, an intervention group (or groups) is compared with a control group that does not receive the intervention, to assess therapeutic benefits and adverse effects. Although the randomization of participants into groups is common to many clinical trials, they may vary greatly in design, including such considerations as placebo use, the number of interventions studied, whether participants and investigators are “blinded” (single-blind vs. double-blind), and whether participants remain on the same arm (parallel design) or are changed to another arm (crossover design) during the course of the study.

OBSERVATIONAL STUDIES

These studies differ from clinical trials in that there are no interventions (treatments) administered to the research participants. Observational studies are particularly useful for examining factors potentially causal to certain diseases, since clinical trials are generally not appropriate for such research. Cohort studies and case-control studies are the two most common types of observational studies.

Cohort studies are based on a design in which the occurrence of a condition is ascertained in a group of individuals exposed to a potential causal factor (exposure) and in a group not exposed to that factor. Prospective (current) cohort studies are those in which the development of the condition occurs after the initiation of the study, while retrospective (historical) cohort studies are those in which the development of the condition occurs before the onset of the study. Prospective cohort studies tend to be performed outside the clinical setting, whereas data for retrospective cohort studies are often derived from clinic and hospital records and also from registries. A study that is designed to follow cigarette smokers and nonsmokers prospectively to compare them for the development of lung cancer is an example of a prospective cohort study, while a study that uses a review of medical records to compare outcomes of different treatments that were administered for lung cancer is an example of a retrospective cohort study.

Case-control studies differ from cohort studies in that the basic design is the measurement of frequencies of exposure in groups with and without a condition. A study that examines the association between lung cancer and cigarette smoking by ascertaining the cigarette smoking history in individuals with (cases) and without (controls) lung cancer is an example of a case-control study. Despite the different designs of cohort and case-control studies, they usually have the same basic purpose—to estimate the association between disease and exposure.

Case-control studies tend to be more applicable to the clinical setting than prospective cohort studies, and they are especially helpful in investigating rare diseases or conditions for which prospective cohort studies would require the long-term follow-up of large numbers of participants. The case-control study design can circumvent this problem, since sufficient numbers of patients with and without a particular condition are often available. For example, a case-control study might be used to examine potential risk factors for rare forms of cancer, such as the case-control study that showed the association between vaginal adenocarcinoma in young women and maternal diethylstilbestrol use.

EPIDEMIOLOGIC MEASURES

The measures discussed here apply to dichotomous outcomes (e.g., the presence or absence of a condition), which are common in observational studies. Clinical trial outcomes may also be dichotomous, but they are often continuous (e.g., cholesterol or blood pressure responses).

INCIDENCE RATE

This is a basic epidemiologic measure that indicates the number of new cases of a condition over the total amount of time that a given population is under observation for the development of that condition. Using a hypothetical example, if 1,000 cigarette smokers are followed for an aggregate duration of 10,000 years for the occurrence of a first myocardial infarction and 20 show signs of that condition, the incidence rate is 20 myocardial infarctions per 10,000 person-years. If 1,000 nonsmokers are followed for the same duration and 10 have myocardial infarctions, the incidence rate is 10 myocardial infarctions per 10,000 person-years.

PREVALENCE RATE

This is the number of existing cases of a condition among a given population at a particular point in time. The prevalence rate is thus a proportion, and it is greater in conditions of either higher incidence or longer duration. If there are 100 individuals with a condition among a population of 100,000, the prevalence rate is 0.001.

RISK

Also termed cumulative incidence, this is the number of new cases of a condition among those who are followed for the development of that condition over a defined period of observation. If 1,000 cigarette smokers are followed for a period of 10 years for the occurrence of a first myocardial infarction and 20 show signs of that condition, the risk is 0.02. If 10 of 1,000 nonsmokers have a first myocardial infarction over 10 years of follow-up, the risk is 0.01. Note that as a proportion, risk has no units; however, it is still a function of the duration of follow-up.

RELATIVE RISK

As discussed earlier, epidemiologic studies are designed to examine the association between a condition and an exposure, such as myocardial infarction and cigarette smoking. Thus, epidemiologic measures have been developed to show the extent of association between a condition and an exposure. The relative risk is a measure used for this purpose. It is the ratio of the risk for those exposed over the risk for those not exposed. The relative risk for the risk data presented above is 2.0. This means that the cigarette smokers had twice the risk of myocardial infarction of nonsmokers. If there had been no difference in the risk between cigarette smokers and nonsmokers, the relative risk would have been 1.0. If those exposed had a lower risk than those not exposed, the relative risk would have been less than 1.0.

RISK DIFFERENCE

Consider a study that assessed the association between another condition and exposure instead of myocardial infarction and cigarette smoking, and the risks for the exposed and nonexposed were 0.2 and 0.1, respectively. The relative risk would be 2.0, the same as that for the myocardial infarction/cigarette smoking example. It is evident, however, that the difference in the risk for the myocardial infarction/cigarette smoking example ($0.02 - 0.01 = 0.01$) is much lower than the difference in the risk for the other example ($0.2 - 0.1 = 0.1$). Thus, another measure, the risk difference, provides an added perspective. The magnitude of the risk difference can have public health implications and can be used to make health policy decisions.

ODDS RATIO

The relative risk cannot be directly obtained from a case-control study. In that study design, participants are not followed over time, which is necessary to measure risk. Since the purpose of performing case-control studies is to examine the association between a condition and an exposure, a measure of association other than the relative risk must be used. This measure is the odds ratio. It can be calculated as the ratio of the exposure odds in the cases over the exposure odds in the controls (Table 42.1). The odds ratios obtained from case-control studies can closely approximate the relative risk, particularly if a condition is rare. Thus, through the calculation of the odds ratio, case-control studies can also be used to obtain a measure of association between a condition and an exposure.

	Cases	Controls	
Exposed	20	10	
Not Exposed	180	190	
Total	200	200	
Odds Ratio	$\frac{20}{180}$	$\frac{10}{190}$	$= \frac{(20)(190)}{(10)(180)} = 2.11$

TABLE 42.1. AN EXAMPLE OF THE CALCULATION OF THE ODDS RATIO FROM A CASE-CONTROL STUDY

HYPOTHESIS TESTING

The epidemiologic measures discussed here are not in themselves indicative of statistical significance. Even though a relative risk of 4.0 (a fourfold risk in those exposed) suggests that there is truly an association between a condition and an exposure, one cannot presume that such a result is statistically significant. An observed relative risk can be assessed for statistical significance by first assuming the null hypothesis (no association between a condition and an exposure, a relative risk of 1.0) and then determining the degree of inconsistency (extent of association) between the observed relative risk that was obtained and the null hypothesis. The greater the degree of inconsistency between the relative risk and the null hypothesis, the lower the probability that the null hypothesis is correct (the higher the probability that the condition and exposure are related).

The p value provides a measure of the degree of inconsistency between the null hypothesis and the relative risk. Put more formally, the p value is indicative of the probability that the relative risk is at least as great as that which would have resulted by chance alone, if it is assumed that there is truly no association. If the p value for the relative risk is below a predetermined level, the null hypothesis is rejected, and the result is considered statistically significant. Most studies use a p value of 0.05 as the cutoff for statistical significance. Thus, if a relative risk of 2.0 corresponds to a p value of 0.05, a relative risk that is greater than 2.0 (even further from the 1.0 null value) would be statistically significant at $p < 0.05$. Although the relative risk has been used as an example, this discussion applies to other measures as well.

CONFIDENCE INTERVALS

The confidence interval provides information with regard to both the magnitude of the epidemiologic measures obtained and the significance testing. It is indicative of the range that contains the true magnitude of a measure with a certain level of assurance. For example, if a relative risk of 3.0 has a 95% confidence interval of 1.3–8.5, there is 95% assurance that the true relative risk is somewhere between 1.3 and 8.5. Besides providing information about the range that contains the true relative risk, the confidence interval also indicates whether a measure is statistically significant. In the example cited previously, the relative risk is statistically significant when 0.05 is the designated cutoff for a p value, since the confidence interval does not cover the value of 1.00 (expected, assuming the null hypothesis).

BIAS

In assessing the results of a study, it is insufficient to consider only the epidemiologic measure and its associated p value, since these may have little meaning if a study is biased. Bias occurs when there is a systematic error in the design or conduct of a study that results in a mistaken estimation of the effect of an exposure. Observational studies are generally more subject to bias than are clinical trials, since the latter are undertaken under more controlled conditions. Among observational studies, case-control and retrospective cohort studies may be particularly subject to bias, since they are often dependent on data previously obtained for clinical rather than research purposes. Although prospective cohort studies are still subject to bias, the more standardized manner of data ascertainment for these studies tends to lessen the likelihood. Still, appreciable bias can be found in these studies when there are differences in exposure and outcome between those who remain in the study and those who are lost to follow-up.

Case-control studies may be dependent on the recall of study participants, which can be faulty. Moreover, case-control studies can be biased if the control group is not selected with care. For instance, consider the example of the case-control study presented earlier. If the control group of patients without lung cancer comprises a number of patients with chronic obstructive pulmonary disease (COPD), there may be an underestimation of the actual association between lung cancer and cigarette smoking. This is because cigarette smokers would be overrepresented in the control group. The faulty recall of study participants can lead to recall bias, while the injudicious selection of a control group can lead to selection bias. A number of other kinds of bias (referral, interviewer) can affect studies.

CONFOUNDING

Consider a study examining the relationship between COPD and alcohol intake. One might incorrectly conclude from the data that there is an association between COPD and alcohol intake if there is not an allowance made for cigarette smoking in the analysis of the data. This is because cigarette smoking is a known cause of COPD and it is associated with alcohol use. In this example, cigarette smoking can be viewed as a confounder, since it satisfies two basic conditions: it is a risk factor for a condition under study, independent of the exposure under study, and it is associated with that exposure. Confounding does not always lead to an overestimation of association between a condition and an exposure, in that it can also have the opposite effect and obscure an association which is actually present.

DIAGNOSTIC TEST INTERPRETATION

Diagnostic test interpretation constitutes a field of clinical epidemiology that is applicable to both research and clinical practice. The terms that are commonly used are defined diagrammatically in Table 42.2. The sensitivity of a test indicates the number of those who test positive among those who have the condition. The false negative rate is equivalent to $1 - \text{sensitivity}$. The specificity of a test indicates the number of those who test negative among those who do not have the condition. The false positive rate is equivalent to $1 - \text{specificity}$.

	Test	Condition	
		+	-
		+ TP	FP
		- FN	TN
Sensitivity = TP/(FN + TP)			
Specificity = TN/(FP + TN)			
FN Rate = FN/(TP + FN)			
FP Rate = FP/(FP + TN)			
Positive Predictive Value = TP/(TP + FP)			
Negative Predictive Value = TN/(FN + TN)			

TP, true-positives; FP, false-positives; FN, false-negatives; TN, true-negatives.

TABLE 42.2. DEFINITIONS OF MEASURES USED FOR THE INTERPRETATION OF DIAGNOSTIC TESTS

In tests with a quantitative result, such as the degree of ST depression in an exercise stress test, the cutoff for test positivity is arbitrary. The values for cutoffs associated with a higher test sensitivity are associated with a lower test specificity and a higher false-positive rate. Thus, a less stringent criterion for test positivity is associated with a higher sensitivity and a higher false-positive rate. Receiver–operator curves are used to show graphically how the sensitivity and false-positive rate vary with cutoff values for tests.

The positive predictive value indicates the number of those who have the condition among those who test positive. The negative predictive value indicates the number of those who do not have the condition among those who test negative. Predictive values vary according to the pretest likelihood that a condition is present in those tested. For a given sensitivity and specificity, a higher pretest likelihood of a condition results in a higher positive predictive value and a lower negative predictive value. Bayes' theorem formulates the relationships of the positive predictive value with test characteristics and the probability of disease. This equation is a useful expression of Bayes' theorem:

$$\text{Positive Predictive Value} = \frac{(\text{Sensitivity})(\text{Probability of Disease})}{(\text{Sensitivity})(\text{Probability of Disease}) + (\text{False Positive Rate})(\text{Probability of No Disease})}$$

CHAPTER 43: EVIDENCE-BASED MEDICINE

MARK T. O'CONNELL

[Identifying a Knowledge Gap and Formulating a Question](#)
[Locating Evidence](#)
[Critical Appraisal and Application of Medical Evidence](#)
[Critical Appraisal of our Clinical Practice Outcomes](#)
[How Can Physicians Assimilate Evidence-Based Medicine into their Professional Practices and Values?](#)

It is conservatively estimated that over 100,000 people die annually in the United States as a result of negligent or inappropriate medical care. This is equivalent to three 747 airliner crashes every 2 days! Yet, society and the health care system have been slow to respond to this alarming lack of quality control in the world's most expensive health care delivery system. The payers and consumers of health care have predictably, if not belatedly, begun to demand that the policies, systems, and outcomes of health care be continuously measured, analyzed, monitored, and modified so that the quality of care received is explicitly determined and continuously improved. Still, by some current studies as little as less than 30% of medical care is based on valid conclusive evidence that this care is effective or sometimes even necessary.

The evidence-based medicine (EBM) paradigm claims that whenever possible, health care decisions should be based primarily on systematically collected data and the valid conclusions that follow from those data. "Best evidence" is being used to justify the rationing of limited resources. Medical evidence is driving the development of clinical pathways and guidelines for care, which are de facto defining "standards of care." Physician behaviors and economic livelihoods are likely to be increasingly affected by the evidence collected and reported about individual and physician group practice patterns, disease-specific outcomes, and resource expenditures.

The nation is calling for accountability from the health care system. At the same time, society is turning to alternative sources of health care, without any significant evidence of effectiveness or value. This paradox reflects a growing general dissatisfaction with our health care system. The tenets of EBM will help to ensure that true quality and value are fundamental characteristics of the American medical care system. Physicians must understand the principles of EBM to efficiently develop valid evidence, accurately interpret this evidence, and optimally apply it to formulating health care policy and providing superior patient care.

Why is this EBM movement gaining momentum and moving to center stage at this time? In part, EBM is an outgrowth of many contemporary factors. As just described, society has recently begun to demand demonstrated value and quality for the expensive health care that it finances and depends on. There is also a relatively new source of evidence in the clinical biomedical literature, in the form of randomized controlled clinical trials. The randomized clinical trial (RCT) is regarded as the optimal study design for determining the effectiveness of treatments and other interventions ([Chapter 42](#)). The first RCTs appeared in the medical literature in the 1950s, but 85% of those published have appeared in the literature within the past 5 years. The techniques of meta-analysis have been significantly refined in the past 5 years, bringing vast amounts of previously weak evidence into a more valid context. The computer revolution has delivered this incredibly robust collection of biomedical evidence into the hands of its primary consumers: physicians, patients, and policy makers.

MEDLINE, with its bibliographic citations, and the rapidly growing collections of full-text on-line periodicals, textbooks, and browsable databases of real world clinical data have brought potentially useful medical evidence to those who need it. Just-in-time knowledge servers are becoming part of modern clinical information systems, providing decision makers with context-sensitive previously validated evidence, often in a seamless fashion at the very point of clinical decision making as medical care is being delivered.

EBM has an extremely important personal context for physicians. The EBM paradigm presents a value system that endorses empirical data-driven behavior and moves away from the traditional emphasis on authority and personal opinion and experiences. The EBM paradigm also promotes values, behaviors, and skills that are axiomatic to effective lifelong adult learning. Although EBM includes a set of values and promotes specific attitudes and consequent behaviors, effective practice of EBM requires mastery of an explicit knowledge domain and skills set. EBM, in this sense, can be described as a five-step process: (1) identify a gap in knowledge; (2) formulate an explicit question to define the information needed; (3) locate the best evidence that answers the question; (4) appraise this evidence for its relevance to clinical practice; and (5) evaluate the outcomes of clinical practice ([Table 43.1](#)).

1. Identify a gap in knowledge
2. Formulate an explicit, structured question
3. Search for the best evidence to answer the question
4. Critically appraise the evidence for validity and clinical applicability
5. Evaluate the outcomes of evidence-based practices

(From Sackett DL, et al. *Evidence-based medicine: how to practice and teach EBM*. New York: Churchill Livingstone, 1997, with permission.)

TABLE 43.1. EVIDENCE-BASED MEDICINE: A FIVE-STEP PROCESS

IDENTIFYING A KNOWLEDGE GAP AND FORMULATING A QUESTION

Many studies have shown that physicians frequently encounter gaps in their knowledge while delivering routine care to their patient. In a typical 4-hour clinic session, the busy generalist physician generates over 15 unanswered questions whose answers would have a direct bearing on patient management. Three to four of these questions address significant issues in the diagnostic or therapeutic decisions for these patients. Still, only 20% of these significant questions are ever answered. Physicians continue to practice in the face of missing information, basing decisions on experience and tradition and not on data or evidence.

Yet, many of these clinical questions can be answered, with information contained in the geometrically expanding medical knowledge base. A question that is well stated has a greater likelihood of being well answered. The EBM working group has explicitly stratified clinical questions into eight categories and proposes that a well-formulated question will fit into one of these categories. Understanding the category and structural component of well-formulated questions has been shown to lead to a more efficient strategy in finding the best clinical evidence to answer these questions ([Table 43.2](#)).

Questions About
Identifying and interpreting a clinical finding
Identifying causes of disease
Formulating a differential diagnosis
Selecting and interpreting a diagnostic test
Estimating a prognosis
Selecting a treatment
Screening and preventing a disease
Professional improvement

Elements of Questions
Patient or clinical problem
what kind of patient or problem?
Questioned intervention
which test, treatment, exposure?
Comparison intervention
compared with what test, treatment, or exposure?
Outcome
what endpoint?

(From Sackett DL, et al. *Evidence-based medicine: how to practice and teach EBM*. New York: Churchill Livingstone, 1997, with permission.)

TABLE 43.2. TYPES AND STRUCTURES OF WELL-FORMULATED QUESTIONS

LOCATING EVIDENCE

In studies of physicians' information needs, physicians usually found the answer to their clinical questions by asking a colleague. Medical journals and textbooks were infrequently used because, for example: "My journals are disorganized," or "I can't get to the library," or "My textbooks are out of date." But information technology has the potential to dramatically alleviate this access-to-evidence problem. Using computers—and more so the internet—to access electronic information sources such as MEDLINE is a fundamental component of the EBM paradigm. Physicians must develop skills in using computers to access and search the internet (a virtual worldwide CD-ROM), specialized databases, full-text periodicals and textbooks, and other meta-evidence sources such as the Cochrane Collaboration (www.cochrane.co.uk) and the Agency for Health Care Policy Research's (www.ahcpr.gov) National Clinical Guideline Clearing House (www.guideline.gov)

Posing well-designed knowledge gap questions to the search engine interfaces surrounding these knowledge sources is a clinical skill that must be learned and practiced, just as any other skill that is required in clinical care. The EBM working group has established the usefulness of including various evidence-based search terms and strategies in queries of the MEDLINE database ([Table 43.3](#)). The value of these strategies in searching other knowledge sources has yet to be established.

Strategies
Explode MeSH terms
Include epidemiologic MeSH terms
Use MeSH subheadings
Use "publication type" field
Example Search
"Should a patient with atrial fibrillation and no other medical problems be treated with warfarin or aspirin to prevent thromboembolic events?"
1. exp Anticoagulants/tu
2. Atrial Fibrillation/ft
3. 1 AND 2
4. exp Research OR exp Clinical Trials
5. 3 AND 4
6. Clinical Trial.pt OR Multi-center Study.pt OR Meta-analysis.pt
7. 3 AND 6
8. 5 OR 7

TABLE 43.3. EVIDENCE-BASED SEARCHING

CRITICAL APPRAISAL AND APPLICATION OF MEDICAL EVIDENCE

How do we manage the overwhelming quantity of biomedical information? When we are perusing the barrage of periodicals delivered to our doorstep weekly or when we are reviewing the results of one of our electronic searches, how do we efficiently identify the information sources that are most likely to contain valid evidence? How can we "separate the wheat from the chaff?" Pioneers in EBM at McMaster University have established an evolving set of guidelines to help with this problem. By separating sources of clinical information in the biomedical literature into several distinct categories, useful screening questions or "filters" can be applied. These filters are designed to screen for systematic biases in the methodology used to collect the study data that may adversely affect the validity of the evidence and any reported conclusions. These filters or screening questions are listed in [Table 43.4](#).

About a Therapy
"Was the assignment of patients to treatments randomized?"
"Were all of the patients who entered the trial properly accounted for and attributed at its conclusion?"
About a Diagnostic Test
"Was there an independent, blind comparison with a reference standard?"
"Did the patient sample include an appropriate spectrum of the types of patients to whom the diagnostic test will be applied in clinical practice?"
About a Harmful Exposure
"Were there clearly defined comparison groups that were similar with respect to important determinants of outcome (other than the outcome of interest)?"
"Were outcomes and exposures measured in the same manner in the groups being compared?"
About a Prognosis
"Was there a representative patient sample at a well-defined point in the course of the disease?"
"Was follow-up sufficiently long and complete?"
(From Sackett DL, et al. Evidence-based medicine: How to practice and teach it. 2nd ed. New York: Churchill Livingstone, 1997, with permission.)

TABLE 43.4. CRITICAL APPRAISAL OF EVIDENCE FOR VALIDITY AND USEFULNESS: GUIDING QUESTIONS

To facilitate the understanding and application of scientific evidence, EBM proposes that some aspect of this evidence be reported in standardized formats ([Table 43.5](#)). It is suggested that these formats offer the physician and patient a more intuitive and useful description of the meaning and potential impact of clinical information. Specifically, all evaluations of a treatment or other intervention may be reported as the relative risk (RR) along with a 95% confidence interval (95% CI) for the true estimation of the RR. In addition, a description of the absolute risk reduction (ARR) and the derived number needed to treat (NNT) are felt to be of particular importance and usefulness to those involved in clinical decision making. For studies establishing the role and reliability of a diagnostic test, it is suggested that the likelihood ratio (LR) be determined and reported. Similarly, for articles reporting a meta-analysis, a strength-of-effect chart may be included to see the individual effect of contributing studies in the meta-analysis. Several periodicals have already begun to adhere to these recommendations ([Chapter 42](#)).

Therapy
Relative risk and confidence intervals (RR, 95% CI)
Relative risk reduction (RRR)
Absolute risk reduction (ARR)
Number needed to treat (NNT)
Number needed to harm (NNH)
Diagnostic Test
Likelihood ratios (LR+, LR-)
Receiver-operator curve (ROC)

TABLE 43.5. RESULTS, EXAMPLES OF PREFERRED FORMATS

Many factors influence whether valid evidence-based treatment and diagnostic procedures and other clinically important issues actually affect the practice behaviors of individual physicians or the way health care policy evolves. Many of these factors are political, financial, or psychologically grounded. Yet, there are important conceptual factors that all physicians should understand to appropriately interpret the generalizability of any medical evidence ([Fig. 43.1](#)). All clinical studies attempt to say something about someone; that is, there is an implied, or specified, reference population. Yet, no clinical study has access to all members of this reference

population. The persons actually studied are different from the target population. Studies are conducted in specific places at specific times by specific people. Thus, there are filters that affect the nature of populations who actually participate in clinical studies. Some of these filters are introduced by the study design (e.g., exclusion of all diabetic patients), but other filters are beyond control (e.g., a study conducted at a large inner-city hospital in a poor Southern community with substantial ethnic and cultural diversity). These issues do not affect the validity of a study's result, but it is extremely important for physicians and patients to appreciate the effect that these filters have on the generalizability of any medical evidence ([Fig. 43.1](#)).

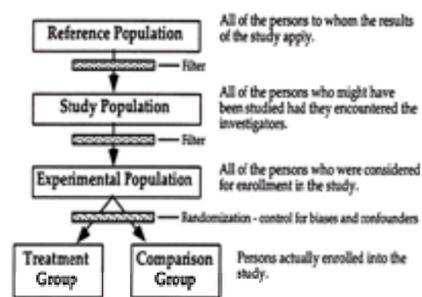

FIGURE 43.1. Generalizability and population filters. Factors that distinguish the reference population from the study and experimental populations act as filters and affect the generalizability and the applicability of a study's results. Factors affecting outcome that are not distributed equally in the experimental groups affect the validity of the study's results.

CRITICAL APPRAISAL OF OUR CLINICAL PRACTICE OUTCOMES

Physicians can no longer practice with the autonomy and minimal scrutiny of previous times. Our practice patterns, our use of resources, and the effectiveness of our interventions will be measured, compared with external standards and with our peers, and reported for all to see. EBM is being cited as the rationale for establishing standards of care, allocating limited resources, and even determining provider reimbursement. Standardized data sets (HEDIS) are used to compare the quality and cost of the care we deliver ([Chapter 46](#)). Individual and provider group report cards are becoming a fact of our professional lives. Physicians will be able to apply the tenets of EBM to these data and understand the validity and generalizability of this evidence describing their professional effectiveness. Physician behavior will change in response to this grading and reporting of our clinical activities. EBM provides a framework from which to approach the collection, analysis, and application of this important evidence. The nature of our medical care system and our physician role in this system depends on appropriate management of this information.

HOW CAN PHYSICIANS ASSIMILATE EVIDENCE-BASED MEDICINE INTO THEIR PROFESSIONAL PRACTICES AND VALUES?

Physicians must understand the proper use of clinical evidence to guide the health care delivery system through these dynamic times. EBM has been rapidly adopted by medical educators in the United States. Accrediting agencies expect that the basic tenets of EBM be included in the undergraduate and graduate medical curricula. Physicians in practice are frequently offered opportunities to attend EBM workshops at society meetings and CME (continuing medical education) courses. Many useful websites on the internet provide access to EBM resources and literature. An extremely useful textbook primer, *Teaching and Practicing EBM* is available. The *Journal of Evidence-Based Medicine* and the *American College of Physicians Journal Club* are two peer-reviewed journals that take an explicit EBM approach to publishing clinical information. It is of paramount importance that physicians understand how EBM is being used to establish definitions of quality, standards of care, and outcomes criteria. Physicians who participate in these decision-making processes assist in protecting the integrity and professionalism of America's medical care. Physicians must expect and demand that clinical decisions be based on the scientific evidence and then also weighed along with the qualitative concerns and values of individual patients, society, and ourselves, the protectors of society's health.

CHAPTER 44: COMPUTERS IN SUPPORT OF CLINICAL DECISION MAKING

EDWARD H. SHORTLIFFE

[Computer Applications in Medical Care](#)
[Issues in Providing Computer-Based Decision Support](#)
[Bringing Clinical Information to the Point of Care](#)
[Status of Computers for Clinical Decision Support](#)
[Research Directions](#)
[Conclusions](#)

COMPUTER APPLICATIONS IN MEDICAL CARE

The expanding influence of computers and communications on society is being felt in medicine as well. Essentially all hospitals and clinics depend on computers for administrative and financial functions and for providing access to clinical data. Most physicians have been exposed to the powerful available systems for searching the biomedical literature by computer, either through local networks or from national resources accessed via the Internet. Modern imaging techniques depend on computers for image generation, analytical computers have become mandatory elements in the research laboratory, and information systems and simulation environments are becoming vital topics for medical education. The clinical community has long anticipated the day when computers would be able to assist routinely with diagnosis and with making decisions about patient management. The pressure for such computer-based innovations is increasing in the era of managed care; both improved clinical productivity and decreased practice variability are often defined as explicit goals. Impressive prototypes and working systems now show that technology increasingly will provide physicians with effective decision-support tools. This chapter describes some of the issues in building such systems and in making them easily available, clinically useful, and broadly acceptable.

ISSUES IN PROVIDING COMPUTER-BASED DECISION SUPPORT

About 30 years ago, the first computer programs for medical diagnosis were shown to be often highly accurate in their diagnostic predictions. Why have such systems resisted widespread implementation and acceptance in the intervening years? The barriers reflect the subtleties and complexities of the medical practice environment and the increasing recognition that good advice from such programs cannot ensure their use and acceptance. Confounding the implementation efforts have been logistical constraints, the sometimes awkward mechanics of computer use, confusion about whether such programs are intended to be tools for clinicians rather than competitors with them, and a pervasive belief that computers do not really “understand” medicine and therefore cannot be expected to reach complex expert decisions. Early successes largely reflect an increased understanding of the importance of such issues and a gradual change in physician attitudes regarding computers and their potential for a beneficial clinical role.

UNDERSTANDING THE NATURE OF MEDICAL KNOWLEDGE

Efforts to construct effective medical decision-support tools are closely tied to research into the nature of medical knowledge and its use for problem solving. Psychological studies have taught us that medical expertise involves the application both of factual knowledge and of skills in using hypotheses to guide data collection. This important distinction between knowing what is true and knowing how to do things has had a profound effect on the development of computer-based advice tools. The research has also affected medical education, demonstrating that it is as important to teach decision-making skills and techniques for knowledge use as it is to expose students to the factual basis of medical practice.

THE NEED FOR ASSISTANCE WITH CLINICAL DECISION MAKING

Knowing how to find the information needed for clinical decision making is as important as trying to memorize it. Innovations such as MEDLINE and its Internet-based implementations such as the National Library of Medicine's PubMed (<http://www.ncbi.nlm.nih.gov/PubMed/>), are a tribute to the way in which computers can be used to help physicians and others find the information that they need to make good decisions. Computers have superb memories, but until recently they could do little with pieces of text information other than display them. Modern decision-support programs contain detailed clinical information and contain the knowledge to help users determine how that information should be applied. Because computer-based tools offer this kind of expertise, physicians have begun to consult programs to understand clinical guidelines, as well as to obtain reasoned advice about diagnosis and management of specific cases. The ultimate decision-making roles are maintained for provider and patient, but the computer is allowing their decisions to be better informed.

OBSTACLES TO THE EFFECTIVE INTRODUCTION OF DECISION-SUPPORT SYSTEMS

Experience in applying computers in medicine over two decades has shown that logistical issues are the principal causes of system failures, especially for decision-support systems that rely on physician interaction for optimal use. Any medical computing system will fail to be accepted if it is unduly time consuming or if the cost (in time or money) is not clearly justified by the benefit gained. There is also an issue of inertia—the disinclination of busy people to use a computer if it requires an interruption in their normal routine. This implies the need for an integrated model in which computers are used routinely for data-management tasks, perhaps in lieu of traditional pen and paper data-recording techniques, and from which the physician obtains advice or access to guidelines as a by-product of this ongoing interaction. Decision-support tools will thus be more feasible as improved medical record and information systems appear in health systems, hospitals, and offices, supporting the integration of guidelines and reminders into the data-management environment.

Equally important is the design of decision-making tools that are sensitive to the traditional independence and skill of physicians. There is a need for system transparency (an ability for the program to provide explanations of its recommendations, perhaps with supporting links to the original literature sources) and for tactful presentation of advice. Such features make it clear that the unique skills of trained physicians are respected and that the system should be viewed as a knowledge-management tool rather than as the decision maker itself.

Medical informatics researchers have long sought to design interactive techniques that avoid clumsiness, typing, or the need for prolonged training of the intended users. Programs have tended to use a pointing device, such as a light pen or a mouse, as the means for manual selection of items and navigation through a program's features. Options for physician-computer interaction have been greatly expanded by the introduction of hand-held mobile computers, controlled by the use of a pen or stylus and capable of communicating with other computers through wireless networks. Considering the clinical settings in which physicians work, moving from room to room or bed to bed, mobile computing is especially attractive and increasingly affordable.

BRINGING CLINICAL INFORMATION TO THE POINT OF CARE

The introduction of the World Wide Web, the most pervasive application on the evolving Internet ([Fig. 44.1](#)), has made it reasonable to expect that physicians will soon use portable devices and wireless communications to access clinically pertinent information and to garner advice from remarkably diverse and distant resources. It is already possible to find a large amount of medical information by searching the Web for topics of interest, although problems with navigation and quality control persist. A wide variety of resources are available, such as MEDLINE search engines, custom-tailored sites for physicians and patients, and libraries of specialized materials such as the compendium of clinical practice guidelines jointly developed by the American Medical Association and the Agency for Healthcare Research and Quality ([Fig. 44.2](#)). We will soon see hand-held machines, controlled by the use of a pen and sufficiently portable to be carried like a clipboard, which will provide wireless access to all the information on the Web from the patient's bedside or the clinic examining room.

FIGURE 44.1. The Internet allows individual computers in homes and offices to be connected to local Internet Service Providers (ISPs), which are connected in turn to regional networks. High-speed “backbones” connect the regional networks, and international links have made the Internet a global phenomenon. A clinician at a hospital connected to a West Coast regional network can access information from a federal health agency in Washington. The World Wide Web and electronic mail are among the most widely used applications of the Internet, which is the infrastructure on which both are built.

FIGURE 44.2. The Agency for Healthcare Research and Quality, working in collaboration with the American Medical Association, has created a central Internet resource for individuals who wish to find clinical guidelines that have been created and reviewed by authoritative government, academic, or professional groups. Users can search the Web site <http://www.guideline.gov> for guidelines that may be available on any clinical topic.

The use of such network-based information resources will be enhanced if the network serves a wide variety of clinical needs. For this reason, medical computing experts are seeking to ensure that the evolving national network is built with the needs of the health care system in mind. A range of facilities can be provided to practitioners and to patients who seek access to the health care system or to information on disease prevention and health promotion (Fig. 44.3). Serious questions exist regarding management of such a complex range of information resources, including quality control, protection of confidential information, and effective means for finding the best information available for a specific clinical problem. Patients and healthy persons are gaining easy access to many of these resources as well, empowering them in new ways and assisting those who wish to be more actively involved in decision making regarding their own care. At the same time, however, they may be exposed to information of poor quality and without scientific validity, which introduces new responsibilities to physicians as they discuss options and recommendations with patients.

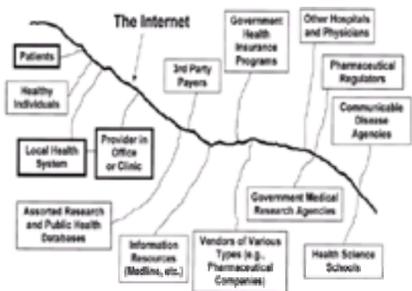

FIGURE 44.3. The evolving national network is increasingly linking persons and computers from a variety of settings that are pertinent to the delivery of health care. Citizens can find health information on the network, and patients are beginning to communicate with their personal physicians by computer and are exploring on-line educational materials regarding their illnesses. Similarly, a wide range of information and communication resources is available to practitioners.

STATUS OF COMPUTERS FOR CLINICAL DECISION SUPPORT

A clinical decision support system is generally viewed as providing patient-specific advice rather than generic information such as that provided by MEDLINE or displayed in text for a clinical practice guideline. Many programs have been developed to address such clinical problems. Since the 1950s, researchers have recognized the relevance of Bayes' rule (Chapter 42) to the task of diagnosis, with computers being used to manipulate the pertinent conditional probabilities. Many bayesian programs are highly accurate in selecting among competing explanations of a patient's disease state. The results of such analyses are probabilities, and their defense is based on Bayes' formula plus the accuracy of the sensitivity, specificity, and prevalence data used. The mathematical orientation of such programs has not always appealed to physicians who are used to discussing a more concept-oriented line of reasoning with their consultants.

Many clinical questions deal more with what actions to take in managing a patient than they do with determining the proper disease classification. Researchers have accordingly developed computer-based tools that draw on the methods of decision analysis. One class of programs permits the specification of decision trees, along with associated probabilities and utilities, and then calculates expected utilities and performs sensitivity analyses. A second class has used prespecified decision-analytic models to advise physicians who are not trained in decision analysis; such programs' usefulness is limited to cases that correspond closely to the decision tree provided.

Since the early 1970s, researchers have been applying the techniques of artificial intelligence (AI) to the development of diagnostic and therapy-management consultation programs. AI is the field of computer science that deals with the symbolic (rather than numeric) representation of knowledge and its use in problem solving. The field is closely tied to psychology and to the modeling of logical processes by computer. Of particular relevance is the subfield of AI research known as expert systems. An expert system is a program that uses knowledge derived from experts in a field to provide the kind of problem analysis and advice that the expert may provide.

RESEARCH DIRECTIONS

Several barriers continue to limit the effective implementation of decision-support tools in clinical settings. However, rapid technologic progress, especially in the development of powerful but inexpensive single-user computers that provide intuitively pleasing interactive environments, has allowed the introduction of the first commercially available diagnostic programs for physicians. The next major step forward will occur when such programs can be smoothly integrated with the patient's

medical record, allowing advice to be generated as a by-product of routine clinical data management.

REPRESENTING MEDICAL KNOWLEDGE

An ongoing research challenge is the need to refine methods for encoding the knowledge used by medical experts. Although powerful techniques exist (e.g., many systems use frames, rules, or belief networks to express relations among medical concepts), several complex challenges remain. For example, physicians use mental models of the three-dimensional associations among body parts and organs when they are interpreting data or planning therapy. Representing such anatomical knowledge and performing spatial reasoning by computer have proved particularly challenging. Similarly, human beings have a remarkable ability to interpret changes in data over time, assessing temporal trends and developing models of disease progression or the response of disease to past therapies. Temporal representation schemes and methods for inferring abstract summaries of temporal trends remain major areas of ongoing research in medical informatics and in computer science in general.

Another kind of expertise is the human skill inherent in knowing how to use what one knows. In medicine, the skill is called *good clinical judgment* to properly differentiate it from the memorization of factual knowledge or of data from the literature. Giving computers factual knowledge does not make them expert unless they also are skilled in the proper application of that knowledge. Improved understanding of human problem solving is helping researchers to develop tools that more closely simulate the reasoning of expert clinicians.

ACQUIRING MEDICAL KNOWLEDGE

Researchers are working to devise methods that will facilitate the development and maintenance of medical knowledge bases, especially in light of the rapid pace at which medical knowledge evolves. Some have formalized the techniques by which experts should be interviewed to infer how they are solving problems. Efforts have been made to develop computer programs that acquire the knowledge base for an advisory program by interacting directly with the expert, thereby avoiding a computer programmer as intermediary. In addition, the field of machine learning focuses on developing programs that can infer new knowledge by analyzing data from observing associated behaviors or outcomes. There is great interest in applying machine-learning techniques to the development of more robust decision-support programs that are sensitive to regional or institutional variations in patient populations, case mix, or demographic parameters.

PHYSICIAN-COMPUTE INTERACTION

It is often claimed that physicians will resist computer-based tools until they can talk to them as they would to a human consultant. Although commercially available programs for speech understanding by computer are beginning to permit reliable free-form spoken interaction, the resulting dictated material is free text and therefore may be difficult for the computer to interpret and apply properly in a decision-support context. Innovative graphic environments and tools for selecting from menus have demonstrated that computer novices can rapidly learn to use software tools for structured data entry, making the need for speech understanding less of an issue.

INTEGRATION WITH DATABASE SYSTEMS

The successful introduction of decision-support tools is likely to be tied to their effective integration with routine data-management tasks. This suggests the need for innovative research on how best to tie knowledge-based computer tools with programs designed to store, manipulate, and retrieve patient-specific information. Now that health systems and clinics tend to use multiple machines, optimized for different tasks, the challenges of integration are inherently tied to issues of networking. It is in the smooth linkage of multiple machines with overlapping functions that distributed but integrated clinical data processing and effective decision support for busy clinicians will be realized.

CONCLUSIONS

With the increasing acceptance of medical informatics as an academic discipline and the training of persons who can work effectively at the interface between medicine and computer science, it is likely that physicians and other health professionals will increasingly be offered clinically useful tools that are sensitive to the realities of the health care environment. Among such systems will be decision-support programs that are integrated with patient data-management systems such as electronic medical records. Such programs will serve as knowledge-access and management tools for physicians who will rely on their support much as they have relied on paper-based reference tools in the past.

Although the scientific and logistical barriers to the successful implementation of decision-support tools are great, progress has been rapid, and new technologies have offered especially promising solutions to many of the problems. The first commercial systems are already in use, the health care industry is calling for more effective implementation of evidence-based advice such as clinical guidelines, and the programs' enhanced integration into routine care environments is expected over the next decade.

CHAPTER 45: QUALITY IMPROVEMENT AND CLINICAL OUTCOMES ASSESSMENT

DAVID SHULKIN

[A History of Outcomes Assessment](#)
[Approaches to Improving Quality](#)
[Outcomes Measurement and Management](#)
[Tools of Quality Assessment](#)
[Future Directions in Clinical Management, Quality Management, Resource Management, and Disease Management](#)

A HISTORY OF OUTCOMES ASSESSMENT

Although the scrutiny of health outcomes has intensified in recent years, assessing quality of care has a long history in health care. At the turn of the century, Codman, a prominent Boston surgeon, first proposed that physicians evaluate the quality of surgical care by looking at the outcomes of the postoperative patient. In the ensuing decades, state licensure agencies began to inspect for quality of care (1920s). In the 1930s, the Joint Commission of Accreditation of Hospitals (JCAH) was established to evaluate the quality of hospitals, and the federal government initiated its own program for evaluating quality with peer-review standards organizations in the 1950s.

The 1970s witnessed the birth of health services research, and data demonstrated wide variation across small geographic areas for the rates of several common surgical procedures. This finding of wide variations in the use of health care resources prompted questions about the necessity of services being delivered and a corresponding call by payers and policy makers for the development of appropriate standards of care. At the same time came the widespread recognition that medical costs were spiraling out of control. The American business community's response to this cost crisis was the initiation of inspection programs, such as precertification, second-opinion requirements, and intensive use review.

The failure of these efforts to control costs in a fee for service reimbursement model was in part responsible for the rapid dissemination of a managed care approach in the 1980s and 1990s. Increasingly, managed care organizations are tying quality measures to reimbursement, and providers who demonstrate high quality, receive higher levels of compensation than other providers do. Managed care organizations have also been active in disseminating data on quality by issuing "report cards" and other public outcome reports ([Chapter 46](#)). This use of quality indicator data has heightened the awareness of the provider community for the need to assess their outcomes in the clinical setting. More recently, the availability of outcomes data through public sources such as the Internet has created a new interest and accessibility for health care data.

Despite the long history of quality improvement in health care, the field has experienced profound transformation in the last decade. The Agency for Health Care Policy and Research (AHCPR), a component of the US Public Health Service, was created to improve the quality, appropriateness, and effectiveness of health care. The agency supports health services research that focuses on understanding the effectiveness of care and the development of clinical practice guidelines. With this resource, the federal government has joined with other agencies, such as the Joint Commission of Accreditation of Healthcare Organizations (JCAHO), the National Committee for Quality Assurance (NCQA), the American Medical Association (AMA), and other organizations to promote use of outcomes data to improve the quality of health care.

APPROACHES TO IMPROVING QUALITY

Historical approaches to quality control in medicine have relied on retrospective case reviews to identify and sanction poor performers. Hospitals were evaluated by looking at structural standards to determine whether they were organized in a way that was capable of inspecting for quality. These methods focused on the individual provider rather than the health care system in which the practitioners work. Health care providers, payers, and others involved in improving health care quality recognized that these traditional methods of evaluating quality, known as "quality assurance," had become outdated, and they began to seek ways to shift the focus of their quality evaluation programs.

American industry recently discovered the power of continuous quality improvement, a technique originally introduced decades earlier by the American scientist W. Edwards Deming and others, such as Walter A. Shewhart and Joseph M. Juran. Deming believed that only 15% of quality improvement advances could be realized by focusing on an individual's performance and that 85% of quality opportunities could be found in systemic factors. Other quality pioneers soon began to apply and refine these concepts to the field of medicine. In place of chart reviews, continuous quality improvement brings the analysis of trended data that seeks to identify common features or systems among management issues in the patient care delivery process.

A core concept of continuous quality improvement is that the process of delivering patient care should be explicitly designed. In addition to the design component, a continuous quality improvement approach includes an assessment phase in which data are collected to determine how it is being delivered; an analysis phase in which data are interpreted and fed back to clinicians; an intervention phase, in which new ways of delivering care may be initiated; and a reassessment phase, in which the outcome of these interventions are evaluated ([Fig. 45.1](#)).

FIGURE 45.1. Approach to continuous quality improvement.

One of the basic tenets of continuous quality improvement is the recognition that outcomes are the result of many factors, such as people, training and supervision, equipment, and the environment in which care is delivered. A multidisciplinary problem-solving approach should be readily evident in the techniques of quality improvement by involving all those who participate in the clinical process, particularly persons who are closest to the work. This means that physicians, nurses, physical therapists, social workers, and unit secretaries often join together to understand a problem and identify solutions for improving quality. Improvements often are accomplished by enhanced training, technical advancement, or process changes that can occur through a series of small incremental changes rather than large shifts in practice.

Although the tenets of continuous quality improvement have been embraced in health care for nearly a decade, significant defects in quality still remain. Large deviations for best practice approaches to care are widely documented. Widely publicized cases of drug dosing errors or wrong site amputations are still frequently reported. More advanced work in quality improvement focuses as much on the implementation of new systems for care as on the design of the process. A comprehensive model for health care improvement must include the design of a best practice, changing physician (and other clinicians) decision-making deployment of the best practices, and measurement and feedback of the outcomes ([Fig. 45.2](#)).

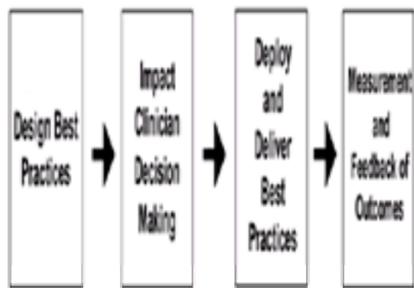

FIGURE 45.2. The model for health care improvement.

If any of the latter four steps is not completed, the maximum potential for improvement in quality will probably not be achieved. Further improvement in quality will result from system changes that will reduce clinician reliance on memory and error-proofing processes through standardization and protocol implementation.

OUTCOMES MEASUREMENT AND MANAGEMENT

Quality of care can be most simply defined as doing the right thing for a patient at the right time and with the best outcome. Using this definition, outcomes management is closely aligned with continuous quality improvement by striving to identify ways to change practice behaviors by correlating variations in patient outcomes with differences in treatment strategies. Outcomes measurements document the impact of a medical intervention on the patient. Traditional outcomes measurements have included mortality, morbidity, and complications of care. For some diagnoses, particularly those involving treatment of high-risk or complex conditions, these measures are adequate in detailing differences in outcomes among groups of patients. However, for most patients, additional and more sensitive measures are needed to document the outcomes of their care. These outcomes measurements may include return to work, the cost of care, patient satisfaction, patient preferences, the functional status before and after treatment for a particular condition, and a measure of appropriateness of care (Fig. 45.3).

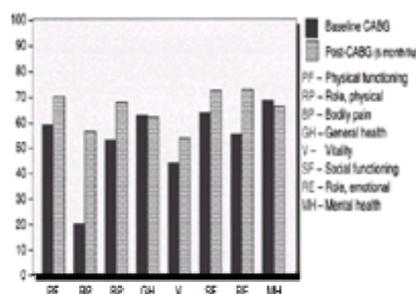

FIGURE 45.3. Functional status measurement before and after a coronary artery bypass graft (CABG).

TOOLS OF QUALITY ASSESSMENT

Quality improvement tools can help standardize medical treatment and reduce variation, but they are not intended to reduce diagnostic and scientific scrutiny and the clinical reasoning process that is essential to the practice of medicine. The best known of the quality improvement tools is the practice guideline, which documents a standard approach to a clinical problem or use of a technology. Practice guidelines may be developed on the basis of existing scientific evidence or by consensus opinion. Groups within a local clinical setting often develop these guidelines, but they are increasingly being published by professional societies and agencies such as the AHCPR.

Critical pathways are another tool useful in improving quality. Critical pathways detail a clinical plan of care from the start of the clinical intervention, such as admission to the hospital, to a clinical end point, such as discharge from the hospital. The pathway outlines the role of each of the involved health care professionals and provides an overview of the specific aspects of care delivered, such as laboratory tests, pharmaceutical services, and wound care, and the activity level of the patient. These improvement processes aimed at best practice implementation are now being expanded to outpatient areas and systematically applied over the entire continuum of care—a field now known as *disease management*.

As in clinical trials, studies of patient outcomes must identify confounding factors to appropriately adjust data to allow for a meaningful interpretation. One of the most important of these factors is the severity of the patient's illness. Several commercial severity-of-illness systems are available to clinicians to adjust outcomes. These systems involve abstraction of clinical details from the patients' records and entry of the data into a database that computes expected outcomes that can be compared with the actual outcomes. Many regulatory agencies have begun to mandate use of these severity-of-illness systems for patients treated in hospitals within their jurisdiction.

FUTURE DIRECTIONS IN CLINICAL MANAGEMENT, QUALITY MANAGEMENT, RESOURCE MANAGEMENT, AND DISEASE MANAGEMENT

The burgeoning field of clinical management strategies, although still in their infancy, are likely to take on an even greater importance in health care as we strive for a system that provides appropriate, effective, and cost-efficient care. Future issues in outcomes management include the refinement of comparative databases for clinicians to compare outcomes with one another. Advances in clinical information system technology and electronic medical records will help populate databases to help clinicians understand and improve clinical care delivery. New databases will include details of how care is provided (i.e., process elements), so the differences in outcomes can be recognized and analyzed. Disease management programs will continue to translate evidence-based findings (Chapter 43) through outcomes research into improvements in the clinical setting (Fig. 45.4).

FIGURE 45.4. The science of disease management.

The concepts of quality improvement and outcomes assessment have begun to be integrated into medical education. Students are increasingly being exposed to these concepts before their introduction to clinical medicine, with reinforcement of these principles after they enter the patient care setting. With the rapid development of integrated delivery systems, implementation of best practice care within an organized model system has provided new opportunities for enhancing quality improvement. New work in health and disease management will coordinate resources of health systems with those of patients, payers, vendors, and other providers to enhance clinical outcomes. These efforts will integrate clinical guidelines, physician and patient education, health risk assessments, care management, and preventive and wellness activities. Most quality improvement efforts have focused on inpatient care or procedures, but quality assessment work will continue to move into the ambulatory setting as more emphasis is being placed on care outside of the hospital. Outcome measurements must gauge the full scope of care with a longitudinal approach that spans inpatient and outpatient care. The continued evolution of quality management will bring about better and more comprehensive measures of care and service that patients face across the entire continuum of care.

CHAPTER 46: ASSESSMENT OF PHYSICIAN PERFORMANCE IN THE NEW CENTURY HEALTH CARE ENVIRONMENT

ROBERTA PARILLO, MARK RIVO AND LAURENCE B. GARDNER

[The Evolution of Physician Performance Measurement](#)
[Assessing Physician Performance: The Basics](#)
[Who will be Assessing Physician Performance?](#)

Health care delivery and medical practice may be expected to look fundamentally different in the twenty-first century. In his latest book, *The Bleeding Edge: The Business of Health Care in the Next Century*, J.D. Kleinke notes that significant and unprecedented economic pressures on health care providers have compelled health care to change from a cottage industry to a full-scale industrial organization. Several key trends may be expected to shape this new health care marketplace. First, continuing cost-control pressures will likely ensure that capitation (a global payment per individual for a broad range of health services) forever replaces traditional fee-for-individual-service as the dominant form of payment. Purchasers of health care, whether they are individuals, businesses, or the government, will function more as educated, empowered consumers able to assess the value they receive and not merely its cost. Second, integrated health care systems (collaboration of physicians, hospitals and other providers and facilities) competing for these capitated payments will need to provide high-quality, accessible, and affordable care to the covered population of persons along with high user satisfaction. Health care systems that are successful will have collaborative providers, comprehensive information systems, efficient delivery mechanisms and will continuously measure and improve the quality of care and service delivered.

The practice of medicine necessarily will evolve in this new health care marketplace. Third, private, solo physicians will continue to join a variety of smaller and larger physician practices and integrated health systems. Fourth, the provision of most care will shift from the hospital to community settings. Computers and the Internet will “virtually” interconnect physicians to physicians, hospitals, and laboratories as well as physicians to their patients in the home, office and hospital. Finally, individual and groups of physicians will be measured and held more accountable for their performance, a rapidly developing field and the focus of this chapter.

THE EVOLUTION OF PHYSICIAN PERFORMANCE MEASUREMENT

In the 1960s and 1970s, the first phase of physician performance measurements that were broadly available was limited to examining a physician's credentials. These credentials included the physician's medical education, including medical school and residency, their board certification status, their hospital privileges, and whether they had a malpractice history.

In the 1980s, the second phase of physician performance measurement began with efforts that attempted to focus on the outcome of care and to compare physicians against each other (*profiling*) for certain measures. After Medicare's prospective payment system (diagnosis-related groups [DRGs]) put hospitals at financial risk for seniors being admitted, hospitals began to measure and compare physicians based on the length of stay for specific conditions. Quality assurance reviews were also established in which physicians were reviewed whether an individual patient died or suffered a complication that fell outside an established standard of care.

In the 1990s, group/staff model health maintenance organizations (HMOs), such as Kaiser Permanente, and IPA (independent practice association)/Network model HMOs, such as US Health Care, began to measure and compare among physicians their use of health services, the delivery of preventive services to a population of patients, and the satisfaction of their patients with the services delivered. Physician “report cards” were developed, shared with the physician, and used in deciding everything from financial bonuses to termination.

ASSESSING PHYSICIAN PERFORMANCE: THE BASICS

Assessing physician performance, often called *physician profiling*, depends on being able to identify a group of similarly trained physicians (e.g., internists, cardiologists, pulmonologists) who are taking care of a defined population of patients.

A broad spectrum of outcomes may be measured, which reflect the quality of care and service provided. In assessing performance, physicians are often measured against a goal or benchmark. An example of a goal may be that 90% of all adults over age 65 will be immunized against pneumococcus infection and influenza. In this instance, the goal is that all the physicians exceed 90% adult immunization.

The value of physician profiling depends on identifying measurable indicators for that outcome desired and obtaining accurate data easily and without significant cost. Some of the more common data sources used in physician profiling include claims information, office encounter data (e.g., ICD-9 and CPT-4 codes), laboratory results, pharmacy prescriptions, medical records, authorizations (e.g., approved referrals and hospitalizations), and surveys. Great care must be placed on developing a methodology for obtaining the data that is reliable, accurate, and affordable. The resultant data plotted out for each physician typically produces a distribution curve allowing measurement of the overall performance of the group of physicians as well as the variance among physicians using standard statistical methods. A complete discussion of the performance measurement process is beyond the scope of this chapter. Several useful resources are identified at the end of the chapter.

Physician profiling is a fundamental step in the continuous quality improvement (CQI) process that is essential in business today, but it is only recently being adopted by the health care system. The CQI process involves (a) identifying the desired outcome and a measurable indicator, (b) defining the practices or guidelines that must be followed to attain the desired outcome, (c) measuring and providing feedback to those involved, and (d) identifying new ways from the feedback received to attain the desired outcome ([Table 46.1](#)).

TABLE 46.1. EXAMPLES OF PHYSICIAN PERFORMANCE MEASURES

WHO WILL BE ASSESSING PHYSICIAN PERFORMANCE?

Physician performance measurement is still in its infancy. In September 1998, the National Coalition on Health Care released a report on various quality-of-care initiatives. The report, by Donald Berwick, MD, President of the Institute for Healthcare Quality, argues that case-by-case improvements have not yet brought what is needed to American health care: “a breakthrough example of system-level performance of unprecedented quality at affordable cost, such as the improvements Toyota and other Japanese manufacturers brought to American industry in the 1980s” (Weissenstein).

Yet, it seems certain that the physician performance measurement will become the norm and not the exception in the health care system of the twenty-first century. Today, many health plans and large physician groups have developed sophisticated physician performance measurement standards and systems. In addition,

employer coalitions, and three well-known health care organizations are also measuring and reporting on outcomes as part of their mission and goals. These initiatives are briefly summarized in the following sections.

EMPLOYER COALITIONS

In heavily penetrated managed care markets such as California, the Indianapolis and St. Paul areas in the midwest, and Boston, employer coalitions have developed some of their own physician assessment instruments and reports. The Midwest Business Group on Health (MBGH) and the Pacific Business Group on Health (PBGH) have developed measures, gather data, and regularly report their outcomes in all three areas of clinical status, functional status, and member/patient satisfaction. Members use this information to decide what health plan, what physician, and what facility they will select.

JOINT COMMISSION ON ACCREDITATION OF HEALTHCARE ORGANIZATIONS

Founded in 1951 as an independent not-for-profit organization, the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) evaluates and accredits over 18,000 health care organizations and programs, including hospitals, integrated delivery networks, medical groups, and organizations, which provide home care, long-term care, behavioral health care, laboratory, and ambulatory care services.

JCAHO has taken steps to incorporate accountability into its accreditation process through a program called ORYX. Under ORYX, all types of health care organizations, starting with hospitals and other inpatient facilities and soon physician groups, are required to select a performance measurement system and track selected clinical indicators. The plan is to progressively increase the number of reported measures.

NATIONAL COMMITTEE FOR QUALITY ASSURANCE

The National Committee for Quality Assurance (NCQA) is a private not-for-profit organization dedicated to assessing and reporting on the quality of managed care plans. NCQA is governed by a board of directors that includes employers, consumer and labor representatives, health plans, quality experts, policy makers, and physicians.

NCQA began accrediting managed care organizations (MCOs) in 1991 in response to the need for standardized objective information about the quality of these organizations. NCQA has expanded the range of organizations that they accredit or certify to include managed behavioral health care organizations, credentials verification organizations, and physician organizations. Many large employers contract only with NCQA accredited health plans.

NCQA adopted and now manages the evolution of the principal performance measurement tool for managed care, the **Health Plan Employer Data and Information Set (HEDIS)**. HEDIS development had input from large employer leaders and health plan leaders and has quickly become the standardized performance measurement system of choice among managed care plans, many of which report HEDIS data to employer clients. HEDIS 99 includes ten effectiveness-of-care measures that are specific for defined populations. Today, many consumers receive HEDIS data in the form of health plan "report cards" from their individual health plans or through published HEDIS reports in national magazines and local newspapers.

One of the biggest challenges for all accrediting bodies is to obtain standardized information that is comparable across all health plans. This includes specific physician information. NCQA Accreditation 99 requires plans to submit audited HEDIS performance results and evaluates those results against certain performance targets.

AMERICAN MEDICAL ASSOCIATION'S AMERICAN MEDICAL ACCREDITATION PROGRAM

Recently, the American Medical Association (AMA) launched a new program, American Medical Accreditation Program (AMAP). AMAP's accreditation process compares a physician's credentials and practice with written standards, with the intent that meeting or exceeding these standards signifies a physician's commitment to provide high-quality care and to make continual improvements. AMAP's second purpose is to provide a standardized and more efficient way for physicians to meet the requirements of the many organizations that require their credentials and review of their office practice and in the future to accomplish the same objective for the growing array of requirements for clinical measurement, feedback, and improvement.

In September 1998, JCAHO, NCQA, and AMAP formed a joint Performance Measurement Coordinating Council (PMCC). The PMCC convened in January 1999 and set a goal of developing a common measurement agenda to integrate measures development efforts in an attempt to streamline the initiatives, save money, and help speed up and improve the process of producing consistent, broadly applicable measures.

STATE AND FEDERAL GOVERNMENT

In 1998, Wisconsin became the first state to require physicians to turn over medical quality and financial data to a government agency—something 37 other states have required only hospitals to do. Physician performance, particularly as it relates to patient outcomes, is an area of scrutiny that is quickly moving to the forefront of determining health care quality and value.

Legislation was recently passed, authorizing the development of a national uniform data set. Such a uniform set of requirements for collecting and reporting data among physician's offices, medical groups, hospitals, health plans, government, and others will significantly reduce the cost and improve the quality of health care performance reporting.

The Future

Unfortunately for physicians who are being assessed, for purchasers who are trying to buy "value," and for the public who is looking for the best available care, little or no consistency exists in physician performance measures. The public mandate requiring like measures and tools when reporting like outcomes has just started. As we move into the twenty-first century, the existence of so many different assessment measures and performance measurement systems is expensive and confusing and may not always produce accurate and reliable information. However, the impetus to publish accurate performance data is being driven by business, health care organizations, government, and the public. Clearly, a movement toward a uniform, standard system and national database to measure performance and quality accurately and consistently is long overdue, considering how much money is spent on health care every year. Given the new health care marketplace and its premium placed on performance measurement, physicians should take an active role in setting the standards, collecting the data, and reporting the results.

The Managed Care Education Clearinghouse

Web site: www.gwumc.edu/mcec/index/htm

The Managed Care Education Clearinghouse site is designed to be a one-stop shopping center for health professionals learning or teaching about managed care. The site is sponsored and maintained by the George Washington University Medical Center and the Pew Charitable Trusts. Browsers may review and download curricula and other educational materials on managed care, medical informatics, and physician performance measurement

National Guideline Clearinghouse

Web site: www.guideline.gov

This site is sponsored by the Agency for Healthcare Policy and Research (AHCPR) in partnership with the American Medical Association (AMA) and the American Association of Health Plans (AAHP). Its purpose is to make evidence-based clinical practice guidelines and related abstract, summary, and comparison materials widely available to health care professionals.

CHAPTER 47: MEDICAL MALPRACTICE AND RISK MANAGEMENT

KIMBERLY A. COOK AND JUAN D. REYES

[Medical Negligence](#)
[Informed Consent](#)
[Patient Expectations](#)
[The Role of Risk Management Department](#)
[Malpractice and Managed Care](#)
[Settlement](#)
[Conclusion](#)

It is extremely likely that most practicing physicians—especially those practicing in large metropolitan areas—will be involved in a medical negligence case at some time in their careers. Involvement can mean actually being named as a defendant in a lawsuit; it can mean that your conduct is being called into question, but only your employer is actually being sued; it can also mean reviewing material for one side or the other and testifying as an expert witness. What follows is a brief review dealing with medical negligence and risk management, the organization that is devoted to helping physicians avoid malpractice suits and to providing support to physicians during the pendency of a lawsuit, if one is filed.

MEDICAL NEGLIGENCE

Medical negligence is defined as the failure to act as a reasonably prudent physician would act under the circumstances, which causes harm to the patient. This is a two-part equation: the care must be proved to be substandard, and it must have caused the damage or injury that is described in the claim or suit. For example, even if a physician failed to diagnose cancer at a particular point in time, unless the failure affects the patient's prognosis, there is no "causation" and the patient has not proved a case of medical negligence. Similarly, the care may have undoubtedly caused the harm, but if the care was not negligent, there is also no proof of medical negligence. For example, an operation may have resulted in damage to a nerve, but if the nerve damage is a known complication and the surgery was performed correctly, there is no malpractice.

Medical negligence cases can involve matters that have nothing to do with patients, but that can greatly affect the outcome of a case. The most important of these issues is documentation. Documentation is always extremely important. It is critical to record all pertinent findings and *never* add to or change an entry—especially on a later date—without indicating *in the chart* that you are making a change. A jury may well find that negligence was committed based solely on the fact that the chart was altered, because this can call the physician's conduct into question.

It is advisable to note telephone conversations in the chart. Even if the patient is not seen in the office, critical information can be discussed that needs to be documented. Save all phone messages and place them in the chart. If e-mails are generated, retain those as well.

INFORMED CONSENT

One category of medical negligence cases involves informed consent. Informed consent is *not* established by ensuring that the patient signs all the consent forms. Informed consent is a process whereby the patient is counseled as to the risks and benefits of the treatment and also as to the alternative methods of treatment. This discussion should be documented in the chart, particularly the risks of the procedure. The questions asked and responses given should also be recorded, if possible. An office note that reflects that the patient is aware that nerve damage can result from a particular treatment, for example, is extremely helpful in defending a case when that patient sues because he or she suffers that very complication. In some states, if the informed consent is well documented, it creates a presumption in favor of the physician, which can be very difficult for the patient to overcome.

Medical negligence in the context of internal medicine usually comes in one of two forms: (a) failure to perform a particular examination or to make a diagnosis based on an examination that is alleged to be faulty or (b) failure to refer a patient to an appropriate specialist. For example, a 45-year-old male patient in whom a rectal examination is not performed sues when he is diagnosed with rectal carcinoma. A woman diagnosed with breast cancer sues her physician for failure to refer her to a surgical oncologist to investigate the lump the physician believed was benign.

PATIENT EXPECTATIONS

In today's world, in which many people seem to believe that they are entitled to perfect outcomes when treated by a physician and in which an unfortunate number of patients assume that malpractice was committed if the result is anything but perfect, medical negligence claims are all too common. It is unrealistic to assume that if "good medicine" is practiced, a suit will not result. Even if the physician is satisfied with the care, the patient may not be, particularly when there is a personality conflict between doctor and patient.

Because the physician and patient may have very different expectations, it is extremely important for the physician to encourage the patient to speak openly and for the physician to answer all questions asked and, to the extent possible, try to ascertain exactly what the patient expects from the treatment. If the patient anticipates an unreasonable result, it is important for the physician to explain the realistic goals of treatment—and to document these discussions in the chart.

THE ROLE OF RISK MANAGEMENT DEPARTMENT

The scope of the duties of risk management departments vary from institution to institution, but all share one common interest: providing assistance to physicians involved in an actual or potential lawsuit. The risk management department should be kept apprised of all instances in which the physician's involvement in a legal proceeding is sought, even though no formal claim or lawsuit has been filed. Many physicians have allowed themselves to be deposed—usually without being represented by an attorney—in an effort to help a patient (or an attorney) only to find that a lawsuit is then filed against them. It is important to assume that any time sworn testimony is given regarding the care of a patient, a record is being created for a lawyer and perhaps some other physician to review, which might provide the basis for the physician being named as an additional defendant in a lawsuit. The physician should not—and cannot—refuse to cooperate when he has treated a patient who has filed a claim or lawsuit against another physician. However, one should be cautious and inform the risk management department of the fact that sworn testimony has been requested.

The risk management department is dedicated to reducing the risk that a physician will become involved in a malpractice case. This is accomplished by collecting information (and sometimes reporting incidents to the state) to target areas that are particularly problematic in terms of the potential for claims and by conducting "in-services," which try to educate and inform the health care providers.

MALPRACTICE AND MANAGED CARE

With the advent of managed care, malpractice claims—and, therefore, the response of risk management—have changed. Not only can a claim be made when the outcome is unsatisfactory, but the physician can be sued for failing to approve care that is allegedly necessary but not covered by a particular insurance plan. The physician's method of reimbursement can also be called into question. Lawyers for the patient argue that capitated fees suggest that the physician is trying to see too many patients to make up for the reduced charge per patient. They may also claim that there is no incentive for the physician to spend an appropriate amount of time with the patient because the fee per patient, regardless of the amount of time spent or the complexity of the treatment provided, is the same. Although these claims are unfair and focus on issues that have nothing to do with the medical care, they are increasingly allowed by the courts.

Managed care provides different methods whereby unsatisfactory outcomes can be addressed. Some of the new "theories of liability," have been previously discussed. However, the fundamental principles remain the same. The health maintenance organization (HMO) has been an easy target, particularly since the patient has no personal relationship to stand in the way of making a claim. The trend seems to be that the court will hold the HMO responsible for the medical care, because it usually requires the patient to choose from several physicians with whom it has contracted, controls the fees the physicians earn, and can disallow recommended

treatment. In many states, the legislatures are also considering passing statutes to ensure that this is the case.

There are instances in which the physician's recommendations for patient care are rejected by the HMO. If this occurs, it is extremely important to document this in the patient's chart or to communicate in writing directly with the managed care entity that denied authorization for the recommended care, setting forth the specific care that has been ordered and the reasons (to the extent that they are known) for the denial.

SETTLEMENT

Another aspect of the process that frustrates many physicians is the evaluation and settlement of claims. It is sometimes hard for the physician to accept that money is paid in a case that he or she feels strongly is medically defensible. However, any physician who has been involved in a trial and who has waited for a jury to deliberate and return a verdict knows very well that medicine sometimes has very little to do with why a case is won or lost. Because the judge and jury are not physicians, each case has to be evaluated by the defense attorneys and by risk management to determine the factors in a particular case that might affect its outcome—even if the case is medically defensible. For example, a record may have been recopied by a doctor after an untoward incident because the paper became soiled; however, the physician makes no reference to the fact that it is being recopied, throws away the first piece of paper, and forgets to record very pertinent information about the patient's condition when the incident occurred. The patient dies and the family files suit. The doctor explains what happened, but in the context of the outcome, the family's lawyer tries to portray the doctor's actions as a "cover-up." This issue significantly complicates the defense of the case and provides the lay jury with a reason other than the medicine to find in favor of the family.

CONCLUSION

Becoming the target in a medical malpractice case is extremely unpleasant and affects different physicians in varying ways. Some are able to stay removed by viewing the process as an unfortunate complication of practicing medicine. Most, however, are profoundly affected and, understandably, are placed under great stress as a result. Although the lawyer on the other side may view the process as "just business," most physicians interpret a suit as an attack on their ability to practice medicine. It is extremely frustrating to have your training, credibility, and ability as a physician called into question by someone who knows very little about medicine and appears interested only in trying to portray the events in a way to help the patient—frequently a distortion of how things actually occurred.

Medical-legal issues have become increasingly more common and are likely to become even more so. An understanding of the process, however, is hoped to make it less emotionally distressing to the individual physician.

CHAPTER 48: ADOLESCENT MEDICINE

GAIL B. SLAP

[Demographic Trends](#)
[Public Health Problems Among Youth](#)
[Physician-Patient Relationship](#)
[Normal Development During Adolescence](#)
[Evaluation of the Adolescent Patient](#)

The transition from pediatric to adult health care is often difficult for patients and physicians. Multidisciplinary adolescent clinics have been shown to improve patient satisfaction and compliance but tend to be limited to large academic training centers. In other settings, the internist often assumes care of the adolescent directly from the pediatrician, and because adolescent medicine is outside the core of traditional training in internal medicine, internists frequently are uncomfortable managing their younger patients.

This chapter provides a medical overview of the adolescent population, beginning with a review of the demography and health needs of this age group. The common concerns, such as legality, confidentiality, and rapport, of the physician who cares for adolescents also are discussed. The normal physiologic development and psychosocial development of adolescents are summarized, followed by suggestions for the routine screening examination of the adolescent patient.

DEMOGRAPHIC TRENDS

The World Health Organization defines adolescents as persons between the ages of 10 and 19 years and youths as persons between the ages of 15 and 24 years. Historically, these populations have received little attention in health care policy, because they tend to have fewer traditional medical problems than the very young or the elderly. However, factors have emerged that bring the health needs of youth into the public eye. The 10- to 19-year-old population in the United States has been increasing since 1990 and is expected to reach 43 million by 2020. Compared with the general population, more adolescents will come from minority and impoverished backgrounds, factors that are associated with injury, homicide, unintentional pregnancy, sexually transmitted disease, and inadequate health care.

Two million adolescents (6%) 10 to 18 years of age have chronic conditions that limit their daily function. The leading cause is mental disorders (32%), followed by chronic respiratory (21%) and musculoskeletal conditions (15%). An estimated 5 million adolescents 12 to 17 years of age have significant emotional or behavioral problems, yet less than one-third receive needed services. Nearly all adolescents with emotional or behavioral conditions and over 85% with chronic medical conditions will survive to require adult medical care.

PUBLIC HEALTH PROBLEMS AMONG YOUTH

INJURY, HOMICIDE, AND SUICIDE

Injury, homicide, and suicide account for over 80% of deaths among 15- to 24-year-old persons in the United States and 55% of youth deaths throughout the world. More years of potential life are lost to injury alone than to cancer and heart disease combined. Motor vehicles account for 75% of adolescent deaths from unintentional injury. One third of adolescents report riding with a driver who has been drinking alcohol, and one quarter report driving after drinking.

Homicide rates among adolescents 15 to 19 years of age are seven times higher for blacks than for whites and six times higher for males than females. The United States ranks first among countries outside Eastern Europe in homicides committed by adolescents under age 18 years.

Suicide is the third leading cause of adolescent death. The rate among adolescents has increased 200% in the past 35 years compared with 17% for the general population. Among those 15 to 19 years of age, white male youths have the highest rate and black female youths have the lowest rate. Known risk factors for youth suicide include a previous attempt, male gender, psychiatric illness, and a family history of suicide. Postulated factors include substance abuse, peer suicide, media reports of suicide, physical abuse, and family dysfunction.

SUBSTANCE ABUSE

The best information on adolescent drug and alcohol use in the United States comes from an annual survey of 50,000 eighth-, tenth-, and twelfth-grade students. In 1998, the rates of use of illicit drugs, alcohol, and tobacco decreased in all three grades for the first time in 6 years. Twenty-two percent of twelfth graders reported daily cigarette smoking, 32% had five or more alcoholic drinks on one occasion within the prior 2 weeks, 23% had used marijuana within the month, and 20% had used another illicit drug. Inhalants were used most by eighth graders, with 12% reporting use within the year.

Risk factors for adolescent substance use include family and peer use; physical and sexual abuse; runaway behavior; family isolation and stress; and emotional and behavioral problems. The signs of use include declining school performance, isolation from family and childhood friends, secrecy, dishonesty, mood swings, and frequent somatic complaints.

SEXUAL AND REPRODUCTIVE HEALTH

The rates of abstinence and condom use among American adolescents increased during the 1990s. Reported use of condoms at last intercourse was 56% in 1997, representing a 22% increase over 7 years. However, the rate of four or more lifetime partners remained high at 16% to 19%. Although pregnancy rates suggest a decline, the United States continues to lead the industrialized world in adolescent pregnancies, deliveries, and abortions.

Of the 12 million cases of sexually transmitted diseases (STDs) reported annually in the United States, 25% occur in adolescents. STD prevalence peaks by age 21 years and then rapidly declines. Biology, as well as behavior, contributes to adolescent risk. The transitional zone from columnar to squamous epithelium is highly susceptible to both infection and dysplasia. This zone recedes into the endocervix from the vaginal canal during adolescence, making it less accessible to infection.

Chlamydia trachomatis is two to three times more prevalent than gonorrhea. It has been isolated in 20% to 60% of adolescents with pelvic inflammatory disease, 40% to 60% of adolescents with cervicitis, 15% of asymptomatic girls, and 8% of asymptomatic boys. The rates of both gonorrhea and chlamydia in adolescents have fallen in the past 10 years, whereas the rates of herpes simplex virus type 2 and human papillomavirus (HPV) have climbed. The association of some types of HPV infection and anogenital cancer has resulted in a declining mean age for cervical intraepithelial neoplasia and invasive cervical cancer.

An estimated 25% of new HIV infections occur in people younger than 22 years of age. The long latency period from HIV infection to the AIDS means that adolescents constitute an asymptomatic and often undiagnosed reservoir for transmission to sexual partners and infants. The risk of HIV infection is increased two- to five-fold by the presence of another STD. Early recognition and treatment of other STDs therefore are central to HIV prevention.

PHYSICIAN–PATIENT RELATIONSHIP

The visit to an internist may be the adolescent's first exposure to the adult health care system. In most cases, the decision to see an internist has been made because the patient feels ready to leave the pediatric setting or wants a more confidential relationship than that previously experienced. Adolescents should be assured of their right to confidentiality, and this should be explained to parents at the time of the first visit. Adolescents and their parents also must understand that confidentiality will not be maintained in life-threatening situations in which parental involvement is essential.

Consent and confidentiality have received increasing attention in state law during the past 10 years. Most states now protect the adolescent's right to medical care, including family planning and substance abuse, without parental consent. The mature minor doctrine states that emancipated minors (i.e., persons younger than 18 years of age who are self-supporting, away at college, in the military, or otherwise independent) can be treated in all states without parental consent. However, adolescent care usually is facilitated by involvement of the parents, and the physician should make every attempt to foster communication within the family about the adolescent's health.

NORMAL DEVELOPMENT DURING ADOLESCENCE

The assessment of growth and development is central to the care of adolescent patients. This holds true for the healthy adolescent who is seen for a periodic screening examination and for the chronically ill adolescent whose pubertal maturation is often delayed.

SOMATIC AND SEXUAL CHANGES OF PUBERTY

The most useful clinical measure of an adolescent's developmental age is the sexual maturity rating or Tanner stage of puberty (Table 48.1). For girls, this is based on breast development and pubic hair growth. For boys, it is based on development of the external genitalia and pubic hair growth. The two components of the pubertal stage of each sex are rated separately on a scale of 1 (prepubertal) to 5 (adult). Puberty in girls normally begins between 8 and 13 years of age with breast development (Fig. 48.1). Puberty in boys typically begins 1 or 2 years later (9.5 to 13.5 years of age) with testicular enlargement (Fig. 48.2). The average duration of puberty is 4 years in girls and 3 years in boys. More than 95% of girls and boys reach a sexual maturity rating of 5 by 16.5 years.

Stage	Breast	Male Genitalia	Pubic Hair
1 (Prepubertal)	Elevation of papilla only	No enlargement of testes, scrotum, penis	None
2	Breast bud; breast and papilla form small mound and areola widens	Scrotum and testes enlarge, scrotal skin reddens	Scanty, downy hair along labia or base of penis
3	Breast and areola enlarge with no separation of their contour	Penis lengthens, continued growth of scrotum and testes	Darker, coarser hair grows sparsely over genitalia
4	Areola and papilla project above the level of the breast	Penis broadens, glans develops, testes enlarge, scrotal skin darkens	Hair is adult in type, but area covered is smaller; no spread to medial thigh
5 (Adult)	Areola recedes to breast level; papilla only projects	Adult in size and shape	Adult in type and quantity

TABLE 48.1. STAGES OF PUBERTY

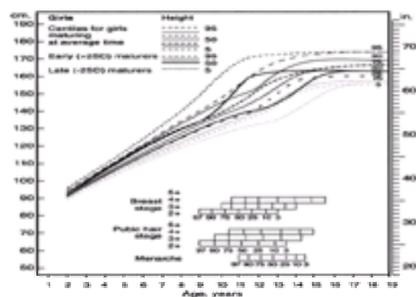

FIGURE 48.1. Percentiles of height for American girls. The heavy solid curves represent girls who are in the 50th percentile for height and 2 standard deviations (SD; 2 years) early or late for puberty. The upper dotted curve represents girls who are in the 95th percentile for height and 2 SD early for puberty. The lower dotted curve represents girls who are in the 5th percentile for height and 2 SD late for puberty. The bottom bars refer to percentile pubertal stage for age (e.g., pubic hair stage 2+ represents stage 2 but not stage 3 pubic hair). (From Tanner JM, Davies PSW. Clinical longitudinal standards for height and weight velocity in North American children. *J Pediatr* 1989;107:317, with permission.)

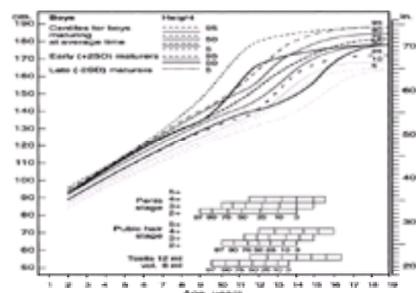

FIGURE 48.2. Percentiles of height for American boys. The heavy solid curves represent boys who are in the 50th percentile for height and 2 standard deviations (SD; 2 years) early or late for puberty. The upper dotted curve represents boys who are in the 95th percentile for height and 2 SD early for puberty. The lower dotted curve represents boys who are in the 5th percentile for height and 2 SD late for puberty. The bottom bars refer to percentile pubertal stage for age (e.g., pubic hair stage 2+ represents stage 2 but not stage 3 pubic hair). (From Tanner JM, Davies PSW. Clinical longitudinal standards for height and weight velocity in North American children. *J Pediatr* 1989;107:317, with permission.)

One of the most dramatic changes of puberty is the rapid growth in height. In girls, the height spurt occurs at a mean age of 11.5 years and with a sexual maturity rating of 2 or 3. In boys, it occurs at a later mean chronologic age (13.5 years) and at a later sexual maturity rating (4). Because the timing of the height spurt correlates with the progression through puberty, a child who has grown along a given percentile curve may deviate from that curve in adolescence if puberty is early or late. New height standards include curves that represent children of normal height whose pubertal progression is at the early (+2 SD) or late (-2 SD) limits of normal.

Pubertal growth accounts for 25% of final adult height and 40% of ideal adult weight. The theory that menarche occurs with attainment of a critical body fat is controversial but commonly is used to explain primary and secondary amenorrhea. Menarche occurs at a mean age of 12.8 years in the United States, and 97% of American girls experience menarche by 14.6 years.

Many systemic changes occur during puberty. The slow increase in blood pressure that occurs during late childhood accelerates rapidly during adolescence. The decrease in heart rate that occurs during childhood stabilizes or even increases during adolescence. In boys, heart weight doubles, hemoglobin increases, respiratory rate decreases, and vital capacity increases.

Few detectable gross changes occur in the brain, despite the enormous cognitive change that occurs during adolescence. The brain achieves 95% of final adult

weight by the age of 10 years, and electroencephalography does not reveal changes that are specific for puberty.

PSYCHOSOCIAL DEVELOPMENT

The developmental tasks of adolescence fall into three broad categories: the establishment of autonomy, psychosexual development, and future orientation. Young adolescents (11 to 14 years) struggle for independence but retreat to parents during perceived crises. They often are preoccupied with bodily changes and look for reassurance that their development is normal. The capacity for abstract reasoning usually is not fully developed, and the perspective of time tends to be oriented to the present. Middle adolescents (15 to 17 years) usually are near completion of puberty and are more comfortable with their adult bodies. The peer group assumes primary importance, and some family conflict is common. By late adolescence (18 to 21 years), this conflict diminishes as the adolescent establishes an independent identity and begins to work toward realistic adult goals.

EVALUATION OF THE ADOLESCENT PATIENT

HISTORY

Most adolescents speak more openly with physicians when interviewed without their parents being present. The parents should be assured that they will join the physician and patient in the office when the physical examination is completed. This gives the physician a chance to obtain additional history from the parents and to discuss the management plan with the patient and parents simultaneously.

Early discussion of the adolescent's family, school performance, social milieu, and interests may guide the remaining history. This also may be the time to discuss sexual activity and the use of cigarettes, alcohol, and drugs. It is essential that these issues be raised at some time during the first visit. The adolescent should understand from the outset that these areas are acceptable for discussion and that confidentiality will be protected whenever possible.

The patient's developmental and immunization histories should be obtained from the parents or the pediatric record. A discussion of nutrition and eating habits is another important part of the adolescent history. Most girls require 2200 to 2500 calories during early adolescence, and most boys require 2500 to 3000 calories. Iron intake is often inadequate in both sexes during adolescence, and girls require three times the amount of iron contained in the average American diet. Obesity, anorexia nervosa, and bulimia are common problems that begin during adolescence and must be managed in a forthright manner with the adolescent and parents.

PHYSICAL EXAMINATION

Several aspects of the adolescent physical examination differ from the adult examination. Height and weight should be measured annually and plotted on a normative scale to indicate the percentile for chronologic age ([Fig. 48.1](#) and [Fig. 48.2](#)). The sexual maturity ratings should be performed at each visit ([Table 48.1](#)), and progression through the stages should be plotted on a normative scale ([Fig. 48.1](#) and [Fig. 48.2](#)).

Scoliosis usually becomes clinically apparent during the height spurt and may progress quickly during this time. It is found in 10% of adolescents and is ten times more common in girls. The patient should be examined for asymmetry of the shoulders, scapulae, pelvis, and breasts. When a patient with scoliosis bends forward at the waist, the rib cage protrudes toward the convex side of the curve. If scoliosis is detected, a radiograph of the spine should be obtained to determine the degree, and the patient should be referred for orthopedic evaluation.

Gynecomastia occurs in up to 60% of 14-year-old boys and is most common at genital stage 2. More than 75% of cases are bilateral and resolve within 12 to 18 months. Gynecomastia that persists for more than 2 years requires evaluation.

Fibroadenomas of the breast are common in adolescent girls, accounting for up to 90% of breast lesions in this age group. Conversely, fibrocystic disease is uncommon until late adolescence, and there is usually more tenderness and fluctuation than with fibroadenomas. Although carcinoma of the breast is rare during adolescence, many physicians begin to encourage self-examination during adolescence to establish it as a health habit by adulthood.

Indications for the first pelvic examination include sexual activity, age 18 to 21 years, diethylstilbestrol exposure in utero (now rare among adolescents), and unexplained pelvic pain, menstrual abnormality, or vaginal discharge. Sexually active adolescents should have visits for contraceptive counseling every 3 months, STD screening every 6 months, and a Papanicolaou smear every year.

LABORATORY EVALUATION

The prevalence of iron-deficiency anemia due to rapid growth and nutritional deficiencies warrants a screening hemoglobin or hematocrit in early and late adolescence for boys and girls. Urinalysis should be done in early, middle, and late adolescence. Routine stool check for occult blood, electrolyte analysis, liver function studies, chest radiograph, and electrocardiogram are unnecessary.

The National Cholesterol Education Program does not recommend routine screening for hypercholesterolemia in children and adolescents younger than 20 years of age. Selective screening is recommended for children and adolescents who have one or more of the following: (a) a parent with a blood cholesterol level of 240 mg per deciliter or more; (b) a parent or grandparent who, at or before 55 years of age, was found to have coronary atherosclerosis on coronary arteriography or who had a documented myocardial infarction, angina pectoris, peripheral vascular disease, cerebrovascular disease, or sudden death; (c) an unobtainable biologic family history. Screening should be strongly considered for adolescents with other risk factors for coronary atherosclerosis, such as cigarette smoking, hypertension, obesity, and diabetes mellitus. The recommended test depends on the reason for screening. If done for parental hypercholesterolemia, a random total cholesterol level is recommended first. If the adolescent's level is above 200 mg per deciliter, a 12-hour fasting lipoprotein analysis should be done to measure high-density lipoprotein (HDL) cholesterol and low-density lipoprotein (LDL) cholesterol. If the adolescent's random cholesterol is borderline (170 to 199 mg per deciliter), a second measurement should be obtained and averaged with the first. If the average is borderline or high, a fasting lipoprotein analysis should be obtained. If the initial screen is indicated because of family cardiovascular disease, two separate lipoprotein analyses following 12-hour fasts should be done and the LDL-cholesterol values should be averaged.

Sexually active female adolescents should have testing every 6 months for gonorrhea and chlamydia and a Papanicolaou smear every year. Sexually active male adolescents should have urine leukocyte esterase screening or urine ligase chain-reaction testing for gonorrhea and chlamydia every 6 months. Adolescents with a history of STD or risk factors for HIV infection should have a serologic test for syphilis. HIV screening should be discussed with adolescents who have had multiple sexual partners, a partner at risk for HIV infection, male homosexual intercourse, other STDs, or a history of injection drug use.

IMMUNIZATION

If there is no written documentation of immunization, the primary series for diphtheria–tetanus (dT) and poliovirus should be administered. A dT booster should then be given every 10 years throughout life. The measles–mumps–rubella (MMR) immunization should be administered to all adolescents who have had only one previous MMR inoculation. Hepatitis B immunization is recommended for all adolescents who have not previously received it. The tuberculin skin test should be done for adolescents who are exposed to active tuberculosis, living in homeless shelters or institutions, or working in health care settings.

CHAPTER 49: PRINCIPLES OF OCCUPATIONAL MEDICINE

MARK R. CULLEN AND LINDA ROSENSTOCK

[General Principles of Occupational Disease](#)
[Specialized Skills in Clinical Occupational Medicine](#)
[Notification and Follow-Through](#)
[Classification of Occupational Disease by Organ System](#)

Concomitant with the increasing attention to the adverse health effects of chemical, biological, and physical agents is the challenge to physicians to recognize, diagnose, and treat occupational diseases. To a degree almost unparalleled in any field of clinical medicine, the physician also plays a pivotal role in disease prevention for individual patients and others similarly affected or at risk.

Most men and women in the United States work outside the home; in almost all occupations, they face risks or perceived risks from workplace exposure. Most of these approximately 100 million workers receive medical care from primary care and other first-contact physicians. The goal of this chapter is to define general principles of occupational disease and to describe an approach to incorporating specialized skills and responsibilities of caring for working patients into traditional clinical practice. Although it is not feasible to provide a comprehensive review of occupational diseases here, the final section of this chapter is an overview by organ system of diagnostic categories with known or likely occupational causes.

GENERAL PRINCIPLES OF OCCUPATIONAL DISEASE

ASSESSING CLINICAL MANIFESTATIONS

The clinical and pathologic manifestations of most occupational diseases are indistinguishable from those of other causes. It often is presumed that diseases that arise out of the workplace have such distinctive features that they are readily recognized or that they should be considered only when more common causes have been excluded. Unique clinical and pathologic findings are the exception, however, rather than the rule. For the clinician, the patient usually presents with a disorder such as chronic bronchitis, which may be caused or aggravated by workplace factors (e.g., mineral and grain dusts, irritant gases, plastics constituents) but is explained commonly by another factor, such as cigarette smoking. Other examples include occupationally induced asthma, which may mimic extrinsic or intrinsic asthma, and lung cancer from asbestos exposure or aplastic anemia from benzene exposure, which may be indistinguishable from diseases caused by other agents.

This basic principle does not mean that the occupational origin of these diseases cannot be firmly established by the clinician. It raises the need to maintain an appropriate index of suspicion and to apply other principles and skills in evaluating conditions that are commonly seen or too readily ascribed to nonoccupational or so-called idiopathic origins.

An important temporal relation exists between exposure and disease onset, with long latent intervals for most chronic disease and all occupational cancers. Many occupational diseases of acute onset or episodic occurrence have a predictable temporal pattern between causative exposure and symptoms. For example, for toxins acting as potent respiratory irritants, symptoms may occur within minutes after exposure (as with soluble gases such as chlorine and ammonia) and usually no later than 24 to 48 hours (as with less soluble gases such as phosgene). The link between the outcome and exposure is almost always obvious and readily determined in these settings.

More difficult to diagnose but strongly suggested by characteristic exposure-response patterns, is occupational asthma associated with certain causative agents. For example, asthma due to exposure to Western red cedar dust usually presents as nocturnal asthma (presumably a delayed hypersensitivity reaction), occasionally as an immediate hypersensitivity response shortly after exposure or as both an immediate and a late response. Acute solvent intoxication, characterized by dizziness, disorientation, irritability, headache, and gastrointestinal disturbance, typically occurs within hours of overexposure, abates within hours of leaving exposure, and usually resolves within 24 to 48 hours.

Most chronic disorders occur remote from exposure to the causative factor and may have been unassociated with symptoms at the time of exposure. Most nonmalignant asbestos-related diseases occur at least 20 years after the first exposure, and the average latency is 25 years for asbestos-related lung cancers and 35 years for mesothelioma. However, increased risk occurs years earlier for both of the latter conditions. Knowledge of these latency factors is of crucial importance for the clinician in seeking a history of possible occupational cause and guides an in-depth history of exposures to recent or past employment.

Etiology

Occupational diseases often have multifactorial causation. Occupational factors may act together or in concert with nonoccupational factors in altering risk for disease. The multiplicative risk for lung cancer from asbestos exposure and cigarette smoking is a well-known example. In those heavily exposed to asbestos who do not smoke, the risk is about fivefold, compared with tenfold for smokers without asbestos exposure and 50-fold for those with both exposures. Another example is the increased risk for compressive mononeuropathies from physical trauma in the setting of diffuse neuropathy, either from toxic or from other causes such as diabetes mellitus. The potentiation of peripheral neurotoxicity from methyl-*n*-butyl ketone in the presence of methylethyl ketone documents the potential interaction of occupational toxins, but the effects of combined exposure remain largely unexplored even when effects of any one agent have been well delineated.

Regardless of whether different factors act synergistically or independently (additively), identification of one or more occupational factors as causative is of major diagnostic and therapeutic importance.

TOXIN EXPOSURE AND DISEASE SEVERITY

For acute and chronic occupational disease, the dose of exposure is a major determinant of risk for or severity of disease. Most occupational exposures to toxins occur by inhalational or dermal routes or both. As with pharmacologic principles of drugs, mechanics of absorption, metabolism, and elimination contribute to cumulative dose. Occupational toxins may be considered to act in one or more of the following ways: as direct cellular toxins, as allergens, and as carcinogens.

Toxins can act as direct cellular toxins, with increasing effect occurring at increasing doses and often no adverse effect observed below a certain threshold dose. Examples include liver and renal toxicity from carbon tetrachloride, central nervous system toxicity in adults exposed to lead, and pulmonary dysfunction from silica dust. In general, increasing doses of exposure to toxins in this group are associated with a greater proportion of exposed persons suffering adverse effects and a greater severity of resultant disease in any given person.

Toxic substances can cause allergic or hypersensitivity reactions, with the exposure dose often affecting the number of exposed persons who become sensitized but even minute exposures capable of precipitating a full-blown response among those sensitized. Examples include the more than 200 agents recognized as causative in occupational asthma, a list that overlaps but is not identical with that associated with occupational dermatitis, and the agents associated with other hypersensitivity pulmonary disorders, such as those caused by cobalt and beryllium.

Toxins are considered carcinogens when increasing risk for tumor occurs with increasing dose and there is no demonstrable safe or threshold level of exposure. Examples are numerous and include asbestos, which acts as a promoter and initiator in carcinogenesis, with lung cancer occurring in as many as 50% of those with heavy exposure who smoke cigarettes and mesothelioma occurring in as many as 10% of those with heavy asbestos exposure independent of smoking status. As with other carcinogens, even small and brief exposures present some theoretical risk, but the risk for these exposures may be unmeasurable and comparable to the increased risk for lung cancer from smoking only a few cigarettes. Understanding a person's risk for cancer after exposure to an occupational carcinogen necessitates extrapolation of risk based on comparability of exposure in epidemiologic studies that define the risk.

TOXICOLOGIC DETERMINATION

Important occupational factors may be difficult to identify and may not have documented clinical significance. An estimated 50,000 chemicals are in widespread industrial use, and about one-third are toxic in doses that may be encountered in the workplace. Identification of these substances often is difficult and made more so by the occurrence of many toxins in mixtures and as contaminants of other products. Hundreds of new substances are introduced annually into the workplace. Toxicologic and human health effects data frequently are inadequate and for some outcomes, such as female reproductive effects, are practically nonexistent.

HOST FACTORS

Host susceptibility factors play a variable role in the occurrence of occupational disease. Although most persons with sufficient exposure to some occupational toxins experience an adverse effect, a significant variation in expression of disease occurs even among those heavily exposed. For example, among those with heavy asbestos exposure, only about 50% develop asbestos-induced pulmonary fibrosis. For some agents that cause occupational asthma, such as platinum, most people who are exposed may become sensitized, but for other agents, such as toluene diisocyanate or Western red cedar, the proportion of those who develop hypersensitivity syndromes is far lower. Atopy has explained the increased risk for some but cannot explain any of the increased risk for sensitization to other agents implicated in occupational asthma and dermatitis.

SPECIALIZED SKILLS IN CLINICAL OCCUPATIONAL MEDICINE

OCCUPATIONAL HEALTH HISTORY

The occupational health history is the foundation on which rests any assessment of known or suspected occupational disease. It should become routinely incorporated into the traditional health history, expanded and adapted as demanded by the clinical setting. The occupational history has two main parts: the work and exposure history and the general health history.

Work and Exposure History

In the work and exposure part of the history, information is elicited about the current or most recent job, including job title, type of industry, and nature of work performed. Simply asking the patient to describe a typical day of work can be rewarding and may have benefits beyond the objectives of the history itself, providing the patient an often-welcome opportunity to discuss an important part of his or her life. Information about the job title and industry for all past jobs, including military experience, should be obtained.

Exploration of potentially hazardous exposures is fundamental to this part of the history. Focusing on recent or remote exposures is guided by whether the disorders under evaluation are acute and recurrent or chronic. A checklist approach to general categories of exposure is a good starting point for this inquiry. Additional exposure information beyond that directly obtainable from the patient is often helpful and sometimes necessary. Sources of additional information include environmental monitoring data, specific biologic testing of the patient, product information sheets (material safety data sheets), and data available from the employer, union, and regulatory agencies. Because dose of exposure is important in assessing potential adverse effects, additional queries should address the use of personal protective equipment, the degree of ventilation and general plant hygiene, and the level of technologic safeguards, such as enclosure of hazardous chemicals.

It is important to ask about exposure to nonwork environmental hazards. These are commonly encountered in household and avocational activities and less commonly in the community.

General Health History

In the general health part of the occupational history, the chief complaint and review of systems components of the traditional health history are augmented by exploring the relation between work and symptoms. An important initial question is whether the patient perceives that his or her health problems are work related. Although these perceptions may not be well founded, a patient's suspicion about a workplace problem should be taken seriously. Coworkers with similar complaints provide further evidence that occupational factors may be important; the clustering of even common problems is often the first clue to a work-related disease.

The timing of onset of symptoms and their variation in relation to time at work and association with certain work processes may provide information of particular importance in assessing acute or recurring conditions. It is useful to ask whether symptoms abate when the patient is away from work, such as on weekends and during vacations. The history of such tempo- ral patterns may be of importance in chronic conditions, such as evaluating nonspecific bronchial hyperreactivity resulting from what was initially a specific response to an occupational exposure.

DIAGNOSTIC DECISION MAKING

Determining whether an illness or condition is work related is often important for assigning insurance benefits and making vital decisions about continued work activities. Although the basic principles used to make such decisions are not very different from those used at the bedside in other clinical areas, the decisions often seem more forced and difficult because of the obvious legal and economic ramifications. Moreover, good practice often leads to differing thresholds or standards for making decisions, even in an individual case. For example, if there is any reasonable likelihood that a patient's exposure may be contributing to progression of a lethal or serious disease, removal based on suspicion is appropriate. Workers' Compensation systems typically require a determination based on "more probable than not," a standard defined as a likelihood greater than 50%. Scientific rigor for inclusion in research papers or other reports usually requires a higher degree of certainty about the diagnosis and cause.

The principles for decision making are straightforward. First, there must be clear evidence of exposure to an agent or agents that have toxicologic potential, based on the occupational history, laboratory tests, or outside records. Second, unless there is compelling evidence to cite a single case as a newly described condition, the agent or agents must have been demonstrated or highly suspected from human studies or animal experiments to cause health effects resembling those of the patient. The dose of exposure, to the extent that it can be estimated by history records or tests, should be of a magnitude similar to those levels reported to have such effects. The interval between exposure and onset of effect should be consistent with available evidence. Also important is determining whether other explanations for the disorder are reasonably likely compared with the likelihood that the disorder is work related. In this way, for example, it could be predicted that the rounded opacities seen on the x-ray film of a rock crusher are almost certainly caused by occupational exposure to silica dust (silicosis), because other possible diagnoses presenting radiographically in this way, such as sarcoidosis, are uncommon.

The criteria for determining the work relatedness of a medical condition are summarized in [Table 49.1](#).

The symptoms, signs, and laboratory tests are consistent with the diagnosis.
The temporal pattern of exposure and disease onset is consistent with known time-response characteristics.
The exposure was of sufficient dose given known dose-response characteristics.
Biologic monitoring of exposures or specific end-organ effects is consistent with dose-response characteristics.
Epidemiologic data support effects at a comparable exposure to those experienced by the patient.
No other condition or exposure more readily explains the disease.

TABLE 49.1. CRITERIA FOR DETERMINING WORK-RELATED MEDICAL CONDITIONS

NOTIFICATION AND FOLLOW-THROUGH

For the physician, the medical treatment of working patients involves special circumstances and evokes special responsibilities that are not usually encountered in traditional practice. Awareness of these is key to the successful practice of clinical occupational medicine.

PHYSICIAN–PATIENT RELATIONSHIP

The physician–patient relationship can be seriously challenged in the diagnosis, treatment, and prevention of occupational diseases, but responses to these challenges can be based on ethical and legal principles derived from general medical practice. One principle addresses the loyalty or allegiance of the physician, which should always remain with the working patient, even when health services are paid for by the employer.

The second principle is maintenance of confidentiality, with the recognition that only in exceptional circumstances should a physician consider violating that fundamental tenet of medical care. In occupational medicine, confidentiality is important for the sake of privacy and because the inappropriate or inadvertent release of information may have serious adverse consequences for the patient, including loss of employment security. After a physician–patient relationship is formed, the same strict rules of confidentiality of the written and verbal release of information should be applied. As in other circumstances, ethical guidelines define two settings in which on a case-by-case basis confidentiality may need to be abandoned: (a) when there are overriding public health consequences, as when other workers may be at significant risk if hazardous conditions or exposures are not disclosed; and (b) when serious harm to the patient will result if information is not revealed. Legal requirements, such as response to subpoena and releasing records for workers' compensation, also may necessitate disclosure. Whether mandated by ethical or legal restraints, the patient should always be informed when an expressed desire for confidentiality cannot be respected.

The third principle of importance is that of informing the patient about medical conditions, including the hazards and potential risks of workplace exposures or diseases, and of discussing decisions that may be anticipated or possible serious consequences such as termination of employment or job relocation. As in other areas of clinical medicine, the physician has an ethical obligation to keep as informed as possible and to recognize when it is in the patient's best interest to seek consultation or referral elsewhere.

REPORTING

In addition to disclosing information to the patient, the physician has broader responsibilities after an occupational disease is diagnosed or suggested. Some of these are legally mandated; some actions not legally required may still have economic or health benefits for the patient. Because occupational diseases are by definition almost all preventable, the potential public health impact of reporting may be significant.

Depending on the medical implications of the problem and considering other factors such as confidentiality, reporting can be accomplished in numerous ways, including notifying the employer, workers and their representatives, public health agencies, and research and regulatory agencies; publishing in scientific journals; and reaching the public through the media. The following summary of potentially important contacts should be considered, recognizing that these same contacts may provide valuable additional information about exposures and therefore may be of assistance at an earlier point in the process of evaluating work-related disease.

Employer

The employer almost always should be notified about identified work hazards or conditions. Many large companies employ professionals who can supply detailed information about the workplace.

Union

Although only about 20% of US workers are members of trade unions, some unions play a key role in workplace health and safety. They may be a source of workplace and exposure information, which may be of assistance in understanding options and implications of job transfer or termination.

Occupational Safety and Health Administration

The state or federal branch of the Occupational Safety and Health Administration (OSHA) serving the physician's region can provide consultation about hazards, including workplace assessments without charge or threat of penalty (through requesting employers). OSHA also serves as the regulatory agency overseeing enforcement of health and safety standards. If necessary, complaints from a patient, the patient's representative, or the patient's physician should prompt an inspection; reports of past inspections also are available and may be an additional source of exposure information.

National Institute for Occupational Safety and Health

The National Institute for Occupational Safety and Health (NIOSH), seated in the Centers for Disease Control and Prevention, is responsible for research and training in occupational health. The many services include supplying information about specific exposures and conducting studies of industries or workplaces with known or suspected health problems.

State and Local Health Departments

Several state and some local health departments are capable of investigating health conditions arising from the workplace. They also may provide information about previously investigated or reported illnesses and injuries and may be the best single referral source for follow-up and intervention for the individual patient and his or her coworkers.

Workers' Compensation

Workers' compensation is a program that covers most US workers, primarily through state programs and for a smaller number through federal programs. Workers' compensation is a no-fault insurance system; in almost all instances, the worker forfeits the right to sue an employer for work-related diseases or injuries in exchange for receiving medical care, rehabilitation, and income replacement.

Because legal duties and responsibilities vary significantly from state to state, the physician needs to become familiar with the major programs that affect his or her patients. This is particularly important in the many jurisdictions in which even a physician's verbal notification to a patient of the presence of an occupational disease may initiate the beginning of a statute of limitations, the period in which a claim must be filed. The physician plays a key role in the workers' compensation system, with the responsibility to initiate workers' compensation claims, to determine the likelihood of work relatedness of the condition, and to be available for the sometimes onerous and often frustrating task of attendant paperwork.

CLASSIFICATION OF OCCUPATIONAL DISEASE BY ORGAN SYSTEM

Classification of major disease groupings with known or strongly suspected occupational causes are presented by organ system in [Table 49.2](#), [Table 49.3](#), [Table 49.4](#), [Table 49.5](#), [Table 49.6](#), [Table 49.7](#) and [Table 49.8](#). Most of these diagnostic categories are associated with multiple occupational factors, but in some, only one agent has been implicated. The information in these tables serves as a useful starting point in considering whether a patient's past or present work is contributing to or causing the diagnosed disorder. For more information about specific diseases, the reader is referred elsewhere in this text and to the bibliography.

Condition	Examples of Associated Exposures
Acute or Recurrent Disorders	
Upper respiratory tract inflammation	Fibrous glass, metal dust, welding and plastic fumes
Airway disorders	Western red cedar, toluene diisocyanate
Asthma	Welding fumes, irritant gases
Airway irritation, including nonspecific hyperactivity	
Rhinitis	Cotton and flax processing
Extrinsic allergic alveolitis	Wood dust, diisocyanates
Toxic pneumonitis	Cadmium, oxides of nitrogen
Pleural effusion	Asbestos
Chronic Disorders	
Interstitial diseases (pneumoconiosis)	Silicates, coal dust
Granulomatous disease	Beryllium
Chronic bronchitis	Metal dusts, coal dust
Chronic pleural diseases	
Pleural thickening or rounded atelectasis	Asbestos
Diffuse malignant mesothelioma	Asbestos
Carcinoma	
Upper respiratory tract	Chromium, nickel, hardwood dust
Bronchiogenic	Coal tar pitch, volatiles, asbestos, arsenic

TABLE 49.2. OCCUPATIONAL DISEASES OF THE RESPIRATORY TRACT

Condition	Examples of Associated Exposures
Anemia	
Hemolytic	Lead, arsine gas
Hypoproliferative	Benzene
Methemoglobinemia	Nitrites
Stem cell disorders	
Aplastic anemia	Benzene, ionizing radiation
Myeloproliferative disorders	Benzene, ionizing radiation
Acute nonlymphocytic leukemia	Benzene, ionizing radiation
Lymphoproliferative disorders	
Multiple myeloma	Ionizing radiation

TABLE 49.3. OCCUPATIONAL HEMATOLOGIC DISORDERS

Condition	Examples of Associated Exposures
Local Disorders	
Raynaud's phenomenon	Vibration, vinyl chloride monomer
Neurovascular compression	Repetitive trauma
Periarticular disorder	Repetitive trauma
Dupuytren's contracture	Repetitive trauma
Aseptic necrosis	Diving (hypobaric trauma)
Systemic Disorders	
Scleroderma	Coal dust
Acro-osteolysis	Vinyl chloride monomer
Metabolic bone diseases	Fluorine, phosphorus
Diffuse arthralgias, myalgias	Lead
Gout	Lead

TABLE 49.4. OCCUPATIONAL RHEUMATOLOGIC DISORDERS

Condition	Examples of Associated Exposures
Acute Renal Disease	
Tubulointerstitial	Carbon tetrachloride
Tubulointerstitial (indirect injury)	Arsine gas, heat
Glomerular	Organic solvents, mercury
Chronic Renal Disease	
Tubulointerstitial	Cadmium, lead
Glomerular	Lead, mercury
Bladder Disease	
Bladder dysfunction (sacral neuropathy)	DMAPM (dimethylaminopropionitrile)
Bladder carcinoma	Benzidine

TABLE 49.5. OCCUPATIONAL DISORDERS OF THE KIDNEY AND BLADDER

Condition	Examples of Associated Exposures
Nonmalignant Liver Disease	
Acute/subacute hepatocellular injury	Carbon tetrachloride, dimethylformamide
Acute cholestatic hepatitis	Methylenedianiline
Chronic, persistent hepatitis	Polychlorinated biphenyls
Granulomatous hepatitis	Beryllium
Hepatoportal sclerosis	Arsenic, vinyl chloride monomer
Neoplasms	
Gastric and esophageal	Asbestos
Colon and rectum	Asbestos
Hepatoma	Arsenic, vinyl chloride monomer
Angiosarcoma (liver)	Arsenic, vinyl chloride monomer

TABLE 49.6. OCCUPATIONAL GASTROINTESTINAL DISORDERS

Condition	Examples of Associated Exposures
Central Nervous System	
Acute toxic encephalopathy	Organic solvents, manganese
Chronic encephalopathy	Lead, carbon disulfide
Parkinsonian movement disorder	Manganese
Peripheral Nervous System	
Toxic polyneuropathy	N-hexane, lead
Neuromuscular blockade	Organophosphate pesticides
Compression/parenchymal mononeuropathy	Repetitive trauma, vibration
Vascular (interstitial) neuropathy	Vibration

TABLE 49.7. OCCUPATIONAL DISORDERS OF THE NERVOUS SYSTEM

Condition	Examples of Associated Exposures
Dermatitis	
Irritant contact dermatitis	Detergents, machining fluids
Allergic contact dermatitis	Fungus, nitro, nickel
Photocontact dermatitis	Ionizing radiation
Occupational Acne	
Oil acne and folliculitis	Oil mist, grease
Acne mechanica	Friction, pressure
Chloracne	Polychlorinated biphenyls, dioxins
Disorders of Pigmentation	
Staining of skin and sclera	Methylmercaptane
Leukoderma	Silver
Hyperpigmentation	Quinones
Neoplastic Disorders	
Squamous cell carcinoma	Aluminum salt, arsenic
Basal cell carcinoma	Sunlight
Melanocytic Disorders	
Pigmented lesions	Polychlorinated biphenyls
Basal induced lesions	Erythema ab igne
Coal-induced lesions	Mellars
Leukoderma	Chelidonium
Leukoderma	Sulfonamide
Leukoderma	Frodoxide
Leukoderma	Sulfonamide
Leukoderma	Delayed allergic response

CHAPTER 50: MEDICAL OPHTHALMOLOGY

MICHELE R. PICCONE AND STUART L. FINE

[Interpretation of Common Ocular Symptoms](#)
[Evaluation of the Red Eye](#)
[Ocular Trauma](#)
[Ocular Manifestations of Aids](#)
[Diabetes and the Eye](#)
[Glaucoma](#)
[Age-Related Macular Degeneration](#)

INTERPRETATION OF COMMON OCULAR SYMPTOMS

Important ocular symptoms include reduced vision, ocular pain, and redness. Any disturbance of vision requires immediate evaluation. The rapidity of onset, the involvement of one or both eyes, and the determination of whether central or peripheral vision is affected are key historical points. Typically, patients with long-standing poor vision in one eye do not notice any visual impairment until the better eye is occluded.

Acute monocular visual loss may be transient or permanent. *Amaurosis fugax* refers to transient visual loss in one eye that can signify retinal embolic disease from the heart or carotids and can precede central or branch retinal artery occlusion. Giant cell arteritis should be considered in elderly patients with amaurosis fugax. Giant cell arteritis can cause sudden and permanent loss of vision as a result of compromised blood flow to the optic nerve or retina. Prompt treatment with systemic corticosteroids may prevent vision loss in the fellow eye.

Other important ocular symptoms include light flashes (photopsia) and floaters, which may signify a retinal tear, detachment, or vitreous hemorrhage. Distortion of vision (metamorphopsia) can be caused by subretinal fluid or blood from many causes. Binocular diplopia results from eye muscle imbalance caused by neurologic or muscular disorders or by mechanical misalignment of the globes.

The character of ocular pain or irritation can help elucidate the cause. Foreign body sensation results from ocular surface abnormalities such as dry eyes, foreign bodies, conjunctivitis, and herpes simplex keratitis. Burning and itching result from dryness or allergy. Aching or throbbing signifies a deeper process such as intraocular inflammation or elevated intraocular pressure.

Headaches and dizziness rarely have an identifiable ocular basis.

EVALUATION OF THE RED EYE

Redness of one or both eyes is common and can result from mild, superficial disorders with little effect on vision or from severe, deeper problems with profound effect on vision. The redness is nonspecific and results from hyperemia of the conjunctival, episcleral or scleral vessels, which can be caused by inflammatory or infectious processes of the conjunctiva, sclera, cornea, iris, ciliary body, or periocular adnexa ([Table 50.1](#)).

	Acute Conjunctivitis	Acute Iritis	Acute Keratitis	Acute Angle-Closure Glaucoma
Symptoms				
Incidence	Very common	Common	Common	Uncommon
Vision	Normal	Normal	Normal	Markedly blurred
Pain	Mild	Moderate-severe	Moderate-severe	Severe
Photophobia	None-mild	Moderate-severe	Moderate-severe	Moderate
Discharge	Moderate-copious	None	Moderate	None
Itch	None	None	None	None
Signs				
Conjunctival hyperemia	Diffusely present	Localized to perilimbal area	Diffusely present	Diffusely present
Pupil abnormalities	None	Small, poorly responsive	Normal	Fixed and moderately dilated
Intraocular pressure	Normal	Low, normal, or high	Normal	High
Corneal epithelial defect	None	None	May be present	None
Corneal opacity	None	None	Local or diffuse	Diffuse
Shallow anterior chamber	None	None	None	None
Periocular lymph nodes	May be present	None	None	None

TABLE 50.1. COMMON SYMPTOMS AND SIGNS OF THE RED EYE

Extreme caution should be exercised in prescribing topical corticosteroids for a red eye. Corticosteroids can mask worsening of the disease process, suppress immunity to infectious diseases, raise intraocular pressure, and cause cataracts.

Topical anesthetics should never be dispensed because they are toxic to the cornea, can cause allergic reactions, and can mask the pain of underlying ocular disease.

Contact lens wearers have a higher risk for corneal infections. Thus, a red eye in a contact lens wearer requires special attention.

Any patient who exhibits worsening of symptoms or decreasing visual acuity despite treatment should be referred to an ophthalmologist.

OCULAR TRAUMA

Corneal abrasions can be diagnosed by topical application of fluorescein dye, which stains the denuded corneal epithelial basement membrane. The abrasion appears green when viewed with a cobalt blue light ([Fig. 50.1](#)). Corneal abrasions usually are treated with topical antibiotics and cycloplegic agents. In general, small abrasions heal quickly. Large epithelial defects can be patched and monitored daily until healing is complete. Patients generally are more comfortable when the eye is patched, but patching should not be used in corneal abrasions related to contact lens wear or those caused by organic matter (e.g., a thorn or tree branch). The cornea is compromised until the epithelial defect is resolved and should be observed frequently for infection.

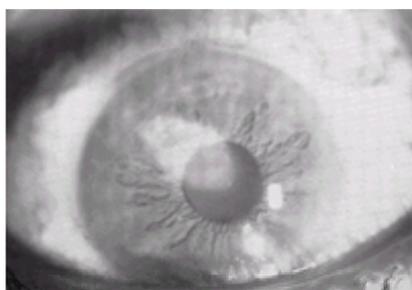

FIGURE 50.1. Neovascularization of the disc and retina.

The eyelids should be everted and inspected for foreign bodies when foreign body sensation or corneal abrasions are present.

All chemical injuries should be irrigated immediately and copiously with any neutral fluid. Alkali injuries have the worst prognosis because of their rapid corneal penetration.

Hyphema (blood in the anterior chamber) usually results from blunt trauma and frequently coexists with other serious ocular injury (e.g., retinal detachment, lens dislocation, ruptured globe, glaucoma). Hyphema should be treated by an ophthalmologist.

Lacerations of the eyelid margin should be referred to an ophthalmologist for surgical repair. Inaccurate reapproximation of the eyelid margin can result in a permanent eyelid notch with subsequent chronic ocular irritation.

Any ocular injury caused by a sharp object or high-velocity missile is reason for a high suspicion for a ruptured globe or an intraocular foreign body. Such injuries should be assessed fully and immediately by an ophthalmologist.

OCULAR MANIFESTATIONS OF AIDS

Cytomegalovirus retinopathy causes retinal necrosis. It occurs in 30% of patients with AIDS and is the most common, severe, blinding ocular infection. Intravenous ganciclovir can slow the spread of the infection but does not eradicate the virus; 50% of patients have reactivation despite low-dose maintenance therapy.

Other ocular infections associated with AIDS include herpes simplex retinitis, *Toxoplasma* retinitis, *Pneumocystis carini* choroiditis, herpes zoster ophthalmicus, and molluscum contagiosum of the eyelids.

Kaposi's sarcoma, a multifocal vascular neoplasm, can affect the conjunctiva, the eyelid margins, and, rarely, the orbit. When Kaposi's sarcoma involves the conjunctiva, it can be mistaken for a subconjunctival hemorrhage. Burkitt's lymphoma can develop in the orbit, causing proptosis with damage to the extraocular muscles and cranial nerves.

Neuro-ophthalmic disturbances, including cranial nerve palsies, papilledema, optic atrophy, and visual field defects, can develop in patients with AIDS. They result from intracranial neoplasms and infectious processes.

DIABETES AND THE EYE

Diabetes can cause retinopathy, glaucoma, an altered refractive state, and cataracts. Diabetic retinopathy is the leading cause of blindness in people younger than 60 years of age in the United States. The likelihood of developing retinopathy increases with the duration of the disease. After 20 years' duration, nearly all patients with type I diabetes have some retinopathy. Patients with type II diabetes may have retinopathy at the time of diagnosis.

Retinopathy can be nonproliferative or proliferative. Nonproliferative retinopathy includes microaneurysms, intraretinal dot and blot hemorrhages, cotton-wool spots, hard yellow exudates, and intraretinal microangiopathy. Proliferative retinopathy refers to neovascularization of the disc and retina ([Fig. 50.2](#)), vitreous hemorrhage, and retinal detachment. Vision loss in patients with diabetic retinopathy is most often due to macular edema or vitreous hemorrhage. Macular edema can be treated with focal laser photocoagulation. Proliferative retinopathy can be treated with panretinal laser photocoagulation, which reduces the risk of vitreous hemorrhage from neovascularization.

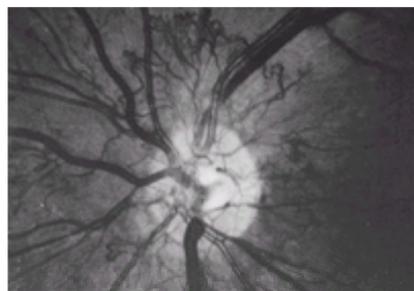

FIGURE 50.2. Corneal abrasion. See [color figure 50.2](#).

Proliferative retinopathy typically is asymptomatic until vitreous hemorrhage develops. Because laser treatment can reduce severe visual loss by 50% to 90%, patients with diabetes must undergo regular eye examinations through dilated pupils by an ophthalmologist.

Patients with type II diabetes should have a complete ophthalmic examination at the time of diagnosis and at least yearly thereafter. Patients with type I diabetes should undergo an eye examination 5 years after diagnosis and then annually unless and until the severity of retinopathy mandates either more frequent assessment or laser treatment. Forty percent of patients with severe nonproliferative diabetic retinopathy progress to proliferative diabetic retinopathy within 1 year. Pregnant patients with type I diabetes should be examined in the first trimester and every 3 months thereafter because pregnancy can accelerate retinopathy. Ideally, women with diabetes who are planning a pregnancy should undergo a baseline examination before conception. Diabetic blindness is largely preventable.

GLAUCOMA

Glaucoma is a progressive optic neuropathy characterized by cupping of the optic nerve head, irreversible visual field loss, and, usually, elevated abnormal intraocular pressure.

Increased intraocular pressure can result from impaired outflow of aqueous through the anterior chamber angle (open-angle glaucoma) or impaired access of aqueous to the drainage system (closed-angle glaucoma). Treatment is directed toward reducing the intraocular pressure and, when possible, correcting the underlying mechanism.

Chronic open-angle glaucoma accounts for 80% to 85% of all glaucoma. Risk factors are older age, diabetes, family history, myopia, and black race.

Because 25% to 30% of patients with glaucoma have normal intraocular pressures (21.5 mm Hg or lower) on initial presentation, evaluation of the optic nerve and visual field is essential for detection.

AGE-RELATED MACULAR DEGENERATION

Age-related macular degeneration (AMD) is the leading cause of severe vision loss in the Western hemisphere. Age over 65 years, a positive family history, and a history of cardiovascular disease are important risk factors. The condition is rare in blacks.

In the early stage of AMD, characterized by drusen, there typically are no symptoms. *Drusen* are yellow-white deposits behind the retina. Drusen identify an eye at risk for vision loss. Visual symptoms include blurred vision, distortion, and a blank spot in the field of vision. Of those patients with AMD who have visual impairment, 80% have the atrophic or dry form and 20% have the neovascular/exudative or wet form. The neovascular form of AMD results from leakage from abnormal choroidal blood vessels that cause macular detachment. Laser treatment is helpful in selected patients with the neovascular form of AMD.

CHAPTER 51: MEDICAL OTOLARYNGOLOGY

ERICA R. THALER AND DAVID W. KENNEDY

[Common Otolaryngologic Infections](#)
[Peripheral Vestibular Disorders](#)
[Tinnitus](#)
[Head and Neck Cancer](#)
[Otolaryngologic Emergencies](#)

Although otolaryngology is a surgical subspecialty, much of the field involves nonsurgical treatment of patients. This chapter reviews the medical management of common otolaryngologic disorders, including infections, neoplasms, and emergencies.

COMMON OTOLARYNGOLOGIC INFECTIONS

ACUTE OTITIS MEDIA

Definition

Acute otitis media (AOM) is a bacterial or viral infection of the middle ear cleft that occurs with rapid onset and resolves within 1 month. It involves the collection of either purulent or serous fluid in the middle ear.

Incidence and Epidemiology

AOM is most prevalent in the pediatric population, affecting at least 2 million children younger than 3 years of age each year. The incidence peaks in the latter half of the first year of life and falls off dramatically after the first decade. Epidemiologic studies suggest that bottle feeding, smoking in the household, and exposure to large day care facilities increase the incidence of AOM.

Etiology and Pathogenesis

The cause of AOM is multifactorial. Underlying predisposing factors include eustachian tube dysfunction, inadequate aeration of the middle ear cleft, and immunologic immaturity or deficiency. A combination of these and other factors leads to inadequate drainage of fluid from the middle ear space with subsequent viral or bacterial infection. The most common bacteria involved are *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Moraxella catarrhalis*, and *Streptococcus pyogenes*. Neonates are more commonly infected by *Staphylococcus aureus* and gram-negative enteric bacilli.

Clinical Findings

Typical clinical findings of AOM are a history of increased irritability, poor oral intake, tugging at the ears, ear pain, and fever. Older children and adults may relate a history of decreased hearing. Generalized symptoms of an upper respiratory tract infection (e.g., rhinorrhea, cough) may be present. A history of imbalance may be elicited. On examination, the auricle and external auditory canal are normal in appearance early in the disease course. The tympanic membrane is thickened, inflamed, bulging, and poorly mobile. Later, perforation may be noted with purulent drainage emanating from the middle ear. Signs and symptoms of complications of AOM include a bulging, doughy, and tender mastoid area, picket-fence fever, mental status changes, and signs of meningeal irritation.

Laboratory Findings

Although laboratory studies are unnecessary in making the diagnosis of AOM, a leukocytosis may be noted. Concern about a possible complication of AOM warrants a contrast-enhanced computed tomographic (CT) scan.

Optimal Management

Evidence suggests that most cases of AOM will resolve spontaneously without antibiotics. However, to treat patients whose AOM will not resolve without intervention and to prevent complications, antibiotic therapy is recommended. First-line therapy for AOM involves a 10-day course of either amoxicillin or trimethoprim-sulfamethoxazole. If these are not successful, broader-spectrum b-lactamase-resistant antibiotics may be necessary. These include amoxicillin-clavulanate, cefaclor, erythromycin-sulfasoxazole, and cefixime. The incidence of b-lactamase-producing pathogens (now 10% to 30%) is rising and may require more aggressive initial antimicrobial regimens. Culture-directed therapy is not necessary for most cases, but may be required for a recalcitrant case or one involving an immunocompromised patient.

OTITIS EXTERNA

Definition

Otitis externa is an infection of the external auditory canal that can be bacterial, fungal, or viral. It typically involves only the skin lining the canal, although cellulitis may extend out onto the auricle. An uncommon variant, malignant otitis externa, is a more severe infection that typically occurs in older patients and involves osteitis of the temporal bone.

Incidence and Epidemiology

Known in the vernacular as “swimmer’s ear,” otitis externa is more common in warm, humid climates. Maceration of the skin lining the canal from water or trauma to the ear canal predisposes to infection. Malignant otitis externa is more common in elderly, diabetic, and immunosuppressed patients.

Etiology and Pathogenesis

Penetration of the skin lining the canal occurs secondary to a break in the protective cerumen. Edema of the canal and bacterial overgrowth and invasion by virulent organisms then occur. This progression often is assisted by trauma to the canal. The most common bacterial pathogens are *Pseudomonas*, *S. aureus*, and various anaerobes. The most common fungal pathogen is *Aspergillus*. Malignant otitis externa is caused by *Pseudomonas aeruginosa*.

Clinical Findings

Patients with otitis externa experience a sensation of obstruction. Hearing may be diminished, depending on the degree of inflammation. Pain can be severe, and tragal tenderness is a hallmark sign. The ear canal is edematous and inflamed, often with purulent discharge. The tympanic membrane may not be visible. Cellulitis of the auricle may be present. If the infection is fungal, a white, cottonlike mass may be seen. Malignant otitis externa typically involves granulation tissue, poor response to local therapy, and unremitting pain, particularly at night.

Laboratory Findings

The diagnosis of external otitis is based on the history and physical examination. Occasionally, cultures of purulent discharge help direct antibiotic therapy. If malignant otitis externa is suspected, a CT scan of the temporal bone should be obtained to assess bone destruction. A gallium 67 radionuclide scan will demonstrate

osteitis and may be used to follow the course of the disease to determine the duration of antibiotic therapy.

Optimal Management

Treatment of uncomplicated external otitis is directed at drying and acidifying the canal. Many combination topical drops are available, which usually include a topical corticosteroid (dexamethasone or hydrocortisone) and an antimicrobial agent (neomycin, polymyxin, tobramycin, clotrimazole, or nystatin). Placement of a wick into the external auditory canal may be necessary for the drops to penetrate the length of the canal. Excessive debris should be removed. Oral antibiotic therapy is reserved for patients with cellulitis or immunosuppression or for those in whom coexisting otitis media is suspected. When required, ciprofloxacin is a good first-line oral agent because it is effective against both *Pseudomonas* and *Staphylococcus*. Malignant otitis externa should be treated with intravenous antibiotics to cover *Pseudomonas* (aminoglycosides have been used traditionally; fluoroquinolones more recently). Surgery to debride granulation tissue or sequestered cartilage and bone may be necessary.

CHRONIC OTITIS MEDIA

Definition

Chronic otitis media (COM) is defined as inflammation or infection of the middle ear cleft and mastoid air cells of more than 1 month's duration. It may involve simply a persistent serous effusion that will not clear despite antibiotic therapy. COM also may involve cholesteatoma, an epithelial ingrowth into the middle ear that proliferates and invades bone.

Incidence and Epidemiology

The incidence of COM has decreased markedly in the last half-century. This usually is attributed to the advent of multiple broad-spectrum antibiotics used to treat AOM and to the widespread use of pressure-equalization tubes to treat serous otitis media and eustachian tube dysfunction.

Etiology and Pathogenesis

Chronic otitis media can be considered along a continuum of middle ear disease that begins with AOM. Many of the same factors that cause AOM lead to COM (eustachian tube dysfunction, mucosal abnormality of the middle ear, immunologic deficiency). These abnormalities may result in the most mild form of COM, serous otitis media. The normal secretions of the middle ear mucosa are not drained properly and thus fill the middle ear cleft. Alternatively, cholesteatoma may result. Cholesteatoma arises from the ingrowth of epithelial tissue, typically into the middle ear. Retraction of the tympanic membrane secondary to eustachian tube dysfunction or perforation of the tympanic membrane may initiate this process. Secondary infection of the desquamated material then occurs. Organisms involved in COM include staphylococci, *P. aeruginosa*, *Proteus*, streptococci, and anaerobes. Cholesteatoma causes bony erosion of both ossicles and the temporal bone. This is due to the production of bone-resorbing enzymes or endogenous mediators such as prostaglandin E₂ and interleukin-1.

FIGURE 51.1. Otoscopic photograph of right tympanic membrane with large attic retraction pocket causing erosion of the bony external auditory canal. A serous effusion is also present. *m*, malleus short process. See [color figure 51.1](#).

Clinical Findings

Typical clinical findings of patients with COM range from decreased hearing to purulent and foul-smelling drainage from the ear. Vertigo or unsteadiness may be present, particularly if cholesteatoma has violated the vestibular labyrinth. Otalgia generally is not present and may be a sign of impending intracranial complication. On examination, the normal architecture of the tympanic membrane rarely is found intact. Serous effusion is identified by a retracted tympanic membrane that is poorly mobile and has fluid behind it. Air bubbles may be noted. The presence of unilateral serous otitis media in an adult always should raise the question of a possible nasopharyngeal mass causing eustachian tube dysfunction, and nasopharyngoscopy must be performed. Perforation, retraction pockets, erosion of the ossicles or external auditory canal, purulent discharge, chronic external otitis, and the pearly white cholesteatoma matrix may be visible ([Fig. 51.1](#)).

Laboratory Findings

Tuning forks and audiometric testing invariably reveal some degree of conductive loss. Sensorineural loss also may be present. CT scanning may be helpful in determining the extent of bony erosion, particularly invasion of the labyrinth and erosion through to dura.

Optimal Management

Management of COM includes 6 to 8 weeks of antibiotics to prevent recurrent AOM. If, after this time, resolution has not occurred, myringotomy is performed and a pressure-equalization tube may be placed to prevent recurrence. Management of more advanced COM includes systemic antibiotic therapy directed by culture of discharge from the middle ear and topical antibiotic drops. Surgery (some form of tympanomastoidectomy) is necessary to improve aeration of the middle ear, debride infected granulation tissue, and remove cholesteatoma. Intravenous antibiotic therapy may be necessary to treat osteitis of the temporal bone.

SINUSITIS

Definition

Sinusitis is inflammation of the mucous membrane of the paranasal sinuses. Viral sinusitis occurs frequently with upper respiratory tract infections and is self-limiting. Bacterial or fungal sinusitis can be acute or chronic (greater than 12 weeks). Sinusitis frequently is associated with a rhinitis, and to designate this, replacement of both terms with rhinosinusitis is now recommended.

Incidence and Epidemiology

Rhinosinusitis is the most common health care complaint in the United States, affecting more than 31 million people per year. Although typically considered a disease of adult life, rhinosinusitis recently has gained recognition in the pediatric age group.

Etiology and Pathogenesis

The most immediate cause of rhinosinusitis is a disruption of mucociliary drainage of the sinuses. This may be the result of mucosal disease from an upper respiratory

tract infection, environmental factors, pollution, or allergies, or it may be due to an underlying anatomical obstruction or narrowing. Pathogens of acute sinusitis include *S. pneumoniae*, *S. aureus*, *S. pyogenes*, and *H. influenzae*. Chronic sinusitis frequently is polymicrobial and associated with *Bacteroides* and other anaerobes, *Pseudomonas*, *Staphylococcus*, *H. influenzae*, and *Streptococcus viridans*. The incidence of gram-negative chronic sinusitis appears to be increasing significantly. The most common fungus found in sinusitis is *Aspergillus*, but many fungi can be pathogenic.

Clinical Findings

Patients with acute rhinosinusitis complain of pain referred from the involved sinuses, nasal obstruction, purulent nasal discharge, and fever. A history of viral rhinitis, allergic rhinitis, or nasal polyposis may be elicited. The nasal mucosa is edematous and erythematous. If nasal endoscopy is performed, purulent discharge may be seen emanating from the middle meatus along the lateral nasal wall or around the eustachian tube orifice. The presentation of chronic rhinosinusitis is more subtle and difficult to diagnose. Nasal congestion, nasal obstruction, postnasal drip, chronic cough, and headache are among the most common complaints. Nasal endoscopy may reveal abnormal, boggy mucosa and mucopurulent discharge from the middle meatus or sphenoidal recess or the presence of nasal or middle meatal polyps.

Laboratory Findings

The diagnosis of rhinosinusitis is based on the history and physical examination. In acute rhinosinusitis, initial therapy is empiric, but antral puncture and aspiration for culture is a consideration in patients who do not demonstrate early response to therapy or in those who are immunocompromised. In chronic rhinosinusitis, cultures of purulent discharge are helpful as a guide for antibiotic therapy. Traditional sinus radiography is of limited use because it demonstrates the maxillary and frontal sinuses only moderately well and provides poor information with regard to the ethmoid sinuses. A coronal CT scan through the sinuses confirms the presence of mucosal disease and may help to elucidate predisposing anatomical abnormalities.

Optimal Management

Management of rhinosinusitis is predominantly medical. Oral antibiotics and decongestants provide the first-line management of acute rhinosinusitis. Antihistamines are indicated when allergy is a component of the illness. In choosing an antibiotic for the treatment of acute rhinosinusitis, the increasing incidence of resistant *Pseudomonas* and of β -lactamase-producing *H. influenzae* must be borne in mind. A 10- to 14-day course is recommended. In chronic rhinosinusitis, the duration of antibiotic therapy may need to be significantly longer. Topical corticosteroids also are helpful in reducing edema in chronic disease. For refractory chronic rhinosinusitis, a course of oral corticosteroids may help to reduce mucosal edema and shrink nasal polyps (Fig. 51.2). Surgery is reserved for disease that is refractory to medical therapy. Endoscopic sinus surgery involves opening the sinuses, particularly in the areas surrounding their ostia, and correcting any anatomical abnormalities impairing mucociliary drainage. In occasional cases, long-term intravenous antibiotic therapy may be necessary to eradicate the osteitis that can accompany long-standing sinusitis.

EPIGLOTTITIS AND CROUP

Definition

Both epiglottitis and croup are infections of the upper airway tract, which can rapidly result in respiratory compromise. Epiglottitis is a bacterial infection of the supraglottic airway. Croup is a viral infection predominantly of the subglottic airway, otherwise known as laryngotracheobronchitis.

Incidence and Epidemiology

Croup typically affects children younger than 5 years of age. Until recently, epiglottitis occurred most commonly in children 2 to 4 years of age, but with the advent of the vaccination for *H. influenzae* type B, the incidence is shifting toward the adult population. Both infections occur most commonly during the winter.

Etiology and Pathogenesis

Croup typically is caused by the parainfluenza virus (types 1 and 3). Influenza A virus, rhinovirus, and respiratory syncytial virus also have been implicated. Despite the vaccine, epiglottitis still is caused most often by *H. influenzae* type B.

Clinical Findings

A patient with croup typically has signs and symptoms of an upper respiratory tract infection, including a low-grade fever followed by the gradual onset of a barking, nonproductive cough. Edema of the glottic and subglottic airway leads to stridor, increased work of breathing, and costal retractions. Epiglottitis has a more rapid onset with high spiking fevers and the development of severe odynophagia and dysphagia, often with drooling. “Hot-potato” or muffled speech is present. Stridor develops with the progression of supraglottic edema. Patients have difficulty lying supine secondary to airway obstruction from edematous and inward collapsing aryepiglottic folds. Complete airway obstruction can develop rapidly. Examination of a child with epiglottitis should be extremely limited because agitation can contribute to airway compromise.

Laboratory Findings

In croup, a posteroanterior neck radiograph reveals a “steeple sign” in the subglottic airway with pinpoint narrowing just beneath the glottis. In a patient with recurrent croup, the subglottic area must be evaluated closely for structural abnormalities such as subglottic stenosis, cysts, or hemangiomas. Epiglottitis can be identified on lateral neck radiography by supraglottic edema (hazy, ill-defined structures) or the classic “thumbprint sign” of a swollen epiglottis. Patients with epiglottitis have a greater leukocytosis, and one-third have blood cultures that are positive for *H. influenzae*.

Optimal Management

Assessing the need for and securing the patient's airway are of paramount importance in both epiglottitis and croup. In epiglottitis, some form of airway intervention typically is performed. In croup, however, careful observation and medical therapy may suffice. For a child, airway management may require intubation in the operating room by an anesthesiologist with an otolaryngologist present to perform emergency tracheotomy, if necessary. In an adult, if the patient is cooperative, awake fiberoptic nasal intubation or an awake tracheotomy is the safest means of securing the airway. Croup is treated with racemic epinephrine and corticosteroids

to reduce edema and with humidified oxygen to assist in thinning secretions. Epiglottitis is treated with intravenous antibiotics effective against *Haemophilus influenzae*. β -Lactamase-resistant cephalosporins such as cefuroxime or ceftriaxone are excellent first-line agents.

PERIPHERAL VESTIBULAR DISORDERS

Definition

Peripheral vestibular disorders include pathologic condition of the sensory labyrinth or vestibular nerve, leading to a disruption in the patient's sense of balance, which may range in severity from a vague sense of unsteadiness to whirling vertigo. These disorders may be further classified by the cause of the disruption in balance, including trauma, viral or bacterial infection, exposure to ototoxic drugs, autoimmune disorders, and neoplasm.

Incidence and Epidemiology

Dizziness is a common complaint, affecting 90 million Americans each year. It is unknown what percentage of these patients has peripheral vestibular disorders. In general, younger patients are more likely to have peripheral vestibular problems, and older patients are more likely to have central causes to their dizziness.

Etiology and Pathogenesis

There is a myriad of peripheral causes to the subjective sense of imbalance. These include head trauma, resulting in basilar skull fracture or labyrinthine concussion; perilymph fistula, in which there is leakage of the perilymph outside the membranous labyrinth; infection, either viral or bacterial, typically the result of otitis media; ototoxic drugs, including many of the aminoglycosides, and aspirin products; neoplasm, most commonly acoustic neuroma of the vestibular portion of the eighth nerve; and autoimmune disease, including many of the common collagen vascular diseases.

Clinical Findings

A careful history and otoscopic and cranial nerve examinations are critical in determining the cause of balance disorders. The sudden onset of vertigo without change in hearing after a viral infection may suggest viral labyrinthitis. Benign positional vertigo is suggested by a temporary whirling vertigo elicited by certain head positions. Acuity of onset, frequency, duration, and quality are important in identifying the underlying cause. Episodic vertigo associated with episodic hearing loss and tinnitus suggest Menière's syndrome.

A positive positional maneuver such as Hallpike's test suggest benign paroxysmal positional vertigo. Nystagmus, if present, should be characterized. Fixation-suppressed, horizontal nystagmus is suggestive of an acute-onset peripheral balance disorder. Peripheral cranial nerve deficits, particularly hearing loss (VIII), facial nerve weakness (VII), or sensory loss of the ear canal (V) will help localize the side and site of pathology and may be suggestive of neoplasm.

Laboratory Findings

Routine blood studies may be helpful in determining the etiology of a peripheral balance disorder, but should be ordered judiciously, based on a suggestive history or physical exam. Balance function testing, including electronystagmography, posturography, and rotational chair testing, combine to elucidate whether the balance problem is peripheral or central, the side and even site of the pathology, and whether there has been compensation. An audiometric assessment of the patient's hearing complements these tests. If there is concern about a central etiology, magnetic resonance imaging (MRI) is the radiographic study of choice. Magnetic resonance angiography may be added if there is special concern about vascular compromise.

Optimal Management

Management very much depends on the cause of the peripheral balance disorder. For acute-onset vertigo, meclizine (12.5 to 25 mg three times daily) may be used as an oral vestibulosuppressant. However, this should be tapered as quickly as possible because it may impede the patient's compensation. For many peripheral balance disorders, vestibular rehabilitation or physical therapy aimed at helping the body compensate for the particular vestibular weakness, has proved very effective. This is particularly true for benign paroxysmal positional vertigo, in which a specific positioning maneuver (Epley's maneuver) may be curative. Certain peripheral vestibular disorders have specific treatments, such as diuretics and sodium restriction for Menière's syndrome. Rarely, surgical ablation of some or all of peripheral vestibular neural input may be beneficial when medical therapy or vestibular rehabilitation have failed.

TINNITUS

Definition

Tinnitus is a perceived sound with no external acoustic stimulus. It may be subjective or objective—in the latter case, being audible to the examiner on auscultation. Tinnitus includes a wide variety of noises, ranging from the infrequent high-pitched cricketlike sounds to steady pulsations.

Incidence and Epidemiology

Approximately one-third of the population has at one time or another experienced tinnitus. Only a small percentage of patients have tinnitus that is severe and disabling. Tinnitus almost always accompanies some degree of hearing loss, usually sensorineural.

Etiology and Pathogenesis

Tinnitus that is the product of sensorineural hearing loss may result from cochlear or retrocochlear degeneration. Pulsatile tinnitus may arise from a high-riding jugular bulb, protruding into the middle ear cleft, an arteriovenous malformation, or a glomus tumor. Rapid muscular contractions, of the stapedius muscle, or tensor tympanic and other palatal muscles, may result in a clicklike rapid-fire noise.

Clinical Findings

History and physical examination may elucidate an underlying cause to the tinnitus, for instance, a history of ototoxic drug exposure or head trauma. A glomus tumor or high-riding jugular bulb may be seen on otoscopic examination as a blue mass behind the tympanic membrane. In some cases, pulsatile tinnitus may be objective. The most common physical examination is normal, however, because of the frequent association of tinnitus with sensorineural hearing loss.

Laboratory Findings

Audiometric assessment of a patient with tinnitus is critical. If a hearing loss is unilateral, further investigation of the site of sensorineural hearing loss is warranted to evaluate for retrocochlear pathology such as tumor. An auditory brain-stem-evoked response (ABR) or MRI are acceptable means of studying this. If a patient's complaints and examination are suggestive of a vascular pathologic condition, magnetic resonance angiography is also important. Serologies are ordered as dictated by a suggestive history. For instance, if the patient has a history of occupational exposure to heavy metals or other industrial pollutants, then screens for these chemicals should be ordered.

Optimal Management

First-line management involves treatment of any underlying cause of tinnitus or sensorineural hearing loss that is reversible, for example, withdrawal of ototoxic drugs such as aspirin. Most often, tinnitus is not treatable. In some circumstances, hearing amplification may help the patient by amplifying external acoustic stimulus out of proportion to the tinnitus. Tinnitus maskers or a variety of other measures may be helpful in enabling the patient contend with tinnitus, including biofeedback,

hypnosis, and antidepressant and anxiolytic medications.

HEAD AND NECK CANCER

SQUAMOUS CELL CARCINOMA OF THE UPPER AERODIGESTIVE TRACT

Definition

Epidermoid or squamous cell carcinoma is the most common cancer of the upper aerodigestive tract. It is categorized as keratinizing or nonkeratinizing and arises from squamous mucosa lining the oral cavity, oropharynx, nasopharynx, hypopharynx, and larynx. Even areas of the upper respiratory tract normally covered by pseudostratified columnar epithelium may undergo squamous metaplasia and the subsequent development of squamous cell carcinoma.

Incidence and Epidemiology

Squamous cell carcinoma makes up 90% of oral cavity cancers, 75% of nasopharyngeal cancers, 89% of oropharyngeal and hypopharyngeal cancers, and 71% of laryngeal cancers. These cancers occur more commonly in men, and the average age of onset is 50 to 80 years of age. Synchronous multiple primary tumors occur in about 10% of patients.

Etiology and Pathogenesis

There is a well-known association between the development of squamous cell carcinoma of the upper aerodigestive tract and tobacco and alcohol abuse. Repetitive exposure to these substances is associated with the proliferation of squamous epithelium with premalignant changes, including hyperplasia, keratosis, and dysplasia. Carcinoma in situ develops next in the face of these noxious stimuli. Other known environmental associations include nickel and squamous cell carcinoma of the sinonasal area, eating of betel nuts in squamous cell carcinoma of the oral cavity, and tobacco chewing in squamous cell carcinoma of the gingiva. Metastasis spreads to the cervical nodes first, then to the lungs and liver.

Clinical Findings

Patients have a variety of complaints depending on the location of the lesion. Local pain, persistent hoarseness, foreign body sensation, dysphagia, halitosis, airway compromise, referred otalgia, and trismus are common on presentation. Examination reveals an indurated, tender, often ulcerated lesion. Mobility must be assessed and careful delineation of the submucosal extent of the lesion undertaken. Neck disease may be present on both ipsilateral and contralateral sides. The size of the nodes, skin involvement, and fixation to deep structures should be identified.

Laboratory Findings

A complete set of blood chemistries, blood cell counts, and liver function tests is obtained. Unless otherwise directed by the review of systems or an abnormal blood test result, a chest radiograph is sufficient for metastatic workup before panendoscopy. CT or MRI of the neck should be obtained from the nasopharynx to the clavicles to help define the lesion and identify clinically occult neck disease.

Optimal Management

Management of squamous cell carcinoma of the upper aerodigestive tract is tailored to the site of the lesion and its TNM stage. Surgery and radiation therapy are the primary modalities used, often in combined fashion for advanced tumors. With appropriate multidisciplinary therapy, overall 5-year cure rates are about 65% and can rise to 96% for localized laryngeal tumors. However, oncologic surgery of the head and neck can be functionally and cosmetically debilitating. Careful rehabilitation, psychological support, and close follow-up are critical. Nutritional support is of utmost importance in caring for these patients. Counseling in overcoming alcohol and tobacco addiction also is crucial. Chemotherapeutic protocols are in place for a variety of tumor stages and sites, but are still under investigation.

OTOLARYNGOLOGIC EMERGENCIES

IDIOPATHIC SUDDEN SENSORINEURAL HEARING LOSS

Definition

Idiopathic sudden sensorineural hearing loss (ISSNHL) is defined as any sensorineural hearing loss of unknown cause that is instantaneous or occurs within several hours. It is associated with tinnitus in most cases and with vertigo in more than 50% of all cases.

Incidence and Epidemiology

The incidence of ISSNHL is between 5 and 20 per 100,000 population each year. There is no sex predilection. The average age of onset is 46 years. It is most commonly unilateral and occurs most often in the spring.

Etiology and Pathogenesis

Several theories have been proposed to explain ISSNHL. One is that it is the result of a viral infection of the labyrinth. This is supported by evidence of a higher incidence of seroconversion to mumps, rubeola, varicella, cytomegalovirus, and influenza B in patients with ISSNHL compared with control subjects. Another theory is that ISSNHL is of vascular origin. In favor of this theory is the low cochlear tolerance to ischemia. Yamasoba has shown MRI evidence of slow blood flow in the vertebrobasilar system in some patients with ISSNHL. A third theory to explain ISSNHL is the so-called membrane break hypothesis. This suggests that membrane breaks within the inner ear (Reissner's membrane) cause ionic imbalance, allowing admixture of endolymph and perilymph. This imbalance prevents normal transmission of the auditory stimulus. Other diseases that can manifest a sudden hearing loss should be ruled out, including the possibility of acoustic neurinoma or a perilymph fistula.

Clinical Findings

Patients with ISSNHL complain of sudden hearing loss, often on arising in the morning. Tinnitus may be the first sign alerting them to a change. Vertigo is present about half the time. A history of loud noise exposure, scuba diving, flying, or recent head trauma suggests a perilymph fistula. Physical examination reveals a normal external ear and tympanic membrane. Nystagmus may be present. Facial nerve function should be tested carefully, but usually is normal.

Laboratory Findings

Audiographic assessment reveals sensorineural hearing loss. There is no characteristic pattern. Brain-stem audiometry should be obtained if this is unilateral, and an MRI with gadolinium should be performed to evaluate for an acoustic neurinoma if there is any suggestion of retrocochlear pathologic lesion. Blood serology, including an erythrocyte sedimentation rate, a blood glucose level, and a rheumatologic panel, help rule out other causes, particularly of the autoimmune system.

Optimal Management

Many pharmacologic agents have been used unsuccessfully to treat ISSNHL. Bed rest may be helpful, particularly if a membrane rupture has occurred. High-dose corticosteroids have been shown to help patients with moderate hearing loss regain hearing. Inhaled carbogen (95% oxygen and 5% carbon dioxide) has been shown to improve hearing by 1 year after treatment. Fortunately, the natural history of the disease is that 65% of patients recover normal or functional hearing within the first

several weeks, regardless of therapy. Causes of sudden hearing loss such as perilymph fistula or acoustic neurinoma usually are treated surgically.

EPISTAXIS

Definition

Epistaxis, or bleeding from the nose, has been categorized as anterior or posterior based on the location of the bleed in the nasal cavity. Anterior epistaxis typically is milder than posterior epistaxis and usually occurs from the region of Kiesselbach's plexus—a capillary network in the mucosa of the cartilaginous nasal septum. Posterior epistaxis typically is arterial, generally from a branch of the sphenopalatine artery.

Incidence and Epidemiology

About one in ten persons has experienced epistaxis. It occurs more commonly in the winter months when drier air diminishes the humidification of the nasal mucosa. The elderly are more affected by the seasonal variation in climate and more often have profuse, posterior bleeds.

Etiology and Pathogenesis

The cause of spontaneous epistaxis is multifactorial. Anatomical abnormalities such as a septal spur may make the mucosa susceptible to drying and crusting, leaving blood vessels more exposed and more susceptible to hemorrhage. Self-inflicted trauma such as repeated nose picking or placement of a foreign body in the nose (more common in children) can lead to epistaxis. Systemic factors such as atherosclerosis and hypertension are associated with an increase in epistaxis. Patients with blood dyscrasias or thrombocytopenia also are more susceptible. Patients who are taking anticoagulants and those who abuse alcohol tend to have profuse, recurrent episodes of epistaxis that are difficult to control. Recurrent epistaxis may also require aspirin therapy to be discontinued.

Clinical Findings

In patients with a mild anterior epistaxis, it often is easy to identify the site of the bleeding. Usually, there are no clinical findings other than the bleed itself. In contrast, in patients with a profuse, posterior epistaxis, many complicating clinical findings are present. It can be difficult to determine the side and site of the bleeding because blood often emanates rapidly from both nostrils and the mouth. There may be airway compromise and aspiration of blood. Emesis occurs secondary to swallowing of blood. Elevated blood pressure in an anxious patient exacerbates bleeding.

Laboratory Findings

Patients with profuse spontaneous epistaxis of uncertain origin should undergo a hematologic workup to rule out the possibility of an underlying blood dyscrasia. Hemoglobin and hematocrit levels are necessary in deciding to perform a transfusion or to initiate iron supplementation. A carotid arteriogram may be indicated in epistaxis that is recurrent and not controlled with packing. This determines the site of bleeding and allows for concurrent embolization of the bleeding vessel.

Optimal Management

Management of epistaxis first involves a rapid search for the site of bleeding. If found, this can be cauterized with silver nitrate or covered with thrombin-coated Gelfoam or Surgical. If a site is not identified, pressure should be applied to the nares. Control of bleeding that does not respond to pressure held for 10 minutes is achieved by packing the nose. A variety of materials are available. A Merocel sponge coated with antibacterial ointment is one effective method of packing. Ointment-coated gauze in long strips is another. For profuse posterior bleeds, a posterior pack may be necessary. This involves placing a balloon catheter into the nasopharynx, then packing the nasal cavity with gauze. This is secured at the nares. An alternative is the Epistat, which has two balloons, one for the nasopharynx and one for the nasal cavity. Packing is left in place for 48 to 72 hours. If bleeding resumes, embolization or surgical ligation is necessary.

ACUTE AIRWAY COMPROMISE

A discussion of otolaryngologic emergencies would be incomplete without mention of airway compromise. This topic encompasses a wide variety of causes and many subtleties in management that are beyond the scope of this chapter. Instead of a systematic review, an algorithmic approach for the management of acute airway compromise is included in [Figure 51.3](#). This provides a framework for safe airway management by any practitioner involved with patients requiring acute resuscitative measures.

FIGURE 51.3. Algorithmic approach for acute airway compromise.

CHAPTER 52: PRINCIPLES OF WOMEN'S MEDICINE

ERIN N. MARCUS

[Violence Against Women](#)
[Gynecologic Issues](#)
[Gynecologic Cancer Screening](#)
[Sexually Transmitted Disease Screening](#)
[Contraception and Family Planning](#)
[Menopausal Issues](#)
[Breast Cancer Screening](#)
[Osteoporosis](#)
[Heart Disease](#)

As women have gained economic and political power in the United States, they have demanded more attention for their unique health problems. Over the past two decades, there has been a proliferation of literature on health issues that affect women primarily, such as breast cancer, as well as research into how ailments such as heart disease differ in women and men.

Because they outlive men and seek out care more frequently, women make up the majority of patients in the United States. A female infant in the United States has a life expectancy of 79 years, 6 more than her male counterpart. The average woman who lives to age 65 can expect to live 19 more years, 3 years longer than a 65-year-old man. Because they live longer, women make up 75% of US nursing home residents.

According to the National Center for Health Statistics (NCHS), women visit doctors' outpatient offices at a rate 1.5 times that of men. Their overall hospitalization rate is higher than men's, and they visit hospital emergency departments slightly more often than men. Women under age 65 are slightly more likely to have health insurance than men, but NCHS surveys indicate they are more likely than men to delay necessary care, regardless of income level.

As with men, cardiovascular disease kills the most women, followed by lung cancer and stroke. Breast cancer, accidents, and chronic obstructive pulmonary disease are the next most common causes of death among women. Certain autoimmune rheumatologic conditions and endocrine conditions are far more common in women than in men.

Multiple cross-sectional surveys indicate that most women in the United States are unaware of the threat of coronary disease and fear breast cancer more than any other condition. A large cross-sectional survey by Legato and associates (1997) found that 58% of women believed they were as likely or more likely to die from breast cancer than from coronary disease. Of those surveyed, 44% considered themselves unlikely to develop heart disease. Perhaps most concerning, 47% of the women at highest risk of coronary disease—those over age 60—said their doctor had never discussed heart disease with them. Yet heart disease is far more prevalent, and deadly, than breast cancer. Phillips and associates (1999) have estimated that of a birth cohort of 1,000 women, 203 will die of cardiovascular causes by the age of 85 years, compared with 33 who will die of breast cancer.

As with the nation as a whole, the ethnic composition of the US female population is changing. Blacks, Hispanics, Asians, Pacific Islanders, and Native Americans make up approximately 28% of women in the United States and overall are growing at a rate faster than that of whites in the population. These women are disproportionately affected by medical issues such as hypertension and diabetes, and many have different assumptions and beliefs about health care and those who provide it. Recent medical decision-making studies have indicated that physicians' own biases may affect how they evaluate women of color with medical problems.

VIOLENCE AGAINST WOMEN

Women are often the target of violence, and all women should be screened for violence in a nonjudgmental, supportive manner. Domestic violence is the leading cause of violent injury to women between the ages of 18 and 44. Sexual assault is common across all age groups. A 1998 Commonwealth Fund survey found that 31% of women reported having experienced domestic violence. Thirty-nine percent reported having experienced some type of abuse or violence in their lifetime. When faced with a victim of abuse or assault, health care workers should carefully document the patient's history and physical findings, assess her immediate safety, and assist her with crisis intervention services.

GYNECOLOGIC ISSUES

Routine gynecologic care is important for all women, because it allows health care providers to detect cancer and sexually transmitted diseases, to provide contraceptive counseling, and to evaluate the patient for conditions with considerable morbidity, such as dysmenorrhea, amenorrhea, sexual dysfunction, menorrhagia, and incontinence.

Over the past two decades, awareness of the need for culturally sensitive and painless pelvic examinations has increased. Young patients may be especially apprehensive about the pelvic examination; similarly, the examination can be uncomfortable for a postmenopausal woman if the examiner fails to use additional lubrication. There are a variety of alternative positions for the disabled patient who cannot lie supine.

GYNECOLOGIC CANCER SCREENING

Since its widespread adoption in the 1970s, Papanicolaou (Pap) screening has drastically reduced the incidence of and mortality from cervical cancer in the United States. Nonetheless, we are experiencing an epidemic of human papilloma virus (HPV), of which several types are associated with cervical cancer, and Pap screening remains extremely important. All young, sexually active women should have an annual gynecologic examination and Pap smear, as should all women older than age 17. Women infected with HIV, who are at an increased risk of invasive cervical cancer, should undergo Pap smear testing every 6 months. Other high-risk women include those who have had first intercourse in their teens when the cervical squamocolumnar junction is believed to be most susceptible to oncogenic change; women with multiple male partners or with men whose previous partners had cervical cancer; women infected with HPV, herpes simplex virus (HSV), or other sexually transmitted diseases; immunosuppressed women; women with a history of substance abuse, including tobacco; and women who have had cervical dysplasia or cancer or endometrial, vaginal, or vulvar cancer.

When to stop annual Pap smear screening remains controversial. No consensus exists among medical groups regarding this issue, but the American College of Obstetricians and Gynecologists now states that low-risk women who have had three consecutive negative annual examinations may, at the discretion of their physician, undergo Pap testing less frequently.

Despite the widespread acceptance of Pap smear testing, many women (particularly those over age 60) have not been adequately screened according to a recent Commonwealth Fund report. Women over age 60 account for 40% of cervical cancer deaths.

There is even less of a consensus regarding screening for ovarian cancer. Manual pelvic examination is insensitive, although a patient with a palpable postmenopausal ovary must be worked up for cancer. Ultrasonography and tumor markers, such as CA 125, are not considered practical screening tests in the general population. However, many physicians use these tests in women at high risk, such as those with a strong family history.

SEXUALLY TRANSMITTED DISEASE SCREENING

In addition to HPV, other sexually transmitted diseases (STDs) such as chlamydia and gonorrhea are very common in the US population, and women are often asymptomatic. All young, sexually active women and women with multiple sexual partners should routinely be screened for chlamydia, the most common bacterial STD in the United States, as well as for gonorrhea. Chlamydia is common throughout all socioeconomic groups in the United States, whereas gonorrhea, syphilis, HSV-2, and HIV are more common in lower-income populations. A recent cross-sectional study of female military recruits by Gaydos and associates found a

chlamydia prevalence rate of 9.2%.

Pelvic inflammatory disease accounts for approximately 275,000 hospitalizations annually in the United States, and silent pelvic inflammatory disease may account for many cases of tubal factor infertility.

AIDS, the most deadly STD, is growing faster in women than in any other group. AIDS is the fourth leading cause of death among all US women between the ages of 25 and 44. In certain cities, such as New York, AIDS is the number one cause of death among women in this age group. Most HIV-positive women in the United States are infected through heterosexual sex, and many of these women are in long-term, monogamous relationships at the time they are diagnosed. A study of recently diagnosed women in Rhode Island, for example, found that 70% of those who acquired HIV sexually had been in a long-term stable relationship for at least 2 years.

CONTRACEPTION AND FAMILY PLANNING

Vasectomy remains a relatively underused birth control method in the United States, and most contraception ends up being left up to the female partner. A recent US Centers for Disease Control study of women between the ages of 15 and 44 found that nearly 28% of women who used contraception chose tubal sterilization. Approximately 27% chose oral contraceptives, followed by condom use at 20%. About 11% of the women reported having partners who had had vasectomies. Tubal ligation was highest among black women over age 35, of whom 66% had been sterilized. Women in their 20's most commonly used oral contraceptives. Overall, 5% of the surveyed women said they never used any method of birth control, even though they were sexually active and were not trying to get pregnant.

Given these statistics, it is not surprising that nearly 50% of the 6.3 million pregnancies in the United States annually are unintended. Of these unplanned pregnancies, about 50% occur in women using birth control, whereas 50% occur in women who never practice contraception. The Alan Guttmacher Institute estimates that 43% of unintended pregnancies end in abortion and 13% end in miscarriage.

Nonetheless, access to legal abortion has become more difficult for many women. The number of abortion providers dropped by 14% between 1992 and 1996, and 86% of all US counties lacked an abortion provider in 1996, according to the Guttmacher Institute.

All women at risk of becoming pregnant should be counseled annually on preconception issues, since the fetus' major organs are formed between 17 and 56 days after conception, at a time when many women may not realize they are pregnant. Women should be advised to consume a daily minimum of 400 µg of folic acid to prevent neural tube defects and should be counseled on the avoidance of tobacco, alcohol, and street drugs, as well as herbal supplements, whose safety has not been established in pregnancy. Health care providers should avoid prescribing teratogenic medications to this group and, if this is not possible, should counsel their patients on pregnancy prevention.

MENOPAUSAL ISSUES

Many women seek medical attention during the perimenopause, the transitional years surrounding the last menstrual period, when hormone levels fluctuate considerably. Health professionals can help perimenopausal women not only by treating hot flashes and other symptoms but also by intervening to prevent osteoporosis and heart disease, which cause considerable morbidity and mortality later on in life.

Menopause is a retrospective diagnosis, made when a woman has not had menses for a year and has a follicle-stimulating hormone (FSH) level greater than 30. Menopause usually occurs between ages 48 and 55. If a woman ceases menstruating before age 40 and is not pregnant, she has premature ovarian failure and must be evaluated for autoimmune and other conditions.

Individual women's responses to menopause vary. In a recent MacArthur Foundation survey of 8,000 adults ages 25 to 74, a majority of postmenopausal women said they felt "only relief" when their menses ceased; 2% of the women reported "only regret." Other surveys have found that major depression is not more common among women at menopause, except among those who had a surgical menopause.

Hot flashes are a true physiologic phenomenon, characterized by a rise in skin temperature, heart rate, and minute ventilation. Between 25% and 75% of women report hot flashes at some point during the perimenopause. Hot flashes are not dangerous but can cause sleep deprivation and diminish quality of life.

Estrogen is the best-established therapy for hot flashes. A dose of 0.625 mg per day of conjugated estrogen is considered the minimum necessary for osteoporosis and coronary artery disease prevention, but some women may need a higher dose to prevent hot flashes. Nonhormonal treatments for hot flashes include clonidine, bellergal, biofeedback, exercise, and avoidance of triggers such as alcohol and caffeine. Many women use herbal supplements such as dong quai and black cohosh, although the efficacy and long-term safety of these supplements are unclear.

The long-term benefits of estrogen use include osteoporosis prevention and treatment, which has been well documented in controlled clinical trials, as well as the primary prevention of coronary artery disease, which has been strongly suggested by many long-term cohort studies. Observational studies also suggest that estrogen may reduce the development of colon cancer and of Alzheimer's dementia. Topical estrogen creams have been found to reduce the risk of recurrent urinary infection and dyspareunia.

There are risks associated with estrogen therapy. Unopposed estrogen markedly increases the risk of endometrial cancer. Therefore, women on estrogen replacement therapy who have not had a hysterectomy must also receive progesterone, which reduces this risk. Estrogen increases the risk of venous thrombosis and of cholelithiasis and increases triglycerides.

The best-publicized and most-feared risk of hormone therapy, breast cancer, remains controversial. The Nurses' Health Study, a cohort study of 121,700 women, found that the relative risk of dying from breast cancer was 1.45 for current hormone users who had used estrogen for 5 years or more, compared with those who had never used it. Other observational studies have yielded conflicting results. The Women's Health Initiative, a 15 year-long US-government-funded study that includes a clinical trial involving 64,500 women, should help elucidate this risk.

Recent data also indicate that estrogen may increase the incidence of new cardiovascular events in women with preexisting heart disease. The Heart and Estrogen/Progestin Replacement Study, a 4-year, controlled clinical trial involving postmenopausal women with documented coronary artery disease, found a statistically significant increase in myocardial infarction and death in the first year of hormone therapy. Over the entire 4-year period, the overall number of coronary events was equal in both the hormone and placebo groups.

Selective estrogen receptor modulators such as raloxifene are a new alternative that may be of benefit in preventing osteoporosis and heart disease. A 2-year controlled trial of raloxifene found that it increased bone mineral density and lowered low-density lipoprotein levels without increasing the rate of endometrial abnormalities. Other studies have found a decrease in breast cancer incidence in women on raloxifene over a 28-month period. However, other literature suggests raloxifene may worsen hot flashes.

BREAST CANCER SCREENING

Mammography is of proven benefit in detecting early cancer and saving lives in women between the ages of 50 and 69. Outside of this age range, however, its use as a screening test is controversial. In a meta-analysis of mammography trial data published in 1995, Kerlikowske and colleagues did not find a statistically significant reduction in breast cancer mortality in women under 50 who were screened. Others have interpreted the individual study results differently, finding a mortality reduction in younger women in five out of the eight major mammography trials.

There is no consensus on screening mammography in women under age 50. As of February 1999, the American Cancer Society recommends screening for all women beginning at 40, whereas the American College of Physicians does not recommend screening of the general population under age 50.

Moreover, there is no clear-cut consensus on when to stop mammography. Women older than 70 have the highest incidence of and mortality from breast cancer, but they have been underrepresented in the major mammography trials. As of 1998, the American Geriatrics Society recommends that women receive mammograms

every 2 or 3 years until age 85. Medicare covers annual screening mammograms in all older women.

There may be a high false-positive rate among women who undergo regular mammogram screening. Elmore and colleagues (1998) have estimated that the cumulative risk of a false-positive mammogram result is 49% in women who have ten screening mammograms. Other studies have indicated that false-positive results can cause anxiety, which may interfere with daily life.

OSTEOPOROSIS

Osteoporosis is epidemic in the United States, and its consequences can be deadly. A 50-year-old white woman in the United States has a 50% chance of developing an osteoporotic fracture during the rest of her life. If she breaks her hip, she has a 10% to 20% chance of dying within 1 year. Hip, vertebral, and forearm fractures can also cause significant pain and morbidity.

Osteoporosis prevention must begin early, because bone mass peaks in the third decade of life. All patients should be counseled on the need for adequate calcium and vitamin D intake. Bone mass drops precipitously during perimenopause, and hormone replacement therapy is of benefit in maintaining and augmenting bone mass during this time. There is no consensus on whether initiating hormone therapy after age 65 is of benefit in treating osteoporosis.

All women should have their height measured periodically, because this is an inexpensive means of screening for osteoporosis. Bone mineral density testing should be done periodically in women at increased risk, such as those with a family history of the disease or a personal history of tobacco, phenytoin, steroid, or heparin use or with hyperthyroidism or other endocrinopathies. Women who are undecided about estrogen replacement therapy are also candidates for bone mineral density testing.

Alendronate is effective in preventing and treating osteoporosis, and nasal calcitonin is approved for treating the condition. For more information, see [Chapter 465](#).

HEART DISEASE

Heart disease strikes two out of three women and is a major cause of disability; nearly one in three will die of coronary disease. It is predominantly a disease of older women, largely because of estrogen's protective effects before menopause, and on average strikes women 10 years later than men. As with men, hypertension, obesity, smoking, and hyperlipidemia increase a woman's risk of coronary disease. Diabetic women are at even greater risk than diabetic men.

Women with coronary artery disease most commonly present with angina. Women with angina are more likely to be older and to have hypertension, diabetes, and heart failure than are men with angina. Women are also more likely to have stable angina before their first myocardial infarction.

Women who develop a myocardial infarction are more likely than men to die both in the hospital and within 30 days after infarction, and black women have a particularly high risk of death at this time. Registry reviews by Maynard and associates and others indicate that women with myocardial infarction were not treated as aggressively and were less likely to undergo acute catheterization, angioplasty, thrombolysis, or coronary artery bypass surgery than men. Other reviews have found that women are more likely than men to delay going to the hospital and that women are more likely to present with complicated myocardial infarction at the time they arrive at the hospital. More research is needed on medical and interventional therapies for myocardial infarction and coronary disease in women.

TABLE 53.2. PREVENTION BENEFITS OF EXERCISE

SCREENING FOR EXERCISE PARTICIPATION

All physically active patients should be evaluated before participation, using a standard medical history with attention to details of risk factors for cardiac disease and a directed sport-specific musculoskeletal review. The results of this assessment will then direct further cardiovascular risk testing using a standard Bruce protocol exercise treadmill test (Table 53.3) for those asymptomatic patients in an age group (men ³45, women ³55 years of age) with two or more risk factors for ischemic cardiovascular disease and for patients with symptomatic cardiac disease. The results of testing, combined with the clinical characteristics, then allow patients to be further categorized into groups that can allow risk stratification and the writing of the appropriate exercise prescription (Table 53.4).

Preexercise Risk Class*	A-1	A-2	A-3	B	C	D
Bad history	None	None	None	No	No	No
Bad history	No	No	No	No	No	No
Fixed exercise tolerance	No ETT	No ETT	No ETT	No	No	No
Exercise tolerance > 20% (Bruce protocol) or > 10% (Bruce protocol) or > 10% (Bruce protocol)	No ETT	No	No	No	No	No
Exercise tolerance > 20% (Bruce protocol) or > 10% (Bruce protocol) or > 10% (Bruce protocol)	No ETT	No	No	No	No	No
Postexercise Risk Class	Class A	Class A	Class A	Class B	Class C	Class D
	Apparently healthy	Apparently healthy	Apparently healthy	Low risk	Moderate risk	High risk

TABLE 53.3. PREEXERCISE TESTING RISK STRATIFICATION

Preexercise Risk Class	Class A	Class B	Class C	Class D
Bad history	None	None	None	No
Bad history	No	No	No	No
Fixed exercise tolerance	No ETT	No ETT	No ETT	No
Exercise tolerance > 20% (Bruce protocol) or > 10% (Bruce protocol) or > 10% (Bruce protocol)	No ETT	No	No	No
Exercise tolerance > 20% (Bruce protocol) or > 10% (Bruce protocol) or > 10% (Bruce protocol)	No ETT	No	No	No
Postexercise Risk Class	Class A	Class A	Class A	Class B
	Apparently healthy	Apparently healthy	Apparently healthy	Low risk

TABLE 53.4. POSTEXERCISE TESTING RISK STRATIFICATION

PRINCIPLES OF THE EXERCISE PRESCRIPTION

The current recommendation is for the active patient to accumulate a minimum of 30 minutes of moderate-intensity physical activity in a frequency of 3 to 5 days per week at an intensity to achieve 55% to 90% of maximum heart rate. This activity can include a minimum of 10-minute periods or a single period. Cardiac risk stratification can guide the exercise prescription for those patients with abnormalities found during exercise testing or who have symptomatic cardiac disease (Table 53.4). Physicians counseling patients with regard to exercise will find that most are receptive to counseling. As in all physician-fostered behavioral change, physicians can exert a considerable impact on facilitating behavioral change through developing a therapeutic alliance with the patient, reviewing the relation between exercise and the patient's current and future health, committing the patient to a specific exercise plan, maintaining ongoing support, and using other health care personnel such as health education counselors in an overall supportive environment.

COMMON MEDICAL ISSUES IN THE EXERCISING PATIENT

Fatigue

The differential diagnosis of sustained fatigue in the competitive highly trained or endurance athlete includes those conditions that cause fatigue in the general population and those that occur secondary to training-specific effects alterations in physiologic recovery mechanisms. When the results of the initial examination (including a history, physical examination, and selected testing) are normal, the sustained fatigue is frequently attributed to an exercise-related overtraining syndrome characterized by fatigue, mood changes, perceived or real decrements in athletic performance or recovery from exercise, and frequent infections, usually of the upper respiratory tract. Affecting primarily elite endurance athletes (cyclists, rowers, runners), sustained fatigue has also been reported in activities defined by muscle power training, such as weight lifting. Although current research suggests that this fatigue results from disruption in neuroendocrine function, whether this set of symptoms truly encompasses a distinct exercise-related syndrome remains unproved, and a consistent diagnostic strategy remains undefined. In addition, the relation between the chronic fatigue syndrome and overtraining in exercise remains unclear. Regardless of this uncertainty, athletes who complain of fatigue benefit from a multidisciplinary evaluation consisting of a thorough medical and psychologic evaluation, review of training history with coaching and athletes, and formulation of long-term training plan that incorporates close attention to the entire training regimen, including influence of competing activities such as schoolwork or other work, amount of sleep and between-exercise rest periods, evaluation of diet, and close attention to training.

Exercised-Induced Asthma

Exercise-induced asthma (EIA) is defined by a drop in FEV₁ (forced expiratory volume in 1 second) of 15% after exercise, occurring in those with or without a prior history of asthma or other atopic illness. Current pathogenic theories suggest a thermal-induced process in which the initial fall in airway temperature during exercise is followed by rapid reheating when ventilation diminishes. The mechanism by which this process results in bronchial narrowing and airway hyperactivity is not well defined. However, clinical observation that the leukotriene modulators can reduce EIA suggests that leukotrienes probably play a major role in this process. Reported in 10% to 25% of athletes in some series, the clinical features of EIA consist of postexercise wheezing or cough, which, in contrast with that which occurs with intrinsic asthma, is not associated with prolonged or intense airway obstruction or a late effect. Other causes of exercise-associated cough such as gastroesophageal reflux, allergic rhinitis, and occult cardiac disease must be excluded. Low ambient temperatures and humidity, exposure to oxidant air pollutants, coexisting respiratory viral infections, and poor physical conditioning worsen severity. Initial treatment with an inhaled b₂-agonist (albuterol) before exercise is the treatment of choice, followed by the addition of inhaled cromolyn sulfate or an oral leukotriene synthesis inhibitor (zileuton) or both, or receptor antagonist (zafirlukast) in selected patients, all of which require daily use. Long-acting b₂-agonists (salmeterol) have had mixed usefulness in clinical use, with some athletes reporting improved control and others having increased symptoms and decreased clinical response to shorter-activity b₂-agonists, a phenomenon attributed to long-term b₂-receptor down-regulation. Inhaled or oral corticosteroids, the mainstays of intrinsic asthma treatment, play no role in the treatment of EIA.

The Female Athlete Triad

Female athletes training for endurance activities (distance running, cycling, cross-country skiing), those involved in activities in which low body mass provides competitive advantage (gymnastics, ballet, diving, figure skating), and those in sports requiring weight categories for participation (horse racing, rowing) are at risk for the development of exercise-associated amenorrhea, a form of hypogonadotropic hypogonadism in which diminished frequency of luteinizing hormone (LH) pulses results from disturbance of the hypothalamic release of gonadotropin-releasing hormone. The exact mechanism that causes this hypothalamic-pituitary axis disruption is not known, but appears to arise from many interrelated factors including a reduction in critical body fat mass, high caloric expenditures, and inadequate nutritional intake in relation to daily caloric demands of exercise. The subsequent amenorrhea, defined as less than three menstrual periods per 12-month period, results in reduced bone density and subsequent increased stress fractures, primarily of the lower extremity, and decreased fertility; it may also make an impact on athletic performance.

The use of hormone replacement of both estrogen and progesterone is the most common treatment approach, and although a few early reports have demonstrated that such therapy will stabilize and, in some cases, increase vertebral and lower extremity bone density in amenorrheic female athletes, the prevention of stress fractures with hormonal replacement has not been reported in this population.

Whether bisphosphonates play a role in this patient population remains to be firmly established. In some female athletes, amenorrhea and osteoporosis are combined with eating disorders to form the so-named "female athlete triad." All female athletes with one component of this triad should be screened for the remaining disorders. In addition to treatment of the hormonal effects of amenorrhea, treatment of these female athletes is optimal when a combination of strategies is provided, including intensive nutritional and psychological counseling and support in addition to standard medical care.

Anemia in the Athlete

The diagnosis and treatment of anemia in the athlete are complicated by both exercise-specific physiologic changes that can interfere with diagnosis and the commonly held but unproven practice of iron supplementation for possible performance enhancement. Athletes may have *pseudoanemia*, in which plasma expansion occurs secondary to intravascular shifts following exercise or to the effects of high-altitude training. *Increased red cell turnover* has also been demonstrated in sports such as running, cycling, and swimming, presumably due to mechanical trauma, increased body temperature, or increased oxidative stress and subsequent increased red cell fragility. The athlete with both low hematocrit and serum ferritin has *iron-deficiency anemia* and should undergo an appropriate clinical evaluation and treatment with oral iron until the anemia has resolved and the serum ferritin has normalized. Replacement of iron in this group has been demonstrated to reverse performance degradation.

Athletes who have low serum ferritin and a normal hematocrit do not seem to benefit from iron supplementation in terms of performance enhancement. Some clinicians suggest that when the serum ferritin is low and the hemoglobin is in the low-normal range, the differential diagnosis of pseudoanemia, increased red cell turnover, or early iron deficiency may be made and would advocate that a minimum of 2 months of oral iron supplementation be supplied with a repeat of the indices after treatment is completed. Athletes who have subsequent unchanged values presumably have a pseudoanemia or increased red cell turnover while those with increased hemoglobin and or serum ferritin may have had early iron deficiency. Whether treating this group of athletes will enhance performance or forestall performance deterioration before frank anemia develops has not been reported in men or women athletes.

OVERUSE MUSCULOSKELETAL INJURIES

General Principles

Musculoskeletal overuse injuries, because of their subacute to chronic nature, often present a treatment challenge to the clinician. In clinical terms, these injuries occur when the rate of musculoskeletal loading exceeds the rate of adaptation within connective tissue and bone (resulting in the clinical syndrome of tendinosis or stress fracture). All overuse injuries are accompanied by pain that has its onset at some point in the connective tissue remodeling process. Because tissue injury results from the accumulation of repetitive forces applied below the single-cycle failure threshold, treatment requires a fundamental understanding of the factors, often subtle, that contribute to the total load.

It is important to recognize that the onset of pain occurs after substantial accumulation of tissue strain but before complete failure of the tissue. In this sense, even though the onset of pain tends to be a "sudden" event (at least historically), effecting a positive outcome requires attention to the subtle causal factors that led to the accumulated load. With running, for example, the load across the ankle or knee joint can exceed eight times a person's body weight, repeated with each step.

Five factors are commonly associated with overuse injuries. These factors are well recognized for lower-extremity injuries associated with sports such as running, but the general principles may be applied to the upper extremity also. Although these risk factors have not been proved to be causative in clinical trials, either because the studies have not been performed or because the methods used have not permitted definitive conclusions, they remain the time-honored approach used by clinicians treating overuse injuries.

Training errors are factors that create a mismatch between the rate of musculoskeletal loading and the rate of tissue adaptation; these include the total volume of training (number of strain cycles connective tissue and bone are exposed to), the increase of training within a given time frame, and the intensity or pace of training (frequency of strain cycles). Factors that affect *muscular shock absorption* influence the magnitude of the load delivered to the musculoskeletal system. The muscle tendon unit absorbs massive amounts of force over time during physical activity and muscle strength (both concentric and eccentric) and endurance capacity (ability to resist fatigue) are important factors for limiting tissue injury. *Intrinsic biomechanical factors* refers to aspects of lower-extremity alignment that affect the duration, magnitude, and site of the load delivered to the skeleton and include foot type (pes cavus and pes planus), tibial varum, genu valgum, genu varum, the quadriceps angle, femoral neck anteversion, and leg-length discrepancies.

A fourth causative factor consists of *extrinsic biomechanical factors*; these include the contribution to overuse injuries resulting from specific equipment such as shoe type, racquet size, and terrain (rigidity and slope of surface). Finally, *specific tissue pathology* such as osteoporosis or muscle atrophy that may affect the stress:strain relation in a given tissue can affect the onset of overuse injury.

Treatment

The treatment for overuse musculoskeletal injuries relies on elucidating the factors responsible for overload and a detailed, anatomically based physical examination of the injured part. In general, treatment is broken into three phases.

Phase I of the treatment begins when correctable causes of the overuse history are identified, including training errors, intrinsic and extrinsic biomechanical factors, and muscular strength and endurance. The offending activity is stopped, but rarely is there a need for immobilization of a limb because atrophy is a deleterious side effect that can be more incapacitating than the injury, particularly to an athlete. Pain can be managed with local physical therapy modalities, nonsteroidal medication, and ice.

Phase II of the treatment involves the prescription of modified activity to maintain cardiopulmonary fitness. The activity must be non-impact loading (rowing, cycling, swimming, water running). Sports that involve skill maneuvers that do not load the affected part are permissible in this phase. During phase II, there is also the need to provide equipment and technique modifications, including footwear and foot orthoses. Muscular strength and endurance exercises that involve overload are prescribed at this point. The length of phase II depends on the time it takes for the patient to be pain-free on a day-to-day basis. An important aspect of phase II when treating competitive athletes is the clear identification of treatment steps before reintroduction of the sport, a factor that maintains confidence within the doctor-patient relationship.

Phase III begins when this is achieved and involves the reintroduction of impact-loading activities. It is important to note that when activity restarts, the patient commonly has a persistent awareness or discomfort. A written program should be devised using the 10% rule: *no increase in volume or intensity should be greater than 10% more than the last workload increment*. In general, workload increments should allow off days and a rate of progression that ensures that symptoms do not return and relapses are avoided.

CHAPTER 54: PRINCIPLES OF REHABILITATION MEDICINE

KRESIMIR BANOVAĆ, DEBBIE FERTEL AND JOSEPH BAUERLEIN

[Neurorehabilitation](#)
[Orthopedic Rehabilitation](#)
[Cardiac Rehabilitation](#)
[Pulmonary Rehabilitation](#)

Rehabilitation medicine is integral to the care of patients and should follow most episodes of acute medical and surgical treatment. Passive convalescence after acute or chronic illness or trauma increases the risk for deterioration of a variety of normal and vital functions and for the development of complications. Economically, neglecting rehabilitation in the early stages of convalescence has been shown to be more costly than that of an early aggressive rehabilitation program. The goals of rehabilitation focus on (a) return of function to the baseline level or as close as possible, (b) the adjustment to any residual disability, and (c) the prevention of complications associated with the primary condition and any residual disability.

Optimal therapy requires the skills of a multidisciplinary team of rehabilitation specialists. [Table 54.1](#) lists the potential members of a rehabilitation team and their roles. The clinical scenario determines the composition of the team and the setting of the program. The rehabilitation team designs and supervises therapy initially.

Discipline	Role
Physiatrist	Medical care, coordination of rehabilitation
Rehabilitation nurse	Daily care, medication, education, reinforcing patient's independence
Physical therapist	Gross motor skills (sitting, standing, transfers, ambulation)
Occupational therapist	Fine motor skills (hygiene, dressing, feeding)
Recreational therapist	Leisure activity, community reintegration
Psychologist	Psychotherapy to patient and family, assessment of emotional, intellectual and perceptual function
Social worker	Helping family and patient to obtain community resources
Speech therapist	Communication, swallowing, assist in cognitive training
Vocational counselor	Testing of skills and interest, recommend training for alternative occupations
Prosthetist/orthotist	Design and fabrication of prosthesis (artificial limbs) and orthosis (splints and braces)

TABLE 54.1. REHABILITATION TEAM

The outcome of rehabilitation depends on not only on several patient-related factors, including the motivation and ability of the patient to participate, the interval from the injury to the start of rehabilitation, and the extent of family support, but also on the team. The involvement of family and friends in the rehabilitation process accelerates and facilitates the reintegration of the patient back into the community. As they move back into the community, patients take on more of the responsibility of supervising the continued therapy designed by the rehabilitation team.

NEUROREHABILITATION

BRAIN INJURY

In patients with traumatic brain injury (TBI), determination of prognosis after rehabilitation is difficult. Patients with TBI have cognitive deficits as their major disability. Rehabilitation goals can be assessed using the Glasgow Coma Scale (GCS), the most commonly used prognostic indicator ([Table 54.2](#)). For patients with mild TBI (GCS score from 13 to 15), the goals are independence in ambulating with or without an assistive device, total independence in activities of daily living (ADL), and reintegration into the community. Many patients demonstrate improvement in problem solving, memory, safety awareness, and recovery of cognitive functions. However, they may initially require supervision at home to ensure safety for several months. Patients with moderate TBI (GCS scores from 9 to 12) may have permanent functional and cognitive deficits, although they may be able to care for themselves and perform some degree of occupational activity. Patients with severe TBI (GCS scores from 3 to 8) are usually dependent on another person for ADL and mobility. They may become ambulatory but are usually not independent owing to impulsive and disinhibited behavior. Often, these patients are left with significant impairments of physical, communicative, and cognitive functions.

Indicator	Category of Response	Grade
Eye opening	Spontaneous	4
	To voice	3
	To pain	2
Verbal response	None	1
	Oriented	5
	Confused	4
	Inappropriate words	3
	Incomprehensible words	2
Motor response	None	1
	Obeys commands	6
	Localizes pain	5
	Withdraw (pain)	4
	Flexion (pain)	3
	Extension (pain)	2
	None	1

TABLE 54.2. GLASGOW COMA SCORE

SPINAL CORD INJURY

Patients with spinal cord injury (SCI) can be divided into those with complete paralysis and those with incomplete paralysis. Patients with complete SCI have no motor and sensory function below the segment of the traumatized spinal cord. The outcome of the rehabilitation of these patients depends on the degree of reversibility and site of the cord lesion ([Table 54.3](#)).

Cord Injury Level	Functional Level
Segments C1–C3	Requires respiratory support ADL dependent on caregivers
Segments C4–C5	Operates a motorized wheelchair Requires assistance with ADL
Segments C6–C8	Operates a manual wheelchair Minimal assistance with ADL
Below T1	Is usually independent in mobility, transfers, ADL, and management of neurogenic bowel/bladder dysfunction

ADL, activities of daily living.

TABLE 54.3. PROGNOSTIC EXPECTATIONS AFTER COMPLETE SPINAL CORD INJURY

Patients with incomplete SCI may have significant recovery of functional status, although some have permanent disability because of severe spasticity and lack of coordination and proprioception. Furthermore, the process of rehabilitation may be limited owing to additional injuries such as skeletal, thoracic, or abdominal trauma. All patients with brain injury require evaluation of swallowing function and preventive measures to avoid aspiration. Treatments of other complications of SCI are outlined in [Table 54.4](#).

Complication	Treatment
DVT	Deep venous thrombosis prophylaxis
Brain injury	Seizure prophylaxis
Neurogenic bladder	Intermittent catheterization
Neurogenic bowel	Bowel program (stool softeners, laxatives)
Spasticity	Aggressive range-of-motion exercises Medication may be useful: <ul style="list-style-type: none"> ■ GABA (γ-aminobutyric acid) agonist (baclofen) ■ α_2-adrenergic agonists (clonidine, tizanidine) ■ Benzodiazepines (clonazepam [Klonopin], diazepam) ■ Calcium release inhibitor (dantrolene [Dantrium])
Agitation	Medication may be useful <ul style="list-style-type: none"> ■ β-adrenergic blocking agent (e.g., propranolol) ■ Neuroleptic (haloperidol)

TABLE 54.4. TREATMENT OF COMPLICATIONS OF SPINAL CORD INJURY

ORTHOPEDIC REHABILITATION

The goals of rehabilitation for the patient with orthopedic injury include reduction of pain, return to independence in ADL, and an improvement of strength and endurance. Early mobilization after injury is critical in reducing the incidence of complications associated with extended immobilization. Muscle atrophy, joint contractures, cardiorespiratory deconditioning, deep venous thrombosis, and, less commonly, osteoporosis, orthostatic hypotension, and decubitus ulcers may significantly alter the course of recovery after multiple trauma. Patients with severe injuries and multiple trauma often require 4 to 6 months of rehabilitation.

Some patients with lower-extremity fractures may need adaptive devices (wheelchair, walker, crutches, or cane) until fracture healing and weight bearing allows for their discontinuation. Complication with wound infection or extensive soft-tissue, nerve, or vascular injuries often require more extended rehabilitation to achieve maximal improvement. Patients with limb amputation may require up to 1 year for the wound to heal and the stump to be prepared for a prosthesis, followed by additional time to train the patient in the use of the artificial limb.

CARDIAC REHABILITATION

Cardiac rehabilitation continues its evolution begun 30 years ago. Therapy begins with inpatient treatment after an acute myocardial infarction (phase I). Activities require less than 3 to 4 METs (metabolic equivalents) and include dressing (2 METs), showering (3 METs), and walking upstairs (4 METs). The patient advances to outpatient therapy (phase II) with the degree of structure and monitoring dependent on the risk of recurrent events. Risk is related to the presence and extent of ischemia, the extent of left ventricular dysfunction, and the presence of significant ventricular arrhythmia. Pressure to decrease inpatient length of stay has placed greater emphasis on outpatient therapy. Finally, the maintenance phase (phase III) encourages the patient to maintain lifetime changes that will improve cardiac function and quality of life. Education is critical in all phases and may lead to lifestyle changes that help slow the progression of coronary artery disease. [Table 54.5](#) summarizes the phases of cardiac rehabilitation.

Phase	Duration/Location	Goals
I	Days/inpatient	ADL, less than 3–4 METs Education (weight, diet, stress reduction, smoking cessation)
II	2–3 months/outpatient or home	Progressive activity level Education
III	Lifetime/home	Relieve symptoms Education

TABLE 54.5. CARDIAC REHABILITATION

Although cardiac rehabilitation has classically been offered to those patients with coronary artery disease following a myocardial infarction, indications have expanded more recently. Patients with congestive heart failure can obtain significant improvement in their functional capacity and sense of well-being. After cardiac transplantation, recuperation is faster with a rehabilitation program.

PULMONARY REHABILITATION

Pulmonary rehabilitation enhances standard therapy in patients with chronic disabling lung disease. Although pulmonary function measurements do not improve with pulmonary rehabilitation, the functional capacity for ambulation, duration of exercise, and ability to perform ambulatory tasks improves significantly, correlates with improvement in quality of life, and may prolong life expectancy. Historically, pulmonary rehabilitation was indicated primarily in patients with chronic obstructive pulmonary disease (COPD), more recently it has been effective in patients with other disabling chronic lung diseases such as cystic fibrosis, interstitial lung diseases, and neuromuscular disorders. The last decade has seen pulmonary rehabilitation become an integral, vital part of recovery from lung volume reduction and lung transplantation surgery.

A pulmonary rehabilitation program is comprehensive and individualized to allow patients to realistically meet their own goals. Therapy is directed toward maximizing patients' functional capacity within the limits of their pulmonary disease. Ideally, the program includes lower extremity training, upper extremity training, ventilatory muscle training, and psychosocial interventions. All therapy is done while monitoring oxygen saturation, vital signs, and electrocardiograms. Supplemental oxygen in incremental doses needs to be used as indicated. Some patients with severe lung disease have resting hypercapnia, requiring intermittent monitoring of the PCO_2 by arterial blood gas or measurement of end-tidal CO_2 . Psychosocial intervention is vital to the success of the program ([Table 54.6](#)). Patients with chronic lung disease frequently suffer from depression, anxiety, loneliness, low self-esteem, and reduced social support.

Modality	Goals
Lower extremity	Treadmills, bicycles, walking, or combination
Upper extremity	Arm ergometer, arm weights to shoulder level
Ventilatory muscles	Hand-held inspiratory resistance devices (especially with chronic obstructive pulmonary disease)
Psychosocial	Diet changes Weight control Appropriate oxygen therapy Exercise Smoking cessation

[Therapeutic Drug Monitoring](#)
[Clinical Toxicology](#)

Many clinicians are repelled by pharmacokinetics because they envision obfuscating mathematical relations that may not seem directly applicable to patient care. Pharmacokinetics need not be intimidating, however, and a physician's ability to design a rational therapeutic regimen can be greatly facilitated by understanding a few simple pharmacokinetic principles. It also is important to realize the limitations of pharmacokinetics. Its practical use represents an attempt to predict in a quantitative fashion how an individual patient will respond to a drug.

Significant variability exists in drug disposition among homogeneous groups of patients, which becomes even greater with such additional influences as disease ([Chapter 167](#)), age ([Chapter 469](#)), and drug interactions. Hence, clinicians should not be overly rigid in the use of pharmacokinetic values but should view them as best "guesstimates" of how an individual patient will handle a drug. These values serve as a starting point of therapy and then must be refined using measures of response in each patient such as blood concentrations of drug and, most important, clinical assessment of response. This is the realm of pharmacodynamics, which describes how an individual patient responds to a dose or concentration of a drug. The pharmacodynamics of drug response also are highly variable among individuals, are influenced, for example, by disease and other drugs, and can be assessed only clinically. Therefore, optimal care of individual patients requires interdigitating of pharmacokinetics with pharmacodynamics.

PHARMACODYNAMICS

In clinical medicine, the term *pharmacodynamics* refers to the response of a patient to a certain dose or serum concentration of a drug; *it is used to define the target concentration of a drug*. Pharmacokinetics then are used to design dosing regimens that allow attainment and maintenance of the desired concentrations, with the overall goal being to obtain the efficacious effects of a drug and avoid the toxic effects.

When drug dose or, more accurately, serum concentration, is related to response, a sigmoid-shaped concentration response curve results ([Fig. 55.1A](#)). The relation shown in [Figure 55.1A](#) could be for any response, whether beneficial or toxic. With some drugs, the distinction between concentrations causing desired compared with adverse effects is great ([Fig. 55.1B](#)). Such drugs are easy to dose, because the objective is to make certain that enough drug is administered to attain benefit with little worry about excessive doses. In this circumstance, recommended doses and concentrations obtained are considerably greater than the minimum necessary. The classic example of this type of drug is penicillin. Clinically used doses are far in excess of those needed to kill bacteria, but, because the dose needed to cause toxicity is massive in comparison (excluding allergic reactions), doses that ensure sufficient drug concentration can be given safely with little, if any, risk of toxicity.

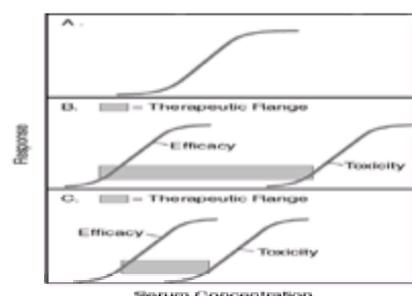

FIGURE 55.1. Schematic curves that relate concentration to response. **A:** A typical sigmoidal concentration response curve. **B:** A drug with a wide therapeutic range. **C:** A drug with a narrow therapeutic range.

Most cardiovascular drugs have narrower therapeutic indices; that is, the difference between therapeutic and toxic concentrations is small ([Fig. 55.1C](#)). With such drugs, as little as a twofold increase in serum concentration can cause toxicity in some patients. Hence, there is little margin for error in dosing, and close attention must be paid to designing a dosing regimen that attains the desired drug concentration without being excessive. Doing so requires knowledge of pharmacokinetic parameters and use of kinetic principles for design of dosing regimens.

Considerable variability in response to a given concentration of a drug occurs among patients. Disease states and patient characteristics also can affect pharmacodynamics, such as the increased sensitivity to central nervous system (CNS) effects of drugs commonly observed in elderly patients ([Chapter 469](#)). To compensate for variability in pharmacodynamics, clinicians must be alert to the need to titrate drug doses individually according to clinical response.

PHARMACOKINETICS

The most important pharmacokinetic parameters (bioavailability, volume of distribution [Vd], clearance [Cl], and half-life) and their application are presented in [Table 55.1](#).

Parameter (Abbreviation)	Clinical Application
Bioavailability (F)	Determines the amount of drug reaching the systemic circulation and therefore the amount at the site of action
Volume of distribution (Vd)	Determines the size of a loading dose
Clearance (Cl)	Determines the maintenance dose
Half-life ($T_{1/2}$)	Determines the amount of time needed to reach steady-state serum concentrations (four times the $T_{1/2}$)

TABLE 55.1. PHARMACOKINETIC PARAMETERS

BIOAVAILABILITY

Bioavailability (F) represents the fraction or percentage of administered drug that reaches the systemic circulation. If the drug is given intravenously, bioavailability is 100% (F = 1.0); if it is given by other routes, bioavailability often is less than 1.0, indicating lack of complete absorption or elimination of the drug before it reaches the systemic circulation. The latter is called either *presystemic elimination* or the *first-pass effect*, and it is important with many drugs. A bioavailability of less than 100% can result from a variety of causes ([Table 55.2](#)). The clinical importance of incomplete bioavailability is most readily apparent when a patient is switched from intravenous (IV) to oral therapy. If the bioavailability of a drug is 50%, an oral dose twice that of the IV dose is needed to attain the same amount of drug in the patient. Hence, clinicians must have an awareness of the bioavailability of the drugs they are using so that appropriate IV and oral doses are administered.

Incomplete product disintegration
Incomplete dissolution
Physicochemical complex formation (e.g., fluoroquinolone antibiotics and calcium, magnesium, aluminum, or iron)
Intestinal metabolism by CYP3A4
Intestinal secretion from cell back into the gut lumen by P-glycoprotein
Presystemic hepatic metabolism

TABLE 55.2. REASON FOR INCOMPLETE BIOAVAILABILITY

Clinicians also should realize that bioavailability can be affected to a substantial degree in many ways. Differences in product formulation can affect the extent of absorption, as can gastrointestinal disorders and drug interactions. For example, inhibition of intestinal wall metabolism and P-glycoprotein secretion of lovastatin or simvastatin can result in increased bioavailability sufficient to increase serum concentrations five- to tenfold with greatly enhanced risk of toxicity. Conversely, administration of most fluoroquinolones in close temporal proximity to many antacids can result in essentially no drug absorption.

The occurrence of such influences and their quantitative importance often are difficult to predict. Consequently, this possibility must be included in the differential diagnosis of vagaries of response to drugs. For example, lack of response of a patient to a loop diuretic should not be ascribed solely to a lack of sensitivity of the patient, but also should include the possibility of incomplete absorption. If a clinician mistakenly assumes only the first possibility, the use of a potentially useful drug may be discontinued. If the drug simply is not being well absorbed, the dose can be increased, or a better and more predictably absorbed preparation can be used. If these possibilities are not considered, they will never be detected, and inappropriate therapeutic behavior may ensue.

VOLUME OF DISTRIBUTION/LOADING DOSE

The Vd is simply a proportionality factor that describes the concentration of a drug attained by a given dose. If a 100-mg dose of a drug is administered to a patient and results in a serum concentration of 5 mg per liter before any metabolism or excretion has been able to occur, the volume in which the dose has distributed to account for this resultant concentration is 20 L:

$$\text{Initial concentration} = \text{dose} / \text{Vd}$$

Or, in the example cited,

$$5 \text{ mg/L} = 100 \text{ mg} / \text{Vd}$$

Therefore:

$$\text{Vd} = 100 \text{ mg} / 5 \text{ mg/L} = 20 \text{ L}$$

This volume does not represent a physiologic space. In general, small Vds usually relate to confinement of the drug in the vascular space or extracellular fluid, whereas very large Vds occur with drugs that distribute extensively into fat ([Chapter 167](#) and [Chapter 469](#)). Proper use of the Vd is to calculate the loading dose of a drug.

Dosing recommendations for many drugs distinguish between a loading dose and maintenance dosing. The former is used in settings in which an efficacious concentration of drug must be attained quickly in a patient. For example, patients with ventricular ectopy with acute myocardial infarction frequently are given a loading dose of lidocaine to obtain therapeutic concentrations quickly. The dose given is determined by the Vd of lidocaine. For example, the Vd of lidocaine in most patients is 1.1 L per kilogram of body weight, and a typical target concentration is 3 mg per liter. From these values and the patient's weight, a loading dose can be calculated.

If the patient weighs 70 kg:

$$\text{Initial concentration} = \text{loading dose} / \text{Vd}$$

or

$$3 \text{ mg/L} = \text{loading dose} / (1.1 \text{ L/kg}) (70 \text{ kg})$$

Therefore:

$$\text{Loading dose} = (3 \text{ mg/L}) (77 \text{ L}) = 231 \text{ mg}$$

Clinically, such loading doses are commonly administered in increments (e.g., a 100-mg bolus followed by one or two additional 50-mg doses based on the patient's response). So doing allows one to tailor therapy according to response of the individual patient.

Numerous disease states can change drug distribution ([Chapter 167](#) and [Chapter 469](#)). If such changes are not anticipated, patients may be inappropriately dosed. For example, if a patient has congestive heart failure and needs lidocaine, the loading dose must be modified. By unknown mechanisms, patients with heart failure have a decreased Vd for lidocaine. Consider the potential consequences if such a change is not taken into account; namely, the patient receives the loading dose calculated previously, but the Vd for lidocaine is actually 0.55 L per kilogram (half of its previous value). If 231 mg was administered, the resulting serum concentration would be as follows:

$$\begin{aligned} \text{Initial concentration} &= 231 \text{ mg} / (0.55 \text{ L/kg}) (70 \text{ kg}) \\ &= 231 \text{ mg} / 38.5 \text{ L} = 6 \text{ mg/L} \end{aligned}$$

Hence, a twofold underestimation of V_d would result in an initial concentration twice that predicted, which could be toxic. If a clinician prospectively considers that a patient's condition (or other concomitantly administered drugs) might affect the V_d of an agent, he or she will be better able to prevent this type of problem. If such a possibility is not considered, a patient's care may be compromised by inappropriate drug dosing. Physicians are accustomed to thinking in terms of doses rather than the pharmacokinetic parameters that dictate those doses. Doing so is not unreasonable, but physicians must avoid the pitfall of assuming that loading doses should be the same for all patients. Generally, if there is any doubt, it is better to administer a dose that is too small rather than one that is too large. If clinical monitoring of the patient reveals insufficient pharmacologic effect, additional drug can be administered. However, if too much drug is given and toxicity ensues, treatment of the adverse effect can be challenging.

Another important consideration when giving a loading dose is the route of administration. Loading doses do not have to be given intravenously and in some instances may be tolerated better if given orally. For example, IV doses of digoxin can cause peripheral vasoconstriction, which may be undesirable. This effect can be avoided with oral dosing. Similarly, phenytoin must be administered cautiously by vein and can precipitate in many IV fluids. Dosing by mouth can prevent such problems. If a loading dose is to be administered by mouth, bioavailability must be taken into account.

The final important point about loading doses concerns the rapidity of administration. Too often, the temptation is to administer a drug as quickly as possible. This causes very high concentrations in serum, which can be associated with adverse effects. Lidocaine is a good example. If the loading dose is given as a rapid-bolus injection, serum concentrations sufficient to cause CNS toxicity frequently occur transiently until distribution into other tissues takes place, lowering the serum concentration to the desired level. However, if the drug is given more slowly, the high serum concentrations can be prevented with less resultant toxicity. For example, when three separate 50-mg bolus doses of lidocaine were given in one study, all patients had CNS toxicity; in contrast, administration of the same dose as a continuous infusion over 18 minutes resulted in toxic effects in less than 10% of patients.

Overall, there is little to gain and a potential for much loss by bolus injection of drugs. Slow, controlled administration is more prudent.

CLEARANCE/MAINTENANCE DOSE

Clearance measures the ability to eliminate drug from the body. This value is always given in units of volume divided by time (e.g., milliliters per minute) and sometimes is normalized to body weight or surface area. Because clearance usually is determined by measuring the decline of serum or plasma drug concentrations, the term generally refers to serum or plasma clearance, although whole blood concentrations are measured with some drugs (e.g., cyclosporin A). The value for clearance expresses the volume of serum from which all drug can be removed per unit time. For example, if a drug's clearance is 100 mL per minute, all drug can be removed from 100 mL of serum in 1 minute.

For most drugs, clearance is a constant value. This property is called *first-order*, or *linear*, kinetics. With some drugs, however, elimination pathways can be saturated at higher drug concentrations, in which case, clearance decreases at these higher concentrations. This property is called *zero-order*, *saturable*, or *Michaelis–Menten* kinetics, and it classically occurs with ethanol, salicylates, and phenytoin. Fortunately, most drugs obey first-order kinetics, which facilitates the design of dosing regimens. With such drugs, a change in dose results in a proportional change in drug serum concentration, that is, doubling the dose doubles the concentration ([Fig. 55.2A](#)). Such a relation makes dose adjustments simple. In contrast, for drugs that follow saturable kinetics, a change in dose causes a disproportionate change in drug serum concentration; in other words, doubling the dose may quadruple the serum concentration ([Fig. 55.2B](#)). Dose adjustments in such circumstances become much less predictable than with drugs that obey first-order kinetics.

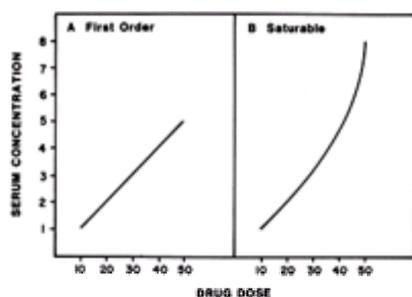

FIGURE 55.2. Relation between the dose of drug administered and the serum concentration that results for a drug that follows first-order kinetics compared with a drug that follows saturable kinetics.

The clearance of a drug determines the dose that must be administered to maintain a constant serum concentration. This relation is best illustrated as follows. At steady state, by definition, the rate of drug entry into the body is equal to the rate of exit: rate in equals rate out. In turn, in the simplest case of a constant IV infusion: rate in equals infusion rate.

In all circumstances,

$$\text{Rate out} = (\text{average drug concentration, or } C_{p_{\text{average}}}) (Cl)$$

Therefore:

$$\text{Infusion rate} = (C_{p_{\text{average}}}) (Cl)$$

or

$$C_{p_{\text{average}}} = \text{infusion rate}/Cl$$

This relation makes intuitive sense in that the higher the infusion rate, the higher the drug concentration; similarly, if the ability to eliminate a drug declines, thereby indicating diminished Cl , as may occur with aging ([Chapter 469](#)) or a variety of diseases ([Chapter 167](#)), the drug concentration is higher for the same rate of administration.

Lidocaine can be used again as an example. In most patients, the clearance of lidocaine is 9 mL per minute per kilogram. If a steady-state average serum concentration of 3 mg per liter is required in a 70-kg patient, the needed infusion rate can be calculated as follows:

$$\begin{aligned} C_{p_{\text{average}}} &= \text{infusion rate}/Cl \\ 3 \text{ mg/L} &= \text{infusion rate}/(9 \text{ mL/min/kg}) (70 \text{ kg}) \\ \text{Infusion rate} &= (3 \text{ mg/L}) (630 \text{ mL/min}) \\ &= 1890 \text{ } \mu\text{g/min} = 1.9 \text{ mg/min} \end{aligned}$$

Proportionality is a vital factor implied in this relation. For example, if a patient's serum lidocaine concentration is 3 mg per liter at an infusion rate of 1.9 mg per minute and it is deemed necessary to attain a new concentration of 4.5 mg per liter, the infusion rate needed to maintain this new target concentration can be readily calculated as 1.5 times the former infusion rate, namely, 2.85 mg per minute. Expressed in another manner, because of the direct proportionality:

$$\text{Old infusion rate/old serum concentration} = \text{new infusion rate/new serum concentration}$$

In this example

$$\begin{aligned} 1.9 \text{ mg/min} / 3 \text{ mg/L} &= \text{new infusion rate} / 4.5 \text{ mg/L} \\ \text{New infusion rate} &= (4.5) (1.9 \text{ mg/min}) / 3 \\ &= 1.5 (1.9 \text{ mg/min}) = 2.85 \text{ mg/min} \end{aligned}$$

A corollary of this relation is that a difference from normal in the patient's clearance of a drug requires a commensurate change in its administration rate. In the preceding example, if a patient had been administered lidocaine at a rate of 1.9 mg per minute, assuming a normal clearance, but the patient in fact had liver disease or heart failure—both of which diminish the clearance of lidocaine—a potentially toxic serum concentration could develop. If, for example, the patient's clearance of lidocaine was half that of the usual patient (4.5 mL per minute per kilogram), the administration of lidocaine at a rate of 1.9 mg per minute would result in a steady-state serum concentration of 6 mg per liter, which could be toxic.

$$\begin{aligned} C_{p \text{ average}} &= 1.9 \text{ mg/min} / (4.5 \text{ mL/min/kg}) (70 \text{ kg}) \\ &= 1.9 \text{ mg/min} / 315 \text{ mL/min} = 0.006 \text{ mg/mL} = 6 \text{ mg/mL} = 6 \text{ mg/L} \end{aligned}$$

These relations demonstrate that clinicians must be aware of potential influences of patients' diseases and other medications on the ability to eliminate therapeutic agents. Using a standard dose predictably results in some patients having subtherapeutic drug concentrations and others having toxic levels. By recognizing the importance of drug clearance as it dictates the maintenance dose of a drug, clinicians can more reliably design dosing regimens for individual patients.

Administering drugs in the form of a constant IV infusion is less common than intermittent oral dosing. Dosing in this fashion also can be incorporated into the relations presented previously:

$$C_{p \text{ average}} = (F) (\text{dose}) / (\text{dosing interval}) (Cl)$$

where F is the fraction of drug absorbed as defined previously. Note that the combination of these parameters remains an administration rate.

This more comprehensive relation stresses other aspects of maintenance dosing. The effect of incomplete bioavailability should be readily apparent; this must be compensated for by administering larger amounts of drug. In addition, the amount of drug administered can be changed by modifying either the dose itself or the frequency of its administration, or both. Hence, the amount given can be diminished either by decreasing each dose, keeping the dosing interval constant, or keeping each individual dose the same and increasing the interval between doses ([Chapter 167](#)). For example, if a patient is receiving 240 mg of a drug every 12 hours, the administration rate is as follows (assuming F = 1.0):

$$\text{Administration rate} = 240 \text{ mg} / 12 \text{ h} = 20 \text{ mg/h}$$

If a clinician wished to halve the administration rate to 10 mg per hour, the dose could be halved to 120 mg, with the frequency of administration maintained at 12 hours,

$$\text{Administration rate} = 120 \text{ mg} / 12 \text{ h} = 20 \text{ mg/h}$$

or the original dose could be maintained at 240 mg and the dosing interval doubled at 24 hours:

$$\text{Administration rate} = 240 \text{ mg} / 24 \text{ h} = 20 \text{ mg/h}$$

Both methods of dose adjustment result in the same average serum concentration of drug. The methods differ, however, in that the more widely spaced dosing interval results in a greater difference between peak and trough drug serum concentrations. With some drugs, too large a magnitude of variation between peak and trough concentrations can be hazardous, with toxicity at the peak and lack of efficacy at the trough. Clinicians must consider this possibility when designing a dosing regimen. If such variations are a problem, they can be prevented by more frequent dosing; alternatively, with many medications, sustained-release preparations have been developed that allow more prolonged dosing intervals and prevent the problem of wide vacillation in serum drug concentrations.

HALF-LIFE/TIME TO REACH STEADY STATE

The concept of half-life often is misused. Traditionally, it has been equated with the capacity for elimination of drug. In reality, it is an indication of the time necessary to reach steady state. Half-life can be affected by changes either in Vd or in clearance. If solely the latter, changes in half-life indeed are a reflection of changes in drug elimination. Such effects would influence the maintenance dose. In contrast, a change in half-life solely on the basis of a change in Vd carries no implications concerning drug elimination and maintenance dose, but rather dictates a need to modify the loading dose. Any change in half-life, however, has the same implications in terms of the time needed to reach steady state.

The half-life of a drug is simply the time necessary for its concentration to decrease by half. This value can be determined easily by measuring the concentrations of a drug as it is eliminated over time. The time needed for a drug to reach steady state is four or five times the half-life. The concept of attainment of a steady state is important when initiating drug therapy but also any time a dosing regimen is changed or the half-life of a drug changes. In both of the latter circumstances, the time needed to reattain a new steady state requires four or five times the half-life. For example, in a patient who is receiving a continuous IV infusion of lidocaine at 2 mg per minute, resulting in a steady-state concentration of 3 mg per liter, it is desired to attain a new concentration of 4.5 mg per liter. As discussed in the previous section, the proportional relation between clearance and $C_{p \text{ average}}$ allows easy calculation of the infusion rate needed to attain this new concentration, namely, 3 mg per minute. If the administration rate is increased to this amount, the time needed to reach 4.5 mg per liter is four or five times the half-life of lidocaine.

In most patients, the half-life of lidocaine is about 2 hours; hence, attainment of the new steady-state concentration requires $(4 \text{ to } 5) \times 2 = 8 \text{ to } 10$ hours. If the time needed to reach a new steady state is not considered, the clinician might assume that the new concentration of lidocaine would occur quickly. In turn, if the patient does not respond, the clinician might misinterpret this as refractoriness to the drug and thereby change the therapeutic strategy. In reality, the patient may respond to the higher serum concentration of lidocaine once it is reached. In this type of circumstance, if it is deemed necessary for the patient to reach the new steady-state serum concentration quickly, an additional loading dose (calculated from the Vd) must be administered to boost the patient from a concentration of 3 to 4.5 mg per liter. The new infusion rate then would maintain the patient at that concentration.

The alternative scenario also is important. Consider a patient receiving 3 mg per minute of lidocaine with a steady-state serum concentration of 4.5 mg per liter that is causing toxic side effects. If the desire is to decrease the patient's lidocaine concentration to 3 mg per liter, the infusion rate could be switched to 2 mg per minute, and four or five times the half-life, or 8 to 10 hours, would be required to reach the newly defined target concentration. Again, if the time necessary to reach steady state is not considered, the clinician might expect the patient's adverse effects to abate quickly. Such expectations clearly are not realistic.

Another strategy is possible in such a circumstance; namely, lidocaine administration could be stopped completely. If this course of action were followed, it would have to be determined when to recommence administering the lidocaine. Again, knowledge of the half-life is helpful. In this example, the patient's lidocaine serum concentration is 4.5 mg per liter and the half-life is 2 hours. If the lidocaine infusion were stopped, then in 2 hours the concentration would decrease by half to 2.25 mg

per liter; similarly, in 1 hour (half a half-life), it would decrease by 1.125 mg per liter to 3.375 mg per liter. Hence, the patient's lidocaine serum concentration would reach the desired new concentration of 3 mg per liter between 1 and 2 hours after the infusion was discontinued. A reasonable strategy would be to discontinue the lidocaine for 75 to 90 minutes and then restart its administration at the new infusion rate.

As noted at the outset of this section, values for half-life per se or changes in half-life in various clinical conditions offer no information about loading or maintenance dosing. This is true because half-life is a function of both Vd and clearance:

$$T_{1/2} = 0.693V_d/C_l$$

Hence, changes in half-life can occur as a result of changes in Vd, clearance, or both. Knowledge of only the half-life value offers no insight regarding the Vd or clearance of a drug. Therefore, such information is not helpful in determining loading or maintenance doses. Examples with lidocaine and digoxin emphasize these points and are provided in [Table 55.3](#).

	V _d (Loading Dose)	C _l (Maintenance Dose)	Half-Life (Time to Reach Steady State)
Lidocaine			
Heart failure	↓	↓	No change
Liver disease	↑	↓	↑↑
Digoxin			
Moderate renal insufficiency	No change	↓	↑
Severe renal insufficiency	↓	↓↓	↑

TABLE 55.3. CHANGES IN LIDOCAINE AND DIGOXIN KINETIC PARAMETERS EMPHASIZING THAT HALF-LIFE IS A FUNCTION OF BOTH VOLUME OF DISTRIBUTION (V_d) AND CLEARANCE (C_l)

In patients with congestive heart failure, the V_d of lidocaine decreases; clearance also decreases, most likely because of congestive hepatopathy. These changes dictate a need to decrease both loading and maintenance doses (to one-half to two-thirds of normal for both) in such patients. Because both parameters decrease in parallel, however, there is no change in lidocaine's half-life; therefore, the time to reach steady state is unchanged. By focusing on half-life, the clinician could be seriously misled in terms of dosing strategy; he or she might conclude that because half-life is unchanged, no adjustment of dosing is necessary. In fact, both loading and maintenance doses need to be modified. Erroneous interpretation of the half-life could thereby result in substantially higher than expected serum concentrations of lidocaine.

In patients with liver disease, a different set of changes occur. In these patients, half-life may be exceedingly prolonged because of the additive effects of an increased V_d (mechanism unknown) and decreased clearance. Hence, the time to reach steady state would be prolonged in such patients, but again the half-life change alone would offer no insight regarding needed modifications of loading and maintenance doses of lidocaine.

The example of digoxin in patients with renal insufficiency also illustrates how overinterpretation of half-life can be misleading. As shown in [Table 55.3](#), both patients with moderate and those with severe renal insufficiency may have half-life values that are similar, despite the fact that the clearance of digoxin in patients with severe renal impairment is considerably less than in patients with moderate renal insufficiency (mandating a much lower maintenance dose in the former). The inability of half-life to discriminate between the two conditions in terms of digoxin elimination occurs because patients with severe renal impairment also have a smaller V_d, which independently affects half-life. Inappropriate interpretation of half-life could lead to potentially disastrous errors in dosing.

DOSING REGIMEN DESIGN

Designing a dosing regimen for an individual patient requires interdigitation of the pharmacokinetic parameters discussed in the preceding sections. Based on data readily available in the medical literature, the values for bioavailability, V_d, clearance, and half-life should be estimated for the patient. Such estimates should include consideration of the influence of the patient's age and weight; concomitant disease (e.g., hepatic, renal, and cardiac function); and drug interactions that might influence pharmacokinetic parameters. Clinicians generally are not accustomed to thinking in terms of these parameters. They are facilitated in this regard by the availability of dosing guidelines for individual drugs in readily available reference sources such as the *Physicians' Desk Reference*. However, such guidelines rarely are comprehensive. They usually do not offer sufficient quantitative information about the effects of disease states or drug interactions on the separate pharmacokinetic parameters. Precision of dosing is much improved if regimens are based on pharmacokinetic values. Subsequent chapters provide values for different drugs, which can be used in dosing regimen design.

The approach to designing a dosing regimen can be considered in several steps. First, the need for a loading dose must be determined. This decision is based on the urgency of attaining an efficacious serum concentration combined with knowledge of the drug's half-life and thereby the time required to reach steady-state concentrations if a loading dose is not administered. If a loading dose is elected, the route of administration must be chosen and the dose calculated based on V_d, the desired concentration, and bioavailability (if the drug is not given intravenously):

$$\text{Loading dose} = (\text{desired initial concentration})(V_d)/F$$

The second step in dosing regimen design is calculation of a maintenance dose that will keep the average serum concentration of the drug at the desired level. This dose is calculated from clearance, the desired concentration, and bioavailability:

$$\text{Maintenance dose} = \text{desired average steady-state concentration} (C_l)/F$$

The route of administration of the maintenance dose also must be selected. If the drug is to be given by mouth, which is the most common situation, a dosing interval must be selected. As a general rule, it is convenient to administer the dose at an interval close to the drug's half-life. When this is done, the difference between peak and trough concentrations at steady state is easily calculated:

$$\text{Difference between peak and trough} = \frac{1}{2}\text{dose}/V_d$$

As pointed out, more frequent dosing minimizes the difference between peak and trough concentrations, and widely spaced dosing accentuates the difference. The regimen that is best for an individual patient depends on the drug used and the disease being treated. In some cases (e.g., procainamide), a drug's half-life is short (about 3 hours), precluding its administration every half-life. Conversely, prescribing the drug at more convenient intervals results in excessive vacillation between peak and trough concentrations. To facilitate dosing regimens in such circumstances, sustained-release preparations have been developed that allow wider dosing intervals and minimize drug level fluctuations. With such preparations, the total dose needed is still calculated based on the average steady-state drug serum concentration to be maintained.

The final step in dosing regimen design is using feedback from patient response and measured concentrations of drug in the patient's serum to modify the dosing regimen and tailor therapy to the needs of the individual. If higher serum concentrations are needed, it must be decided whether it is necessary to administer another loading dose or whether it is sufficient simply to increase the maintenance dose and await attainment of a new steady state after a period equal to four or five times the drug's half-life. Conversely, if a lower serum concentration is needed, it must be decided whether simply to switch to a smaller maintenance dose or to discontinue the drug altogether until the desired concentration is reached and then initiate the new maintenance dose. These types of dose adjustments in particular are facilitated

by knowledge of the individual pharmacokinetic parameters of a drug in a patient.

Clinicians always should be cognizant of the dynamic nature of drug therapy and the capacity for changes in drug disposition and response. Changes in a patient's primary disease and drug interactions can affect all the pharmacokinetic parameters discussed. The likelihood that handling of and response to a drug will change over time dictates that the clinician be alert for the necessity to change drug dosing regimens. So doing will maximize efficacy and minimize toxicity.

THERAPEUTIC DRUG MONITORING

Measuring drug serum concentrations is referred to as therapeutic drug monitoring. This strategy is used to guide therapy for drugs with narrow therapeutic margins for which optimal therapy requires attainment of a drug serum concentration within narrow bounds. Such monitoring allows the highest level of precision in adjusting doses to compensate for variability among individuals.

For example, consider a commonly encountered patient administered lidocaine. As in previous examples, the average V_d of 1.1 L per kilogram and clearance of 9 mL per minute per kilogram can be used to calculate loading and maintenance doses of 231 mg and 1.9 mg per minute, respectively, to attain a target serum concentration of 3 mg per liter in a 70-kg patient. If, however, a patient's pharmacokinetic parameters are at the high end of the range of normal (e.g., 50% higher V_d and clearance), the actually attained lidocaine serum concentration will be 50% lower. If the patient had not responded to the originally derived dosing regimen, the clinician could not distinguish too low a drug concentration from refractoriness to the drug unless a concentration were actually measured. If a low concentration of lidocaine were documented, the preferred strategy would be to increase the dose to attain a desired concentration and then reassess the patient's response.

The converse scenario also is possible, namely, the patient's pharmacokinetic parameters may be at the low end of the normal range. In this case, an actual lidocaine serum concentration as much as 50% higher than expected might occur. If the patient had not responded to lidocaine in this circumstance and it was known that the lidocaine serum concentration was sufficient (if not at the high end of the therapeutic range), the clinician might elect to use another drug rather than give larger doses of lidocaine and risk toxicity.

The actually measured drug concentration is extremely useful in adjusting dosing regimens. The proportionality of the relations between V_d and loading dose and between clearance and maintenance dose makes this possible. Hence, if a steady-state serum concentration of a drug is too low, the desired new target concentration can be defined and the maintenance dose increased proportionately. Such dose adjustments were discussed in detail in the previous section.

Interpretation of measured serum concentrations often is inappropriate (Table 55.4). For example, surveys have shown that as many as half the samples measured for digoxin in a clinical laboratory are useless and potentially misleading. The most common reason for this failing is inattention to simple pharmacokinetic principles. *Proper interpretation requires knowledge of the relation between the time a sample was drawn and the time the dose of drug was administered.* If a value is interpreted based on the belief that it is a trough concentration (obtained immediately before the next dose), whereas it actually is a peak sample or one obtained in the middle of the dosing interval, dose adjustment based on false assumptions may ensue.

Lack of knowledge about the timing of the sample in relation to dosing of the drug
Sampling during the distribution phase
Not realizing the futility of defining a peak concentration after oral dosing
Ignoring the concept of steady state
Ignoring the possibility of noncompliance
Forgetting that there is considerable pharmacodynamic as well as pharmacokinetic variability among patients

TABLE 55.4. REASONS FOR IMPROPER INTERPRETATION OF DRUG SERUM CONCENTRATIONS

Another common error is obtaining a sample during the distribution phase of a drug. This phase is the time necessary for the drug to equilibrate between serum and tissues. Until equilibration occurs, the serum concentration is not reflective of drug concentration at the site of action and, thereby, is not interpretable. For most drugs, equilibration occurs quickly and problems do not occur. For lidocaine and digoxin, however, this potential error must be prevented. After a loading dose of lidocaine has been given, about 30 minutes (and preferably longer) should elapse before a sample is obtained. The distribution phase for digoxin is long, lasting up to 6 hours. Hence, samples for digoxin measurements should never be obtained less than 6 hours after a dose.

A similar error is sampling during the absorption phase when a drug has been administered by other than IV routes. Variability in the time course of drug absorption is immense and is influenced by factors such as drug formulation, disease state, food consumption, and drug interactions. Hence, a drug serum concentration obtained after an oral dose could represent ascent to the peak concentration, the peak itself, or descent from the peak. Which of these possibilities is actually the case cannot be ascertained unless frequent samples are obtained sufficient to define the absorption profile of the drug. Such efforts rarely are indicated.

These three pitfalls in interpretation of drug serum concentrations can be prevented by a simple strategy, namely, obtaining only trough samples. Usually, such values are sufficient to guide therapy and avoid the most common errors that occur in therapeutic drug monitoring.

Proper interpretation of a drug serum concentration during maintenance therapy requires an assessment of whether steady-state concentrations have been reached. So doing requires knowledge of a drug's half-life. If a patient were started on a maintenance regimen and evaluated before steady state was attained, the concentration would increase with continued dosing. If the measured value was interpreted erroneously as the steady-state concentration, inappropriate dosing decisions might ensue. For example, the average half-life for digoxin is about 36 hours. Hence, about a week of dosing is required to reach steady state. If a digoxin serum concentration is obtained after 3 days, found to be less than desired, and in error interpreted as reflective of steady state, a potentially disastrous increase in dose might be prescribed. This type of problem can be prevented by always assessing the patient's drug dosing status with regard to the time needed for steady-state conditions to occur.

Many clinicians tend to overlook lack of compliance with medication regimens as an explanation for measured drug concentrations that differ from those expected. If a person on an outpatient dosing regimen has a drug serum concentration lower than anticipated, the discrepancy could be explained by a greater than expected drug clearance or a lower bioavailability in the specific patient or by poor compliance. All these possibilities must be considered.

A pitfall that must be avoided in therapeutic drug monitoring is using a drug serum concentration itself as a therapeutic goal or definitive diagnostic tool. This is inappropriate because of pharmacodynamic variability among patients; hence, a given drug serum concentration may be subtherapeutic in one patient, ideal in another, and toxic in yet another. A good example of the application of this tenet is digoxin. In a patient with atrial fibrillation in whom digoxin is used to control the ventricular rate, a needed digoxin serum concentration may be high and an average "normal" value of 1.5 ng per milliliter may be subtherapeutic. In contrast, in many patients with congestive heart failure, a concentration of 1.5 ng per milliliter might be ideal. At the other extreme, a patient who is potassium- or magnesium-depleted may experience digoxin toxicity at a serum concentration of 1.5 ng per milliliter.

Proper use of a measured drug concentration in an individual patient requires treatment of the serum concentration value as simply another item of information that must be integrated with other clinical end points to determine how the specific patient is responding to a particular dose and concentration of drug. Once this clinical assessment is made, the concentration value can be used to design or modify the patient's dosing regimen based on pharmacokinetic principles. Optimal therapy is possible only by interdigitating both pharmacokinetic and pharmacodynamic principles.

CLINICAL TOXICOLOGY

Poisoning is the extreme of pharmacokinetics and pharmacodynamics; its treatment can be considered in terms of the foregoing concepts.

The first principle of clinical toxicology is general support of the patient. Proper ventilation and circulatory support should be the therapeutic focus after which one can consider "detoxification." The pharmacodynamic component of poisoning is consideration of ways to counteract the toxic effect of the poison. The pharmacokinetic component is using methods to either preclude further absorption of the toxin or to enhance its elimination.

Antidotes to some poisons are available. Use of atropine in organophosphate poisoning, N-acetylcysteine for acetaminophen overdose, and numerous others are pertinent. See [Chapter 57](#) (Emergency Medicine). Toxicology texts should be accessible for identifying antidotes as well as their mode of administration. In addition, physicians should know how to contact the nearest poison control center, which can provide this information.

All aforementioned pharmacokinetic principles are relevant to poisoning settings. In terms of bioavailability, a number of therapeutic strategies can be used to prevent additional absorption of the poison. Some are as simple as stripping the patient and bathing him or her to remove poisons such as organophosphates, which may be in the clothing and on the skin through which many poisons can be absorbed. With most ingested poisons (except hydrocarbons), emesis can be induced or activated charcoal can be given. With some drugs, activated charcoal actually enhances elimination by interrupting enterohepatic cycling.

Distribution of a drug is also important. Reversing systemic acidemia enhances distribution of salicylate out of the CNS, thereby diminishing its toxicity. Binding of digoxin to Fab fragments actually extracts digoxin out of tissues and back into the plasma where it can be excreted. Distribution of a drug is also significant regarding whether dialytic removal of a poison might be helpful. Drugs with high degrees of protein binding (more than 90%) cannot be removed by dialysis. In addition, drugs with large volumes of distribution (in general more than 1 L per kilogram) are negligibly removed by dialytic procedures including resin hemoperfusion. Most of the body burden of such drugs is in peripheral tissues. As such, even if the dialytic procedure can remove a substantial percentage of poison in the serum, this amount is trivial in proportion to that in the rest of the body.

With some poisons, one can also enhance elimination. The effect of activated charcoal and dialysis has been mentioned. Drugs with renal excretion that is influenced by urinary pH can have their elimination enhanced by adjusting urine pH and enhancing urinary flow. Excretion of organic acids such as salicylate and phenobarbital is increased by an alkaline urine. The converse applies for organic bases.

Some poisons such as methanol and ethylene glycol are metabolized to their toxins. Understanding that this metabolism occurs through alcohol dehydrogenase and knowing that ethanol is the preferred substrate for this enzyme has allowed use of ethanol infusions as therapy for poisoning with these agents. This example and the principles previously enumerated illustrate how the same principles of clinical pharmacology are logically applied to toxicology.

CHAPTER 56: ALTERNATIVE MEDICINE: PREVALENCE, COST, AND USEFULNESS

MARK MULTACH

[Herbal Medicine and Other Natural Supplements](#)
[Acupuncture](#)
[Magnet Therapy](#)

Alternative or complementary medicine is a major growth industry in the United States within the medical, lay, and financial communities. Patients have far outstripped the medical community in their willingness to use these therapies. Americans now make more visits to nontraditional healers than to their family doctors and spend almost as much (out of pocket) on alternative medicine as on unreimbursed physician services (\$27 billion versus \$29 billion).

Recently, organized medicine has begun to address alternative therapies. Many medical centers have or are developing centers for the study and use of complementary medicine. Research funding, especially at the federal level, is increasing at an unprecedented growth rate.

The allopathic approach to alternative medicine has not been an easy one. Although the traditional medical community deals in epidemiology, biostatistics, randomized placebo-controlled studies, and gold standards, many alternative therapies cannot be studied by this approach. For example, the study of acupuncture has run into difficulties in attempting to carry out double-blind, placebo-controlled studies. The ethical and practical issues have required years of debate to attempt to resolve.

HERBAL MEDICINE AND OTHER NATURAL SUPPLEMENTS

Herbal remedies are used more and more frequently by patients. In the early 1990s, one survey estimated that 54 million Americans used herbal medicines, at a cost of approximately \$54 per person per year. Annual sales of botanicals in the United States alone have risen from \$1.6 billion in 1994 to \$16 billion in sales in 1998, demonstrating the impact since 1994 of Congress's approval of the Dietary Supplement Health and Education Act.

Although more than one-third of the population has tried an herbal remedy within the past few years, more than 60 million Americans used herbal medicines on a more regular basis in 1997. More than 7 million used St. John's wort (in Germany, five times more people use this remedy than Prozac [fluoxetine]), similar to the number using echinacea. Owing in part to release of data recently suggesting a direct effect, ginkgo biloba is used by more than 10 million Americans regularly.

Regulation of this industry is in its infancy. Some manufacturers in the industry have implemented strict quality control measures; however, no such standard is in place across the industry. Contents of "active" (the definition of which is unclear) ingredients may vary by as much as 300% to 1,000% according to manufacturer and even according to batch from a single manufacturer. At the extreme, studies have demonstrated no active ingredient in some products sampled.

Herbal supplements undergo no testing to determine whether they contain what they claim. The Food & Drug Administration (FDA) does not regulate claims of benefit. In fact, the Dietary Supplement Health and Education Act allows that as long as labeling makes no specific claim on the packaging regarding treatment of a disease, companies can sell any supplement. Labeling need only contain promises for improvement of general structure and function. This further complicates the situation for patients. Treatment for specific diseases cannot be listed on the packaging; therefore, no dosages for specific indications can be listed either. Patients are left to their own devices to guess what dosage to use for a specific ailment, which can lead to potential overdoses. Rules regulating advertising for herbal products fall below even the standard set for packaging.

Of equal importance is the potential for adverse reactions or interactions of herbal supplements with prescription drugs or other remedies. Although herbal remedies are advertised as harmless, the problems with many preparations are well documented in both the lay and the medical literature.

Studies of supplements also are the subject of controversy. In the history of the FDA, regulations have become stricter since the thalidomide scare of the 1960s. Large well-controlled studies are required to look at drug safety and benefit, in addition to ongoing surveillance of drug safety. The literature on supplements falls far short of this level of rigor.

Finally, what constitutes a supplement and what constitutes a drug are unclear. The FDA is responsible for supervision and approval of drugs. The Dietary Supplement Health and Education Act categorized vitamins, minerals herbs, amino acids, some hormones, and other products as *supplements*, which are unregulated by the FDA. Some supplements are chemically similar to prescription drugs but, with the removal of some of the labeling, are distributed as supplements. Cholestin, a popular treatment in China for hypercholesterolemia, contains a yeast and is classified as a supplement. However, a product of the species of yeast, which appears to be the active ingredient, is chemically similar to lovastatin.

Some hope of clearing up the picture is in sight. A presidential commission was appointed 2 years ago and has reviewed the current state of supplements. It has made preliminary recommendations to the FDA on how to regulate supplements. The suggestions included creating a panel, under the auspices of the National Institutes of Health's Office of Alternative Medicine, to review all herbs and to make recommendations regarding claims of current supplements and to recommend that packaging be more extensive in documentation of claims for the patient.

In 1978, in Germany a review panel (referred to as Commission E) was appointed to start an ongoing review process of supplements. The commission included physicians, pharmacists, pharmacologists, toxicologists, representatives of the pharmaceutical industry, and lay persons who reviewed the current literature on herbs then on the market. The commission has produced monographs on more than 300 supplements to date. Based on this ongoing review, approximately 200 supplements have been approved as nonprescription drugs. An English translation of these monographs was made available in August 1998.

In contrast to the paucity of scientific data supporting herbal preparations is the list of current medications that were derived from botanicals. These include aspirin (white willow bark), digitalis (foxglove), paclitaxel (Taxol; from yew tree bark), and oral contraceptives (Mexican yam).

SPECIFIC HERBS

St. John's Wort

Perhaps the best evidence supporting efficacy of a botanical is for St. John's wort ([Table 56.1](#)). More than 20 trials to date have been performed following traditional medical literature standards. Trials usually involve a comparison with a placebo or a tricyclic antidepressant. Studies have consistently demonstrated improvement in objective assessments of depression at least equivalent to standard therapy (tricyclic antidepressants) with significantly fewer side effects. Short-term studies showed side effects to be equal to placebo and to be approximately 50% of those of tricyclic antidepressants. Unfortunately, studies were short-term only, lasting less than 6 months at maximum. The most common complaints were photosensitivity (especially in fair-skinned persons), dizziness, gastrointestinal upset, fatigue, and confusion.

- **Production**
Hypericin (active ingredient) extracted from the stem of the plant *Hypericum perforatum*
- **Dosage**
Depression: 2–4 g daily (0.2–1 mg of hypericin)
- **Mechanism of Action**—unknown

TABLE 56.1. ST. JOHN'S WORT

Ginkgo Biloba

Ginkgo biloba has been studied in the United States. Its pharmacology and mechanism of action have been reviewed and have shown many unique effects ([Table 56.2](#)). Several studies of ginkgo biloba in the United States have shown improvement in objective criteria of neuropsychological functioning in patients with senile dementia, Alzheimer's type. The clinical usefulness of these observations has yet to be demonstrated. The onset of the herb's effect was delayed up to 6 to 8 weeks. Similarly, in studies in the United States and Europe using lower dosages of ginkgo, patients with peripheral vascular disease showed significant improvement.

- **Production**
Extracted from the leaves of the plant *Ginkgo biloba*
- **Dosage** (native dried extract, split doses)
For dementia: 120–240 mg/day
For peripheral vascular disease: 120–160 mg/day
- **Mechanism of action** (from animal data)
Improved hypoxic tolerance (especially cerebral tissue)
Inhibition of cerebral edema in response to trauma/toxin
Acceleration of regression of cerebral edema
Inhibition of age-related reduction of muscarinic cholinergic receptors and 1-adrenoreceptors
Stimulation of choline uptake in the hippocampus
Inactivation of oxygen radicals
Improved rheologic properties of the blood
Increased blood flow (especially microcirculation)

TABLE 56.2. GINKGO BILOBA

Echinacea

Echinacea (*Echinacea angustifolia*; purple coneflower) is a genus with a medicinal history going back to Native American medicine ([Table 56.3](#)). Although there are many species, the most commonly used medicinally is echinacea purpurea. The combination of many species and preparations has made interpretation of the literature very difficult. Many clinical effects have been claimed for echinacea (some infections, chronic fatigue, cancer, and chronic arthritis, to name a few), but it is most frequently used for the common cold. Three studies to date have focused on this application with scientific rigor. In all three studies, cold symptoms were of shorter duration (statistically significant in two of three, the third having a small population limiting its power to detect differences), whereas symptoms were significantly improved in one of three, unchanged in one, and not specifically studied in the third. Some concern has been expressed among both herbalists and allopathic physicians about the immune-enhancing properties of echinacea and potentially harmful immune reactions (severe allergic reactions have been reported). Goldenseal is often found combined with echinacea. Studies have demonstrated no benefit from the use of goldenseal.

- **Production**
Derived from the many parts primarily of the plant species *Echinacea purpurea* or its extracts
- **Dosage** (native dried extract, split doses)
Depression: 2–4 g/d (0.2–1 mg of hypericin)
- **Mechanism of action** (many nonspecific effects on the immune system)
Phagocyte stimulation
Acute phase reactions
Monocyte activation (secretion of tumor necrosis factor- α , as well as interleukins 1 and 6)

TABLE 56.3. ECHINACEA

Kava Kava

Kava kava comes from the dried root of *Piperis methystici* G. Forster, is derived from dried above-ground parts of the plant *Hypericum perforatum* and contains the chemical kavapyrones (kavain). Animal studies have shown significant central nervous system (CNS) depression. As a result of this and observations in humans of drowsiness and slowing of reflexive responses, concern has been expressed over its use, especially in conjunction with other CNS active medications (e.g., alcohol, barbiturates). Adequate studies of kava kava in humans are not available.

Saw Palmetto

Saw palmetto berry is rapidly increasing in use by men for prostate-induced urinary symptoms. Clinical trials (and one meta-analysis) indicate significant decrease in urinary symptoms. The effect is most likely antiandrogenic in nature. Dosages used were 0.5 to 1.0 g per day of the dried berry (0.6 to 1.5 mL of extract).

ACUPUNCTURE

Acupuncture has similarly shown a rapid growth in popularity. Acupuncture includes a number of techniques and tools combined to produce its effects. Various types of needles or other instruments to induce pressure are combined with different types of manipulation of the needle (including twisting, heat [also known as moxibustion], pressure [acupressure], and electricity). In addition to different techniques, a number of historical schools of acupuncture are in existence as well as several newer systems of treatment ([Table 56.4](#)).

- Traditional Chinese medicine
- French energetics
- Korean Hand acupuncture
- Five phases (five elements)
- Auricular
- Myofascial
- Local injection

TABLE 56.4. SCHOOLS OR SYSTEMS OF ACUPUNCTURE

Approximately 9 to 12 million patients visit acupuncturists yearly, averaging 19 visits per patient. Because this expense is not covered by almost all third-party payers, patients can expect to pay approximately \$30 per visit out of pocket. Patients seeking acupuncture care tend to be from a higher socioeconomic group, are younger (25- to 49-year age range on average), and have a higher educational status (college education on average) than the general population. Patients are more likely to be white or of Asian rather than African-American descent. Men and women use acupuncture with about the same frequency. Patients who use acupuncture on a regular basis tend to have chronic medical problems of more than 1 year's duration. Most consult with a traditional physician for the same complaint. However, more than 75% of these patients do not mention acupuncture to their Western-trained physician.

HISTORY OF ACUPUNCTURE

The history of acupuncture dates to 1500 B.C. with the advent of the Taoist philosophy. The first notations of use of acupuncture appear in 500 B.C. with descriptions of the use of stone needles. In 200 B.C., the first definitive description of the principles of health and illness was outlined in the *Yellow Emperor's Internal Classic* in which basic concepts of health and disease were defined. Health was felt to be a balance of *Qi*, the energy flow throughout the body. Illness was a result of some perturbation in this flow. The Internal Classic further defined two systems for describing health and illness: *yin* and *yang*. These systems represented one balanced system of health. Yin represented darkness, passivity, decline, whereas Yang was brightness, excitement, and upwardness. Illnesses and organs were described as either yin (heart, lungs, spleen, liver, kidney, pericardium) or yang (small and large intestines, stomach, gallbladder, bladder). The body balanced these forces in health, whereas in illness there was an imbalance between the two. Treatment was aimed at bringing a healthy balance back by any of a number of modalities including diet and acupuncture.

The second organizing theme of the Internal Classic revolves around *five elements* or natural resources (wood, fire, earth, metal, and water). According to this system, the organs are related to the five elements as well as to each other.

BASICS OF ACUPUNCTURE

The basic principle of acupuncture is modification of body energies focused at specific points along specific lines around the body. Illnesses are felt to be systemic processes in which the energy flow and balance in the body as a whole are disordered. Manipulation of the energy channels along these lines or meridians can realign and rebalance the *Qi*.

Practitioners use stainless-steel or (more expensive) alloys. Needles may be the single-use type or reusable. The FDA has mandated single use. However, there is still concern about actual adherence to this requirement.

Diseases represent symptoms of a complex dysfunction of the balancing forces just mentioned. *Qi* flows along a system of *meridians*, imaginary lines running longitudinally in and around the body. Twelve major meridians exist, which communicate by a series of transverse collaterals. In addition, a number of other lines exist, including divergent meridians, 12 muscle meridians, 8 minor meridians, and 12 cutaneous meridians. Each meridian is connected to specific yin and yang organs. Working with the major and minor meridians, 361 acupuncture points are defined. These points are defined in terms related to anatomical structures and easy defined measurements (*Cun*). Each point has a name and serial number description.

The most studied of the acupuncture techniques involves the use of needles and direct manipulation or electrical stimulation. Scientific data relating to other modalities are more scarce. Modern theories and research have attempted to relate the meridians and acupuncture points to anatomical structures and physiologic processes. This approach has had a fair degree of success in defining a scientific basis for acupuncture.

Acupuncture points and major meridians are often associated with underlying nerves. Manipulation of acupuncture points is associated with changes in the release of neurotransmitters, both positive and negative. Some investigators have also found unique electrical properties associated with some acupuncture points and meridians. Many of the effects of acupuncture are clearly associated with nerve function.

In human studies, many observations have begun to elucidate the physiologic processes involved in acupuncture. The effects of acupuncture can be abolished with local pretreatment with procaine, an effect not seen with placebo injections. Acupuncture has been shown to be ineffective in quadriplegics and paraplegics below the level of their neurologic injury. Use of the opiate antagonist, naloxone, eliminates the therapeutic effect of acupuncture, an effect not seen with placebo injections. Alcohol decreases or eliminates the effect of acupuncture, so patients are advised to avoid alcohol before therapy. Finally, corticosteroids are known to inhibit the effect of acupuncture, leading to the recommendation that they be avoided for 6 to 12 weeks before therapy.

In animals, studies have shown a strong association between physiologic processes and efficacy of acupuncture. Use of acupuncture has been shown to induce production of specific messenger RNA sequences and proteins for opiate receptors and endorphins. The effects are blocked with the help of receptor antagonists. Finally, induced hypothalamic lesions (site of b-endorphin release) abolish acupuncture effects.

THERAPY

The acupuncture therapist inserts and immediately knows when the needle was correctly placed. If inserted into an appropriate acupuncture point, the patient describes a sensation of heaviness, fullness, and numbness without pain (*De Qi*). After treatment, the patient usually feels generalized body fatigue; this effect is seen minutes to hours later. As a result, patients are advised to avoid strenuous activity or driving immediately after treatment. A rebound phenomenon may occur 24 to 48 hours later before improvement of symptoms. Note that although there are no studies documenting adverse effects of acupuncture on pregnancy, the lack of such studies on safety has led to naming pregnancy as a relative contraindication to acupuncture.

The most common side effects of acupuncture are warmth, relaxation, a sense of well-being, and an improved energy level. Rarely, patients have a vasovagal episode with the initial needle insertion, nausea, anorexia, and local irritation. Very rare case reports have described pneumothorax, hepatitis B, and pericardial tamponade.

EFFICACY

Acupuncture has been studied in many diseases and ailments, including osteoarthritis, chemotherapy-induced and postoperative nausea, asthma, back pain, fibromyalgia, dysmenorrhea, bladder instability, migraine headaches, chronic pain, substance abuse, and stress.

In patients with pulmonary disease (especially asthma), a small number of studies have been performed. Acupuncture has significant effects on dynamic pulmonary volumes including forced expiratory volume in 1 second (FEV_1), forced vital capacity (FVC), and maximum voluntary ventilation (MVV). Use of acupuncture has been

associated with significant reductions (up to 50%) in the cost of caring for these patients, including medication costs, use of laboratory examinations, and need for hospitalizations. Studies have shown that 90% or more of patients with pulmonary disease significantly decrease medication requirements and use. The best-studied example has been methacholine-induced bronchoconstriction. Double-blind studies using sham acupuncture points have shown statistically significant efficacy greater than placebo, although statistically not as effective as bronchodilators.

In patients with chemotherapy-induced or postoperative nausea, single-blind studies have shown statistically significant improvement in symptoms. However, acupuncture is not believed to be as effective as traditional antiemetic medications.

Various pain syndromes have been studied with regard to acupuncture, including postoperative pain, postdental procedure pain, some musculoskeletal conditions (e.g., fibromyalgia, fibromyofascial pain), and low back pain. The argument has been that traditional therapies have such documented toxicity that acupuncture may be an acceptable alternative with at least as much benefit and considerably less potential for toxicity. Studies vary, with little efficacy seen in patients with osteoarthritis but consistent patterns of symptomatic relief in patients with lumbar disk herniation syndromes. In the latter, although in poorly designed studies, improvements have been seen in patients who have failed traditional, conservative therapy.

An area with considerable use for acupuncture therapy is substance abuse (see [Chapter 35](#), Approach to the Problem of Substance Abuse). The quality of the data is similar to other areas of acupuncture treatment. Many studies of varying design and quality have yet to document efficacy beyond placebo thus far.

Other areas of active research include National Institutes of Health (NIH)-funded studies on unipolar depression, osteoarthritis, oral postsurgical pain, and HIV (in combination with Chinese herbal medicine), and even pregnant women with breech presentation to induce version of the baby.

MAGNET THERAPY

Finally, an addition to the armamentarium of some orthopedic surgeons has been the use of magnets in the healing of fractures. Anecdotal reports date back at least two decades. Therapy is applied with local placement of a magnet at the site of the fracture within the cast or stabilizing device. Two well-controlled studies, totaling more than 100 patients, showed statistically significant improvement in symptoms compared with those of controls. However, no data exist as to the benefit in healing. Studies in this area are ongoing.

CHAPTER 57: GENERAL PRINCIPLES IN THE APPROACH TO THE PATIENT WITH AN ACUTE EMERGENCY

SHELDON JACOBSON

Ventilation–Respiration
Pulse, Rhythm, and Cardiac Monitoring
Blood Pressure
Temperature
Mental State
Presenting Complaint—Focused Care
Chest Discomfort
Abdominal Pain
Weakness and Dizziness
Acute Onset of Headache
Approach to Multisystem-Trauma Patients
Emergency Equipment

When a patient presents with an acute, potentially life-threatening complaint or requires immediate resuscitation, an approach must be taken that is different from the traditional practice of internal medicine. To allow rapid assessment and treatment to be carried out simultaneously, the database to initially draw from is usually very limited. There may be no history available other than that given by prehospital personnel. Until the situation becomes less chaotic, care is delivered in a more stereotypical way using resuscitation algorithmic approaches and an analysis of the presenting physical data, especially the vital signs, but also including diagnostic studies and a vectored but thorough comprehensive physical examination. In this overview, we discuss the basic principles in the approach to these situations and the essential issues in the management of a range of presenting problems.

The first and overriding principle is that on arrival, patients are presumed to be unstable or in need of resuscitation until proven otherwise. The ABCDEs (airway, breathing, circulation and cervical spine injury, disrobe, engage) are applied according to the standards of basic cardiac life support (BCLS) promulgated by the American Heart Association. Immediately superimposed on the BCLS algorithms are those of advanced cardiac life support (ACLS), which are also established by the American Heart Association (Fig. 57.1). Note that although these standards were initially focused on the victim of a myocardial infarction who is unstable or sustains a cardiac arrest, the procedures and approaches actually have almost universal applicability to situations involving resuscitation of unstable patients. An overview of the approach to the patient with an acute non-trauma-related emergency has also been developed (Fig. 57.2).

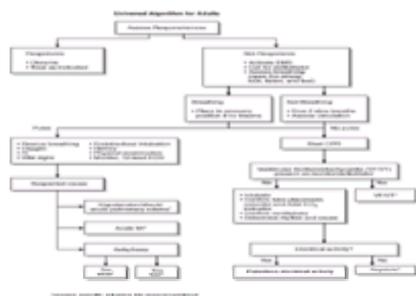

FIGURE 57.1. Standards initially focused on the victim of a myocardial infarction who is unstable or sustains a cardiac arrest; these approaches have almost universal applicability in the resuscitation of unstable patients.

FIGURE 57.2. An overview of the approach to the patient with an acute non-trauma-related emergency.

After it has been established that resuscitation is not needed, the next principle is to obtain the presenting complaint and develop the history of the present illness, interpret and treat the abnormal vital signs, or monitor them as the case would require. In addition to the traditional vital signs, namely, respiration rate, pulse, temperature, and blood pressure, the scope of basic vital signs has been enlarged to include the mental status and the determination of the oxygen saturation of arterial blood by pulse oximetry. Given the very short treatment windows for major perturbations of the vital signs, treatment and diagnosis must be carried out at the same time. Thus, immediate management of hypotension, hypoxemia, hypoventilation and malignant hyperthermia can be instituted without a specific primary or underlying diagnosis or a complete understanding of the underlying pathophysiology. Each deviation from the norm of a vital sign suggests a therapeutic option as well as a set of differential diagnostic possibilities.

VENTILATION–RESPIRATION

First, an assessment of the adequacy of the minute ventilation (a proxy for the alveolar ventilation) and cellular respiration (gas exchange as well as cellular oxygen utilization) is needed. The respiratory rate is only one parameter gauging the adequacy of this function. If the respiratory rate is normal (10 to 12 breaths per minute), the patient appears well oxygenated, is alert and oriented, and has a pulse oximetry reading higher than 95%, significant abnormality of alveolar ventilation or cellular respiration is unlikely. Further investigation to monitor the respiratory and ventilatory function may include arterial blood gas determination while the patient is breathing room air, venous or arterial blood lactate, serum creatinine, and electrolytes. This data set will also provide the information needed to determine the patient's alveolar–arterial (A-a) gradient for oxygen, as well as the patient's acid–base status and degree of compensation or inadequate compensation for the acid–base abnormalities. The A-a gradient is a measure of the severity of ventilation/perfusion mismatches. If there is still uncertainty, adequacy of ventilation can also be assessed by bedside pulmonary function testing. These parameters include vital capacity (VC), peak flow, maximal midexpiratory flow rate, the forced expiratory volume in 1 second (FEV_1), and the FEV_1/VC . Normal values for these functions are given in Table 57.1.

Room air arterial blood gas
 pH 7.35–7.45
 P_aCO₂ 40–42 mmHg
 P_aO₂ 95–98 mmHg
 Pulse oximetry (room air)
 95–100% saturation
 Tidal volume
 6–7 mL/kg
 Vital capacity (VC)
 60–70 mL/kg
 Forced vital capacity in 1 second = (FEV₁) – FEV₁/VC = 80–90%
 Peak flow = 400–600 L/sec
 Alveolar-arterial oxygen gradient (A-a)
 A = 150-P_aCO₂ × 0.8
 a = P_aO₂
 Normal 10–15 mmHg (older patients, approximately 1/3 age)
 Arterial lactate 0.5–1.5 mmol/L
 Venous lactate 0.5–2.2 mmol/L

TABLE 57.1. NORMAL VALUES FOR SOME KEY CARDIOPULMONARY FUNCTIONS

In many situations, pulse oximetry is monitored continuously and displayed along with the cardiac rhythm. The use of pulse oximetry is very helpful, but it has three significant limitations leading to misinterpretation of the value and meaning of the results.

First, the gold standard for oximetry is the use of another type of oximeter, a clinical cooximeter. The cooximeter can measure oxygen saturation of hemoglobin as well as the level of carboxyhemoglobin and methemoglobin. Pulse oximetry devices misread carboxyhemoglobin (usually artificially raising the oxygen saturation) and methemoglobin (usually lowering the oxygen saturation). Second, the pulse oximeter depends on adequate pulsatile flow to separate arterial from venous reflectance. If the patient is in shock or otherwise has poor peripheral blood flow, the reading may be unreliable. Finally, because of the hemoglobin dissociation curve, initial reductions in partial pressure of arterial oxygen (Pa O₂) produces minimal decreases in oxygen saturation until the Pa O₂ reaches the shoulder of the dissociation curve at a PaO₂ of approximately 60 mm, corresponding to a saturation of approximately 90%. Based on these parameters and the clinical situation, a decision can be made to intervene with endotracheal intubation and ventilatory support of breathing ([Table 57.2.](#)). Waveform capnometry, the measurement of the concentration of CO₂ in exhaled air, is very useful because it allows estimation of VC and degree of airway obstruction. In addition, it is very helpful in ascertaining endotracheal tube placement and the adequacy of cardiopulmonary resuscitation.

Failure of mechanics of breathing
 ■ Tachypnea >35–40 breaths/min
 ■ Bradypnea <8 breaths/min
 ■ Vital capacity <15 mL/kg (normal 65–75 mL/kg)
 ■ Negative inspiratory force <–25 cm H₂O (normal –65 to –75 cm H₂O)
 Failure of oxygenation
 ■ P_aO₂ <60 while breathing 50% oxygen via face mask
 Failure of ventilation
 ■ P_aCO₂ >60
 Unstable airway
 ■ Intermittent obstruction via tongue; not treatable with nasal airway; aspiration of secretions

TABLE 57.2. GENERAL INDICATIONS FOR ENDOTRACHEAL INTUBATION AND VENTILATOR MANAGEMENT

PULSE, RHYTHM, AND CARDIAC MONITORING

The pulse is automatically counted on the cardiac monitor and pulse oximeter. An estimation of the pulse wave by palpation or from the waveform on the pulse oximeter can also be very useful. For example, the patient with critical aortic stenosis has a slow upstroke and a long systolic ejection time, the so-called *pulsus parvus et tardus*, whereas patients with thyrotoxicosis, high fevers, sepsis, arteriovenous fistula, beriberi heart disease, or CO₂ narcosis often have rapid bounding pulses as evidence of their hyperdynamic circulation.

Most acutely ill patients require continuous cardiac monitoring in addition to a baseline standard 12-lead electrocardiogram (ECG) for recognition of characteristic patterns of injury, electrolyte disturbance, infarction, conduction disturbances, or dysrhythmia. The standard 12-lead tracing has been found to be inadequate for diagnosing isolated or predominant right ventricular infarction and true posterior infarction. The former is usually obvious on a V₄R lead, whereas diagnosis of the latter is best served by obtaining a V₈ or V₉ lead. In the future, the standard 12-lead ECG will most likely become a 14-lead study.

Patients with a rapid regular rhythm can have either a sinus tachycardia or a supraventricular or ventricular dysrhythmia. The maximal predicted exercise heart rate in sinus rhythm is approximately 220 beats per minute minus the patient's age with 1 standard deviation (SD) of ten beats. Thus, if a patient has a heart rate greater than this maximal rate at rest, a sinus tachycardia is much less likely. A resting sinus tachycardia can be seen with major physiologic derangements or with an increase in sympathetic tone. [Table 57.3](#) contains a list of differential diagnostic possibilities in patients with unexplained sinus tachycardia. Patients with rapid tachycardias may present with instability of their vital signs due to the rapid rate and decreased diastolic filling time and with heart failure due to the myocardial workload. In some cases of ventricular tachycardia, the loss of the normal sequence of atrioventricular activation and contraction may in and of itself reduce cardiac output. These unstable patients usually require electrical cardioversion as quickly as possible.

Pulmonary embolism
 Hypoglycemia
 Hyperthyroidism
 Pheochromocytoma
 Occult heart failure
 Sinus nodal reentry
 Low peripheral vascular resistance
 Vasodilatory medication
 Fistula
 Cirrhosis
 CO₂ narcosis
 Beri-beri heart disease

TABLE 57.3. CAUSES OF UNEXPLAINED SINUS TACHYCARDIA

Both sinus tachycardia and atrial flutter can present with rates of 140 to 150 beats per minute and thus can be easily confused. Differentiation can be achieved by response to the Valsalva maneuver or carotid massage. With these maneuvers, sinus tachycardia usually slows somewhat and then returns to the prior rate, whereas atrial flutter either shows no change or slows by increases in block (e.g., from 2:1 to 3:1 or 4:1). Atrioventricular (AV) nodal reentry tachycardias either “break”

(resolve) with vagal maneuvers or remain constant. Sinus bradycardia, a pulse rate of less than 60, is often due to physical conditioning, increased vagal tone, or sympathetic blockade ([Table 57.4](#)). Slow rates are compensated by increasing stroke volume in the normal heart. Patients with heart failure attempt to compensate partially by rate increases, and slow heart rates lead to abrupt declines in cardiac output and progression of heart failure. Sudden slowing of the heart rate can be associated with presyncope or actual loss of consciousness if compensatory increase in the peripheral vascular resistance is inadequate in improving arterial and venous pressure. This is the pathophysiologic mechanism of vasovagal syncope. Occult causes of sinus bradycardia are listed in [Table 57.4](#).

Athletic training
Hypothermia
Sick sinus syndrome
Increased intracranial pressure
Digitalis toxicity
 β -blockade
Hypothyroidism
Cardiac ischemia

TABLE 57.4. OCCULT CAUSES OF SINUS BRADYCARDIA

BLOOD PRESSURE

In all patients who have potentially life threatening problems, blood pressure monitoring should be instituted as soon as possible. The bladder of the arm cuff must approximate 60% to 80% of upper arm circumference to reduce artifactual readings. If there is a discrepancy between the indirect measurement and the patient's condition (i.e., low blood pressure measurement without signs of shock, or extraordinarily high readings), measurement of the blood pressure in the forearm or thigh may be helpful. The blood pressure measurements in these sites normally approximate brachial blood pressures. If a significant unresolved discrepancy continues, then direct invasive measurement of the radial blood pressure using a pressure transducer should be carried out. This problem is encountered most frequently in obese patients with pendulous skin folds.

HYPERTENSION

Hypertensive emergencies are defined as an elevated blood pressure with acute end-organ damage. The target organs for this damage are the brain, the heart, and the kidneys. Thus, if a patient presents with a blood pressure of 200/140 and has new focal neurologic signs or symptoms, he or she has, by definition, a hypertensive emergency. The level of hypertension does not correlate with the degree of end-organ damage. In pregnancy, a blood pressure of 140/90 may be the presenting reading in a patient with eclampsia. On the other hand, if during a routine physical examination, an asymptomatic patient is found to have a blood pressure of 200/140 and the only finding on physical examination is some copper wiring and spasm of the retinal arteries, this patient is considered to have a hypertensive urgency. The former patient would be admitted to the intensive care unit and receive parenteral antihypertensive therapy, whereas the latter patient would be started on oral antihypertensive agents and, after some partial response to the inception of treatment with an oral antihypertensive, the patient would be closely monitored in the ambulatory setting while workup is completed. Although many drugs and regimens have been evaluated (including labetalol, other β -blockers, clonidine, captopril, enalapril, nifedipine) the optimal choice or choices for these patients has not been studied. Overly aggressive treatment of the patient with a hypertensive urgency is a common occurrence and can lead to cardiovascular and cerebrovascular events.

HYPOTENSION

Hypotension is defined loosely as a systolic blood pressure of less than 90 mm systolic. However, because very few people walk about with a systolic pressure lower than 100 mm, it is best to consider a systolic blood pressure below 100 mm to be hypotension if the patient cannot assume the upright position and function normally. Even patients with a normal blood pressure may have inadequate systemic perfusion. Because blood pressure equals cardiac output times peripheral vascular resistance, a "normal blood pressure" should not be equated with normal systemic blood flow. In patients with a healthy autonomic nervous system, vasoconstriction can compensate for a blood volume deficit of 15% to 25% before hypotension ensues. During this period of compensated shock, there should be evidence of decreased perfusion of the skin (cold, mottled), a narrow pulse pressure, and decreased urinary output. Sinus tachycardia and orthostatic changes in blood pressure and pulse are not reliable because of the varying response in normal subjects to positional change and the variable responses of patients to acute hypovolemia. In general, however, a pulse increase of 30 beats per minute or more when the patient stands upright or the development of orthostatic dizziness and hypotension can be viewed as a sign of blood volume loss in the appropriate clinical situation. Smaller changes in orthostatic vital signs may be significant if clinical correlations support the diagnosis.

SHOCK

Hypotension associated with other signs and symptoms of hypovolemia or hypoperfusion (e.g., peripheral cyanosis and mottling, altered mental states) should be considered to place the patient in a state of shock. Although there are various classifications of shock, for practical purposes in the emergency department we can divide them into (a) shock states that can improve—at least to some extent—to volume replacement and (b) cardiogenic shock, which usually does not improve to fluid challenges. Patients with right ventricular infarction and some with very high left ventricular compliance curves (diastolic dysfunction) can respond to volume loading, but most patients with cardiogenic shock decompensate further when given saline rapidly. Patients with so-called distributive shock (e.g., pulmonary embolism, cardiac tamponade, and tension pneumothorax) usually respond to volume loading, at least initially. The patient with cardiogenic shock usually presents with pulmonary and cardiac signs of congestive heart failure; this should be confirmed with a portable chest film. The ECG may reveal extensive damage, often both acute and remote.

All unstable patients should have two large-gauge (no. 18 or larger) intravenous cannulas inserted into a peripheral vein. For the former group of functionally hypovolemic patients, repeated boluses of intravenous saline 200 to 500 mL per challenge dose should be given every 5 minutes while the vital signs, mental state, lung sounds, lactate level, and urinary output are monitored.

TEMPERATURE

Life-threatening problems involving extremes of body temperature present insidiously and are often initially overlooked. Reading via oral or tympanic thermometry should be confirmed by rectal thermometer or a continuous-reading rectal or bladder temperature probe.

HYPOTHERMIA

The differential diagnosis of severe hypothermia is listed in [Table 57.5](#). In general, hypothermia is suspected from the mechanism of injury (e.g., cold water immersion) or the environmental circumstance of the patient. Severe hypothermia with core body temperatures of less than 89° F is associated with depression of cardiac and neuronal function, and the cause of death in such cases at a core temperature of less than 70° F is usually a malignant ventricular rhythm disturbance. Milder degrees of hypothermia may be associated with sepsis, inanition, hepatic or renal failure, electrolyte depletion, drug interaction, or hypoglycemia. Gentle rewarming of frostbitten tissue proceeds *pari passu* (at the same time) with systemic rewarming. Controversy exists as to the best method of body rewarming in cases of severe hypothermia. We feel it best to simultaneously use both external (radiant heating) and central (e.g., breathing warmed humidified gases) rewarming techniques.

- Exposure/immersion
- Hypoglycemia
- Renal and hepatic failure
- Inanition
- Myxedema coma
- Sepsis

TABLE 57.5. CAUSES OF SEVERE HYPOTHERMIA (CORE TEMPERATURE <90° F)

HYPERTHERMIA

Hyperthermia is generally a much more aggressive and destructive disease process than hypothermia. The diagnosis of heatstroke or of another type of critical heat illness should be made when a patient presents with a temperature greater than 104° F and an acute change in mental status. In these situations, time is of the essence and active cooling should be started immediately. The causes of life-threatening hyperthermia are listed in [Table 57.6](#). Active cooling can be achieved by immersion in cold water baths or by evaporative cooling, depending on the ambient humidity and the extent of heat storage and organ damage.

- Heatstroke
- Neuroleptic, malignant syndrome
- Malignant catatonia
- Serotonergic crises
- Hypothalamic dysfunction
- Malignant hyperthermia (due to anesthetics and muscle relaxants)
- Adrenergic intoxication (cocaine, hallucinogens)
- Status epilepticus
- Thyroid storm
- Anticholinergic toxidrome

TABLE 57.6. LIFE-THREATENING HYPERTHERMIA (TEMPERATURE >104° F)

MENTAL STATE

The mental status is the ultimate vital sign because the central nervous system is the most sensitive indicator of the integration of all the physiologic processes of the patient. If the mental status is normal, the other vital signs are unlikely to be significantly abnormal. A number of different indexes and scales are useful in documenting the patient's mental state. These include the Glasgow Coma Scale, which is most useful in head-injured patients ([Table 57.7](#)). The Mini-Mental Status Examination is also very helpful in documenting cognitive deficits in patients with dementia ([Table 57.8](#)). For the initial evaluation, we are concerned with the patient's position on the continuum from alertness to deep coma. An alert patient is awake and verbal and responds appropriately to questions regarding his or her orientation (person, place, and time). If the patient does not respond to verbal stimulation and appears to be asleep, he or she may be lethargic, stuporous, or comatose.

TABLE 57.7. GLASGOW COMA SCALE

TABLE 57.8. MINI-MENTAL STATE EXAMINATION

To differentiate these states, it is necessary to apply a noxious stimulus. This can be achieved by stimulating the extremities with a blunted pin or needle or with a sternal rub. A patient who awakens and is then alert is said to be *lethargic*. A patient who awakens with maximal stimulation and is then cognitively impaired (disoriented and unable to respond appropriately to simple questions) is said to be *stuporous*. Stupor is a very dynamic state, since very few patients remain stuporous for long. Either they awaken or they progress to coma. A number of indexes reflect the depth of coma. Suffice it to say that coma can be either light, in which a patient responds to noxious stimuli, or deep, in which the patient does not respond to stimulation. In the latter situation, the patient has spontaneous

cardiopulmonary activity, although with abnormal vital signs, and is functioning on a subcortical or brain-stem level.

COMA

It is important to always be careful to rule out the “locked-in” patient when making the diagnosis of coma. Such patients have either a pontine or lower mid-brain lesion that interrupts the corticospinal and corticobulbar tract. They retain third cranial nerve function but have no voluntary motor function below this level. These patients can blink their answers and have full comprehension of what is being said unless they also have another defect at the cortical level. Another group of locked-in patients consists of those with very severe and pervasive neuromuscular diseases, such as botulism, myasthenia gravis, periodic paralysis, and amyotrophic lateral sclerosis. This group usually has some residual motor function. Diagnostic signs or laboratory findings help to make the differential diagnosis.

The final group of patients that may present with coma are those who feign coma or feign seizures and postictal states. These patients often have residual motor tone and demonstrate normal optokinetic nystagmus, indicating that they are awake and are tracking the revolving drum. They also demonstrate normal corneal and blink reflexes. If a definitive answer cannot be obtained, ice water irrigation of their external canals is very useful in confirming the presence of true coma. In the awake patient, ice water causes nystagmus with the rapid component away from the irrigated ear. In true coma with intact brain-stem reflexes, patients respond with tonic deviation of their eyes to the side of the cold water irrigation.

In patients presenting with coma or other acute changes in neurologic functioning, one must exclude either an acute structural lesion, such as a subarachnoid hemorrhage or acute epidural hematoma, or a medical (metabolic or infectious) cause of coma. The central nervous system functioning at 98.6° F has an absolute minute-to-minute requirement for oxygen and glucose. The intervals of hypoxia or hypoglycemia that can be tolerated by the central nervous system without permanent neuronal loss is referred to as the warm ischemia and warm hypoglycemia times, respectively. The warm ischemia time is thought to be 4 to 6 minutes of total absence of perfusion or oxygenation. The warm hypoglycemia time is less readily established and depends on the rate of decline of the blood glucose and the preexisting glucose level. Thus, diabetics who consistently have high blood glucose concentrations may have signs or symptoms of hypoglycemia at a blood glucose level of 80 to 90 mg per deciliter, whereas a previously euglycemic patient may not be symptomatic until a level below 50 mg per deciliter is reached.

These factors have led to the use of the so-called “coma cocktail” in approaching the comatose patient. After a rapid assessment of baseline functioning, including the patient's ventilatory and respiratory status, either an accurate bedside glucose is obtained, or a blood glucose is sent to the laboratory and 50 mL of 50% glucose is given intravenously. When a glucose bolus is given, 100 mg of thiamine are also administered to prevent thiamine-deficient patients from developing acute Wernicke's encephalopathy (confusion, ophthalmoplegia, coma). It is far preferable to measure the blood glucose at the bedside than to give a hypertonic bolus of glucose blindly, because the hypertonic bolus can raise the serum potassium to dangerous levels if the patient is already hyperkalemic and hypertonic. In addition, a few patients with cerebral edema may transiently improve owing to the osmotic effect of hypertonic glucose, leading to the wrong diagnostic conclusions.

In most situations, the coma cocktail includes intravenous naloxone to reverse opioid intoxication. The only complication of administering the latter drug is its potential to cause acute narcotic withdrawal in patients who are addicted to narcotics or on methadone maintenance. These patients can be treated using sedation or can be given small incremental doses of morphine, if necessary. There have been a few case reports of false-positive responses to naloxone in patients depressed by sedative hypnotic drugs, but these are few and far between. Because naloxone competes with endogenous opioids for the opioid receptor, the occasional response may be related to this mechanism and not to drug antagonism. At this writing, there appears to be little benefit for the routine use of the benzodiazepine antagonist flumazenil in the coma cocktail. It is most helpful in patients in whom the benzodiazepine effect requires reversal after a procedure has been carried out under conscious sedation with a short-acting benzodiazepine.

OTHER CHANGES

There are two key issues relating to emergencies involving changes in the mental state that are not covered in the definitions given above. These areas are the delirious patient and the patient entering with suicidal or homicidal ideation.

Delirium

Delirium is a condition that can be obvious even to the uninitiated, as in the manifestations of alcohol withdrawal syndrome or delirium tremens. On the other hand, patients with so-called quiet delirium can present with changes in their personality such as paranoid ideation, forgetfulness, or inattention to social and personal relationships. It is useful to think of this state as a reversible, perhaps humoral, alteration of neuronal functioning that is superimposed on the premorbid personality. Delirium is common in intensive care units, especially in patients who already have an underlying dementia.

The management of delirium relates to its secondary nature; that is, the amelioration of the underlying conditions or stressors will lead to reversal of this state. In the interim, consistency of the environment and caregivers and repetition of reassurances and orienting information are very helpful. Because sedation interferes with memory and thus orientation, use of sedative-hypnotic agents in delirious patients is potentially harmful. The exception to this general rule is the patient with an agitated delirium due to the withdrawal of sedative-hypnotic drugs, such as alcohol or benzodiazepines, in whom administration of benzodiazepines are essential.

Suicidal Ideation

Determination of the presence of suicidal or homicidal thoughts or actions must be determined in every responsive patient with an altered mental status. If the patient believes it is safe to confide in the health care provider, this information is usually forthcoming when an inquiry is made. If such a situation is thought to exist, then, while obtaining psychiatric consultation, one should initiate security coverage to safeguard the patient and staff from an immediate acceleration of the thoughts into action. This one-to-one coverage also is important because it prevents the patient from leaving the protected environment of the institution until an appropriate disposition can be made. In the interim, while the psychiatric situation is in flux the practitioner can help defuse the acute situation by supportive measures. The VVV system, validate, ventilate, venture hope of recovery, can be extremely helpful in this context. The provider allows the patient to ventilate his or her thoughts and feelings and then validates the reality of the patient's problems and ventures his or her impression that the problems and situations that precipitated the crisis are amenable to intervention.

The most significant initial problem in these cases is engaging the patient and developing a trusting relationship with him or her. This process is facilitated by using the help system. The provider continuously states that the patient needs help, that help is being provided, and that more help is on the way. By the physician using the word help again and again, the patient, who in reality is frightened and looking for help, will begin to respond positively to the intervention. When all else fails and the patient is displaying accelerating agitation and paranoia, a show of force is necessary. In this procedure, a team approach is used to place the patient into four-point restraints. This team consists of a leader and at least five other persons who can immobilize the patient if he or she does not agree to go into restraints willingly. The time that a patient stays in restraints should be monitored and reassessed frequently because the patient can develop pressure necrosis from the devices used and he or she may aspirate vomitus in the immobilized supine position. Thus, as soon as the patient is secured, a course of chemical restraints is initiated using intravenous short-acting neuroleptic agents, such as haloperidol, and sedation with a short- or intermediate-acting benzodiazepine, such as lorazepam.

PRESENTING COMPLAINT—FOCUSED CARE

There are approximately 30 different presenting complaints or diagnostic categories that encompass almost the entire universe of adult patients seeking care in emergency departments (Fig. 57.3). About 50% of these categories have a high potential for life-threatening disease processes. To arrive at a reasonable number of functional approaches to these subpopulations, we have condensed some major categories and expanded others. Thus, all major trauma patients are grouped together. Our thesis is that understanding the diagnostic entities in each group that are the most critical and prognostically significant allows one to develop a hierarchical approach that is conservative in its use of resources. This approach is also safe in that it will prevent an untoward patient outcome from a missed diagnosis and management opportunity. In the following text, we outline the approach to a number of presenting problems chosen for their high frequency in emergency departments and their responses to appropriate active interventions.

FIGURE 57.3. Presenting complaints or diagnostic categories that encompass almost all adult patients seeking care in emergency departments.

SHORTNESS OF BREATH

The chief complaint of shortness of breath is a common problem and a rather broad diagnostic category, which includes the following potentially life-threatening entities: left ventricular failure; noncardiogenic pulmonary edema; obstructive, restrictive, and neuromuscular diseases of the lung; pneumothorax; pulmonary embolism; metabolic acidosis; salicylate intoxication and severe anemia. Primary hyperventilation syndrome, a psychological entity caused by anxiety or stress, should be seriously considered as the major diagnosis when there is little or no evidence for the presence of the disease categories noted above. However, caution should be taken because hyperventilation may mask the signs and symptoms of the serious underlying condition. The use of bedside pulmonary function testing, arterial blood gas analysis, chest radiography, ECG, and routine complete blood cell count (CBC), blood glucose, and electrolyte testing will narrow the field in most cases to one or two entities, which can usually be isolated on further specific testing.

CHEST DISCOMFORT

A chief complaint of chest pain is almost universally a signal to begin an immediate evaluation of the patient for an acute myocardial infarction or an unstable coronary ischemic syndrome (Chapter 65). In addition, the other disease entities that one must consider in this category are dissecting aneurysm of the aorta, leaking atherosclerotic aortic aneurysm, critical aortic stenosis, pericarditis, acute cor pulmonale, and esophageal rupture. The patient can be evaluated for the relatively benign entities, such as musculoskeletal chest pain and gastroesophageal reflux or spasm, after these other entities are found to be very unlikely. Patients with chest pain can be differentiated by the characteristics of their pain, by the results of the cardiopulmonary examinations, and by the use of the ECG and chest film. After these patients with chest pain have had their initial evaluations, they can be subdivided into three groups or risk categories. These correlate roughly with the pain syndromes of noncardiac pain, atypical chest pain, and ischemic cardiac pain.

- Noncardiac chest pain consists of a pain pattern and supporting data that make diagnosis of an ischemic syndrome unlikely. Noncardiac pain usually begins abruptly or is related to position or breathing. These patients have normal ECGs.
- Atypical chest pain syndromes are present in patients who present with chest discomfort and patterns of discomfort that have features of both ischemic and nonischemic chest pain. The ECGs in this category are either normal or display minor ST segment and I wave abnormalities.
- Cardiac chest pain is actually not strictly a painful sensation as in somatic pain, but it is described as substernal pressure, fullness, or constriction. This is why esophageal disease and myocardial ischemia are so difficult to differentiate; both are visceral stimuli using the same or overlapping autonomic sensory pathways.

In the current medicolegal, professional, and managed care environment, it is crucial for patients with undiagnosed chest discomfort to have their atypical chest pain evaluated acutely over the short term for the presence of cardiac ischemia. Based on a one-time evaluation, approximately 3% of patients with acute cardiac ischemia are missed and discharged from an emergency department. This group of patients has a much higher probability of cardiac arrest than that of similar patients admitted to a hospital. This has led to the concept of chest pain evaluation centers within or in collaboration with emergency departments. In such programs, when all preliminary tests, cardiac enzymes, and serial ECGs are negative over a period of 12 hours or so, these patients can undergo some form of cardiac stress testing. Those patients whose tests show evidence of ischemia or infarction are transferred to the appropriate inpatient locus. Patients who successfully pass these protocols have less than a 1% chance of having active cardiac ischemic disease as the cause of their chest pain.

It is important at this point to touch upon the issue of “silent ischemia,” since we tend to become fixated on patients presenting with ischemic chest discomfort while overlooking patients with silent ischemic or variant angina. Silent ischemia is said to be present at some time in over 80% of patients with intermittent or overt ischemia. The lack of chest discomfort occurs either because of a high central pain perception threshold, a small area of myocardium at risk, or some abnormality of the autonomic nerves. Whether the ischemia is truly silent is open to some discussion, because these patients can present with poorly differentiated complaints. These complaints include unexplained fatigue, recent onset of dyspnea on exertion, palpitations, and light-headedness. The undifferentiated nature of these complaints creates significant delays in the recognition of the seriousness of the underlying process. Thus, in patients who have risk factors for coronary artery disease or a past history of this problem, the latter undifferentiated complaints should be evaluated in the context of possible silent ischemia.

ABDOMINAL PAIN

The approach to patients who have abdominal pain as their major complaint also follows the approach developed above in that the immediate life-threatening entities have to be specifically considered initially before the less urgent conditions are investigated. These life-threatening entities include acute myocardial infarction, leaking atherosclerotic aortic aneurysm, and mesenteric ischemia. Leaking aortic aneurysms can be very hard to palpate and can present as renal colic, sciatica, or acute scrotal swellings. In addition, several other acute surgical disease processes require immediate recognition and surgical management. These include gangrenous cholecystitis, ascending cholangitis, and perforation of a hollow viscus with intra-abdominal sepsis (e.g., peptic ulcer, sigmoid diverticulitis, appendicitis). Strangulated closed-loop obstructions, including sigmoid and cecal volvulus and strangulated hernias, are also potentially life-threatening. In women of child-bearing age, the abdominal pain evaluation should include evaluations for possible ectopic pregnancy, ovarian torsion, and extensive pelvic inflammatory disease.

Early surgical consultation and rapid access to an operating room should be the major focus in management for most of these conditions. Fluid resuscitation, treatment for sepsis, and pain control are, of course, key supportive measures. Abdominal computed tomography (CT) imaging with oral and intravenous contrast is extremely useful in delineating most of the processes just noted.

WEAKNESS AND DIZZINESS

A chief complaint of generalized weakness and dizziness usually results in an extended history, physical examination, and laboratory testing often without a resulting satisfactory diagnosis. Perhaps 10% of affected patients have an underlying chronic illness and, as a result of deconditioning or physical disability, have difficulty with their functioning. In a large percentage of these patients, an emotional or psychological illness is a potential source of their symptoms. These psychiatric conditions include anxiety and depression, panic disorder, hypochondriasis, somatization disorders, conversion reactions, and so-called neurocirculatory asthenia. Within this category is a small number of patients with an underlying acute neuromuscular disorder, who have to be differentiated from the very large “functional” and chronic disease group. The acute neuromuscular disease entities to be considered here are an acute myopathy with the possibility of rhabdomyolysis syndrome (myoglobinuria, acute renal failure, hyperkalemia, and hypocalcemia), organophosphate poisoning, Guillain–Barre(c) syndrome, myasthenia gravis, marked derangements of electrolyte balance (hypo- and hyperkalemia, hypophosphatemia, hypermagnesemia), periodic paralysis, transverse myelitis, spinal cord ischemia, botulism, tetanus, and rabies.

The differentiation here should start with the evaluation of the stability and adequacy of the patient's airway before proceeding down the differential diagnostic algorithmic approach. This can be ascertained simply by the patient's ability to answer questions and the admitting pulse oximetry values. If there is uncertainty, further evaluation is indicated, as described earlier (when intubating patients with neuromuscular diseases, muscle paralysis should not be achieved using succinylcholine, because it can lead to malignant hyperkalemia). The differentiation, then, of the entities noted in the preceding paragraph requires meticulous neurologic evaluation seeking to define the lesions that may exist within the muscle, at the myoneural junction, in the peripheral nerves at the level of the nerve

terminals or trunks, or at the level of the central nervous system. As a general rule, reflexes are lost early with neuropathic problems and very late with myopathic process. The cranial nerves are spared except in patients with myasthenia gravis, botulism, rabies, and the Miller Fisher variant of Guillain–Barre(c) syndrome. In patients presenting with muscle pain and weakness who are thought to have a myopathy, acute myositis should be differentiated from polymyalgia rheumatica (PMR). The creatine phosphokinase (PK) level should be normal in patients with PMR which is associated with a paucity of other findings on physical examination. Both entities can be associated with a high sedimentation rate. Muscle biopsy and electromyography are very helpful in diagnosis.

ACUTE ONSET OF HEADACHE

The most prognostically significant entities associated with acute onset of headache are subarachnoid hemorrhage (SAH) from ruptured berry aneurysms and AV malformations, hypertensive intracranial hemorrhage, meningitis, and hypertensive crisis. If the pain is retro-orbital, consider acute narrow-angle glaucoma, cluster migraine, and temporal arteritis. High-yield historical information leading one to suspect SAH includes sudden onset, with the peak pain appearing in less than 1 minute, association with transient loss of consciousness, occipital location of the pain, the worst headache the patient has ever experienced, meningismus, altered mental status or new neurologic deficits. Although for some patients this syndrome of “thunderclap” headache can be due to migraine, there is no definitive way to differentiate SAH from a “benign” vascular headache without a neuroimaging study. Before carrying out the study, however, one must decide whether the patient is high risk. In most instances, high-risk patients require a lumbar puncture if the imaging study is negative. If the patient has been diagnosed as *migraineur* in the past but has never had a brain imaging study, the diagnosis should be set aside until SAH is ruled out.

Another pitfall is the use of a therapeutic diagnostic test involving the use of antimigraine medications. Patients with a thunderclap headache who have all or most of their pain relieved by these medications should not then be automatically considered to have a benign vascular headache. There are now a number of SAH patients in whom sumatriptan seems to have been effective, although temporarily. Patients with increased intracranial pressure usually have the worst headache pain on arising. Later, they develop nausea and vomiting and become sleepy and cognitively impaired. At that point, there are usually focal localizing signs from the expanding intracranial mass and false localizing signs secondary to the herniation syndromes. The most commonly seen in the latter group are palsies of cranial nerves III and VI.

APPROACH TO MULTISYSTEM-TRAUMA PATIENTS

The internist rather than the surgeon may occasionally treat patients with multisystem trauma. In this circumstance, it is key to recognize the significance of the mechanism of injury as well as to be wary of subtle or hidden diagnoses. In evaluating patients with head or spine injuries, one must be cognizant of the difficulty in discovering other significant injuries of the chest and especially the abdomen. In addition, patients may have what is termed a *distracting injury*. Thus, a patient with a very painful fracture dislocation may not react to a painful injury of the abdomen. Similarly, patients who are intoxicated may have a very high pain threshold, and the extent of their injuries may be grossly underestimated.

Each area of the trunk is divided into zones, each of which has vital structures located within it. In addition, each zone has its own potential for missed injuries and may require special diagnostic studies to “clear” the zone. Thus, the anterior midline zone of the chest has a great potential for these injuries. Many patients will need an ECG and undergo CT scanning of their chest, and many will require an echocardiogram to rule out a myocardial contusion, laceration, or infarction. If the mechanism of injury is sudden acceleration or deceleration, aortic disruption (usually just distal to the left subclavian take-off) should be considered and aortic imaging performed when indicated. Injuries to the upper flank regions can involve the kidneys and great vessels in the retroperitoneum, but also can be associated with injuries to the bases of the lungs.

EMERGENCY EQUIPMENT

Emergency equipment that may be essential in emergency situations outside the hospital, such as in the office setting, is listed in [Table 57.9](#). The use of an automated external defibrillator (AED) is probably the most potentially life-saving piece of equipment. The primary concentration is care within the first 5 minutes because most jurisdictions have prehospital personnel available after that time frame.

1. Cell phone
2. Automatic external defibrillator (probably the most useful piece of equipment)
3. Bag valve mask or valve airway mask device
4. Oral airways
5. Gloves (6 pairs)
6. Sterile saline in bags or pour bottle (4 units)
7. Epinephrine 1/1000 single-dose prefilled syringe for subcutaneous use
8. 50 mL 50% glucose (2 doses) in prefilled syringe
9. Lorazepam 1 mg in prefilled syringes (5–7 doses)
10. IV tubing and cannula
11. 2 blankets
12. Assorted bandages and tape
13. Blood pressure cuff
14. Cold packs
15. Flashlights or lanterns (3 units)
16. Road flares

CHAPTER 58: ANIMAL BITES AND STINGS

FAITH T. FITZGERALD

[Insects and Spiders](#)
[Reptiles](#)
[Marine Animals](#)
[Mammals](#)

As travel, pet keeping, and out-of-doors activity increase, so does the risk of animal bites and stings. Injury can result from direct trauma, superinfection, allergy (by far the most morbid), and injected or applied toxins.

INSECTS AND SPIDERS

Although death is rare and due principally to Hymenoptera allergy, the morbidity of arthropod bites in the United States is considerable. Several species infest or attack humans. Nonvenomous but annoying and potentially dangerous arthropods are outlined in [Table 58.1](#).

Species	Clinical Features	Diagnosis	Treatment
Fleas	Pruritic bites, erythematous papules, excoriations, allergic dermatitis	History, physical examination, identification of flea	Topical insecticides, oral antiparasitics, symptomatic treatment
Lice	Pruritic bites, erythematous papules, excoriations	History, physical examination, identification of louse	Topical insecticides, oral antiparasitics, symptomatic treatment
Ticks	Local reactions, neurotoxic ascending paralysis, rickettsial, viral, bacterial, spirochetal, and protozoal diseases	History, physical examination, identification of tick	Removal of tick, symptomatic treatment, antibiotics for bacterial diseases
Spiders	Local reactions, neurotoxic ascending paralysis, rickettsial, viral, bacterial, spirochetal, and protozoal diseases	History, physical examination, identification of spider	Removal of spider, symptomatic treatment, antivenom for severe cases

TABLE 58.1. NONVENOMOUS ARTHROPODS

Stings of *wasps and bees*, which are members of the order Hymenoptera, can be life-threatening to hypersensitive patients (see [Chapter 173](#)). Although the venom of Africanized honeybees is no more allergenic or toxic than that of European honeybees, the Africanized bees are more aggressive and multiple stings can lead to death. Local therapy in nonallergic individuals consists of removing the stingers and applying ice. With multiple stings, toxic systemic reactions include faintness, headache, fever, muscle spasms, and gastrointestinal upset. *Fire ants*, *Solenopsis invicta* and *S. richteri*, are nonwinged hymenopterans that are endemic in the southeastern United States, where the often multiple bites create painful, burning papules, vesicles, and pustules with potential for necrosis and scarring. Toxic systemic effects include nausea, vomiting, dizziness, and blurred vision. Allergic reactions may also occur.

Hard and soft *ticks* are noted mainly for their carriage of rickettsial, viral, bacterial, spirochetal, and protozoal diseases. Uninfected bites can cause local dermal reactions and, rarely, a neurotoxic ascending paralysis. Embedded mouth parts can stimulate a granuloma. Ticks should be removed by the application of petrolatum and careful use of blunt forceps. Surgical excision occasionally is required. *Blister beetles* do not bite or sting, but rough contact with their carapace, which contains the vesicant cantharidin, can give painful blisters, which are treated as chemical burns. Several species of caterpillars, including the *saddleback*, *buck moth*, and *pus caterpillar* of the southern United States, have hairs that penetrate skin and inject venom, causing intense local pain, urticaria, and, rarely, shock. Removal of hairs can be done with cellophane tape or tweezers; antihistamines, corticosteroids, analgesics, and intravenous calcium gluconate help pain and urticaria. The *gypsy moth caterpillar* in the northeastern United States causes an erythematous papular dermatitis.

Of *centipedes*, only the bite of the giant *Scolopendra heros* of the southwestern United States is life threatening, principally to children. It injects hemolytic and cardiotoxic venom, causing local necrosis, severe systemic symptoms, and even rhabdomyolytic renal failure. Treatment is supportive.

Many *spiders* bite, but there are only two major venomous species in the United States: the black widow, *Latrodectus mactans*, and the brown spiders, *Loxosceles*. The female black widow haunts privies, houses, garages, and woodpiles across the United States. It is about 6 mm in diameter and shiny black, with variable red ventral markings sometimes (not always) in an hourglass shape. It is aggressive. About 10% of black widow bites result in envenomation from a neurotoxin, causing an outpouring of various neurotransmitters that produce lactrodectism. A sharp local pain signals the bite. Within a half hour, there is local redness and swelling or a pallid area with a red–blue border. Systemic effects may follow and include muscular rigidity and fibrillations, abdominal pain of such severity as to be misdiagnosed as peritonitis, nausea, vomiting, hypersalivation, swings in blood pressure and pulse, ischemic electrocardiographic changes, cardiac dysrhythmias, hemolysis, rhabdomyolysis, renal failure, hyperglycemia, neutrophilia, coma, and, rarely, death. Muscle relaxants and narcotics treat pain and muscle spasm. An effective antivenin (Lyovac) is a horse serum product, likely to produce hypersensitivity reactions, and is used in severe cases (see [Chapter 138](#)).

Loxosceles species, the brown spiders (fiddlebacks), are small, nocturnal, shy creatures with a dark, violin-shaped mark on their backs. They live in homes and clothing, and bite when disturbed. They inject a venom containing necrotizing, hemolytic, and spreading factors. A sudden mild pain at the bite may produce only erythema, induration pain, and pruritus at the site or be followed within hours to days by a characteristic violaceous erythema and necrosis extending to the underlying muscle. Fever, chills, arthralgia, morbilliform rash, malaise, coagulopathy, jaundice, hematuria, renal failure, and, rarely, death may all complicate severe envenomation 24 to 48 hours after the bite. Supportive treatment with splinting and support of the affected part, analgesics, tetanus toxoid, antibiotics for superinfection, and occasional surgical debridement is required. The use of the sulfa drug dapsone, 50 mg orally twice daily for 2 days (increased to 100 mg orally twice daily thereafter if necrosis is progressing), is controversial as benefit is unclear and dapsone can cause agranulocytosis and methemoglobinemia. Intermittent cold packs applied to the site for the first 48 hours also may help.

The two most dangerous species of *scorpions* in the southwestern United States are *Centruroides sculpturatus* and *C. gertschi*. Their venom, delivered by sting from a tail sac, is potent but seldom lethal. Local reactions to many scorpion stings can be severe, but the most venomous southwestern scorpions usually produce little local response. Neurotoxin injection leads within hours to perinasal and oral itching; nystagmus, trismus, numbness, dizziness, agitation, confusion, convulsions; circulatory, renal, and respiratory failure; hemolysis; and death. Therapy is with local ice packs and support. In severe reactions, in very young children, which can be lethal, specific antivenin may be used.

REPTILES

Of *snake bites* in the United States, fewer than 25% are poisonous, and death is rare. Most venomous bites in the United States are caused by rattlesnakes, copperheads, and cottonmouths (all Crotalidae, or pit vipers) or by the coral snake (Elapidae). A few snake bites are by imported exotic species. Confronted by a snake bite victim, the physician must determine the species of snake, which is best done if the reptile is brought in (dead, in a closed container) with the patient. A snake with catlike pupils, a triangular head, and pits between the nostrils and eyes is a pit viper. The coral snake has black bands abutting yellow (“black on yellow, kill a fellow”), and the harmless look-alike snake has red bands adjacent to black (“red on black, venom lack”). Even if the snake is poisonous, not all bites contain venom, and of those that do, the fate of the patient may depend on the size of the snake, the size of the bite, the interval between the bite and the onset of local or systemic signs and symptoms, the field therapy that was given, and the age, size, and general condition of the victim.

Field therapy for snake bite is controversial, but it probably is best to do no more than immobilize the body part, calm the victim, and transport him or her to the

hospital as soon as possible. Tourniquets, pressure bands, incision and suction, snake venom extractors, electric shock therapy, and the application of heat or cold to the bite are of no proven benefit and might be harmful. Ingestion of alcohol should absolutely be avoided. Definitive therapy in the hospital depends on the type and severity of envenomation. A severity score for crotalid snake bites has been developed and is useful in predicting the course of events and need for antivenin.

Local effects of pit viper bites include pain, erythema, ecchymosis, local bleeding, and necrosis. Systemic venom produces perioral tingling, a metallic taste, muscle fasciculation, hypotension, disseminated intravascular coagulation, respiratory distress, and renal failure. Large-bore intravenous access should be established and initial blood samples drawn for a complete blood cell count, coagulation studies, renal function tests, and blood for type and cross match. Physical examination should be repeated frequently and laboratory studies repeated after 4 hours in the asymptomatic patient. Electrocardiograms should be obtained on the severely ill and all patients older than 40 years of age. In patients with major systemic symptoms or laboratory derangements, antivenin therapy is given. Because antivenin is horse serum, the patient first should be skin-tested for immediate hypersensitivity. Ten to twenty vials of antivenin, depending on the patient's degree of envenomation, is given intravenously in 500 mg of 5% dextrose and water or normal saline over 1 to 2 hours. Then, based on signs and symptoms, more is given as needed. Local wound care may include debridement, broad-spectrum antibiotics, and tetanus prophylaxis. Should fear of compartment syndrome arise, compartment monitoring and expert surgical consultation are mandated, with fasciotomy only if the pressure is increasing measurably. Extensive debridement is no longer recommended. Serum sickness occurs about 10 days after the receipt of 5 or more vials of antivenin in almost all patients.

Coral snake venom is neurotoxic, and the onset of any neurologic symptoms in a patient with multiple punctures or scratches in the bite (the snake injects venom by chewing) requires specific antivenin (after skin testing), with 3 to 5 vials given intravenously. This may be repeated if symptoms progress. The patient should be observed for at least 48 hours, even in the absence of symptoms, because the onset of toxin effects may be delayed.

Nonvenomous snakes can transmit anaerobic and enteric bacteria, and their bite wounds require careful cleaning and cultures. Antibiotics may be needed if the bites are infected, although rates of infection are low and prophylaxis with antibiotics is not necessary. Tetanus immunization or booster should be considered.

Gila monsters (*Heloderma* species) are the only venomous lizards in the United States and are found in the Southwest. Bites are rare, but the lizard is bulldog-like in the tenacity of its grip. In 70% of bites, a serotonin-containing toxin is injected, causing local edema, tenderness, lymphangitis, and lymphadenitis. Occasionally, the victim experiences weakness, faintness, dizziness, sweating, nausea, vomiting, shock, or coagulopathy. Treatment is supportive.

Information and consultation on venomous bites may be obtained by calling the Antivenom Index in Tucson, Arizona (602-626-6016).

MARINE ANIMALS

The number of sports divers and snorkelers is increasing, and injuries caused by reef and beach creatures are correspondingly more common. Marine injuries and envenomation caused by simple contact are outlined in [Table 58.2](#).

Species	Clinical Picture	Therapy
Coral	Cuts, abrasions, irritability, edema, pain, severe itching, severe allergic response in skin, secondary infection	Irrigation, use of water, tetanus prophylaxis, topical antibiotics or corticosteroid ointments, antibiotics, analgesics for itching, elevation
Sponges	Spine pain, dermatitis, itching, pain, severe pain, red, raised, urticarial, vesicular, pustular, or necrotic lesions, lymphangitis, lymphadenitis, gangrene	Remove sponges, antibiotics for infection and inflammation
Sea urchins	Spine pierce, irritability, pain, severe pain, red, raised, urticarial, vesicular, pustular, or necrotic lesions, lymphangitis, lymphadenitis, gangrene	Remove spines, antibiotics for infection and inflammation
Coral skull	Redness, pain, severe pain, red, raised, urticarial, vesicular, pustular, or necrotic lesions, lymphangitis, lymphadenitis, gangrene	Tetanus prophylaxis
Starfish	Redness, pain, severe pain, red, raised, urticarial, vesicular, pustular, or necrotic lesions, lymphangitis, lymphadenitis, gangrene	Tetanus prophylaxis
Alcornoque plant (brown of beach)	Redness, pain, severe pain, red, raised, urticarial, vesicular, pustular, or necrotic lesions, lymphangitis, lymphadenitis, gangrene	Remove berries, use of water, tetanus prophylaxis, antibiotics for infection and inflammation
Water tortoise	Redness, pain, severe pain, red, raised, urticarial, vesicular, pustular, or necrotic lesions, lymphangitis, lymphadenitis, gangrene	Remove tortoise, use of water, tetanus prophylaxis, antibiotics for infection and inflammation
Sea urchin	Redness, pain, severe pain, red, raised, urticarial, vesicular, pustular, or necrotic lesions, lymphangitis, lymphadenitis, gangrene	Remove spines, use of water, tetanus prophylaxis, antibiotics for infection and inflammation
Sea slug (sea slug)	Redness, pain, severe pain, red, raised, urticarial, vesicular, pustular, or necrotic lesions, lymphangitis, lymphadenitis, gangrene	Remove slug, use of water, tetanus prophylaxis, antibiotics for infection and inflammation
Sea slug (sea slug)	Redness, pain, severe pain, red, raised, urticarial, vesicular, pustular, or necrotic lesions, lymphangitis, lymphadenitis, gangrene	Remove slug, use of water, tetanus prophylaxis, antibiotics for infection and inflammation

TABLE 58.2. MARINE CONTACT ENVENOMATIONS

Many species of *fish* and *rays* carry toxic barbs on their tails (e.g., stingray) or fins (e.g., catfish, lionfish, scorpionfish, weaverfish, stonefish, toadfish, ratfish, rabbitfish, leatherback, some sharks). Injury is by deposition of the barb and venom, or the venom alone, leading to local injury or destruction of neural or cardiac tissue, which can be lethal. The local site should be cleaned and soaked in warm [115°F to 120°F (46°C to 48°C)] water for 30 to 60 minutes to inactivate protein toxins. Support and surgical removal of the barb might be required. Antivenins are available for some species. Superinfection with *Vibrio* or *Aeromonas* species can occur.

A bite from the horny beak of the blue-ringed *octopus* of the Pacific, from Australia to Japan, releases a mix of tetrodotoxin, histamine, serotonin, and other poisons into the wound, causing numbness, paralysis, hypotension, and respiratory failure. Another dangerous species, found in the Caribbean, is *Octopus joubini*. Because venomous octopi are small, no octopi less than 6 in. in length should be handled without protective gloves. There is no antivenin.

Numerous species of venomous *sea snakes* live in Indo-Pacific waters. Bites, although rarely lethal, can cause death by rhabdomyolysis and hyperkalemia. Antivenin is available for those associated with extreme toxicity.

MAMMALS

The most common mammal bites are those of dogs, cats, humans, and rats. When *dogs* bite, infection rates reportedly range from 3% to 18%. Cultures may show polymicrobial aerobic and anaerobic organisms, including *Pasteurella canis*, *P. multocida*, *Staphylococcus*, *Streptococcus*, *Corynebacterium*, and *Capnocytophaga canimorsus* (which in sepsis mimics a Shwartzman reaction), as well as many other. Tetanus, rabies, and mycobacterial disease rarely are transmitted by dog bite in the United States. *Cat* bites become infected 28% to 80% of the time. *Pasteurella multocida* is the major pathogen; it may cause local injury, such as cellulitis, osteomyelitis, septic arthritis, or tenosynovitis, or it may lead to systemic disease with bacteremia, especially in patients with liver disease. Other pathogens include *Erysipelothrix*, *Streptococcus*, *Staphylococcus*, *Moraxella*, and many others. Cat scratches also can carry *P. multocida*, and both bites and scratches can lead to cat-scratch fever (see [Chapter 292](#)). *Human* bites typically occur on the knuckles during fistfights, and the potential for both direct injury and infection is high. Organisms implicated in human bite infections include *Streptococcus*, *Staphylococcus*, *Corynebacterium*, *Bacteroides*, and *Eikenella corrodens*. Anaerobes are common. Syphilis, hepatitis B, and, rarely, rabies have been reported from human bites, but no cases of the acquired immunodeficiency syndrome have been reported. *Rat* bites can transmit rat-bite fever and hemorrhagic fever caused by Hantaan virus.

In evaluating bites, initial steps are careful examination for bone or tendon injury, performance of aerobic and anaerobic cultures, meticulous wound irrigation with 1% povidone-iodine (Betadine), and categorization as low or high risk for the development of infection ([Table 58.3](#)). In low-risk wounds, antibiotics are unnecessary and suturing may be appropriate. High-risk wounds should be treated with antibiotics but not sutured. Empirical antibiotic therapy for bites should be directed against *pasteurellae*, *streptococci*, *staphylococci*, and anaerobes. A b-lactam antibiotic with b-lactamase inhibitor, and a second-generation cephalosporin with anaerobic activity, or penicillin plus first-generation cephalosporin, or clindamycin and fluoroquinolone, are recommended. In suspected rabies exposure, therapy includes rabies vaccine (1 mL in the deltoid on days 0, 3, 7, 14, and 28) combined with 20 IU rabies immunoglobulin per kilogram of body weight. As much as possible of the immunoglobulin should be infiltrated at the wound site and the residual given intramuscularly at a site distant from the wound. Bite victims should be considered for tetanus and hepatitis B prophylaxis, as well as rabies prophylaxis (see [Chapter 318](#)).

High Risk	Low Risk
Punctures	Lacerations
Hand and foot wounds	Extremities
Treatment delay over 12 hr	Torso
Immunocompromised host	Face
Human bites

CHAPTER 59: NEAR DROWNING

LEONARD D. HUDSON AND KENNETH P. STEINBERG

[Pathophysiology](#)
[Clinical Features](#)
[Treatment](#)
[Survival and Prognosis](#)

Drowning accidents account for an estimated 7,000 to 8,000 deaths in the United States annually; most victims are children and young adults. The incidence of near drowning is unknown, but it has been estimated to be as high as 90,000 cases per year. Conventionally, episodes that result in immediate death are called drowning, and those in which the patient survives, even temporarily, are called near drowning. Although the diagnosis is readily apparent from the clinical setting, there is a broad spectrum of clinical severity determined by factors such as length of submersion, water temperature, volume and type of aspirated liquid, and associated complications or injuries.

Immersion accidents are often classified according to whether they occur in freshwater or saltwater. Differences in serum electrolyte concentrations and blood volume changes between these two forms of drowning were stressed in the early literature. Subsequent experimental studies demonstrated that electrolyte and blood volume changes are usually relatively minor or are so transient as to be clinically inapparent by the time the victim has been transported to a medical facility. The clinical problems associated with drowning in saltwater and freshwater are quite similar and include pulmonary injury, cerebral hypoxia, and hypothermia.

PATHOPHYSIOLOGY

Although most drowning victims inhale a significant quantity of water into the lungs, autopsy studies indicate that little or no fluid enters the lungs in about 10% of cases. This phenomenon has been called dry drowning and is presumably caused by reflex laryngospasm, producing airway obstruction and asphyxiation. When this occurs, resuscitation at the scene of the accident usually results in a rapid return of spontaneous ventilation. Recovery is often dramatic and complete if the anoxic episode has not been prolonged.

The differential diagnosis of the cause of the immersion accident includes diving accidents with head or spinal injury, syncope, cardiac arrhythmia, myocardial infarction, seizure disorders, and scuba diving accidents such as decompression injury and systemic air embolism.

In most cases of near drowning, some degree of lung injury occurs because of the aspiration of water and foreign materials such as organic debris, sand, or vomitus. Seawater is markedly hypertonic compared with plasma and other body fluids. Aspirated saltwater causes alveolar edema by exerting an osmotic effect that draws free water into the lungs and by causing irritant damage to alveolar epithelial cells, increasing their permeability. Aspiration of freshwater is thought to cause a loss of surfactant, leading to alveolar instability, but it also causes damage to epithelial and endothelial cells, disrupting the integrity of the gas exchange barrier. In either situation, even in patients who improve rapidly with resuscitative efforts, the lung injury process may progress, leading to acute respiratory distress syndrome with widespread pulmonary edema and microatelectasis.

Tissue hypoxia related to prolonged submersion accounts for most of the other manifestations of near drowning. These include cerebral hypoxia, metabolic acidosis, depressed cardiac function, and dysrhythmias. Hypothermia, often profound, is seen frequently after near drowning and may contribute to the cardiovascular, metabolic, and central nervous system (CNS) changes.

CLINICAL FEATURES

PULMONARY CHANGES

Approximately 90% of patients admitted to the hospital after near drowning have some evidence of pulmonary aspiration. Gas exchange abnormalities and radiographic changes are extremely common and may progress after the patient reaches the emergency department. The mechanism of hypoxemia appears to be intrapulmonary venoarterial shunting due to alveolar edema and collapse. The chest radiograph often shows patchy, ill-defined infiltrates at the time of admission, with resolution or progression to more widespread involvement occurring over the next 12 to 24 hours. Lung compliance is usually reduced. Pulmonary infection is a common complication and may occur as a result of the lung injury process itself, prolonged intubation with acquisition of nosocomial pathogens, or airway obstruction due to aspirated foreign material.

METABOLIC ABNORMALITIES

Metabolic acidosis with a widened anion gap is extremely common and may persist for several hours, even when resuscitative efforts have been successful. This may reflect delayed lactic acid clearance or persistent tissue hypoxia with ongoing generation of lactic acid.

Experimental observations suggest that significant changes in blood volume or electrolyte concentrations occur only when the quantity of fluid inhaled has been great enough to severely limit survival. Except for life-threatening cardiac dysrhythmias in the period immediately after rescue, such changes are thought to be relatively unimportant determinants of disordered organ physiology after immersion injury.

Aspiration of freshwater leads acutely to hemodilution, a transient increase in blood volume, and dilution of electrolytes, primarily manifested as hyponatremia. These changes may explain the higher incidence of ventricular fibrillation in freshwater near drowning patients.

The aspiration of saltwater causes hemoconcentration, and a reduction in circulating blood volume as free water is drawn from the vasculature into the alveolar space. In those who survive the initial insult, restoration of normal blood volume and electrolyte concentrations is usually complete within 10 to 30 minutes.

Changes in the hematocrit may occur transiently owing to hemodilution or hemoconcentration. Freshwater aspiration may also be associated with mild degrees of hemolysis.

NEUROLOGIC CHANGES

Injury to the CNS is probably the most serious and least reversible clinical event after immersion injury. Cerebral anoxia occurs within minutes after submersion under water and is compounded by circulatory collapse. The resulting cerebral edema leads to further reduction in cerebral perfusion, seizures, and eventually to irreversible brain damage.

Hypoxemia, acidosis, and hypothermia may contribute to neurologic abnormalities at the time of admission. The clinician should also be alert to associated abnormalities that may have predisposed the patient to a serious immersion accident. These include intoxication with alcohol or other drugs and the possibility of CNS trauma (e.g., subdural hematoma, cervical spine fracture associated with a diving injury).

CARDIOVASCULAR ABNORMALITIES

Changes in cardiovascular function after immersion injury result from hypoxemia, acidosis, and hypothermia. The most life-threatening cardiovascular complication of near drowning is the development of ventricular fibrillation, which occurs most commonly in freshwater drowning and in episodes involving massive fluid aspiration. Ventricular fibrillation in hypothermic patients may be extremely refractory to attempts at cardioversion. In such patients, prolonged and aggressive resuscitation efforts are well justified because of the potential for complete recovery.

Bradycardia, hypotension, and myocardial depression are common in the early hours of hospitalization. In addition to ventricular and supraventricular dysrhythmias, the electrocardiogram may show ST-T-wave changes and the presence of J (or Osborn) waves in patients who are hypothermic. J waves represent prolonged depolarization of the ventricle and manifest as a prominent hump at the junction of the QRS complex and ST segment.

Aspiration of a large amount of seawater may result in hypovolemia because of a shift of intravascular fluid to the intra-alveolar space. If enough freshwater is aspirated, hypervolemia occurs initially. However, with rapid redistribution of fluid, especially as pulmonary edema develops, hypovolemia may exist by the time the patient reaches the hospital.

HYPOTHERMIA

Hypothermia is a prominent feature of immersion injury and may contribute to many of the physiologic abnormalities seen in near-drowning victims. Hypothermia occurring at the time of the near drowning may also exert a protective effect, particularly in the CNS, by slowing tissue metabolism and minimizing the effects of hypoxia. Ventricular fibrillation is much more common and difficult to treat in patients with a body temperature below 28°C (83°F). When the body temperature is in this range, active core rewarming should be initiated using intravenous solutions warmed to body temperature; warmed electrolyte solutions for gastric, bladder, and peritoneal lavage; and ventilation with warmed, humidified gases. Continuous arteriovenous rewarming or cardiopulmonary bypass should be considered for severe hypothermia. Passive rewarming measures to prevent further heat loss should be undertaken for all hypothermic patients.

TREATMENT

The initial treatment should occur at the scene of the immersion accident. The goal of therapy is to restore adequate oxygen delivery as rapidly as possible because tissue hypoxia is the major cause of morbidity and mortality. If the victim cannot be removed from the water quickly, ventilation should be initiated while the victim is still in the water. Attempts to drain water from the lungs are usually ineffective, may delay the initiation of cardiopulmonary resuscitation (CPR), and increase the risk of vomiting and aspiration of gastric contents. An abdominal thrust (Heimlich) maneuver should not be used routinely in submersion victims; it is reserved for cases in which obstruction of the airway with a foreign body is suspected or when the patient does not respond to mouth-to-mouth resuscitation.

Cardiopulmonary resuscitation should be started immediately. After the patient's vital signs have been established, supplemental oxygen should be administered if available and the trachea should be intubated if the patient is comatose and appropriate equipment and personnel are available. After vital signs have been stabilized, the victim should be transported directly to the hospital.

Immediately upon admission to the hospital, electrolytes and arterial blood gases should be checked to assess metabolic and pulmonary function. There is controversy about whether to correct blood gas values for temperature in hypothermic patients. The clinician should be aware of whether or not the laboratory has corrected blood gas values for hypothermia. Intravenous access should be established and electrolyte solutions administered, with careful attention paid to possible electrolyte abnormalities and intravascular volume state. Measures to correct hypothermia should be initiated if indicated. Management of respiratory failure should follow the guidelines for treating the acute respiratory distress syndrome discussed in [Chapter 357](#).

Although occasionally caused by the aspiration of grossly contaminated material, pulmonary infection is most commonly caused by hospital-acquired pathogens. Careful surveillance and institution of directed antibiotic therapy is most important. The use of prophylactic antibiotics is not recommended. When fever and leukocytosis are prolonged despite antibiotic therapy, the clinician should consider the possibility of bronchial obstruction due to aspirated foreign material, infection of the pleural space, or purulent sinusitis.

A variety of pharmacologic and other interventions directed at controlling cerebral edema have been used in victims of near drowning. Elevating the head of the bed, if the patient is hemodynamically stable, may alleviate cerebral swelling. It is also helpful to minimize the risk of further aspiration of gastric contents. Although controlled hyperventilation may be of some benefit in patients with elevated intracranial pressure, there are no data to support the use of corticosteroids or osmotic agents in this setting. Similarly, controlled hypothermia and barbiturate coma have not improved neurologic recovery or survival of patients who are comatose after immersion injury. Uncontrolled intracranial hypertension is associated with a uniformly poor prognosis.

SURVIVAL AND PROGNOSIS

Survival depends primarily on the success of initial resuscitative efforts and the recovery of neurologic function. Although respiratory failure can often be severe and prolonged, the prognosis for recovery of lung function is excellent in those who survive. The prognosis for neurologic recovery is influenced by age, duration of submersion, water temperature, and delays in the initiation of adequate CPR. The likelihood of survival is enhanced in children younger than 10 years. The importance of water temperature is emphasized by case reports describing submersion for as long as 40 minutes in extremely cold water with subsequent normal psychometric testing. Such cases are almost entirely limited to children. The immediacy and adequacy of initial CPR is more important than therapy, however sophisticated, after the patient has been taken to the hospital.

Prognosis for neurologic recovery can be assessed on the basis of clinical findings in the first hour of therapy. Spontaneous respiration in the period immediately after CPR is a favorable prognostic factor for neurologic recovery. In one retrospective series, all patients who exhibited spontaneous respirations at the conclusion of CPR survived without significant neurologic sequelae, and those who remained apneic died or survived with severe residual neurologic impairment. In another large series, the level of consciousness on admission to the emergency department was an important predictor. Of those who were alert and fully conscious on arrival or obtunded but arousable, 90% survived without neurologic sequelae. Of those who were comatose on arrival in the emergency department, 55% survived with normal function, 10% survived with persistent brain damage, and 34% died.

CHAPTER 60: TREATMENT OF ANAPHYLAXIS

MARC S. MCMORRIS

[Hypotension](#)
[Airway Obstruction](#)

Anaphylaxis is an immediate systemic reaction caused by immunoglobulin E (IgE)-mediated release of mediators from mast cells and basophils. An anaphylactoid reaction is a similar reaction independent of IgE. A variety of substances including drugs, foods, latex, insect stings, and other environmental factors have been associated with anaphylactic or anaphylactoid reactions.

The recognition and treatment of anaphylaxis must be instituted promptly, even if the onset appears mild, because its manifestations can progress rapidly to severe hypotension, as well as shock or acute respiratory obstruction. The differential diagnosis can be broad, including conditions such as vasovagal syncope, adverse drug reactions, seizures, myocardial infarction, arrhythmias, catastrophic asthma, epiglottitis, foreign body aspiration with airway obstruction, mastocytosis, carcinoid, and hereditary angioedema. Vasovagal syncope is generally associated with pallor, diaphoresis and bradycardia in the absence of pruritis or urticaria. Implicit in the diagnosis are risks of airway obstruction, hypotension, tachycardia, gastrointestinal symptoms, and generalized cutaneous reactions alone or in combination. Symptoms generally occur within 5 to 30 minutes of exposure. Urticaria and angioedema are the most common manifestations of anaphylaxis occurring in over 90% of patients. This is followed in frequency by respiratory symptoms, including upper airway obstruction, dyspnea, and wheezing. Gastrointestinal symptoms of nausea, vomiting, or diarrhea are generally less common. Unfortunately, cardiovascular collapse can occur in patients without other antecedent signs or symptoms. One must be aware that anaphylaxis may be biphasic with a recurrence of symptoms 4 to 8 hours after the initial reaction.

Prompt assessment of the clinical symptoms and their severity is essential for appropriate therapy, with attention to the cardiovascular and respiratory systems especially indicated. Aqueous epinephrine is the initial treatment of choice because of its rapid onset of action and favorable effects on target organs; an antiallergic action (i.e., prevents mediator release from mast cells and basophils), bronchodilatation, and a normalizing effect on vascular permeability and systemic hypotension. An H₁ receptor antagonist such as diphenhydramine (Benadryl) should be administered promptly accompanied by monitoring heart rate, cardiac rhythm, and blood pressure. Supplemental oxygen should be given as needed by nasal cannula ([Fig. 60.1](#)).

FIGURE 60.1. Treatment of anaphylaxis.

EVIDENCE LEVEL: B. References: Atkinson TP. Anaphylaxis. *clin Allergy* 1992;76:8. Bechner BS. Anaphylaxis. *N Engl J Med* 1991;324:1785.

HYPOTENSION

Anaphylactic collapse and shock is an ominous manifestation that can result in death if not reversed promptly. A profound drop in blood pressure can be the first sign of an anaphylactic reaction. If there is any evidence of hypotension during the initial evaluation, an intravenous line should be established immediately for fluid replacement, preferably with a large-bore needle or catheter. Hypovolemia primarily reflects massive extravascular loss of fluid, brought on by the increased vascular permeability in anaphylactic reactions. The resultant low filling pressures must be treated specifically with rapid infusions of fluid as the blood pressure is monitored. If repeated doses of aqueous epinephrine and volume expansion are not effective in normalizing blood pressure, other vasoactive drugs may be used. Special consideration must be given to pregnant patients or patients taking β -blocking agents. Refractory patients may respond to glucagon administration or the addition of an H₂ receptor antagonist such as cimetidine or ranitidine. Glucagon has both positive inotropic and chronotropic characteristics. The inotropic effect is not dependent on catecholamines or their receptors and is, therefore, unaffected by β blockade.

The cardiovascular effects of histamine in anaphylaxis appear to be mediated through both H₁ and H₂ receptors. Therefore, the combined use of H₁- and H₂-receptor blockers may be indicated. Patients receiving β -blocking agents should not be given cimetidine because it may impair hepatic metabolism of the β -blocking agent. Ranitidine should be used instead of cimetidine in patients receiving theophylline preparations to prevent the possibility of theophylline toxicity.

Intravenous corticosteroids, such as methylprednisolone, should be administered. A resultant increase in adrenergic responsiveness may be seen within 2 hours, although the onset of action of the anti-inflammatory effects of corticosteroids may be delayed for several hours. The delayed pharmacologic action of corticosteroids may be beneficial because protracted or biphasic anaphylactic reactions have been reported. Corticosteroids block the late-phase response of IgE-mediated reactions, which may worsen or prolong anaphylactic responses several hours after their onset. Finally, antishock trousers may be useful in severe and intractable situations dominated by hypotension.

AIRWAY OBSTRUCTION

If airway obstruction is present, the upper or lower tract may be the involved site, with each requiring specific therapy. With angioedema of the larynx, no wheezing may be audible on auscultation of the lungs, but stridor and irritative cough may be prominent. In this situation, aqueous epinephrine is indicated. Endotracheal intubation or a tracheostomy may be imperative if laryngoscopy reveals progression to significant laryngeal obstruction. Tracheal puncture with a large-bore needle may be life saving if rapidly progressive laryngeal edema does not respond to epinephrine and a tracheostomy set with proper operating room preparation is not readily available. If bronchospasm predominates, nebulized β -agonists (metaproterenol or albuterol) should be used in addition to the epinephrine. Severe bronchospasm that is unresponsive to systemic or repeated administration of aerosol adrenergic agents is an indication for aminophylline. If the patient is already receiving theophylline, a lower initial dose is indicated, preferably after the serum theophylline level has been determined. If significant bronchospasm persists, intravenous corticosteroids are indicated, especially if the patient has asthma or has received corticosteroid treatment within the past year. Although corticosteroids may not act for several hours after administration, they should be started as soon as it is determined that other treatment measures are not producing satisfactory results, and they should be delivered at 6-hour intervals. Blood gas determinations and electrocardiographic monitoring is appropriate if significant bronchospasm is present. Supplemental oxygen is indicated if significant respiratory obstruction persists. With Pa CO₂ elevation denoting respiratory failure, intubation and assistance of ventilation are necessary.

After immediate evaluation and therapy has been instituted, subsequent treatment and follow-up must be individualized to each patient. Patients with mild reactions who respond fully to antihistamine or epinephrine may be sent home when the symptoms subside. However, they should recognize that symptoms may recur several hours later (a possible late-phase response) and should return promptly for evaluation if this occurs. Patients also should have oral antihistamines and adrenergic medications to take if symptoms recur.

Patients with significant shock or airway obstruction should be admitted to the hospital for continuous, intensive treatment and observation for at least 24 hours after

stabilization, so that resurgent/biphasic anaphylactic reactions can be recognized and treated promptly. The delayed pharmacologic action of corticosteroids may be beneficial in such situations. Complications of shock (cardiac dysrhythmias, hypoxic seizure, metabolic acidosis) should be recognized and treated.

OTHER MEASURES

If the reaction is mild and characterized only by urticaria, angioedema without airway involvement, or gastrointestinal symptoms (nausea, vomiting, colicky abdominal cramping), epinephrine may not be essential or may suffice alone. These manifestations usually are not life threatening, and they respond eventually to antihistamines. Diphenhydramine, 25 to 50 mg orally or parenterally, is a commonly effective H₁-blocking antihistamine and may be administered again after 4 to 6 hours. Epinephrine also is effective in erythema and edematous tissue swelling; its vasoconstrictive action is beneficial, and its onset of action is much faster than that of oral antihistamines. If an injection or insect sting is the cause of the reaction, a venous tourniquet should be applied proximal to the site and loosened at appropriate intervals. The stinger may be removed carefully without compressing the venom sac if it is still in the skin.

The prevention of future anaphylactic episodes is an important aspect of comprehensive treatment. If possible, the cause should be determined and the patient made aware of risks and preventive strategies. Patients with medical conditions treated with b-blocking agents should be treated with an alternative medication if one is available. The allergic person should carry a card or wear a bracelet identifying the allergenic food or drug that poses a health risk and scrupulously avoid that factor. If risk factors are unknown or potentially unavoidable (e.g., stinging insects, foods), exposure reduction, carrying a preloaded epinephrine syringe, and, if feasible, specific immunotherapy are indicated. Patients known to experience reactions to radiocontrast media should be pretreated with antihistamines and corticosteroids before the required radiographic procedures are administered. Patients who experience recurrent idiopathic anaphylaxis may require high doses of daily oral corticosteroids (prednisone, 60 to 100 mg) and must have the appropriate follow-up. Oral aspirin, insulin, penicillin, and cephalosporin "desensitization" can be attempted in patients who are allergic to these medications and who specifically require them for urgent treatment indications. The IgA-deficient patients who require transfusions should receive compatible blood from donors also lacking IgA or carefully washed, cross-matched, red blood cells.

CHAPTER 61: CARDIOPULMONARY RESUSCITATION

KATHLEEN S. SCHRANK

[Adult Basic Life Support Techniques](#)
[Advanced Cardiac Life Support Guidelines](#)
[Postresuscitation Management](#)

Cardiopulmonary resuscitation (CPR) techniques seek to restore effective cardiovascular and neurologic function following cardiac arrest. These measures are primarily designed for victims of premature sudden cardiac death and are readily used in a variety of medical emergencies; however, they are not intended for reflexive application to those who have truly reached the end of their lives with other severe underlying illnesses. Although the overall death rate from cardiovascular disease has declined, sudden cardiac death still claims over 600 victims each day in the United States. The majority are due to ischemic heart disease, and about two-thirds occur outside the hospital. Until closed-chest CPR and external defibrillation techniques were introduced in the 1960s, death from cardiac arrest was considered inevitable. Since then, widespread public education (on use of CPR, cardiac warning signs, risk reduction, the use of “911”), development of advanced cardiac life support (ACLS) guidelines, and deployment of ACLS treatment to prehospital settings have impacted survival. Today about 20% of victims of primary ventricular fibrillation can survive if the elements of rapid emergency care are in place.

Cardiopulmonary resuscitation techniques include basic life support measures, advanced life support measures, and post-resuscitation stabilization. In cardiopulmonary arrests due to airway obstruction or respiratory failure, CPR alone may restore life. However, resuscitation from cardiac arrhythmias by CPR alone is rare, and the perfusion achieved with CPR declines rapidly with time. Therefore, further rapid interventions are crucial. Ventricular fibrillation (VF) is the most common arrest rhythm; immediate recognition with defibrillation is the most critical action in restoring life to the largest number of arrest victims. Additional interventions are guided by cardiac rhythm and underlying etiologic factors. The ACLS guidelines from the American Heart Association provide an organized framework for cardiac arrest management, and the clinician must consider other causes and actions when a patient fails to respond promptly to them.

ADULT BASIC LIFE SUPPORT TECHNIQUES

Basic CPR includes chest compressions and ventilation aimed at maintaining enough perfusion to the brain and heart to preserve cellular viability until effective spontaneous circulation can be restored. Performance is readily learned by health care workers and laypersons; family members of cardiac patients should be encouraged to learn. The rescuer must assess the victim for unresponsiveness; initiate a call for help (generally by telephoning “911”); assess airway, breathing, and circulation status; and begin CPR if arrest is confirmed. The airway is opened by positioning the patient with the head tilted back and chin lifted forward. If cervical spine injury is suspected, then the airway is opened by thrusting the jaw forward, with the neck remaining in a neutral position. The rescuer may then give two slow breaths, watching for chest rise to confirm air flow. If the airway is obstructed, the head and neck should be repositioned. Then a Heimlich maneuver may be done if needed, by placing the heel of the hand between the navel and xiphoid, then thrusting cephalad up to five times. Other methods to relieve obstruction include a finger sweep of the oropharynx, chest compressions, or back blows. Suctioning, laryngoscopy, or cricothyrotomy may be needed if all of the above fail.

Chest compressions are performed with the heel of the hand at a point two-finger breadths above the xiphoid, at a rate of 80 to 100 compressions per minute. Compressions are alternated with breaths (15:2 if one rescuer, 5:1 if two rescuers). The patient must be supine on a hard surface. Compression force determines aortic pressure and should be as vigorous as possible without causing rib fractures. Timing the compression to occupy half of each stroke cycle also improves flow; this tends to occur naturally at the recommended compression rate. The blood flow achieved with CPR drops rapidly with any delay in its initiation and with time. The addition of α -adrenergic drugs augments CPR flow to the heart and brain considerably. Cardiopulmonary resuscitation should be started as soon as arrest is recognized, and continued until a spontaneous pulse is restored or efforts terminated, with brief interruptions for critical interventions such as defibrillation.

The exact means by which CPR provides perfusion remains under debate. Cardiopulmonary resuscitation may directly compress the heart between the sternum and vertebrae, resulting in forward flow because passive closure of the mitral and tricuspid valves prevents backflow (the “cardiac pump” theory). Alternatively, each compression/release cycle produces dramatic changes in intrathoracic pressure, creating a gradient that pulls blood into the chest upon each release, with backflow prevented by competent venous valves; the entire thorax contributes the necessary pressure gradients (the “thoracic pump” theory). Evidence for and against each mechanism exists in various animal models and in humans. In reality, both probably contribute in human CPR, with the thoracic pump mechanism predominating. Trials of alternative methods of CPR based on the latter theory have produced mixed results, with better perfusion but no overall improved survival thus far. Open-chest CPR produces markedly better flow but is not a practical option. Immediate assisted circulation via cardiopulmonary bypass pump is under active investigation.

ADVANCED CARDIAC LIFE SUPPORT GUIDELINES

GENERAL PRINCIPLES

Restarting the heart is the essential first step toward restoration of normal cardiovascular and neurologic function. Cardiac rhythm must be determined initially and again after each intervention or status change, with management shifted accordingly. The patient should be reassessed for the presence of a palpable pulse every few minutes and whenever the rhythm changes. The three major treatment algorithms (ventricular fibrillation, asystole, and pulseless electrical activity) are based on underlying rhythm; each is discussed below. Immediate identification of VF with defibrillation is the highest priority. Common management components include CPR, oxygenation, ventilation, intravenous access, acid–base management, and initial drug therapy with epinephrine.

Optimal ventilation and oxygenation is achieved by early endotracheal intubation with high-flow oxygen. Correct tube placement is critical, and confirmation includes the use of both clinical assessment and bedside devices (end-tidal CO_2 monitors, oximetry, or residual air detection devices). Repeated assessments provide early detection of tube displacement and of pneumothoraces that may occur as a result of the blunt chest trauma of CPR, of procedures, or of positive-pressure ventilation. Vomiting with aspiration frequently complicates emergency intubation; cricoid pressure during intubation plus vigorous suctioning can minimize this risk.

Initial intravenous (IV) access may be rapidly established via the antecubital vein with a large-bore catheter. Central venous access takes more time and expertise, has greater risk, and is less appropriate initially. Drug entry into central circulation is augmented by a fluid bolus given after the drug, plus elevation of the arm. Intraosseous access (tibia, femur, sternum) is an excellent route in children, and sternal devices for adults are now available. Endotracheal administration is effective for several drugs (epinephrine, lidocaine, atropine), especially when intravenous access is delayed. Drugs are absorbed from distal bronchioles, so delivery is improved by using about 10 ml total fluid volume given through a small catheter threaded down the endotracheal tube. Given by any of these routes, drugs will need 1 to 2 minutes to circulate and begin to act.

Most arrest victims have both metabolic and respiratory acidoses. Hyperventilation provides rapid correction of lethal acidoses and is the primary acid–base intervention. Lowering the CO_2 tension appears to be more beneficial to cellular function than pH correction with base. Excess sodium bicarbonate may produce hyponatremia, hyperosmolality, hypokalemia, or severe alkalosis, so that its use is best guided by arterial blood gas results; if not readily available, then 1 to 2 mEq per kg may be given empirically if the patient does not respond to initial ACLS measures plus hyperventilation. Patients with hyperkalemia and those likely to have had severe metabolic acidosis prior to arrest (drowning, seizures, shock) are most likely to benefit from bicarbonate use combined with hyperventilation.

The initial drug used in arrest management today is epinephrine. It significantly augments central perfusion during arrest via α -adrenergic actions, which constrict only peripheral vessels. The optimal dosage remains controversial, but at least 1 mg is appropriate every 3 to 5 minutes while pulseless. Anecdotal successes with high doses (0.1 to 0.2 mg per kg per dose) have not translated into improved long-range survival in controlled trials, though research is ongoing.

During cardiac arrest care, the rescuer must also look for reversible underlying disorders and situations that merit specific interventions ([Table 61.1](#)). Hypovolemia, hypoglycemia, potassium imbalance, or pneumothorax may need prompt correction. Some poisonings have specific antagonists that could be essential. Also, if the patient does not respond to ACLS interventions, everything must be rechecked: intravenous patency, breath sounds, oxygenation, rhythm.

The category of pulseless electrical activity (PEA) includes every rhythm that has a reasonable rate but no pulse. Often, the heart muscle is contracting, but without effective output. Therefore, the older term “electromechanical dissociation,” which implies absence of muscle contraction, is now used to describe a subset of PEA. Initial management of PEA (Fig. 61.3) includes CPR, endotracheal intubation, intravenous access, and epinephrine. Fluid boluses are recommended early, for correction of potential volume depletion, and pressors may be added once volume is adequate. The clinician must search rapidly for a treatable underlying cause (Table 61.2), particularly profound hypovolemia or tension pneumothorax. Massive myocardial infarction may produce PEA through total pump failure or rupture; survival from full arrest is unlikely. Massive pulmonary embolism may obstruct right heart outflow; if any pulse can be restored, the patient might survive to embolectomy or thrombolysis. Overall survival from PEA is poor because these rhythms are usually the end stage of global heart disease, sepsis, or multi-organ damage.

Acidosis	Hyperkalemia
Air embolism	Hypothermia
Aortic dissection	Hypovolemia
Cardiac valve rupture	Hypoxemia
Drug toxicity:	Myocardial infarction
β-Blockers	Myocardial pump failure
Calcium channel blockers	Myocardial wall rupture
Digoxin/digitalis	Pericardial tamponade
Tricyclic antidepressants	Pulmonary embolism
	Tension pneumothorax

TABLE 61.2. CAUSES OF PULSELESS ELECTRICAL ACTIVITY(PEA)

POSTRESUSCITATION MANAGEMENT

Immediate postarrest care includes support of ventilation, oxygenation, and blood pressure. Hypotension is common; evaluation of its hemodynamic significance and cause will guide therapy. Moderate hypertension is not harmful and does not need correction. Electrolytes (especially potassium, magnesium, and phosphorus), glucose, hematocrit, arterial blood gases, chest radiograph, and a 12-lead ECG are needed promptly. Complications of resuscitation efforts (aspiration, rib fractures, liver or spleen lacerations) require prompt recognition. Acute myocardial infarctions cause a large portion of arrests; ECGs, laboratory markers, and echocardiography will assist prompt diagnosis and further interventions. Active ischemia warrants anti-ischemic pharmacotherapy, including nitroglycerin and aspirin. Rhythm monitoring is essential, and antiarrhythmic drugs are needed after VF/VT. Sinus tachycardia is common after arrest and often resolves spontaneously, especially if due to previous epinephrine. Volume depletion, hypoxia, ischemia, congestive heart failure, or agitation may also cause persistent sinus tachycardia.

Brain resuscitation raises several issues distinct from cardiac resuscitation, although rapid restoration of effective circulation is unquestionably the best way to assure brain recovery. The mechanisms of ischemic brain injury remain the focus of intensive research. Neuronal damage begins during cardiac arrest with ischemia and anaerobic metabolism, and a diverse array of processes continue during reperfusion that may produce permanent damage. Contributing factors include local fluxes of potassium and calcium, loss of vasomotor control, endothelial damage, edema, release of tissue mediators, metabolic changes, and induction of apoptosis. Proposed therapies have unfortunately not produced overall improvement. General supportive measures include adequate CPR, oxygenation, and epinephrine during arrest. After arrest, the brain benefits from normal to moderately elevated blood pressure, mild hyperventilation, normalization of glucose, elevation of the head to about 20°, prevention of further insults, and nutritional support. Conditions that increase neuronal metabolic demands (agitation, fever, seizures) must be avoided.

Longer term management and rehabilitation must be tailored to the patient's functional status and underlying disease processes. In the absence of acute infarction, extensive diagnostic studies may be needed to determine etiology, cardiac function, and electrophysiologic stability.

TABLE 62.3. FACTORS PREDISPOSING TO HYPOTHERMIA

Temperature (°C)	Response
37-31.7	Vasoconstriction, shivering, tachycardia, increased blood pressure, diuresis
31.7-23.9	Muscles stiffen, shivering decreases, blood pressure and pulse decrease
23.9 and below	Poikilothermic. Might appear dead.

TABLE 62.4. THE BODY'S RESPONSE TO COOLING

Below 23.9°C (75°F), all responses are so affected by the cold that the patient loses heat as would a poikilotherm and the victim begins to approach a deathlike state. If a patient appears dead but has a history of hypothermic exposure, he or she should be warmed before being pronounced dead because patients with temperatures as low as 10°C (50°F) have survived.

Physical examination is difficult in a very cold patient. The temperature should be taken with a thermometer designed to read below the standard 34.4°C (94°F) lowest marking. The skin usually is cold, dry, and pale, but may show edema even in the face of intravascular volume depletion. Warm skin on a cold patient suggests that the hypothermia is caused by sepsis, skin disease, or vasodilator drugs. Respiratory compromise ranges from cold-induced bronchorrhea and aspiration pneumonia to noncardiogenic pulmonary edema. Blood gases, warmed by the laboratory to 37°C (98.6°F) as the measurements are made, may show hypoxemia, hypercarbia, and acidemia. Even if the blood gases show significant hypoxemia, cold protects the patient by decreasing tissue oxygen requirements. Pulse oximeters may not be accurate in patients with hypothermia and vasoconstriction.

Cardiovascular volume is depleted in most patients with chronic hypothermia as a result of the early diuresis described and a later cold-induced renal tubular concentrating defect. Hemoconcentration plus circulatory slowing may lead to intravascular sludging and microvascular occlusion. This, plus myofibrillar enzyme leaks across the cold cell membranes of skeletal and cardiac muscle, can cause dramatic elevations of creatine kinase (including MB) and lactic dehydrogenase. Electrocardiographic changes in hypothermia include increases in the PR interval, QT prolongation, bradycardia, atrial fibrillation with slow ventricular response, nodal rhythm, asystole, and the classic (although not pathognomonic) camel hump sign of Osborn, also called the J wave, a little "hump" on the down slope of the QRS complex, seen at 32.2°C (90°F) and below ([Fig. 62.1](#)).

FIGURE 62.1. The camel hump sign, also called the Osborn wave or J wave (*arrow*; 81°F; lead V₅).

The abdomen may have rigid musculature and decreased bowel sounds. Gastrointestinal submucosal hemorrhage, if present, seldom is of major clinical significance. The amylase level may be increased, the platelet count decreased, and the prothrombin time prolonged. Hepatic and renal clearance of drugs, and their tissue effects, are unpredictable. Renal tubular glycosuria, myoglobinuria, and renal failure may occur.

Consciousness and reflexes are depressed and pupillary reflexes unreliable; the electroencephalogram may be flat below 20°C (68°F), and hypothermia is exclusionary of the diagnosis of brain death by electroencephalography.

Therapy for hypothermia is directed both to discovering and correcting the underlying cause of the hypothermia while rewarming the victim without causing harm. All patients, after blood samples for appropriate laboratory studies have been drawn, should receive 100 mg of thiamine, 50 g of glucose and naloxone (Narcan), 1 to 2 mg intravenously. Other drugs should not be used unless absolutely necessary, given their uncertain effects at the patient's depressed temperature. Because sepsis is hidden in hypothermia, blood cultures and empirical antibiotics may be needed. Stress level corticosteroids are unnecessary unless adrenal insufficiency is a serious possibility. Patients with temperatures less than 32.2°C (90°F) should be admitted to the intensive care unit.

Appropriate initial and serial laboratory studies include a complete blood cell count; determination of electrolyte, calcium, albumin, amylase, and creatine kinase levels; renal and hepatic function tests; and urinalysis, coagulation studies, blood cultures, chest radiography, electrocardiography, and arterial blood gas analysis. Cardiac monitoring may be sufficient, although seriously ill patients may require right-sided heart catheterization. The latter should be done judiciously because dysrhythmias are common in hypothermia and may be stimulated by the placement of an intracardiac line. Volume replacement should be with normal saline and with dextrose and water. Lactated Ringer's solution should not be used because the hypothermic liver may not be able to metabolize lactate to bicarbonate. The patient should be reassessed continually because physical examination and laboratory studies will change with rewarming.

The great debate in therapy revolves around rewarming therapy itself. Three major methods exist: external active rewarming, central active rewarming, and passive rewarming. External active rewarming includes immersing the patient in hot water or covering him or her with heating blankets. Although this rarely may be necessary in the profoundly cold, asystolic patient, it usually is not required and can be dangerous, leading to more profound hypothermia (the "afterdrop phenomenon"), cutaneous burns, or death. Central active rewarming involves either the use of warmed peritoneal or gastric lavage, which can be complicated by aspiration or infection, or the safer but more difficult to arrange use of warming hemodialysis or inhaled supplemental oxygen delivered as mist, keeping the inspired oxygen at 40°C (104°F) or less to prevent pulmonary burns. All intravenous fluids should be warmed to 37°C (98.6°F).

There is no proven benefit to more rapid rewarming. In all but the most severe cases, passive rewarming (correcting the underlying pathologic process if possible, removing the patient from the cold, and using warm—not hot—blankets) suffices, although airway warming at temperatures less than 32°C (89.6°F) and aggressive central active rewarming at temperatures less than 28°C (82.4°F) may be necessary, especially if the patient is in cardiac arrest.

- [Cost Effectiveness](#)

PRESENTATION

Accidental radiation injuries are rare and usually involve only a few individuals exposed in a laboratory or industrial accident. There is the extremely unlikely potential for large-scale exposure related to nuclear power and fuel processing. Nuclear war overwhelms meaningful medical response, but terrorism is a potential threat to be planned for.

Patients may have well-defined, acute, whole-body radiation syndromes ([Table 63.1](#)) or local radiation burns. Exposures might or might not be associated with radionuclide contamination. Lesser exposures, although causing no acute symptoms, may be carcinogenic and mutagenic. In most instances, radiation exposure is obvious to patient and physician, but rarely unsuspected irradiation can lead to bizarre local burns and myelosuppression.

TABLE 63.1. CHARACTERISTICS OF VARIOUS RADIATION EXPOSURE SYNDROMES

PATHOPHYSIOLOGY

The ionizing radiations and units of measurement and effect are presented in [Table 63.2](#) and [Table 63.3](#). Energy deposited by ionizing radiation results in formation of free radicals and reactive intermediaries, or in direct damage to DNA and other macromolecules. At high doses this leads to acute cell death and swelling. Lower doses cause mitotic arrest of stem cells in marrow, gonads, and gut epithelium. Lymphocytes are highly sensitive, and irradiation causes depletion in marrow, spleen, thymus, and blood. Inflammatory responses are deficient because of leukopenia. Microvascular injury leads to obliterative endarteritis, fibrosis, and atrophy. Delayed effects in survivors of acute injury or individuals with asymptomatic low-dose exposure may lead to carcinogenesis (acute lymphoblastic, myeloblastic, or chronic granulocytic leukemias, or solid tumors of breast, lung, salivary gland, gut, and lymph node) after latent intervals of 3 years to decades. Germ cell irradiation may lead to heritable mutagenesis. Estimated risks of low doses are extrapolated from high doses and depend on the model used. No threshold is assumed, although partial repair of radiation damage to DNA is possible. Effects of radiation exposure are influenced by volume of tissue exposed, dose rate, and modifying factors (e.g., hyperthermia, cytotoxic chemicals). Bone marrow, gut, and gonads are most sensitive, whereas muscle and connective tissue are resistant.

Radiation Type	Quality Factor
High-energy electromagnetic radiation	
γ-Rays (of nuclear origin)	1
x-Rays (of electron origin)	1
Charged particles	
β-Rays	1
Auger and conversion electrons	5
α-Rays	20
Protons	10
Neutrons	20

^a Quality factor takes into account dose rate, relative biologic effectiveness, and other factors to convert absorbed radiation dose to dose equivalent. (See [Table 63.3](#).)

TABLE 63.2. CLASSIFICATION OF TYPES OF IONIZING RADIATION

Definition	Traditional Unit	Modern SI Unit
Absorbed radiation dose: energy deposited per unit volume of tissue	rad (100 erg/g)	1 rad (100 erg/g) = 0.01 Gy (1 J/kg)
Dose equivalent: the biologic effect of a given absorbed radiation dose	rem (radiation equivalent man)	1 rem (100 erg/g) = 0.01 Sv (1 J/kg)
Activity: Amount of radioactivity, number of disintegrations per time	1 curie (Ci)	1 Ci = 3.7 × 10 ¹⁰ Bq
Exposure: Degree of ionization of air by low energy x and γ-rays	Röntgen (R)	1 R = 2.58 × 10 ⁻⁴ C/kg
LET: Density of ionization and energy deposition per unit path length	Ion pair/cm	10 ¹⁷ ion pair/m
RBE: Relative effectiveness of a given radiation in producing a given effect compared with a reference radiation (250-kVp x-rays; RBE is proportional to QF)	Ratio or percentage	Ratio or percentage
Quality factor (QF): Takes into account dose rate, RBE, and other factors to convert absorbed radiation dose to dose equivalent	QF = 1 or 2 or 5 or 10 or 20	QF = 1 or 5 or 10 or 20

LET: linear energy transfer; RBE, relative biologic effectiveness.

TABLE 63.3. CLASSIFICATION OF UNITS OF MEASURE FOR IONIZING RADIATION

HISTORY AND PHYSICAL EXAMINATION

Special attention must be paid to the exact nature, timing, and circumstances of exposure, whether radionuclide contamination was possible, and whether radiation dosimeters were worn. Whole-body exposure syndromes evolve through four phases, the duration being inversely related to the dose. A prodrome is followed by a latent interval, the characteristic syndrome, and, if this is survived, recovery. Except for patients with the central nervous system syndrome, most patients with whole-body exposure are seen in the prodromal phase. Subsequent symptoms and signs depend on dose ([Table 63.1](#)). Local radiation burns in the early phase manifest only mild paresthesia, pain, and erythema, but over time may evolve to extensive tissue injury and loss. Associated nonradiation injuries also should be noted.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

Appropriate radiation detectors are used to monitor for external and internal radionuclide contamination and to identify the radionuclides. Measurements are also made on the blood, urine, feces, and sputum, or on swabs from the nose, ears, and wounds. Neutron exposure can be deduced from the presence of sodium 24 in blood and from activation of metal objects on the patient. These measurements and those from dosimeters (if worn) are used to calculate absorbed radiation dose. Chromosomal analysis of lymphocytes might also provide estimates of the radiation dose. Serial blood cell counts document initial lymphopenia, which predicts subsequent course, and development of myelosuppression with a nadir at 4 to 6 weeks. Marrow biopsy demonstrates aplasia or hypoplasia. Major electrolyte, fluid, and acid–base disturbances follow loss of gastrointestinal epithelium. Cellular damage may result in the elevation of serum transaminase, lactic dehydrogenase, and uric acid levels. Cultures of blood, urine, and sputum identify infections in these immunocompromised patients. Radiography, arteriography, and three-phase bone scans may be used to evaluate viability of irradiated extremities.

DIFFERENTIAL DIAGNOSIS

Radiation exposure usually is well documented, and there is no differential diagnosis. Rarely, persons exposed to lost industrial radiation sources present with bizarre burnlike lesions or myelosuppression. Failure to consider radiation exposure may result in ongoing exposure.

STRATEGIES FOR OPTIMAL CARE

There is no substitute for prevention. Exposure is minimized by maintaining distance, shielding, and minimizing exposure time. Because radiation accidents are rare and potentially disastrous, detailed and rehearsed response plans by teams, including emergency and nuclear medicine physicians, hematologists, and health physicists, are required. Mass casualties will require triage.

MANAGEMENT

After first aid, patients should be evacuated, with care taken not to spread potential contamination. Hemorrhage, shock, and the airway should be managed in the usual fashion.

External contamination is best managed with soap or nonionic detergent and water. Care should be taken not to abrade skin and cause internal contamination. Contaminated wounds should be irrigated and, if necessary, widely debrided. Contamination of nasopharynx, ears, eyes, and mouth is removed by lavage. Lower respiratory tract contamination resists therapy, but expectorants and bronchoalveolar lavage can be attempted. Ingested contamination can be minimized by reducing absorption (e.g., vomiting, gastric lavage, activated charcoal) or by binding to specific agents (e.g., Prussian blue for cesium, thallium, and rubidium; barium sulfate, alginates, and alumina-containing antacids for strontium and radium; and phytates for calcium, magnesium, zinc, or iron). Once radionuclides are absorbed, isotopic dilution may reduce risk of incorporation. Stable iodide, 300 mg potassium iodide or sodium iodide, administered early reduces thyroid radioiodine uptake (once incorporated into thyroid hormones, this is useless). Radioactive strontium, calcium, phosphate, zinc, and iron can be similarly diluted. Turnover can be accelerated by water diuresis for tritium and by diuretics for radioactive sodium and potassium. Parathyroid hormone may mobilize radioactive strontium, calcium, or phosphate from bone. Chelation enhances renal excretion of radiometals (e.g., calcium or zinc ethylenediaminetetraacetic acid for transuranic and rare earth elements; desferrioxamine for plutonium and iron; penicillamine for copper and cobalt; and dimercaprol for mercury, lead, arsenic, bismuth, chromium, and nickel).

The prodrome of acute whole-body exposure is self-limiting but may require antiemetics and anxiolytics. The central nervous system syndrome is inevitably fatal and only symptomatic management is warranted. In the gastrointestinal syndrome, intravenous fluids, plasma, blood fractions, and broad-spectrum antibiotics benefit some patients. The hematologic syndrome can be self-limiting, and supportive therapy may permit survival until marrow regeneration occurs. This requires reverse isolation, asepsis, and broad-spectrum antibacterial and antifungal therapy with granulocyte levels of less than 800 per L. Activation of latent viral infections necessitates antiviral therapy. Platelet and red blood cell transfusions correct thrombocytopenia and anemia. Recombinant granulocyte colony-stimulating factor may speed recovery. Marrow transplantation also may have a role.

Pain of local injuries is often severe, necessitating narcotics. Local management is similar to that of thermal burns: debridement of nonviable tissue, administration of local and systemic antibiotics, and skin grafting. Severe extremity injuries may require amputation. Healing is slow, and late breakdown of healed lesions is common.

Survivors of acute exposure require education and surveillance for late effects. Management of radiation-induced leukemias and tumors does not differ from that of spontaneous disorders. Visual impairment necessitates cataract removal.

COMPLICATIONS AND PITFALLS

It must be established that a radiation exposure has occurred, as many apparent accidents are false alarms. It is important to allay anxiety associated with radiation exposure; all but the most severely exposed recover completely. Skin decontamination should be gentle to prevent injury and conversion of external to internal contamination. Except for iodides, drugs to reduce incorporation or hasten excretion of radionuclides may cause side effects, and their use should be weighed carefully.

HOSPITALIZATION

Except for trivial exposures and contamination, patients should be hospitalized until radiation exposure has been estimated or the nature of injury is apparent. All patients with hematologic, gastrointestinal, or central nervous system acute exposure syndromes and those requiring chelation therapy, repeated extensive external decontamination, or management of significant local radiation injuries require hospitalization. Major whole-body exposures might be best managed on a hematology or bone marrow transplant service and local injuries in a burn unit.

REFERRAL

Seriously exposures are best treated at institutions with experienced nuclear physicians, hematologists, and facilities for the isolation and treatment of severe hematopoietic suppression. Assistance is available through the Radiation Emergency Assistance Center/Training Sites (REAC/TS) of the Medical and Health Science Division of Oak Ridge Associated Universities (423-481-1000, ext. 1502).

COST EFFECTIVENESS

All hospitals are required to have written radiation accident response plans. Although rarely activated, failure to prepare may lead to dire consequences.

CHAPTER 64: ESSENTIAL FEATURES OF THE CARDIAC HISTORY AND PHYSICAL EXAM

ELIZABETH G. NABEL

[Cardiovascular History](#)
[Physical Examination](#)

The cardiovascular evaluation consists of the history, the physical examination, and selected laboratory studies. In some situations, the correct diagnosis is based on information from only one of these components. More commonly, it results from the careful integration of information from several or all parts of the evaluation process.

The availability and role of laboratory studies have grown at an impressive rate. Although these specialized studies provide valuable diagnostic information, they do not diminish the central role of the bedside evaluation of patients with suspected cardiovascular disease. The selection of laboratory studies requires a carefully defined differential diagnosis gleaned from the history and physical examination. An accurate and complete clinical assessment allows the physician to more readily detect changes as the patient's course is followed over time ([Table 64.1](#)).

Symptoms	Signs
Dyspnea	Peripheral edema
Fatigue	Pulmonary rales
Chest pain	Heart murmur
Palpitations	Gallop rhythm
Syncope	Irregular pulse

TABLE 64.1. IMPORTANT SYMPTOMS AND SIGNS OF CARDIAC DISEASE

CARDIOVASCULAR HISTORY

Information from the medical history often provides the first clue in the recognition of specific cardiovascular disorders. In some cases, the initial diagnosis is based solely on the history. Many patients with angina pectoris, for example, have entirely normal physical examinations and resting electrocardiograms between episodes of discomfort. Beyond its role in diagnosis, the medical history is central in the determination of the patient's functional capacity or the degree to which the disorder limits his or her activities and lifestyle. This assessment is often used when considering medical, interventional, and/or surgical therapy. When the functional aspect is not concordant with the physical findings and laboratory results, it raises the suspicion that other factors, such as anxiety, depression, or other medical illness, might be contributing to the patient's limitation. Special attention to patients with chronic slowly progressive heart disease is also required because symptoms can develop so insidiously that the patients slowly adjust their lifestyles without recognizing the true extent of disability. It is often helpful to have such patients describe their activities during a typical day.

Through the history, the physician can learn about concurrent disorders or habits, such as diabetes mellitus or cigarette smoking, that can affect cardiovascular function or place it at risk. Careful attention to the patient's medications is similarly important because of their pharmacologic and toxic actions. Several cardiovascular disorders have a heritable tendency, amplifying the importance of a careful family history. This includes inquiry about premature or sudden death.

The major symptoms associated with cardiovascular disease are dyspnea, fatigue, chest pain, palpitations, and syncope. These symptoms are not confined to cardiovascular disorders, and even when they occur in patients with known heart disease, the physician must be alert to possible extracardiac influences.

DYSPNEA

Pulmonary congestion secondary to left ventricular failure or mitral stenosis typically results in dyspnea that is worsened by exertion. Dyspnea is also worsened by the recumbent position (i.e., orthopnea) because the added venous return from the no longer dependent lower extremities contributes to an already engorged pulmonary vascular bed. At times, congestion leads to a nonproductive cough. Patients may awaken after several hours of sleep because of acute respiratory distress (paroxysmal nocturnal dyspnea) that forces them to sit or stand and to seek "fresh air." Wheezing may accompany the dyspnea. Paroxysmal nocturnal dyspnea results from interstitial pulmonary edema. It is more intense and alarming to the patient than is orthopnea, and a longer time is required before the dyspnea improves.

Dyspnea of effort can result from several other causes, including chronic pulmonary disease, poor physical conditioning, and obesity. Differentiating cardiac from pulmonary dyspnea can be particularly difficult. Chronic lung disease can also lead to orthopnea. Anxiety-related dyspnea is usually less predictable than cardiac dyspnea, is often reported as an inability to take a full or deep breath, and is commonly accompanied by other signs of anxiety or by sighing.

Acute pulmonary edema, whether occurring as an initial feature or as a culmination of progressive cardiac failure, is the most severe and dramatic cause of dyspnea in patients with heart disease. The severe breathlessness is typically acute in onset and may be accompanied by cough, at times producing frothy and even blood-tinged sputum. Other causes to be considered in patients with acute, severe dyspnea include pulmonary embolus, pneumonia, and pneumothorax.

FATIGUE

When excessive fatigue results from cardiovascular disease, it is presumed to be a manifestation of inadequate cardiac output and as such is typically related to effort. In evaluating a patient with fatigue, the physician must understand the nature of the fatigue and the intensity of activities that elicit it, and the pattern of development. Fatigue is reported by patients with a wide variety of extracardiac disorders, including anxiety and depression. The use of certain medications can elicit or exacerbate fatigue; examples include excessive diuretic treatment and inordinate lowering of heart rate and blood pressure by antihypertensive or antianginal drugs.

EDEMA

Edema, typically of the lower extremities, is a common complaint of patients with heart failure. Pitting ankle and lower leg edema characteristically involves both lower extremities, increases in magnitude during the day, and decreases overnight because of the enhanced venous return from the legs after assumption of the recumbent position. If the patient is bedridden, edema may be confined to the presacral area. If the elevation of venous pressure is marked and prolonged, fluid accumulates in the liver and abdominal cavity (ascites), prompting the patient to experience an aching or "heavy" discomfort in the right upper quadrant or abdominal distention. Edema can also result when central venous return to the heart is impeded, as in constrictive pericarditis.

Edema occurs in patients with a variety of extracardiac disorders, including local venous insufficiency, lymphatic blockage, and chronic liver or kidney disease. The

location of the edema sometimes provides information about its underlying cause. For example, the edema associated with the nephrotic syndrome is often prominent about the face and eyes. Edema limited to the face, neck, and upper arms can result from obstruction of the superior vena cava (e.g., by carcinoma of the lung). Edema confined to one lower extremity is likely to be the result of a local problem (e.g., venous obstruction or inflammation).

CHEST PAIN

Chest pain can be the result of cardiac, vascular, respiratory, musculoskeletal, or gastrointestinal disorders. It can also accompany anxiety. Patients with angina pectoris typically describe pressure-like heaviness or tightness. Many insist that it is not a true pain but rather an uncomfortable sensation. It is characteristically substernal in location and is diffuse rather than focal. Radiation of the discomfort to the left shoulder and arm is common, and it can radiate to the base of the neck and jaw and, less commonly, to the back.

Angina pectoris is typically brought on by physical exertion or emotional stress, lasts a matter of minutes, and is relieved by rest or promptly alleviated by sublingual nitroglycerin. Most patients can describe activities that predictably elicit angina, and some variability in activity tolerance is common. Some patients, for example, report that exertion carried out early in the morning is more likely to precipitate discomfort. Physical activity in cold weather or after meals might also be more likely to provoke angina pectoris. Unfortunately, angina is atypical in one or more of its characteristics in some patients, making its presence more difficult to establish clearly by history. Some patients describe it as sharp or burning. In others, discomfort may be confined to the arms or neck. Some patients experience dyspnea rather than chest discomfort during myocardial ischemia. This angina-equivalent dyspnea resembles angina pectoris in other respects (e.g., duration, relation to stress) and carries the same significance.

Variant angina, also called Prinzmetal's angina, is similar in character to stress-induced angina pectoris but is characteristically unpredictable and nonexertional—features consistent with its cause of coronary artery spasm. Variant angina may occur in the early morning hours, and some patients also report other vasomotor-related symptoms such as migraine headaches or Raynaud's phenomenon.

Angina pectoris that has recently become more frequent or severe or has progressed to occur at rest is considered unstable angina pectoris. Unstable angina also includes angina of recent onset, particularly if it occurs with low levels of activity or at rest. The pain of acute myocardial infarction is characteristically more intense than angina pectoris, lasts longer (30 minutes), radiates more widely, and is not relieved by sublingual nitroglycerin. Nausea and diaphoresis frequently accompany the discomfort. Nonetheless, the intensity of symptoms does vary in patients with acute myocardial infarction, and the physician must remember that as many as 20% of patients with heart attack do not seek medical attention because the symptoms are atypical or mild, or because there are no symptoms. Silent and atypical infarctions appear to be more common in patients with diabetes mellitus and in the elderly.

Although angina pectoris is usually the result of obstructive coronary artery disease, similar discomfort can occur in patients with aortic stenosis, hypertrophic cardiomyopathy, or pulmonary arterial hypertension. One proposed mechanism is ischemia due to the excessive work of the hypertrophied, overloaded ventricle. In patients with pulmonary arterial hypertension, distention of the pulmonary artery may contribute to the discomfort. Acute dissection of the thoracic aorta typically results in excruciating pain that is abrupt in onset and that attains peak intensity almost immediately. Although the distribution of the pain can be similar to that of myocardial pain, the pain of dissection more frequently radiates to the back. A history of hypertension is commonly present. The chest pain from acute pericarditis is sharp and parasternal or precordial. The pain may be referred to the shoulder and ridge of the trapezius muscle. It is aggravated by breathing or twisting of the torso. Patients often report that the pain is diminished by sitting up and leaning forward.

Gastrointestinal disorders such as gastroesophageal reflux, esophageal motor abnormality, and peptic ulcer disease are common causes of substernal and epigastric discomfort. An important part of the evaluation of chest pain is the identification of its relation to food intake, recumbent position, and, at times, the response to antacids. Chest wall injury or inflammation can cause chest pain, but it is typically more focal, often superficial, and may be elicited by local movement and accompanied by chest tenderness. Psychogenic or anxiety-related chest discomfort can have various characteristics. Frequently, it is localized to the cardiac apex, where it may be described as a constant ache lasting for hours or as a brief, sharp, stabbing inframammary pain. This discomfort is not predictably related to exertion. It may be accompanied by other manifestations of anxiety, such as hyperventilation.

PALPITATIONS AND SYNCOPE

Palpitation denotes an awareness of the heartbeat and can be the result of alterations in heart rate, rhythm, or force of contraction. Patients vary remarkably in the degree to which they have symptoms related to such alterations. Some are aware of every premature beat, whereas others are unaware of grossly irregular or potentially serious dysrhythmias. In evaluating a patient with palpitations, it is important to know the type of irregularity he or she experiences, what precipitates it, and whether there are associated symptoms.

Commonly, patients describe a skipped heart beat, which results from the pause and subsequent forceful systole after a premature contraction. Premature heartbeats are occasionally accompanied by a fleeting sharp pain at the cardiac apex. Paroxysms of rapid dysrhythmias are sometimes felt as a beating in the throat or a fluttering in the chest. Dysrhythmias that are sufficiently rapid or slow can interfere with cardiac output and cerebral perfusion, leading to weakness, lightheadedness, or syncope. In patients with coronary artery disease, rapid dysrhythmias can precipitate angina pectoris.

The circumstances associated with palpitations are important. Do they occur after meals or after the drinking of caffeine-containing beverages, with exertion or position change, or during periods of emotional stress? Equally important is the manner of onset and termination of the palpitations. Paroxysmal supraventricular tachycardia, for example, is characteristically abrupt in onset and termination, but sinus tachycardia accompanying anxiety resolves slowly. It can be helpful to have the patient tap out his or her palpitations to assess their rate and regularity.

Dysrhythmias can cause syncope because of excessively slow or rapid heart rates. Syncope resulting from bradycardia secondary to atrioventricular heart block (Stokes–Adams attack) is characteristically abrupt and can occur in any position. Consciousness is usually regained promptly. Syncope caused by rapid dysrhythmias can also be abrupt or can follow a graying-out period of seconds to minutes. The patient may describe palpitations before loss of consciousness, but the absence of palpitations does not exclude a dysrhythmia as the cause of the syncope. In some patients (usually elderly), marked bradycardia with syncope can follow stimulation of a hypersensitive carotid sinus. The stimulation may result from activities such as turning the head abruptly, shaving, or buttoning a tight collar. Aortic stenosis and hypertrophic cardiomyopathy can also cause syncope, typically with or after exertion.

The most common cause of syncope is a vasovagal episode—the common faint. Such episodes usually follow a strong emotional stimulus, such as severe pain or the sight of blood. Orthostatic hypotension is an important cause of syncope, particularly in patients receiving diuretic drugs and in patients with autonomic and peripheral nervous system dysfunction (e.g., from diabetes mellitus). The investigation of syncope should always include inquiry about its relation to position change. Seizure is a potential cause of loss of consciousness in some patients. Information from witnesses with regard to tonic-clonic movements and from the patient about aura, urinary incontinence, and tongue trauma can aid in its recognition.

PHYSICAL EXAMINATION

The cardiac examination is not performed in isolation; it is part of the systematic and complete evaluation of the patient. Extracardiac findings commonly provide key information that points to a specific cardiac diagnosis.

Noncardiac disorders can contribute to or worsen the manifestations of heart disease. To provide optimal treatment, it is essential that these disorders be identified.

The physical examination of a patient with heart disease begins while the patient is providing the medical history. During this time, the physician is listening to and observing the patient.

The examination need not be limited to the resting state. Important information can be obtained in some patients, for example, by evaluation during the Valsalva maneuver after position change or after exercise.

GENERAL INSPECTION

Beyond assessment of the general medical condition, inspection of the patient from head to foot can provide clues to the presence of heritable or acquired systemic disorders that place the patient at risk for specific cardiovascular abnormalities. For example, tall stature, long fingers, and an arm span greater than the patient's height suggests Marfan's syndrome, which can be associated with aortic aneurysm, aortic valve regurgitation, and mitral valve prolapse. Even in the absence of the full features of Marfan's syndrome, a tall, thin stature or sternal abnormalities such as pectus excavatum can be associated with mitral valve prolapse. Recognition of the characteristic appearance of Down's syndrome or Turner's syndrome alerts the physician to possible associated cardiovascular anomalies, such as endocardial cushion defect or coarctation of the aorta, respectively.

The skin, mucous membranes, and nail beds often contain important clues to the diagnosis of cardiovascular disorders. Xanthomas may indicate lipid abnormalities. Thick, taut skin of the face and extremities can result from scleroderma, a condition in which cardiovascular complications can be severe and even life threatening. Cyanosis is most evident in the nail beds and mucous membranes, and its distribution may provide information about its mechanism of development. Central cyanosis due to intracardiac or intrapulmonary shunting of blood may affect the extremities and the oral mucosae. Peripheral cyanosis, which results from localized oxygen desaturation of slowly moving capillary blood (e.g., after cold exposure with peripheral vasospasm), is limited to exposed or distal areas, such as the fingers, toes, and ear lobes. Chronic conditions leading to central cyanosis can result in clubbing of the fingers and toes. Endocarditis and chronic liver disease can also be accompanied by clubbing of the fingers, and clubbing occasionally occurs as an isolated heritable trait.

In patients with infective endocarditis, embolic or immunologic mechanisms can lead to several skin and mucous membrane findings. These include conjunctival petechia and splinter hemorrhage of the nail beds.

BLOOD PRESSURE AND PULSE EVALUATION

Information from the vital signs, particularly the blood pressure and pulse determination, contributes to an assessment of the patient's overall hemodynamic status and in many cases also suggests specific underlying cardiovascular abnormalities.

Arterial Pressure

The accurate determination of blood pressure requires a properly placed sphygmomanometer of appropriate size for the patient (see [Chapter 30](#)). The patient must be comfortable and without anxiety during the determination to avoid spurious elevations of the blood pressure. Blood pressure should be measured in the recumbent and standing positions to detect orthostatic hypotension and, during the initial examination, in the left and right arms to recognize certain vascular anomalies, such as some types of aortic coarctation or dissection. If hypertension is suspected, blood pressure should also be measured in the leg.

Attention should be paid to the effects of respiration on the blood pressure. A decline in systolic blood pressure greater than 10 mm Hg during inspiration is called *pulsus paradoxus*, which is a misnomer because it is not paradoxical but rather an exaggeration of the normally small decline in the pressure during inspiration. *Pulsus paradoxus* is a cardinal sign of cardiac tamponade, and its detection can lead to identification of a potentially life-threatening situation. However, a paradoxical pulse is not specific for tamponade. Pulmonary insufficiency can result in an exaggerated decrease in blood pressure during inspiration.

Proper analysis of the blood pressure is not limited to isolated consideration of the systolic or diastolic values. The relation of the two, called the *pulse pressure*, is also important. A narrow (reduced) pulse pressure, for example, is commonly present in patients with advanced cardiac failure and in many patients with severe aortic stenosis. In these cases, the systolic pressure is typically limited by the small stroke volume, and the diastolic pressure is increased because of a compensatory rise in systemic vascular resistance. Conversely, situations in which there is a large stroke volume or an abnormal run-off channel from the systemic arterial system lead to a widened (increased) pulse pressure. Examples include aortic regurgitation and large arteriovenous fistula. Fever and bradycardia can also lead to some increase in the pulse pressure.

Pulse Examination

The pulse examination usually begins with palpation of the radial artery to assess heart rate and regularity. Increased heart rate can be an important early sign of a cardiac disorder (e.g., heart failure, pericarditis) as well as a physiologic response to extracardiac factors (e.g., anxiety, hypovolemia, hyperthyroidism). The detection of an unexplained or persistent tachycardia, even when sinus in origin, should always elicit a careful search for its underlying cause. Disorders of pulse rhythm should be characterized by the pattern of their irregularity. The irregularity may occur at regular or repetitive intervals, as in a bigeminal pulse secondary to coupled extrasystoles. In other cases, the irregularity is erratic. Although an electrocardiogram (ECG) is usually required to identify specific dysrhythmias, the pulse rhythm sometimes provides important diagnostic information, particularly when coupled with other physical findings. For example, an "irregularly irregular" radial pulse rate combined with an apical heart rate, as determined by auscultation, that exceeds the radial pulse rate (*pulse deficit*) suggests atrial fibrillation. A rapid, regular pulse rate along with intermittent cannon waves in the jugular venous pulse suggests ventricular tachycardia or, less commonly, junctional tachycardia. In some patients with advanced left ventricular dysfunction, the pulse rate is regular, but the amplitude of every other heart beat is reduced—a phenomenon called *pulsus alternans*.

The pulse examination includes sequential palpation of the carotid arterial pulses, which is taken as a reflection of the central arterial pulse from left ventricular ejection, and of the major palpable peripheral arteries to detect signs of local vascular disease or certain congenital anomalies (e.g., radial–femoral artery pulse lag due to coarctation). The extent to which the arterial system is surveyed depends in part on the age of the patient and the clinical situation. In adults, the carotid, radial, and femoral arteries and the abdominal aorta are routinely evaluated. In older persons, the popliteal, dorsalis pedis, and posterior tibial vessels are also carefully examined.

The carotid arteries are the primary sites for pulse contour analysis ([Fig. 64.1](#)). The artery examination includes assessment of the pulse upstroke, its amplitude, and its duration. All three of these parameters are typically (but not invariably) altered, for example, in patients with severe aortic stenosis. The resultant slow-rising, low-amplitude, and prolonged pulse is called *pulsus parvus et tardus*. In some patients with severe aortic stenosis, palpation of the carotid artery reveals coarse systolic vibrations or a "shuddering" sensation. The pulse amplitude can be reduced by any disorder that leads to small stroke volume (e.g., advanced cardiac failure). Attention to the upstroke of a low-amplitude pulse can help differentiate primary reduction in stroke volume from that caused by aortic stenosis. Conversely, the carotid pulse is brisk and bounding when significant aortic regurgitation is present. Some patients with aortic regurgitation have a double pulse, in which two discrete systolic peaks can be palpated. Hypertrophic cardiomyopathy with obstruction also can cause a *bisferious pulse*.

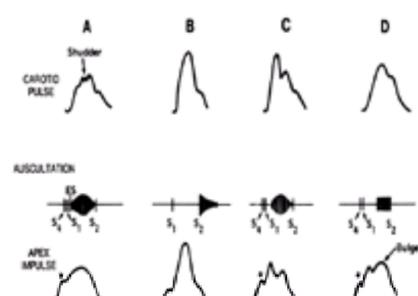

FIGURE 64.1. Examples of carotid pulse, auscultation, and apex impulse findings with aortic stenosis (**A**), aortic regurgitation (**B**), hypertrophic cardiomyopathy (**C**), and myocardial infarction (**D**). Example D includes mitral regurgitation murmur due to papillary muscle dysfunction and palpable precordial bulge. Apex impulses in A, C, and D also include palpable correlate of the fourth heart sound (a). ES, ejection sound.

The carotid pulse can be altered by local vascular disease, which commonly leads to asymmetry of the pulse amplitudes. Palpation of the carotid vessels must be done with particular caution when local obstructive disease is suspected or when the clinical history suggests the possibility of a hypersensitive carotid sinus. After

assessment of the carotid vessels, the other major arteries should be palpated. This is followed by auscultation over the carotid arteries, abdominal aorta, femoral vessels, and other sites where local vascular disease is suspected. The auscultation is performed to detect bruits due to blood flow turbulence that can result from obstructive arterial disease. The intensity of a bruit is also influenced by cardiac output and collateral flow; if an obstruction is very advanced, blood flow may be insufficient to generate audible sound. The duration of the bruit (e.g., extending into diastole) may be more reliably related to the presence of a high-grade obstruction. In patients with hypertension, auscultation in the epigastric area is particularly important because a bruit can indicate renal artery stenosis as a cause for the elevated blood pressure.

Venous Pulse Examination

The jugular venous system is evaluated for its pressure level and wave contour. The former permits an estimation of right-sided cardiac filling pressure, and the latter provides information about the mechanics of right ventricular filling, tricuspid valve function, and the temporal relation of atrial and ventricular systole. For analysis of the jugular venous system, the patient is placed in the position in which the venous blood level and undulations are most visible. Patients with highly elevated jugular venous pressure may have to sit upright. Conversely, persons with low jugular pressure often must be placed fully supine before the individual waves can be identified.

The internal jugular vein is preferred for venous pulse analysis because it is closer and courses in a more direct manner to empty into the right atrium and because it does not have venous valves. Its pressure level and wave contour generally reflect comparable values and events in the right atrium. Pulsations from the external jugular vein are easier to detect but are also more likely to be influenced by the vein's tortuous course and venous valves.

The jugular venous pressure is estimated by measuring the height of the filled jugular vein relative to a reference point, commonly the sternal angle. With normal jugular venous pressure, the top of the column of blood is less than 3 cm above the sternal angle. Elevated pressures can result from right-sided cardiac failure and from conditions that mechanically restrict filling or emptying of the right atrium, such as cardiac tamponade or tricuspid stenosis, respectively. In patients with borderline jugular pressure levels and cardiac failure or tricuspid regurgitation, the application of pressure to the right upper quadrant or periumbilical area may lead to a sustained increase in the jugular pressure level during the maneuver, a response known as *hepatojugular reflux*.

In patients with heart or lung disease, the right-sided filling pressure cannot be taken as an indirect sign of left ventricular filling pressure. The pressure–volume correlations of the two ventricles can be altered to different degrees in individual patients with cardiac disease. An acute disparity in right- and left-sided filling pressures is demonstrated most dramatically in some patients with right ventricular infarction. In this setting, inadequate filling of the left ventricle, to the degree that hypotension results, can occur despite markedly elevated jugular venous and right atrial pressures.

In some patients with obstructive pulmonary disease, an increase in intrathoracic pressure during expiration leads to elevated jugular venous pressure, independent of the right-sided cardiac pressures. In this case, however, the jugular pressure elevation is typically confined to expiration, abating promptly during inspiration. In cardiac failure, the jugular distention persists to some degree throughout the respiratory cycle. Kussmaul's sign represents a paradoxical increase in jugular venous pressure during inspiration. Although not specific, it can indicate restricted cardiac filling secondary to constrictive pericarditis.

The bedside evaluation of the jugular wave contour focuses on the relative magnitude of two outward movements, the *a* and *v* waves, and of two retractions, the X and Y descents (Fig. 64.2A). The *a* wave reflects right atrial contraction, and the resultant emptying and relaxation of the atrium produces the X descent. The subsequent filling of the right atrium against the closed tricuspid valve leads to the *v* wave. The Y descent begins when the tricuspid valve then opens. Identification of the individual venous waves is accomplished by establishing their timing relative to the cardiac cycle, which is best done by simultaneous cardiac auscultation.

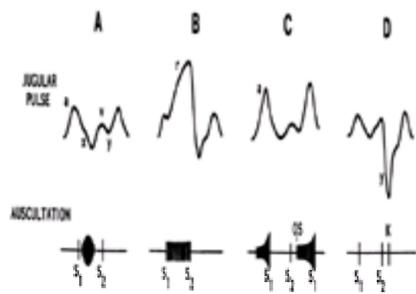

FIGURE 64.2. Examples of jugular pulse and auscultation findings. **(A)** A normal jugular tracing in a patient who has a functional heart murmur. The other tracings are in patients with **(B)** tricuspid regurgitation, **(C)** mitral stenosis with pulmonary hypertension, and **(D)** constrictive pericarditis. *r*, regurgitant wave; OS, opening snap of mitral valve; K, pericardial knock.

In normal persons, the *a* wave is somewhat more prominent than the *v* wave. Abnormally large *a* waves result when atrial contraction occurs against increased resistance to right ventricular filling. The resistance can be at the tricuspid valve level (e.g., tricuspid stenosis) or within the ventricle because of reduced wall compliance, as in pulmonic stenosis or pulmonary arterial hypertension (Fig. 64.2C). Very large *a* waves, called cannon *a* waves, arise when atrial contraction occurs while the tricuspid valve is closed because of simultaneous ventricular systole. An ectopic ventricular beat can cause a cannon *a* wave. Atrioventricular heart block or ventricular tachycardia with atrioventricular dissociation can lead to sporadic cannon *a* waves, and junctional tachycardia is a potential cause of regularly occurring cannon *a* waves. Because genesis of the *a* wave requires effective atrial contraction, it does not occur in patients with atrial fibrillation.

In patients with tricuspid regurgitation, the usual systolic collapse of the venous pulse wave (X descent) is reduced or replaced by a positive systolic wave. When the tricuspid regurgitation is marked, the regurgitant wave fuses with the usual *v* wave, producing a single, sustained outward wave during systole (Fig. 64.2B). The duration and amplitude of the visible wave are generally related to the severity of the valve regurgitation. If, however, the right atrium is large, the effects of the regurgitant flow on the jugular venous wave may be attenuated.

HEART SOUNDS

The third and fourth heart sounds are low-pitched sounds coincident with the rapid ventricular filling phase of early diastole and with atrial systole, respectively (Fig. 64.3). The third and fourth heart sounds are generated within the ventricle, and either can arise from the left or the right side of the heart. When they result from cardiac disease, they often lead to a characteristic auscultatory cadence that resembles the canter of a horse, explaining their designation as *gallop rhythms*. During rapid heart rates, third and fourth heart sounds can occur almost simultaneously, producing a single prominent summation gallop rhythm.

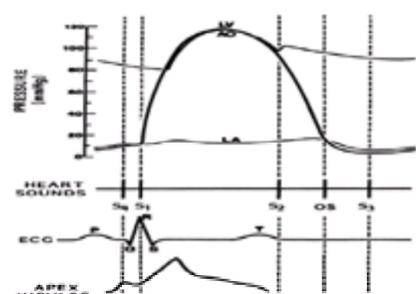

FIGURE 64.3. Diagram of left-sided pressure curves, heart sounds, ECG, and apex impulse. LV, left ventricle; LA, left atrium; Ao, aorta; S₄, fourth heart sound; S₃, third heart sound; OS, opening snap.

A left ventricular third heart sound can occur in normal children and young adults. After 35 to 40 years of age, the third heart sound is an abnormal finding whose major clinical implication is cardiac failure secondary to ventricular dysfunction. Ventricular dilatation is often present. A third heart sound is commonly detected in patients with ventricular dilatation caused by volume overload of the ventricle (e.g., from chronic aortic regurgitation).

The fourth heart sound denotes increased resistance to filling of the left or right ventricle because of a reduction in ventricular wall compliance, as occurs with hypertrophy or cardiac ischemia (Fig. 64.1A, C, D). The presence of the fourth heart sound does not necessarily imply reduced systolic function of the ventricle or cardiac failure. There is some controversy about the significance of a fourth heart sound in older persons. Some studies have indicated the common presence of a fourth heart sound in healthy persons 50 years of age or older. During the bedside assessment, the clinician must consider the patient's age, the presence or absence of other abnormal signs, and the intensity of the fourth heart sound. The clinical significance of an audible fourth heart sound is greatly strengthened by the presence of its palpable correlate. A prominent audible and palpable fourth heart sound is almost always an abnormal finding. Because vigorous atrial contraction is required for its genesis, a fourth heart sound does not occur in patients with atrial fibrillation.

A left ventricular third or fourth heart sound is best heard at the cardiac apex, with the patient in the left lateral recumbent position. Right ventricular third or fourth heart sounds (e.g., from cor pulmonale) are most prominent at the lower left sternal border or occasionally in the epigastrium.

MURMURS

Murmurs result from turbulence associated with blood flow. Such turbulence within the heart can result from normal flow (e.g., functional murmur) or from increased blood flow across a normal valve (e.g., atrial septal defect). Alternatively, the turbulence can result from a stenotic or incompetent cardiac valve or directly from an abnormal communication within the heart (Table 64.2). At the bedside, the resultant murmurs should be characterized by their timing, duration, pitch, configuration, intensity, location, and radiation. By convention, a I to VI grading system is used to denote a murmur's intensity; the faintest murmurs are grade I. Murmurs of grade IV or more in intensity have associated thrills (i.e., are palpable). Grade VI murmurs can be heard with the stethoscope removed from the chest surface. Selected murmurs are described in the following paragraphs to illustrate these principles.

Diastolic	Increased flow across aortic or pulmonic valve (e.g., secondary to aortic regurgitation or atrial septal defect) Aortic valve leaflet sclerosis (e.g., in elderly patients) Aortic or pulmonic insufficiency (aortic valve sclerosis, subaortic, supravalvular) Stenosis of aortic root or proximal pulmonary artery Papillary muscle dysfunction
Holosystolic	Mitral or tricuspid regurgitation Ventricular septal defect
Late Systolic	Mitral or tricuspid valve prolapse Papillary muscle dysfunction
Early Diastolic	Aortic or pulmonic valve insufficiency
Mitral Stenosis	Mitral or tricuspid stenosis Increased flow across mitral or tricuspid valve (e.g., secondary to aortic regurgitation or atrial septal defect)
Physiologic	Mitral stenosis (with sinus rhythm)
Conduction System Abnormalities	Bundle branch block Coronary artery disease Prolonged QT interval Atrioventricular fistula

TABLE 64.2. EXAMPLES OF MAJOR HEART MURMURS

The ejection murmur is typically middle- to high-pitched, has a crescendo–decrescendo configuration, and begins shortly after the first heart sound. A common example is the functional ejection murmur occurring in the absence of cardiac disease (Fig. 64.2A). Typically heard best at the left sternal border, it is soft, short in duration, and unaccompanied by other abnormal signs.

The ejection murmur of aortic or pulmonic valve stenosis (particularly if congenital in origin) often begins with a discrete high-frequency ejection sound (Fig. 64.1A). The pulmonic stenosis murmur is most prominent at the left sternal border, but the aortic stenosis murmur is typically heard best at the second right intercostal space, with radiation to the neck. However, the aortic stenosis murmur can be equally or more prominent at the cardiac apex. Although the harsh murmur of severe aortic stenosis is often pronounced enough to result in a thrill, the murmur's intensity is not a consistently reliable guide to the severity of the valve obstruction. The duration of the murmur (particularly the duration to maximal intensity) is more directly related to the degree of stenosis of the aortic or pulmonic valve.

The ejection murmur of hypertrophic cardiomyopathy differs in several respects from that of valvular aortic stenosis. It is typically more midsystolic in onset and may vary in intensity and duration (Fig. 64.1C). It is heard best at the left sternal border, lower than valvular aortic stenosis. Consistent with the subvalvular site of obstruction, it is not accompanied by an ejection sound. Maneuvers that reduce ventricular filling, such as prompt standing or the Valsalva maneuver, increase the duration and intensity of the murmur.

Systolic murmurs from atrioventricular valve regurgitation are also heard best with the diaphragm of the stethoscope but, in contrast to ejection murmurs, are typically plateau in configuration. Some are harsh and can have a honking quality. Although classically holosystolic, regurgitant murmurs can be confined to early, middle, or late systole, depending on the mechanism and amount of the regurgitation. The murmur of mitral valve prolapse, for example, is characteristically late systolic, with its onset after a midsystolic click. On prompt standing or Valsalva maneuver, the click moves toward the first heart sound, and the murmur becomes longer. Regurgitation secondary to papillary muscle dysfunction is often confined to middle or late systole (Fig. 64.1D). The murmur of severe acute mitral regurgitation can be nonholosystolic and can resemble an ejection murmur in quality.

The murmur of mitral valve regurgitation is heard best at the lower left sternal border or cardiac apex, typically with radiation to the axilla. Sometimes the murmur radiates to the back or to the lower left sternal border or even the base of the heart, depending on the direction of the regurgitation jet. The murmur of tricuspid regurgitation is detected at the left sternal border. Like most right-sided murmurs, its intensity is often increased during inspiration, although this characteristic may be lost in the presence of advanced right ventricular failure. Tricuspid regurgitation murmurs are often nonholosystolic.

Uncomplicated ventricular septal defect also results in a holosystolic murmur. It is typically heard best along the left sternal border at the third or fourth interspace. Distinction from mitral regurgitation is based on the murmur's location and radiation, as well as ancillary findings. In the presence of pulmonary arterial hypertension and resultant right-to-left shunting, the murmur associated with a ventricular septal defect becomes shorter and can assume an ejection quality.

The important diastolic murmurs result from aortic or pulmonic insufficiency and from mitral or tricuspid stenosis. The insufficiency murmurs are high-pitched, decrescendo sounds and are most prominent at the left sternal border (Fig. 64.1B). Because pulmonic and aortic insufficiency murmurs are similar in location and quality, they often must be discriminated by associated findings, such as the blood pressure, character of the arterial pulse, and palpation of the ventricles. Faint aortic regurgitation murmurs may be heard only with the patient in the sitting position, leaning forward. Generally, the duration of the aortic regurgitation murmur is related to the severity of the regurgitation. This association is lost in especially severe regurgitation and with the onset of congestive heart failure. In some patients with severe aortic regurgitation, a low-pitched diastolic murmur (Austin Flint murmur) simulating mitral stenosis can be heard at the cardiac apex.

Mitral or tricuspid stenosis produces a low-pitched rumbling diastolic murmur. The initial component of the murmur occurs in early diastole, during the rapid filling phase of the ventricle. If the patient has sinus rhythm, the murmur recurs or its intensity increases in late diastole as the valvular gradient is increased by atrial contraction (Fig. 64.2C). In some patients, only this presystolic component can be readily detected. The rumble of mitral stenosis is best detected with the patient in

the left lateral recumbent position. The rumble of tricuspid stenosis is best heard at the left sternal border.

Murmurs that extend uninterrupted through the second heart sound are called *continuous murmurs*. They can arise in blood vessels (e.g., patent ductus arteriosus, arteriovenous fistula) or, less commonly, in the heart (e.g., ruptured sinus of Valsalva aneurysm). The innocent or cervical venous hum is another continuous murmur, occurring primarily in children but also in older persons during hyperkinetic states such as anemia. Its correct identification is important because it can be confused with patent ductus arteriosus. The hum is heard with the stethoscope bell applied to the right supraclavicular fossa while the patient is in the sitting position. Manual pressure applied to the jugular vein or assumption of the recumbent position attenuates the murmur.

A pericardial friction rub typically has a scratchy, grating quality and is heard best with the stethoscope diaphragm. It consists of a prominent systolic component and one or two diastolic components. At times, only the systolic component can be detected. In a given patient, the number, duration, and intensity of the components can vary considerably over time. The rub is often most prominent at the left sternal border and may be easier to detect with the patient in the sitting position, leaning forward.

CHAPTER 65: APPROACH TO THE PATIENT WITH CHEST PAIN

ELIZABETH G. NABEL

[Chest Pain Due to Cardiac Disease](#)
[Nonischemic Cardiovascular Chest Pain](#)
[Chest Pain Due to Gastrointestinal Disorders](#)
[Chest Wall and Cervical Spine Disorders](#)
[Anxiety-Related Chest Pain](#)
[Evaluation of the Patient with Chest Pain](#)
[Treatment](#)
[Management of Chest Pain Due to Myocardial Ischemia](#)

Chest pain is a common symptom that can result from a number of causes ([Table 65.1](#)). It may denote serious or even life-threatening disease; on the other hand, it may result from a disorder that is in no way dangerous but is nonetheless disabling because of the patient's concern and anxiety about the discomfort. In either case, identifying the correct etiology requires a thorough understanding of the patient's discomfort and the disorders that can cause chest pain. This includes careful characterization of the chest pain: its manner of onset (sudden or gradual), precipitating factors (e.g., exertion, position, inspiration, food), its character (visceral, pleuritic, superficial), its radiation, any associated symptoms (e.g., dyspnea, nausea), and duration.

Cardiac disease
Angina pectoris
Myocardial infarction
Pulmonary hypertension
Pericarditis
Mitral valve prolapse
Dissection of the aorta
Pulmonary disease

Gastrointestinal disorders
Gastroesophageal reflux
Esophageal motor disorder (spasm)
Biliary colic/cholecystitis
Liver disease
Anxiety/hyperventilation

TABLE 65.1. CAUSES OF CHEST PAIN

Often the diagnosis is strongly suggested by the history and physical findings, but the physician must also appreciate the limitations of the bedside evaluation. Some patients have difficulty describing their symptoms, and some may minimize or exaggerate their discomfort because of denial or secondary gain, respectively. Moreover, the underlying disorders often do not present in a classic manner but rather are atypical in one or more of their characteristics. With some types of chest pain, such as angina pectoris, the physical examination in the resting state may be entirely normal.

This chapter provides an overview of the disorders that commonly must be considered in a patient with chest pain, along with an approach to the patient with this common symptom. The specific causes and their evaluation and treatment are detailed in other chapters.

CHEST PAIN DUE TO CARDIAC DISEASE

ANGINA PECTORIS

Angina pectoris is typically described as a substernal chest discomfort perceived as a tightness, heaviness, pressure, or burning sensation. It is characteristically nonfocal; that is, the patient does not indicate the location with one finger. The discomfort may radiate to the left shoulder or the arms, or to the neck and jaw. Some patients describe their angina in more atypical terms, such as sharp; a “gas pain”; discomfort in the jaw, teeth, forearms, or back; or discomfort beginning in the epigastric region and radiating up into the chest. Some patients describe it as shortness of breath with no definite discomfort, a symptom called angina-equivalent dyspnea.

Angina results when myocardial oxygen demand is increased to levels that cannot be met through coronary blood flow, usually because of stenotic atherosclerotic lesions in one or more of the epicardial coronary vessels. Accordingly, angina is typically brought on by physical exertion or emotional stress. Most patients with stable angina can identify specific activities or situations that predictably elicit the discomfort; walking up an incline and hurrying are common examples. Some variability in the effort threshold is not uncommon. Activity done in cold weather, after meals, or early in the morning may also be more likely to evoke angina. Some patients report that activity with their arms above their heads is more likely to produce the discomfort. The variable effort threshold for angina in some patients suggests that dynamic alterations in coronary blood flow (e.g., because of an intermittent increase in coronary vasomotor tone) contribute to fixed atherosclerotic stenosis in limiting blood flow. Episodes of stable angina usually begin gradually and last for 2 to 10 minutes. Discomfort is usually relieved promptly by rest or sublingual nitroglycerin.

Stress-induced angina also occurs in some patients with severe aortic valvular stenosis, left ventricular hypertrophy, or pulmonary arterial hypertension in the absence of significant coronary artery stenoses. In these situations, even normal coronary blood flow may be inadequate to meet the heightened myocardial oxygen demand. Angina may also develop in persons with very dilated left ventricles, particularly when accompanied by reduced diastolic coronary perfusion pressure, as in advanced aortic regurgitation.

Angina pectoris that has recently progressed or spontaneously increased in severity, frequency, or duration—particularly if accompanied by rest pain—is considered unstable angina. Patients with the recent onset of angina, particularly if it occurs at low levels of activity or at rest, are also included in this category. Most unstable angina patients have underlying obstructive coronary disease; the unpredictable onset of symptoms or conversion from a stable to an unstable pattern usually results from atherosclerotic plaque fissuring with superimposed platelet- or fibrin-rich thrombi. An unstable pattern can also be precipitated by extracoronary factors (secondary unstable angina). Severe anemia or carbon monoxide exposure, for example, limits blood's capacity to carry or release oxygen and can result in angina under conditions that a patient with coronary disease might otherwise tolerate well. Uncontrolled systemic arterial hypertension, rapid dysrhythmias, or hypoxemia due to pulmonary disease can also provoke angina, as can hyperthyroidism.

Prinzmetal's angina is similar in character and location to stable angina and often responds to nitroglycerin. It characteristically occurs at rest, however, without obvious provocation or a preceding increase in heart rate or blood pressure. These features are explained by its underlying mechanism: transient coronary artery spasm. Often, the episodes occur in the early morning. Some patients with Prinzmetal's angina report other vasomotor-related symptoms such as migraine headache or Raynaud's phenomenon.

ACUTE MYOCARDIAL INFARCTION

Typically, the chest pain of acute myocardial infarction (MI) is severe and prolonged (more than 30 minutes) and is unrelieved by sublingual nitroglycerin. It is often accompanied by nausea and diaphoresis. In some patients, the infarction symptoms are precipitated by vigorous exertion or other stresses that markedly increase myocardial oxygen demand. Commonly, however, acute MI occurs at rest or during normal activities. Some patients, in retrospect, describe crescendo angina before the infarction, but many do not, and MI is often the patient's first clinical feature of coronary heart disease.

The abrupt and unpredictable onset of symptoms arises from underlying acute thrombosis at the site of an ulcerated atherosclerotic plaque. These changes can occur

in atherosclerotic lesions that were nonobstructive before the acute event.

Although the features of infarction pain described earlier are characteristic, they are not always present. Indeed, patients vary considerably in the intensity of the acute symptoms. As many as 30% of patients do not seek medical attention, either because the symptoms are atypical or mild or because there are no symptoms (silent infarction). Silent and atypical infarctions appear to be more prevalent in patients with diabetes mellitus and in the elderly.

NONISCHEMIC CARDIOVASCULAR CHEST PAIN

The pain of pericarditis is typically sharp and commonly involves the substernal or precordial area, with radiation to the neck, left shoulder, or trapezius ridge. Pericarditis can also result in a steadier, oppressive substernal discomfort that can be difficult to distinguish from that due to myocardial ischemia. Precordial pain is often worsened by inspiration and by the recumbent position. It is lessened by leaning forward while in the sitting position. The pain of acute aortic dissection is characteristically sudden in onset, intense (reaching peak intensity almost immediately), and prolonged; depending on the site of the dissection, the pain may radiate to the back. It may be "tearing" in quality, and patients often state that it is the worst pain they have ever experienced. A history of hypertension is usually present, unless the patient has Marfan's syndrome or idiopathic cystic medial necrosis.

The atypical discomforts that may occur in patients with mitral valve prolapse have variable characteristics. They may be precordial, fleeting, and unpredictable, without a clear-cut relation to physical effort. The pain is often sharp or like a pin prick, but some patients report substernal discomfort that lasts for hours. In some cases, the autonomic dysfunction that can be associated with mitral valve prolapse may contribute to some of the atypical symptoms.

CHEST PAIN DUE TO GASTROINTESTINAL DISORDERS

Gastroesophageal reflux is a particularly common cause of visceral discomfort in the substernal and epigastric areas. It can result in a diffuse burning sensation or the feeling that warm fluid is climbing toward the throat. Some patients report an epigastric pressure sensation. Reflux (as well as primary esophageal motor disorders) can also be associated with frank esophageal spasm with substernal discomfort that is similar in character to that of angina pectoris and that may radiate to the throat and left arm. It may also be relieved by the smooth-muscle relaxant action of sublingual nitroglycerin. Chest pain due to reflux is typically provoked by eating large meals, assuming the recumbent position after eating, bending forward, or straining. However, reflux can be provoked by exercise in some patients. It may be improved by standing upright, drinking water, belching, or taking antacids. Patients with reflux may also experience dysphagia, and some report nocturnal wheezing or coughing due to regurgitation into the bronchi.

Although typically localized in the epigastrium, the pain of peptic ulcer disease may radiate to the back and occasionally to the substernal area. Peptic ulcer discomfort is classically described as gnawing, aching, or dull, and is usually relieved by food or antacids. Discomfort also occurs at night, but early-morning pain before breakfast is unexpected. In some ulcer patients, discomfort is precipitated by eating.

Biliary colic associated with gallstones leads to episodic steady discomfort that usually is sudden, aching, or pressure-like, and is maximal in the epigastrium or right upper quadrant. Radiation to the scapular area is common. Discomfort may persist for 1 hour to several hours before subsiding, and may be followed by a more prolonged uncomfortable sensation or tenderness in the right subcostal area. Nausea and vomiting may accompany the episode.

The discomfort from pancreatitis, although usually localized to the epigastric or periumbilical areas, can radiate to the chest and back, as well as to the flank and lower abdomen. The discomfort is constant and often severe and may be worsened by the supine position. Nausea and vomiting are usually present.

CHEST WALL AND CERVICAL SPINE DISORDERS

The anterior chest discomfort of costochondritis can be either sharp and brief, or a dull ache lasting for hours to days. Localized muscle spasm can contribute to the discomfort. Costochondritis discomfort is usually worsened by chest movement or deep inspiration. Occasionally, the inflammation results in obvious swelling of the tender costochondral junction (Tietze's syndrome). Careful inquiry may reveal recent minor trauma or a new or unusual activity as the cause of chest wall discomfort.

Discomfort from cervical spine disease is usually localized to the neck and back of the head. Because it can radiate to the shoulder and arm, however, it can occasionally be confused with angina pectoris. When cervical radiculitis is present, the patient may report constant aching discomfort in the arm, and there is often a sensory deficit and paresthesias. Weakness may also result. Discomfort may be elicited by movement of the neck, and the neck motion is limited. Bursitis and thoracic outlet syndromes (e.g., neurovascular compression by a cervical rib or scalenus anterior muscle) are additional causes of shoulder pain. Discomfort from these disorders is often elicited by shoulder motion or certain positions rather than exertion itself. Paresthesias may be reported as well.

In its prevesicular phase, herpes zoster involving the left chest can mimic cardiac discomfort. The correct diagnosis is supported by its bandlike dermatome location, its persistence, and the subsequent development of vesicles.

PULMONARY CAUSES OF CHEST PAIN

The discomfort accompanying many pulmonary disorders arises from inflammation of adjacent pleural surfaces. Pleural discomfort usually is sharp or catchlike, and is often unilateral. When the diaphragmatic pleura is involved, the discomfort may radiate to the shoulder. The most important characteristic of pleural pain is its exacerbation by deep inspiration or cough. Movement of the torso may increase its intensity. Associated fever and productive cough suggest pneumonia as the cause. Spontaneous pneumothorax produces an abrupt onset of chest pain with dyspnea. Pulmonary infarction secondary to embolism is another cause of pleuritic pain and may be accompanied by hemoptysis. Massive pulmonary embolism can also lead to central chest pain, similar in character to myocardial ischemia. The combination of chest pain and hemoptysis can also suggest a lung neoplasm.

ANXIETY-RELATED CHEST PAIN

Anxiety-related chest pain can take several forms. Often focal and precordial in location, it may be a constant ache, present for hours or longer. It can also be an unpredictable fleeting or jabbing pain, unrelated to effort. Chest tenderness may accompany the discomfort. Palpitations and somatic complaints are common. Careful inquiry often elicits a relation to emotional stress and other symptoms, such as hyperventilation, characteristic of anxiety states. This chest pain may be partially and variably responsive to several therapeutic measures.

EVALUATION OF THE PATIENT WITH CHEST PAIN

HISTORY AND PHYSICAL EXAMINATION

For the patient with chest pain, the urgency of the evaluation and the decision to perform it in an ambulatory or hospital setting are determined by several factors, including the acuity and severity of the symptoms and findings. When acute chest pain is accompanied by marked dyspnea, hypotension, agitation, or profuse diaphoresis, the diagnostic possibilities may include acute MI, pulmonary embolus, dissecting aneurysm, pericardial tamponade, and pneumothorax; clearly, emergent evaluation is required. Independent of the intensity of the initial symptoms, the physician must also determine if the underlying cause of the chest pain has the potential to progress to a serious or life-threatening state. Discomfort that is not perceived by the patient as severe or that has resolved by the time of presentation can nonetheless represent a serious or unstable condition (e.g., unstable angina). In other cases, particularly when the chest discomfort has occurred episodically over a longer period of time, is not severe, and is not accompanied by acute physical findings or ECG changes, the evaluation may be performed in a more elective manner.

When the characteristics of the chest discomfort are typical, its cause may be strongly suggested by the history. The history, coupled with a careful physical examination, can shorten the list of possible diagnoses or rule out the more serious causes of chest discomfort. The general history and physical examination may also reveal conditions that place the patient at enhanced risk for specific causes of chest discomfort; identification of the classic features of Marfan's syndrome, for example, can suggest the possibility of aortic dissection as a cause of chest pain. The presence of risk factors such as hypertension, cigarette smoking, diabetes mellitus, hypercholesterolemia, or a family history of premature coronary heart disease heightens the risk of coronary heart disease. Risk factors are just that, however; their presence does not prove the diagnosis, nor does their absence exclude it. A patient may also have more than one disorder that can cause chest

discomfort. Gastroesophageal reflux and coronary disease often coexist, for example. Also, the stresses associated with one illness (e.g., cholecystitis) may provoke another cause of discomfort, such as angina pectoris in a person with previously unrecognized coronary heart disease.

When chest pain results from musculoskeletal causes, the discomfort may be reproduced by palpation or localized movement. Tenderness on palpation of the epigastrium or right upper quadrant may be present in patients with peptic ulcer or gallbladder disease. Localized chest findings, such as signs of lung consolidation or collapse, pleural rub, or rales, can indicate a pulmonary cause for chest discomfort.

In patients with angina pectoris, the physical examination between episodes of discomfort may be normal. Examination during an episode of angina can help in its recognition. Often, the heart rate and blood pressure are increased during the episode. In some patients, however, the blood pressure may fall, particularly if a large amount of myocardium is rendered ischemic. An audible (and often palpable) fourth heart sound is commonly present, attesting to reduction of ventricular compliance. Some patients develop transient murmurs of mitral regurgitation as a consequence of ischemia-induced papillary muscle dysfunction. The physical examination, of course, is also central in the identification of other disorders, such as aortic stenosis, pulmonary arterial hypertension, or severe systemic arterial hypertension, that can cause or exacerbate anginal chest discomfort.

Physical examination during the early stages of acute MI commonly reveals an obviously distressed patient. The skin may be cool, with diaphoresis. In the absence of a complication, the blood pressure and heart rate are often increased. In patients with acute inferior infarction, bradycardia and hypotension may develop during the early stages due to systemic vagotonia (Bezold—Jarisch reflex). In other patients with acute infarction, the blood pressure may be low because extensive infarction has resulted in cardiac failure. In this case, the heart rate is characteristically increased, unless there is an associated conduction disturbance. Precordial palpation may reveal an apical late systolic bulge, as well as the palpable correlate of a fourth heart sound. An audible fourth heart sound is present in almost all patients with acute infarction, if sinus rhythm is present. An apical systolic murmur, representing mitral regurgitation from papillary muscle dysfunction, is also often evident. In some patients, a friction rub from inflammation of the adjacent pericardium is transiently or intermittently present.

The detection of a new aortic regurgitation murmur in a susceptible patient with severe chest pain can suggest acute proximal aortic dissection. Neurologic defects or asymmetry of the arterial pulses, due to vessel occlusion or compromise, can also occur. Detection of a two- or three-component pericardial friction rub is pathognomonic of pericarditis, although pericarditis can also follow acute MI. Pericardial friction rubs can vary in intensity, and their recognition can be more difficult if only one component is clearly audible. Particularly when the history or physical findings suggest pericarditis, the examination must include a careful search for elevated jugular pressure and paradoxical pulse, which can indicate cardiac tamponade.

LABORATORY STUDIES

For most patients with chest pain, the initial evaluation includes an ECG and chest radiographs. An immediate ECG in any patient with prolonged or severe chest pain is especially important, as it may serve to identify candidates for thrombolytic therapy or emergent angioplasty. The need for and timing of additional laboratory studies are based on the tentative diagnoses derived from the history and physical examination. If, for example, gastroesophageal reflux is suspected, a trial of medical therapy may be chosen, assuming there are no indications or risk factors of advanced disease or complications (e.g., bleeding, dysphagia). If the picture is less clear-cut, if complications are suspected, or if the patient does not respond readily to treatment, then radiographic or endoscopic studies are obtained to confirm the diagnosis and assess its severity. If the diagnostic possibilities include both angina pectoris and a gastrointestinal disorder, the former should be evaluated first before proceeding with procedures such as endoscopy or esophageal studies. If gallstone disease is suspected, the laboratory evaluation initially includes abdominal ultrasonography as well as a blood leukocyte count and standard liver function tests.

Arterial blood gas analysis, ventilation–perfusion scanning, or angiography is required to confirm a tentative diagnosis of pulmonary embolus. If aortic dissection is present, the chest radiograph may demonstrate widening of the mediastinum, but this finding is nonspecific. If the clinical features suggest aortic dissection, an imaging study should be obtained promptly. Emergent transesophageal echocardiography, computed tomography with contrast enhancement, or magnetic resonance imaging can be used. If readily available, transesophageal echocardiography is the study of choice. Aortography may be required to confirm the extent of the arterial disease and to assess coexistent coronary disease.

In a patient with pericarditis, the ECG typically demonstrates a widespread current of injury (ST-segment elevation), and there may be depression of the PR segment. Sinus tachycardia is usually present. An echocardiogram is indicated when pericarditis is suspected; detection of a pericardial effusion supports the diagnosis. Sometimes the echocardiogram can provide information about the underlying cause of the pericarditis and may demonstrate signs (e.g., right ventricular systolic collapse) indicating the hemodynamic effects of the associated effusion. If a diagnosis of pericarditis is made, the laboratory investigation then focuses on the underlying cause. Depending on the clinical situation, this may include skin testing with purified protein derivative, serologic testing for histoplasmosis, analysis of renal function, blood cultures, and blood tests to exclude a systemic inflammatory state, such as lupus erythematosus. Metastatic neoplasm is also included in the list of possible causes in many cases.

EVALUATION OF ISCHEMIC CARDIAC PAIN

Typical chest discomfort that occurs with exercise or emotion and that is relieved by rest or nitroglycerin is presumptive evidence that the patient is experiencing angina. The ECG can aid in its diagnosis and provide information about the myocardial location of the ischemia underlying the angina. Between episodes of discomfort, however, the ECG may be normal, demonstrate nonspecific changes, or show signs of prior infarction. Diagnostically, the ECG is most valuable when it is obtained during an episode of chest discomfort. Typically but not invariably, angina is accompanied by transient ST-segment depression, T-wave inversion, or both. Less commonly, angina may lead to transient normalization of previously depressed ST segments or T waves or to the development of negative U waves. Transient myocardial ischemia also sometimes results in ST-segment elevation, generally indicating substantial (transmural) ischemia. Transient ST-segment elevation is characteristically present in patients with Prinzmetal's angina.

Exercise testing is usually recommended for patients with suspected angina, provided the symptoms are stable. (Exercise testing is contraindicated in the unstable patient until stabilization has been accomplished.) Beyond providing objective signs of ischemia, the exercise study is helpful in establishing the patient's functional capacity, and it may reveal signs suggesting advanced disease or high-risk state. It may also disclose hypertensive or hyperkinetic responses to exertion, responses that can influence the choice of antianginal medications. The selection of a standard exercise ECG or exercise imaging (e.g., by nuclear medicine or echocardiographic techniques) is based on several factors, including the baseline ECG pattern, concomitant medications, and the estimated pretest likelihood of coronary disease (Table 65.2). Imaging techniques are usually recommended for women (in whom false-positive ECG changes are more common), patients with atypical symptoms (in whom the predictability of exercise testing is reduced because of lower pretest likelihood of disease), and patients with an abnormal resting ECG or hyperventilation-induced ECG changes.

Test	Comment
Exercise electrocardiography	Useful for risk stratification; can aid in selection of treatment regimen
Exercise imaging study (e.g., thallium perfusion or echocardiography)	Particularly valuable if baseline ECG abnormal or hyperventilation-induced ECG changes
Pharmacologic study (e.g., dipyridole thallium or dobutamine echocardiography)	Particularly helpful for patients who cannot exercise (e.g., due to orthopedic problems)

TABLE 65.2. STRESS TESTING IN PATIENTS WITH STABLE ANGINA PECTORIS

For patients with angina, particularly those with historical or ECG evidence of prior infarction, left ventricular function is a major determinant of prognosis and can

influence the selection of bypass surgery. Left ventricular function can be assessed noninvasively by echocardiography or radionuclide ventriculography.

Coronary arteriography is the definitive way to detect the presence and extent of coronary stenosis. Coronary arteriography may be required for diagnosis in patients whose clinical features and noninvasive test results are inconclusive. Cardiac catheterization is recommended for angina patients when revascularization is contemplated because of refractory symptoms, reduced functional capacity, or the presence of signs during exercise testing suggesting advanced disease or high-risk state. The patient's age and left ventricular function also influence this decision. The guidelines for the selection of revascularization are discussed in [Chapter 72](#).

Patients with the presumptive diagnosis of unstable angina are a somewhat heterogeneous group with regard to the extent of coronary disease and prognosis. The evaluation and treatment are influenced in part by an estimation of risk (see [Chapter 65](#)). Patients at higher risk include those with prolonged (more than 20 minutes) rest pain, dynamic ECG changes, and associated signs of cardiac failure, hemodynamic instability, or new mitral regurgitation murmur. Up to 20% or so of patients hospitalized with suspected unstable angina may not have obstructive coronary disease.

The ECGs and cardiac enzyme studies, performed serially, help confirm or exclude the diagnosis when acute MI is suspected. As noted previously, an ECG should be obtained immediately to aid in diagnosis and to help identify candidates for thrombolytic therapy. The ECG findings of acute MI are described in [Chapter 72](#) and [Chapter 84](#). The initial ECG findings are often nonspecific and may be subtle. Occasionally, the first ECG is normal. A left bundle-branch pattern can obscure the ECG findings of infarction, and in its presence the diagnosis must usually be made by other means.

The most sensitive and specific standard enzyme tests for acute MI are troponin and the MB isoenzyme of creatine kinase. In the first few hours after the onset of pain, the initial troponin and MB values may be normal. Enzyme levels then characteristically rise. Troponin may stay elevated for several days, while the MB isoenzyme falls, usually returning to normal within a few days. Elevated serum levels of troponins may precede elevations of creatine kinase MB and may remain elevated longer. Skeletal muscle injury does not lead to elevated serum troponin levels. Troponin levels are increased in some unstable angina patients and may provide prognostic information.

The blood lactate dehydrogenase level and its isoenzyme pattern may be helpful in the patient who presents several days after suspected infarction. Lactate dehydrogenase activity generally peaks 3 to 6 days after the onset of pain and may remain abnormal for several days after that. Late presentation of acute MI is more commonly detected by persistent elevation of troponin.

Echocardiography is also performed in patients with suspected acute MI. In addition to confirming the presence and location of a segmental wall motion abnormality, the echocardiogram can provide prognostic information by estimating the infarct size and global ventricular function. Some of the complications of acute infarction can also be recognized or confirmed.

TREATMENT

The treatment of the patient with chest pain is determined by its cause.

Patients with reflux are instructed to avoid large meals and postprandial recumbency and to limit ingestion of caffeine and ethanol. Abstinence from smoking is also important. Elevating the head of the bed is often beneficial. Treatment can include antacids and drugs, such as the H₂-receptor blockers that decrease gastric acid secretion.

If recurrent cholecystitis is present, elective surgical therapy is usually recommended. Nonsurgical alternatives are available for some patients with gallstone disease.

For the patient with costochondritis or other chest wall pains, analgesic or nonsteroidal anti-inflammatory drugs and reassurance are usually effective. Occasionally, it is necessary to inject the involved area with local anesthetic.

When pleuritic chest pain is the result of pneumonia, the treatment focuses on the underlying infection. Anti-inflammatory agents such as indomethacin may help control associated pleural discomfort.

When chest pain is due to pulmonary embolus, anticoagulation with heparin is promptly performed. Distinguishing the pleural pain associated with pulmonary embolus from the discomfort of pericarditis is important, as anticoagulation is generally contraindicated in patients with acute pericarditis because of the risk of hemorrhage into the pericardial sac, leading to tamponade. The specific treatment of pericarditis depends on its cause. If tuberculous, fungal, neoplastic, and bacterial causes can be excluded, anti-inflammatory therapy is usually used for presumed idiopathic or postviral pericarditis. Commonly, this begins with salicylates or nonsteroidal anti-inflammatory drugs. Corticosteroid therapy may be required for patients who do not tolerate or respond to the nonsteroidal anti-inflammatory agents.

MANAGEMENT OF CHEST PAIN DUE TO MYOCARDIAL ISCHEMIA

The medical management of the patient with stable angina is not limited to the use of drugs. The patient is instructed to avoid activities that predictably elicit angina and cautioned about exertion after meals or in cold weather. He or she should be encouraged to remain active otherwise, including, if possible, a walking or bicycle exercise program to enhance conditioning. The instruction should include the proper use of sublingual nitroglycerin, including its prophylactic use before necessary activities that the patient thinks might induce discomfort. The patient should also understand the warning signs of progressive angina and the importance of promptly seeking medical evaluation should they occur. This includes angina that is not relieved by two or three nitroglycerin tablets each taken 5 minutes apart. All the preceding should be done compassionately, with appropriate reassurance and care to avoid inducing undue anxiety and incapacitation. Treatment should also include efforts to correct underlying risk factors, such as smoking, systemic arterial hypertension, hypercholesterolemia, and overweight habitus. Aspirin should also be taken daily.

The medicines designed to prevent recurrent episodes of angina fall into three general categories: long-acting nitrates, b-adrenergic blocking drugs, and calcium channel antagonists. There is no universally accepted optimal drug regimen; rather, the choice of regimen is a matter of clinical judgment and is based on several factors, including the pattern and severity of the angina; the pretreatment heart rate, blood pressure, and ventricular function; and the presence or absence of extracardiac disorders that would enhance the likelihood of side effects with a specific agent. The patient's age and occupation can influence the choice. If the angina is mild and infrequent, a single drug, commonly a nitrate or b-blocker, may be chosen. For patients with a significant degree of angina, however, initial therapy often includes both agents, assuming there is no contraindication to their use.

The antianginal effectiveness of the calcium antagonists appears to be comparable to that of the b-adrenergic blocking drugs. They provide an alternative if the latter are not tolerated or are contraindicated by bronchospastic lung disease. Calcium antagonists also play a front-line role when the clinical characteristics (variable anginal threshold) suggest that vasomotor changes play a prominent role in the angina. This is particularly true for Prinzmetal's angina. Calcium antagonists can also be added to the regimen of patients with exertional angina when symptoms are not effectively controlled by nitrates and b-blockers. The major calcium channel antagonists differ in the degree to which they systematically vasodilate and affect the heart's electrical and contractile functions. Calcium channel drugs are described further in [Chapter 90](#).

Reperfusion therapy with percutaneous angioplasty or coronary bypass surgery is considered for angina patients with refractory symptoms or an unacceptable lifestyle. Surgery is also usually recommended for patients with high-risk angiographic findings, such as obstruction of the left main coronary artery or triple-vessel coronary disease with inducible cardiac ischemia or associated left ventricular dysfunction. In diabetic patients, coronary artery bypass graft is recommended for three-vessel disease and normal left ventricular dysfunction.

Patients with unstable angina and rest pain should be hospitalized in a monitored cardiac unit. In some cases, acute MI must be excluded. Treatment typically includes aspirin and continuous therapeutic heparin infusion, along with antianginal medications as described above. If the episodes prompting admission are severe or prolonged, nitroglycerin is often given initially as an intravenous infusion.

The hospitalized patient with recurrent unstable angina despite medical therapy is at particularly high risk. Cardiac catheterization is indicated for consideration of coronary angioplasty or bypass surgery. Patients with hemodynamic instability and refractory symptoms may benefit from intra-aortic balloon counterpulsation before

coronary arteriography.

The symptoms of most hospitalized patients stabilize with medical therapy. If angina recurs as activity is increased or if there are symptoms or signs of ischemia on an exercise study, then coronary arteriography is recommended. Even for patients whose symptoms stabilize in the hospital, coronary arteriography is commonly recommended, if there are no other life-threatening medical illnesses and if the patient's age is not very advanced. The decision to perform revascularization can be influenced by several factors, including the response to medical therapy and the severity of the underlying coronary disease.

The treatment of patients with acute MI and its complications are described in [Chapter 73](#), and several points about the early approach to the patient warrant emphasis here also. The most important step is consideration of reperfusion of the infarct-related artery. Early restoration or maintenance of perfusion of the infarct-related coronary artery is critical. Current approaches include intravenous thrombolytic therapy or immediate (primary) angioplasty. Myocardial necrosis occurs progressively after coronary occlusion; patients must be assessed rapidly as candidates for treatment. This includes excluding patients at prohibitive risk for a thrombolytic complication (e.g., bleeding, stroke). Candidates for thrombolytic treatment generally include patients with ongoing acute infarction who present within 12 hours of symptom onset and have associated ST-segment elevation (current of injury) or new (or presumably new) left bundle-branch pattern along with no contraindications (See [Chapter 73](#) for detailed inclusion and exclusion criteria and a discussion of thrombolytic agent and adjunctive therapy). Aspirin and heparin are also used in the early treatment of patients (e.g., those with non-Q-wave infarction) who do not meet current ECG inclusion criteria for thrombolytic therapy.

For patients in the coronary care unit, the prompt establishment of intravenous access and continuous ECG monitoring are important, as the risk of life-threatening ventricular dysrhythmias is greatest during the first 6 hours of the infarction process. Other immediate measures include oxygen supplementation, along with nitroglycerin and morphine (administered intravenously) for pain relief. Aspirin is administered for its antiplatelet effect. Control of heart rate and blood pressure is important, as they are major determinants of myocardial oxygen demand. Elevated blood pressure may respond to intravenous infusion of nitroglycerin. Nitroglycerin infusion is also often used empirically (e.g., during the first 24 hours); it may aid in pain relief and provide anti-ischemic and some unloading effects. It is important that the drug not lower blood pressure excessively or lead to a reflex increase in heart rate. Particularly when the blood pressure, heart rate, or both are elevated, cautious intravenous use of a b-adrenergic blocking drug (e.g., metoprolol or atenolol) can be beneficial. However, increased heart rate can be a compensatory response to significant left ventricular dysfunction in some patients. b-Adrenergic blocking therapy should not be used in patients with clinically important heart failure or hypotension. If b-blocking action is indicated but there is concern about precipitating left ventricular failure, a short-acting agent (e.g., esmolol) may be useful. Additional cardiac contraindications to b-blocker use include bradycardia and conduction disturbances (complications particularly common during the acute phase of inferior MI). Hypotension can also be especially prominent if there is associated right ventricular infarction. In the absence of overt pulmonary congestion, fluid administration can be performed with caution.

[Epidemiology and Presentation](#)
[Pathophysiology of Systolic Dysfunction](#)
[Cardiac History](#)
[Physical Examination](#)
[Laboratory Tests](#)
[Strategies for Management](#)
[Chronic Pharmacologic Therapy](#)
[Treatment of Advanced Heart Failure](#)

EPIDEMIOLOGY AND PRESENTATION

Heart failure (HF) is not a disease. It is a wide-ranging clinical expression of left ventricular (LV) dysfunction, occurring as the result of diverse etiologies. That term is now preferred to congestive heart failure, as not all heart failure patients are “congested,” and experts feel that the latter description has limited diagnostic accuracy. Over 500,000 new patients are diagnosed with HF annually in the United States, and this number will likely increase as more patients survive acute myocardial infarction, with progressive LV dysfunction, and as the overall population ages. The goal of therapy is to prevent, or delay, the progression of ventricular dysfunction to advanced stages.

Usually, the clinical manifestations of HF develop in patients with known histories of cardiovascular disease. A history of coronary artery disease or hypertension is common. Heart murmurs also may have been noted in the past. Increasingly, however, the first manifestation of heart disease may be symptoms of HF. In such patients with no history or signs of cardiac involvement, the diagnosis of idiopathic cardiomyopathy often is made. Heart failure is the most common diagnosis leading to hospitalization in patients over age 65. Aging of the myocardium and peripheral vasculature contribute directly to a depression of cardiac performance.

PATHOPHYSIOLOGY OF SYSTOLIC DYSFUNCTION

CARDIAC PUMP FAILURE

Systolic ventricular dysfunction represents failure of the heart as a pump, with loss of systolic power output that subsequently stimulates a cascade of compensatory responses. Systolic ventricular failure can be abrupt in onset, following myocardial infarction, or more insidious in onset, as in idiopathic cardiomyopathy or hypertension. The remodeling process that ensues in response to the inciting myocardial damage involves the contractile proteins, the microvasculature, and the cytoskeletal matrix of collagen, elastin, and other connective tissue elements. Loss of normal ventricular geometry and pumping efficiency further perpetuates the remodeling process but does not predict clinical findings. The presence of a dilated ventricular chamber or a reduced ejection fraction characterizes systolic ventricular dysfunction. The clinical expression of HF can be seen in the presence of normal systolic function. Heart failure with normal systolic function (so-called diastolic HF) is difficult to characterize and is a focus of current studies.

Heart failure is often an insidious process that may remain undetected for many years. To identify the onset and early progression of HF, the best opportunity is within the population of patients with LV dysfunction following acute myocardial infarction. Other processes, such as idiopathic cardiomyopathy or hypertension, do not permit identification of the index event or have a protracted course, so that follow-up of disease progression is difficult. The onset of ventricular dysfunction following acute myocardial infarction is readily linked to its index event. Patients may remain in an asymptomatic state, or rapidly advance to overt congestive HF, by mechanisms that remain obscure. Progression of HF may be secondary to cellular growth factors, abnormal autonomic nervous system activity, activation of hormonal or vasoactive substances, subendocardial ischemia, and mechanical stress factors.

CONDUCTION AND RHYTHM ABNORMALITIES

Conduction abnormalities and cardiac arrhythmias are common in HF. Atrial arrhythmias also occur in the form of premature beats and other atrial arrhythmias. Perhaps the most common atrial arrhythmia in this population is atrial fibrillation. This may occur in acute failure, following an acute myocardial infarction, or at any time during the course of disease progression. Sinus node dysfunction, atrioventricular (AV) junctional block, and intraventricular conduction defects are common and may necessitate permanent pacemaker implantation. Ventricular arrhythmias are common in the HF population. Sudden death accounts for anywhere from 35% to 70% of total mortality. However, not all sudden deaths are due to ventricular tachycardia or fibrillation.

VASCULAR ADAPTATION

A fundamental lesion in HF is the abnormal function of the vasculature. Several mechanisms contribute to vasoconstriction. Clinically relevant information regarding the “myogenic hypothesis,” metabolic and local regulating factors, and regional neurogenic control are not well characterized in HF. Intrinsic structural adaptation of the vasculature in HF likely parallels changes observed in hypertension. Preceding long-term structural changes are abnormalities in ventricular vascular coupling, with an increase of characteristic impedance. These rapid changes occur in a time frame that may be too rapid to be explained by structural changes. When “vasoconstrictor mechanisms” are discussed in congestive HF, this concept generally refers to neurohormonal substances that adversely increase vascular tone.

NEUROHORMONAL MECHANISMS

With progressive ventricular dysfunction, the nervous system, particularly the autonomic nervous system, undergoes an adaptive response that favors augmentation of sympathetic nervous system activity and reduction of parasympathetic activity. Early studies demonstrated increased plasma norepinephrine in HF patients, correlated with reduced cardiac performance and increased mortality. Baroreflex and mechanoreflex abnormalities such as the cold pressor test, tilt, and lower body negative pressure were shown to be abnormal. These abnormalities demonstrated partial correction with successful therapeutic interventions.

Activation of the renin–angiotensin system is one of the predominant abnormalities of HF. Studies in milder and asymptomatic HF demonstrate relatively less activation, but values are increased compared to normal. The degree of activity is intensified in the presence of diuretic therapy. In addition to vasoconstriction, angiotensin II stimulates aldosterone secretion by the adrenal gland, producing sodium retention and potassium excretion at the distal nephron. Renin system components have been identified in the myocardium and vasculature, where they adversely affect fibrosis and remodeling, as well as cellular dysfunction.

There are other important factors. Arginine vasopressin is stimulated in the course of congestive HF. It reduces free water clearance and produces vasoconstriction in regional circulations. Natriuretic peptides are produced by cardiac myocytes in response to increased wall stress. When released in the circulation, natriuretic peptides promote sodium and water excretion, as well as vasodilatation. Eventually, activation of opposing vasoconstrictive and sodium-retentive hormonal substances at later stages of HF overwhelms the favorable effects of natriuretic peptides. More recently, the endothelium has been identified as a source of vasoactive substances, such as nitric oxide, which produces vasodilatation, and endothelin, a potent vasoconstrictor.

EDEMA AND SODIUM RETENTION

Sodium and water retention in HF accounts for many of the symptoms that occur in this population. With reduction of glomerular filtration rate, proximal tubular sodium reabsorption is enhanced, with reduction of sodium delivery to the distal nephron. Reduced distal nephron sodium enhances renin secretion from the juxtaglomerular apparatus. Increased renin system activity favors sodium retention and potassium excretion, as well as stimulating vasopressin release, which increase free water retention. A neural environment that is dominated by increased sympathetic nervous system activity and abnormal baroreceptor function produces further renal vasoconstriction. This cascade of events, producing sodium and water retention, accounts for an increase of “classic” HF symptoms and separates symptomatic HF from asymptomatic HF in patients with comparable reduction of ejection fraction.

CARDIAC HISTORY

The usual reason for a patient's seeking medical attention is breathlessness or fatigue limiting exercise tolerance. Sometimes the first recognized manifestation of HF is orthopnea or paroxysmal nocturnal dyspnea; in other patients, pedal edema may be the first recognized abnormality. Thus, the secondary manifestations of HF (such as circulatory congestion) bring the patient to medical attention, rather than the primary cardiac contractile abnormality.

PHYSICAL EXAMINATION

GENERAL

Asymptomatic patients may not have distinguishing characteristics on general appearance. Patients with chronic HF will have features of chronic disease, such as pallor and general weakness. In more advanced stages of the disease, wasting of limb-girdle and facial muscles is common, and there may be the appearance of overall cachexia. The abdomen may be distended from hepatomegaly and ascites. Long-standing peripheral edema will be associated with darkened skin due to chronic hemosiderin deposition and scarring from chronic skin lesions. Body weight may be misleading in HF. Accumulation of edema may be insidious and balanced by loss of lean body mass, thereby masking fluid retention. Virtually any weight abnormality may be present, and certainly, the presence of obesity will completely obscure any attempt to characterize weight in relation to the severity of HF.

PULSE AND BLOOD PRESSURE

Tachycardia, in the absence of other known causes, represents chronotropic compensation for the reduced cardiac output of pump failure. A 2:1 ratio of apical to radial pulse may reflect pulses alternans, secondary to the severity of HF. Alternatively, a very slow peripheral pulse may represent sinus node dysfunction (structural or secondary to medications) or heart block. An irregular pulse most typically reflects atrial fibrillation. A narrow pulse pressure is consistent with a low stroke volume or inadequate diastolic filling time. Assessment of the carotids and pulses therefore provides information regarding ventricular contraction and the overall circulatory status.

The measurement of systolic and diastolic blood pressure provides important clues to the etiology of HF. If blood pressure exceeds 140/90 mm Hg on repeated measurements, lowering of the blood pressure is mandatory in HF patients. In contrast, many patients with long-standing HF have hypotension, which is accentuated with upright posture ("orthostatic hypotension"). When documented, this should be correlated with symptoms of dizziness and fatigue. In general, most therapies of HF will produce low blood pressure, and may require adjustment, in the setting of symptomatic orthostatic hypotension.

VENOUS SYSTEM

The magnitude of jugular venous distention provides an estimate of cardiac filling pressure and circulatory volume status. It is most convenient to use the right atrium as the reference point for this measurement by taking the midaxillary point at the nipple level. The simplest stress test is the hepatojugular reflux test performed by exerting constant firm pressure over the right upper quadrant of the abdomen. A positive hepatojugular reflux test may be interpreted as evidence for impaired right ventricular response to volume load, a dilated heart that can be compressed by a rising diaphragm, and a volume overload state. An alternate approach to stressing the circulation is leg raising or exercise. In evaluating the peripheral venous system, look for varicose veins or prior surgical scars that may increase the tendency for edema, particularly in an asymmetric fashion. Peripheral pitting edema secondary to HF should be distinguished from the heavy ankles of lipedema. The pitting quality of edema distinguishes it from lymphedema.

LUNGS

Tachypnea is a typical finding of HF and may be present under resting conditions during the physical examination. Dyspnea in the course of a patient interview is a finding of inadequate cardiac compensation. The most characteristic finding on pulmonary examination is the presence of rales, indicative of increased pulmonary capillary pressure and transudation of fluid into the alveolar airspace. In general, rales provide an estimate of the severity of LV decompensation, as the height of the rales in the lung fields is proportionate to the severity of the decompensation. Rales will be obscured by the presence of pleural effusion, which is more often a marker of chronic decompensation.

CARDIAC

Precordial palpation provides valuable information in HF, indicating the extent of cardiac enlargement and providing information regarding the degree of contractile impairment and valvular function. Displacement of the apical impulse away from the midsternal line is typical of HF. A diffuse apical impulse is characteristic of ventricular enlargement, and a heaving quality may indicate ventricular dyskinesis or underlying left atrial lift. The palpation of thrills may provide a clue to the presence of valvular disease. Auscultation of the heart should confirm the abnormalities already identified by observation and palpation. In particular, one is interested in the presence of murmurs or diastolic filling sounds. Mitral regurgitation is common in patients with HF and may result in an apical murmur radiating toward the axilla. Tricuspid regurgitation may also be present on auscultation. An accentuated pulmonic closure sound (P₂) suggests pulmonary hypertension, a fourth heart sound (S₄) indicates abnormal atrioventricular filling characteristics, and a third heart sound (S₃) indicates ventricular dysfunction or decompensation.

LABORATORY TESTS

CHEST ROENTGENOGRAPHY

The chest roentgenogram provides an estimate of ventricular chamber size, but it often serves as a screening technique to identify the presence of heart disease. The cardiothoracic ratio measured on a standard posteroanterior chest film provides an estimate of overall heart enlargement. The degree of LV enlargement is better assessed by lateral or oblique views. In the presence of a high pulmonary capillary pressure secondary to LV failure, pulmonary blood volume often is redistributed to the upper lobes in an upright film, producing the cephalization characteristic of left-sided HF. Pulmonary infiltrates and fibrosis occasionally masquerade as HF.

ELECTROCARDIOGRAM

Prior, or acute, myocardial infarction can be identified by Q waves on the electrocardiogram (ECG). Myocardial hypertrophy almost invariably accompanies HF, so that increased voltage or conduction abnormalities are often present. Left ventricular hypertrophy and cardiomyopathy may present with what appears to be localized loss of electrical forces that may be mistaken for a prior myocardial infarction (see [Chapter 84](#)). Evidence of atrial conduction delay (i.e., prolongation of the PR interval, QRS duration, and QT interval) is common in HF patients. These changes may predispose to cardiac arrhythmias. Both atrial and ventricular dysrhythmias are a common manifestation of HF, and evidence for their existence may be detected on a random ECG. Longer monitoring periods, especially 24-hour Holter monitoring, are likely to detect these arrhythmias.

BLOOD CHEMISTRY

The most important blood studies in the patient with HF are the serum electrolyte and renal function measurements. A low serum sodium concentration indicates a stimulated renin-angiotensin system as well as increased vasopressin, and will be observed in those patients requiring large doses of loop diuretics. A low serum potassium and contraction alkalosis may be observed with diuretic therapy as well. An elevated blood urea nitrogen or serum creatinine suggests either organic or functional renal impairment, due to vasoconstriction, and decreased cardiac output. Liver function abnormalities may suggest hepatic congestion.

VENTRICULAR PERFORMANCE

Ventricular function can be quantitated by imaging techniques, using either echocardiography or radionuclide gated blood pool scanning. An LV ejection fraction below 45% at rest is considered abnormal. Echocardiography also provides information about valve function and regional wall motion. Doppler flow measurements also identify the functional significance of observed stenotic and regurgitant valve lesions, which provides a better global assessment of the impact of HF on cardiac

function, as well as etiologic information.

CARDIAC CATHETERIZATION

Noninvasive methods limit the requirement for contrast determination of LV function at angiography. Coronary angiography is often necessary to clarify etiology. Identification of high-grade coronary artery disease should prompt analysis for revascularization, as ongoing ischemia is a prominent cause for LV dysfunction and HF. Measurement of right heart and pulmonary artery pressures confirms the diagnosis of HF. Right heart catheterization is important when moderate to severe pulmonary hypertension has been suggested by physical examination or noninvasive studies. This procedure is also valuable in the management of complex HF. With quality echocardiography and Doppler studies, right heart catheterization is not required in all patients.

EXERCISE TESTING

Exercise testing can be carried out safely on the patient with HF, and the information obtained from this test is important in diagnostic and therapeutic efforts. An exercise test can be performed either informally in the examining room, by having the patient perform a 6-minute walk test, or formally with the use of a standard stress test using either a bicycle ergometer or a treadmill. The formal test obviously provides more information. Monitoring the ECG during exercise provides additional information that can give a clue to the presence of ischemic heart disease. Performing the stress test while monitoring gas exchange allows more precise assessment of the exercise burden at the point where the patient reaches his or her anaerobic threshold and the peak oxygen consumption that he or she can achieve. Its added value is distinguishing between cardiac, pulmonary, deconditioning, and nonmotivational disability.

STRATEGIES FOR MANAGEMENT

MANAGEMENT OVERVIEW

The goals of treatment for congestive HF are several. These include identification of correctable etiologies and cofactors, prevention of disease progression, maintenance of physical activity, reversal of sodium retention, and reduction of the risk of mortality. Of course, some of these factors can only be achieved or optimized through medical therapy of HF, particularly as the disorder reaches advanced stages. The angiotensin-converting enzyme (ACE) inhibitors are recommended for all stages of HF, not only for treatment but to prevent progression of ventricular dysfunction. Spironolactone, an aldosterone antagonist, has recently been shown to significantly reduce mortality when added to standard therapy. Diuretic therapy is used for the symptomatic and clinical relief of edema, but there are no data that identify a primary role for prevention of disease progression. Most clinicians believe that digoxin is safe and effective. More recently, β -adrenergic blockade has emerged as important therapy of HF, dispelling previous misconceptions regarding lack of benefit or even additive risk. It may be necessary to combine drugs with vasodilator properties to achieve desired end points, such as blood pressure reduction or clinical attenuation of mitral regurgitation. Additional issues include control of rhythm disturbances when possible and anticoagulation therapy when indicated. Parenteral therapy is used for decompensation of HF in order to stabilize a patient who has progressive deterioration.

COMORBIDITIES

The first major issue is ongoing myocardial ischemia or infarction. Progressive transmural or endocardial ischemia, or a new myocardial infarction, can produce abrupt decompensation in a previously stable HF patient. The presence of valvular heart disease should be apparent from the physical examination or echocardiographic evaluation. Mitral regurgitation of any origin produces an adverse effect on myocardial function in an otherwise stable HF patient, particularly since the severity of mitral regurgitation is not correlated with the acoustic properties of the accompanying murmur. In addition, the appearance of a new rhythm disorder, most commonly atrial fibrillation, will produce decompensation. Coexistent hypertension may not receive sufficient management in the presence of coexistent HF. In fact, the presence of a systolic arterial pressure of 140 to 150 mm Hg may erroneously be interpreted as evidence of good ventricular function. Quite contrary to this perception, a systolic blood pressure in the 130 to 140 mm Hg range, or a diastolic blood pressure in the 85 to 100 mm Hg range, requires aggressive blood pressure reduction in an individual with ventricular dysfunction and HF. Additional coexisting medical disorders may trigger decompensation. Insulin-dependent diabetes mellitus, progressive renal dysfunction, and pulmonary disease can adversely influence outcome. Pulmonary embolic events and chronic lung disease are not unusual in the HF patient. Pulmonary and upper respiratory infections are common in patients with stable HF, particularly in fall and winter. Likewise, urinary tract infections are not uncommon in the elderly HF population. These disorders are difficult to differentiate from progressive HF yet may trigger decompensation.

PATIENT DIRECTIVES

It is important to emphasize moderate sodium intake to avoid and/or manage advanced congestive HF. This is defined as 2 to 3 g of sodium (80 to 120 mEq), which is defined as the "normal" sodium requirement in humans and is palatable. Replacement of sodium with salt substitutes, which usually provide excess potassium, is often a suitable option. Weight loss in patients who are above ideal body weight is also a goal in the treatment of HF.

Restriction of physical activity produces deconditioning of skeletal muscle and reflex control of the circulation; therefore, it is not recommended. Low-level exercise is tolerated, even in later stages of HF. If necessary, cardiac exercise testing can be used as a means to recommend the level of exercise permitted during chronic follow-up. Dynamic exercise, including swimming and vigorous walking, should be encouraged within the limits of tolerance. The benefits of exercise probably do not extend to isometric forms of exercise, which increase ventricular afterload.

CHRONIC PHARMACOLOGIC THERAPY

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

The hemodynamic benefits of ACE inhibitors in HF and hypertension have been firmly established. The predominant hemodynamic effect of ACE inhibitors is to decrease systemic vascular resistance, associated with a significant increase of cardiac output. In addition, they improve clinical signs and symptoms, as well as improve exercise tolerance in patients with moderate to severe HF treated with diuretics and digoxin. The ACE inhibitors also slow the onset of symptomatic HF and clinical progression in patients with mild HF. The ACE inhibitors have been shown to prolong survival in HF patients, including asymptomatic and symptomatic LV dysfunction in the setting of acute myocardial infarction. As the major etiologic factor for HF in most patients is coronary artery disease or previous myocardial infarction, the observation that limiting LV enlargement and progressive HF after myocardial infarction is beneficial has been a strong factor for the early use of ACE inhibitors.

General guidelines can be identified that are applicable for all ACE inhibitors. First, consider the baseline renal function and extent of diuretic-induced prerenal azotemia, particularly in the elderly patient. Second, initiate ACE inhibitor therapy in relatively small doses. When initiating ACE inhibitors for HF, upward titration from a low starting dose is recommended, followed by progressive increase in ACE inhibitor dosage toward levels utilized in clinical trials that have established long-term benefit. The diuretic dosage should be reduced if hypotension develops. Symptomatic hypotension, or reduction of systolic blood pressure below physiologic lower limits of 80 to 85 mm Hg, would be reason to postpone ACE inhibitor therapy until diuretics are further decreased or until the cause of hypotension has been clarified. However, reduction of blood pressure to the range of 90 to 100 mm Hg should not be considered an adverse effect and is evidence of achieving the therapeutic end point. In patients with HF, renal perfusion and function is typically impaired. With the known underlying renal impairment of HF, transient reduction of renal function may occur but should not discourage continued use of the ACE inhibitor. During longer term use, renal function will return toward baseline in most individuals. Both reducing diuretic dosage and avoiding cyclo-oxygenase inhibitors, such as indomethacin, and nonsteroidal anti-inflammatory agents is important to minimize the impact of ACE inhibitors on renal function. Other class effects of ACE inhibitors include hyperkalemia, nonproductive cough, skin rash, altered taste, and, rarely, angioedema. Of course, use of ACE inhibitors in pregnant females is contraindicated.

The typical dosage range of ACE inhibitors is supported by clinical trial outcomes. For captopril, initial dosage is 6.25 mg t.i.d., increasing to 50 mg t.i.d. For enalapril, initial dosage is 2.5 mg b.i.d., increasing to 20 mg b.i.d. Lisinopril is initiated at 5 mg daily, increased to 40 mg daily. Quinapril dosage is initiated at 2.5 mg b.i.d. and can be increased to 20 mg b.i.d. Ramapril is initiated at 1.25 mg twice daily, increasing to 20 or 40 mg daily. Fosinopril is initiated at 2.5 mg daily, increasing to 20 mg daily. The final dose chosen for all ACE inhibitors is established according to tolerance, with the realization that the maximal dose might not be achieved.

The specific angiotensin II AT₁ antagonists are beneficial in the treatment of hypertension and demonstrate evidence of benefit in some HF trials. There is currently controversy regarding the role of this class of therapy in HF, and none of these agents has been approved for the treatment of HF. Physicians appear to be using

these agents “off label” for the treatment of HF in those individuals suspected of having an ACE inhibitor cough. It is advisable to evaluate the differential diagnosis of cough (including worsening failure) prior to assuming an ACE inhibitor cough.

Another renin system inhibitor is a very old drug, with very recent results in an international trial. Spironolactone is a specific aldosterone antagonist. In high doses, it has weak diuretic properties and has been used for decades, with the adverse potential for gynecomastia in men and hyperkalemia in certain clinical situations. In the recent RALES trial, spironolactone, added to standard therapy of ACE inhibitor, diuretic, and digoxin, produced a highly significant reduction of mortality compared to placebo. The effective target dose in the trial was 25 mg daily, which is much lower than the historical dosage of this drug. At this dose, the risk of hyperkalemia and gynecomastia are low but still present. Evaluation of serum potassium is required at intervals.

OTHER VASODILATORS

In patients who cannot tolerate ACE inhibitors, the combination of hydralazine and isosorbide dinitrate is a very acceptable and proven therapeutic option. In two successive Veterans Administration cooperative trials, this combination has been shown to significantly reduce mortality. In a direct comparison with the ACE inhibitor enalapril, hydralazine/isosorbide dinitrate did not produce as great a mortality reduction as enalapril. However, the combination did produce a greater improvement of exercise duration than enalapril, as well as a small but significantly greater increase in ejection fraction. Hydralazine dosage should be titrated up to 75 or 100 mg 4 times a day, to achieve optimal hemodynamic effect without an undue risk of side effects. Most experience exists with isosorbide dinitrate. This has been administered in doses of 20 to 60 mg 3 or 4 times daily. Nitroglycerin patches may be used, but less information exists regarding their efficacy, compared with isosorbide dinitrate. Tolerance to the hemodynamic benefit of nitrates is well known. It can be minimized by deletion of a daily dose of nitrates (the last dose of the day), or the patch can be removed for several hours each day.

The calcium channel blockers have become popular in cardiovascular medicine. These are pharmacologically diverse compounds. While verapamil was the prototypical agent, diltiazem and the dihydropyridine class of calcium channel blockers are particularly utilized. The prominent vasodilator effect of these agents stimulated the notion that they may be effective for the treatment of HF. However, this has not been substantiated by clinical trials. Therefore, no calcium channel blocker is approved for the treatment of HF, and they should only be used for the treatment of the comorbid conditions of hypertension or active angina.

Vasodilators, such as the α -blockers, and minoxidil failed to demonstrate long-term benefit in HF. Their use should be considered ancillary therapy: to provide intermittent symptomatic relief of HF, for coexistent hypertension, or for symptoms of prostatic hypertrophy (α -blockers).

DIURETICS

By reducing the intravascular volume, these drugs also relieve increased interstitial fluid by allowing its reabsorption into the vascular space. There is no single laboratory test or diagnostic study that provides a simple assessment of volume status in the HF patient. Findings on physical exam remain the most valuable means to assess fluid status. The central venous pressure, particularly its response to abdominal pressure or leg raising, may provide an estimate of venous volume. It is less accurate in the setting of tricuspid regurgitation. Peripheral pitting edema is also a valuable sign of total body volume expansion. The presence of rales also indicates excessive pulmonary fluid. The value of body weight is best determined with serial measurements, where recent fluctuation identifies the need for alteration in diuretic dosage.

The loop diuretics, including furosemide, are the mainstay of diuretic therapy in most patients with HF. Dosage should not exceed known ceiling levels. In mild failure, thiazides may be adequate to attenuate sodium retention. The dosage of loop diuretics must be carefully adjusted and modified when the fluid status changes. Patients should be instructed in sodium intake, the importance of daily weights, and the potential for intermittent adjustment of diuretics.

It is not unusual for a patient with congestive HF to become resistant to diuretics, and several clinical issues can influence such resistance, including renal insufficiency and aging. Edema of the gastrointestinal tract can also reduce drug absorption, thereby limiting efficacy. Different classes of diuretic agents may act at different locations within the nephron, so that combination therapy, as discussed below, may be appropriate in the patient with developing refractory HF. At the very least, a patient should not be considered “refractory to diuretic” if receiving only moderate doses of an oral loop diuretic. There are several approaches to the management of resistance to diuretics that can aid in the optimization of diuretic therapy for the refractory HF patient. A single large bolus of intravenous diuretics may substantially improve urinary flow and natriuresis. Continuous intravenous infusion of a loop diuretic may be efficacious. Perhaps the most versatile and effective approach is the combination of a loop diuretic with a thiazide-type diuretic. Long-standing treatment with a loop diuretic can result in hypertrophy of the distal segment of the nephron, producing enhanced sodium reabsorption. This adverse effect can be overcome by coadministration of a thiazide-type diuretic. If the patient remains resistant to diuretics, additional treatment modalities can be considered. Ultrafiltration, hemofiltration, hemodialysis, or peritoneal dialysis can be utilized for rapid removal of fluid.

Hypokalemia is a common manifestation in patients treated with diuretics and may contribute to dysrhythmias, especially in patients receiving digoxin. Most commonly, diuretic-induced hypokalemia is associated with a metabolic alkalosis and a coexisting chloride deficit. Therefore, chloride is the preferred form of potassium in this setting. Frequent measurement of the serum potassium level is necessary during stages of intense diuresis.

Chronic diuretic therapy also leads to hypomagnesemia. Potassium and magnesium have an interrelationship whereas magnesium is a cofactor in the appropriate function of the Na^+, K^+ -ATPase pump. Therefore, hypokalemia may persist until the magnesium deficiency is corrected. Low serum magnesium levels may contribute to dysrhythmias in patients with HF. Oral magnesium replacement should be considered in all patients with low serum levels and when increased arrhythmias are noted in the setting of intense diuretic therapy.

DIGOXIN

There is a role for digoxin therapy in HF patients in normal sinus rhythm. This was established by multicenter studies demonstrating favorable benefits of digoxin therapy. Furthermore, mechanistic studies have demonstrated beneficial effects of digoxin upon electrophysiologic and neurohormonal abnormalities. Based on most recent clinical trials, use of a standard digoxin dosage of 0.125 or 0.25 mg daily is sufficient. Reduction of the dose to an every-other-day regimen is recommended for patients with significant renal disease (serum creatinine greater than 2.5 to 3.0 mg per dL), the elderly, or patients receiving other drugs that interfere with the metabolism of digoxin. When an individual is receiving digoxin for the first time, a loading dose given either orally or intravenously is required. In patients with atrial fibrillation or advanced HF, the digoxin dosage may be increased to 0.375 mg daily. Routine surveillance of digoxin levels is generally not required when routine doses are utilized. If a patient requires dose reduction for concomitant renal failure, then more routine surveillance of serum levels may be required. Serum levels should be measured at dose nadir, to avoid erroneous determinations.

β -ADRENORECEPTOR BLOCKERS

β -Adrenergic blockade is emerging as the most important “new” breakthrough in the treatment of HF, with at least three major survival analyses demonstrating significant reduction of mortality, with three different drugs. Long considered as “negative inotropes,” it is clear that β -blockers exert favorable effects in HF, through reduction of heart rate, suppression of the renin system, and resetting of abnormal sympathetic nervous system and baroreflex abnormalities. The size of the heart decreases, and β -blockers produce a significant increase of ventricular ejection fraction, which would not have been predicted by their putative negative inotropic effects.

A highly significant reduction of mortality with bisoprolol and metoprolol, in their respective trials, prompted early termination of the randomized trials. The target dose of bisoprolol is 10 mg daily; the target dose of metoprolol (in its extended release preparation) is 100 mg b.i.d. A unique “ β -blocker” is carvedilol, which also reduced mortality and was associated with dose-dependent clinical improvement. This compound, while predominantly a β -blocker, also has α -blocking and antioxidant properties, with vasodilator effects. The target dose is 25 mg b.i.d. In these trials, the β -blocker was added to standard therapy and therefore should not be considered a substitute for ACE inhibitor therapy.

For all of these drugs, the key to therapy is to begin with the lowest possible dose and gradually advance to the target dose over the course of 1 to 3 months. In complicated patients, up-titration may require close vigilance. At early stages of therapy, observe for signs of increased dyspnea or edema, requiring temporary up-titration of diuretics. Symptomatic hypotension with carvedilol may require a slower rate of up-titration. At all stages, particularly with coadministration of digoxin or amiodarone, monitor for bradycardia or heart block.

ANTIARRHYTHMIC THERAPY AND DEVICES

The absence of synchronized atrial contraction contributes to functional impairment and deterioration in this population. Reasonable attempts should be made to convert a patient to normal sinus rhythm prior to the development of marked left atrial enlargement, which would lessen the likelihood of successful conversion. Pharmacologic or electrical cardioversions in this population are similar to those in other patients with atrial fibrillation. Atrioventricular junctional block and intraventricular conduction defects occur, necessitating permanent pacemaker implantation.

Treatment of ventricular arrhythmias is covered elsewhere in this text. However, electrolyte replacement and optimization of therapy for HF, including effective doses of an ACE inhibitor, should be utilized prior to consideration of specific therapy for ventricular arrhythmia. High-grade ventricular arrhythmias may be noted on routine ambulatory heart rate monitoring in many patients with moderate to severe HF. Sudden death accounts for anywhere from 35% to 70% of total mortality in published studies of the HF population. However, not all sudden death is due to ventricular tachycardia or fibrillation. However, the clinical significance of ventricular premature beats, often in couplets and runs, remains uncertain. Random suppression of these isolated events could expose patients to adverse proarrhythmic actions of many antiarrhythmic drugs, as well as depression of ventricular function. A mortality benefit of amiodarone in HF has been reported but not conclusively established in other HF trials. In HF patients with symptomatic ventricular arrhythmias, implanting a cardiac defibrillator is justified to prevent sudden death.

ANTICOAGULATION

Patients with severe chronic HF are at risk of developing mural thrombi in the dilated left atrium or left ventricle. Patients with chronic atrial fibrillation are particularly at risk of developing atrial thrombi. These thrombi are potential sources of systemic emboli. If clinical symptoms or signs (atrial fibrillation, evidence of thrombi by noninvasive tests such as echocardiography) suggest the presence of intracardiac thrombi, the patient should be treated with warfarin, unless there are specific contraindications. Aspirin may serve as an alternative to warfarin in some individuals.

TREATMENT OF ADVANCED HEART FAILURE

ACUTE MEDICAL MANAGEMENT

The phrase "refractory HF" should be reserved for progressive decompensation despite adequate dosage of digoxin, diuretics, and an ACE inhibitor (or adequate alternate vasodilator regimen). This distinguishes the refractory HF syndrome from forms of acute HF such as cardiogenic shock due to myocardial infarction (see [Chapter 71](#)).

In some cases, refractory HF may respond to intravenous diuretic therapy. However, management of refractory HF typically requires short-term hospitalization. Intravenous dobutamine, given in a range of 2.5 to 10 µg per kg per minute over the course of 24 to 96 hours provides clinical and hemodynamic stabilization. The favorable response to short-term dobutamine cannot be extrapolated to continuous or intermittent outpatient therapy. This latter practice remains questionable. Use of intravenous milrinone parallels the use of dobutamine. Milrinone requires an initial bolus dose and has direct vasodilator properties at higher doses of 0.5 and 0.75 µg per kg per minute. The reader should refer to [Chapter 71](#) for additional information.

SURGICAL CONSIDERATIONS

If coronary angiography discloses significant lesions that could be contributing to myocardial dysfunction, coronary bypass surgery or angioplasty should be considered. In the presence of severe LV dysfunction, a myocardial imaging study should be obtained to document reversible ischemia. Ventricular assistance devices are being used as a bridge to transplant in many patients, and studies are in progress to determine their role as primary therapy in patients who are not transplant candidates. Heart transplantation is now a practical clinical approach to the management of severe HF in appropriate patients. The major limiting factor is lack of availability of donor hearts. The reader is referred to [Chapter 93](#) for additional information.

CHAPTER 67: APPROACH TO THE PATIENT WITH CARDIAC ARRHYTHMIAS

S. ADAM STRICKBERGER, DOUGLAS P. ZIPES AND FRED MORADY

[Pharmacologic Therapy](#)
[Electrical Therapy of Cardiac Arrhythmias](#)
[Radiofrequency Ablation Therapy](#)
[Surgical Therapy of Tachyarrhythmias](#)

Evaluation of the patient with a cardiac arrhythmia begins with the consideration of five questions:

- Does the patient have a cardiac arrhythmia?
- What are the consequences of the arrhythmia?
- Does the patient have associated cardiac problems?
- What is the cause of the arrhythmia?
- What, if anything, should be done?

Does the patient have a cardiac arrhythmia? Obtaining a careful history and performing a thorough physical examination provides the initial clues to the presence of a cardiac arrhythmia. Palpitations, syncope, presyncope, chest pain, or symptoms of congestive heart failure may result from the arrhythmia and are revealed during the history taking. Some patients may be able to tap their fingers in the cadence of a perceived palpitation or recognize the beat tapped out by a physician and, in so doing, establish not only the presence of an arrhythmia but also its rate and rhythm. The patient, or sometimes a close relative, should be instructed in how to determine the pulse rate during the arrhythmia. A rapid, grossly irregular rhythm may suggest atrial fibrillation; a regular rhythm at a rate of 150 beats per minute, atrial flutter with 2:1 conduction; a regular rhythm at a rate of 180 to 200 beats per minute, paroxysmal supraventricular or ventricular tachycardia; or a regular rhythm at a rate of 40 beats per minute, sinus bradycardia or heart block.

The patient's characteristics also help refine the interpretation of data obtained in the history. For example, in a young, otherwise healthy individual with a heart rate of 180 beats per minute, paroxysmal supraventricular tachycardia would be suggested, whereas in an older patient with presyncope, ventricular tachycardia would be more likely. A heart rate of 40 beats per minute in a young person might be a normal sinus bradycardia but signify acquired atrioventricular (AV) block in an elderly individual.

Documenting the arrhythmia by electrocardiogram (ECG) clearly establishes its presence. The electrocardiographic characteristics of the arrhythmia are considered elsewhere in this text. However, physical findings caused by the arrhythmia, in addition to changes in cardiac rate and rhythm, might be helpful. Findings that indicate the presence of AV dissociation, such as a variable peak systolic blood pressure, variable intensity of the first heart sound, and intermittent cannon *a* waves in the jugular venous pulse, suggest arrhythmias like ventricular tachycardia or complete AV block. The second heart sound may be paradoxically split during a QRS complex with a left bundle-branch block contour or widely split without becoming single during expiration caused by right bundle-branch block.

Carotid sinus massage increases vagal tone, which slows the rate of sinus node discharge, and prolongs AV nodal conduction time and refractoriness. These responses can cause (a) a sinus tachycardia to slow gradually or terminate, (b) AV nodal reentry, AV reciprocating tachycardias in the Wolff–Parkinson–White (WPW) syndrome, and some atrial tachycardias to terminate abruptly, and (c) the ventricular response to atrial flutter, atrial fibrillation, and some atrial tachycardias to decrease. Rarely, carotid sinus massage terminates a ventricular tachycardia.

What are the consequences of the arrhythmia? A consideration of the consequences of the arrhythmia in an individual patient is important because arrhythmias are not isolated events and should be managed in the context of the entire clinical situation. When a patient develops a tachyarrhythmia, slowing the ventricular rate is the initial and often most important therapeutic maneuver. Therapy might differ radically for the same arrhythmia in two different patients, however, because the consequences of the tachycardia differ. For example, a supraventricular tachycardia at a rate of 200 beats per minute may produce few or no symptoms in a healthy young adult and therefore might require little or no therapy if it is usually self-limited. The same arrhythmia can precipitate pulmonary edema in a patient with mitral stenosis, syncope in a patient with aortic stenosis, or shock in a patient with acute myocardial infarction. In addition to hemodynamic consequences, the presence of structural heart disease may have other effects. For example, having mitral stenosis may increase the chance of emboli developing in patients with atrial fibrillation. A persistent, uncontrollable tachycardia can result in cardiomegaly and congestive heart failure, often reversible if the tachycardia is stopped. This is called a tachycardia-induced cardiomyopathy. Thus, the presence of heart disease influences the effects of an arrhythmia, but the latter can also cause heart disease.

Does the patient have associated cardiac problems? Whereas the presence of associated cardiac problems influences the consequences of the arrhythmia, certain cardiac lesions are associated with, or predispose to the development of, certain arrhythmias. For example, Ebstein's anomaly is associated with the WPW syndrome. Repair of some congenital cardiac defects such as tetralogy of Fallot can predispose to the subsequent development of cardiac arrhythmias. The presence of a left ventricular aneurysm or a ventricular tumor (usually in infants) can set the stage for ventricular arrhythmias.

What is the cause of the arrhythmia? Information about circumstances that trigger the tachycardia, such as excessive caffeine or alcohol intake, cigarette smoking, or emotionally upsetting events, are important. Nonprescription cold medications can contain sympathomimetic drugs that can produce arrhythmias. Disease states such as ischemia, thyrotoxicosis, hypotension, infection, anemia, or valvular heart disease should be considered.

The cause of the arrhythmia may influence therapy. Electrolyte imbalance, acidosis or alkalosis, hypoxemia, congestive heart failure, and many drugs can produce rhythm disturbances ([Table 67.1](#)), and their identification and treatment can abolish or prevent these arrhythmias. Mild sedation or reassurance may be successful in treating some arrhythmias related to emotional stress. Because therapy always involves some risk, one must be sure, particularly as the therapeutic regimen escalates, that the risks of not treating the arrhythmia continue to outweigh the risks of therapy with potentially hazardous antiarrhythmic measures; correction of precipitating factors is often the simplest and safest form of therapy.

Antiarrhythmic agents*
Flecainide
Procainamide
Propafenone
Quinidine
Sotalol
Antibiotics
Erythromycin
Pentamidine
Trimethoprim and sulfamethoxazole
Antifungal agents
Fluconazole
Ketoconazole
Antihistamines
Astemizole
Terfenadine
Cisapride
Phenothiazine derivatives
Probucoil
Tricyclic antidepressants (amitriptyline)

* Amiodarone is rarely associated with ventricular proarrhythmia.

TABLE 67.1. DRUGS ASSOCIATED WITH VENTRICULAR PROARRHYTHMIA

What, if anything, should be done? Therapy of cardiac arrhythmias involves a choice of three modalities: pharmacologic, electrical, and surgical. These are considered in the following sections.

PHARMACOLOGIC THERAPY

Pharmacologic therapy to maintain sinus rhythm is no longer the mainstay of therapy. While drugs still often are used, non-pharmacologic therapy, including catheter ablation and implantable defibrillators, is frequently prescribed for symptomatic paroxysmal supraventricular tachycardia and for the treatment of ventricular tachycardia and fibrillation, respectively. However, pharmacologic therapy is the mainstay of therapy for atrial fibrillation. Many experts believe that ablation therapy for atrial fibrillation will be commonly utilized within 5 to 10 years. A brief discussion regarding ablation therapy follows in this chapter.

The primary objective of pharmacologic therapy is to reach, as rapidly as possible, an effective and well-tolerated serum drug concentration that controls the arrhythmia and to maintain this serum drug concentration for as long as required without producing adverse effects. So-called therapeutic drug concentrations are based on concentrations of drugs that exert therapeutic effects without adverse effects in most patients. The therapeutic serum concentration varies from one patient to another, but for any individual patient, it is the amount of drug required to suppress or terminate the cardiac arrhythmia in that patient without producing adverse effects. Thus, the actual serum concentration of the drug in a specific patient is often of secondary importance. Careful dosing is essential because antiarrhythmic agents have narrow toxic/therapeutic relationships, and important adverse effects can result from amounts of drug that only slightly exceed the amount necessary to produce beneficial effects. An understanding of drug pharmacokinetics—which consists of an understanding of drug absorption, distribution, metabolism, and excretion—is essential.

A complete discussion of the common antiarrhythmic agents can be found in [Chapter 90](#).

ELECTRICAL THERAPY OF CARDIAC ARRHYTHMIAS

CARDIOVERSION AND DEFIBRILLATION

Electrical cardioversion (shock delivered synchronously with the QRS complex) and defibrillation (shock delivered without synchronization to the QRS complex to terminate ventricular fibrillation) appear to terminate most effectively those tachycardias presumed to be due to reentry, including atrial flutter and atrial fibrillation, AV nodal reentry, reciprocating tachycardias associated with the WPW syndrome, most forms of ventricular tachycardia ([Fig. 67.1](#)), ventricular flutter, and ventricular fibrillation ([Fig. 67.2](#)). The electric shock, by depolarizing all excitable myocardium and prolonging refractoriness, interrupts reentrant circuits and establishes electrical homogeneity that terminates reentry. For elective cardioversion, self-adhesive pads applied in the standard apex–anterior or apex–posterior paddle positions are quite effective. A synchronized shock is used for all cardioversions except for very rapid ventricular tachyarrhythmias, such as ventricular flutter or fibrillation. Shocks generally are titrated when the clinical situation permits. The starting level to terminate atrial fibrillation should probably be 50 to 100 J. For patients with stable ventricular tachycardia, starting levels in the range of 25 to 50 J may be employed. If there is some urgency to terminate the tachyarrhythmia, one can begin with higher energies. To terminate ventricular fibrillation, 200 to 360 J generally is used, although much lower energies terminate ventricular fibrillation when the shock is delivered at the very onset of the arrhythmia. During elective cardioversion, a short-acting barbiturate such as methohexital or an amnesic, such as diazepam, should be used. A physician skilled in airway management should be in attendance, intravenous access should be established, and all equipment necessary for emergency resuscitation should be immediately accessible.

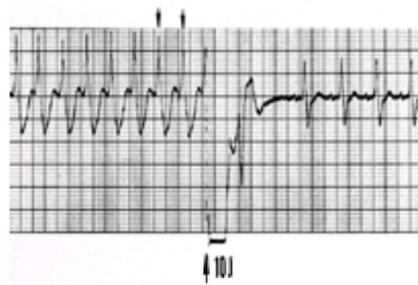

FIGURE 67.1. Electrical cardioversion of ventricular tachycardia. Artifacts indicating synchronization of the external cardioverter to the QRS complex (*inverted arrows*) are seen before delivery of a 10-J shock (*upright arrow*) that is followed by a repetitive ventricular response and the restoration of sinus rhythm.

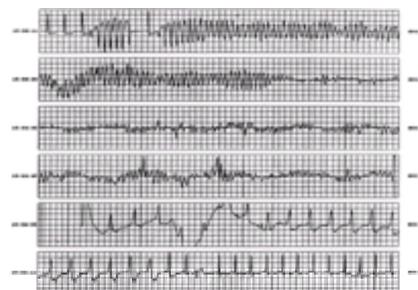

FIGURE 67.2. Direct current defibrillation. Spontaneous onset of ventricular tachycardia occurs in the top strip. It degenerates to ventricular fibrillation, terminated by a transthoracic shock at the end of the fourth strip. Time on left is in hours:minutes:seconds.

Generally, any tachycardia that produces hypotension, congestive heart failure, or angina and that does not respond quickly and appropriately to medical management should be terminated electrically. Direct current countershock of digitalis-induced tachyarrhythmias is contraindicated because more severe arrhythmias might result from the shock. Electrical cardioversion restores sinus rhythm in 70% to 95% of patients, depending on the type of tachyarrhythmia. If the first shock fails to restore sinus rhythm or does so only transiently, a second shock should be delivered at a higher energy level or after antiarrhythmic drug administration.

Arrhythmias induced by the shock generally are caused by inadequate synchronization, with the shock occurring during the ST segment or T wave. It is important to remember, however, that occasionally even a properly synchronized shock can produce ventricular fibrillation. Postshock arrhythmias usually are transient and do not require therapy. Embolic episodes are reported in 1% to 3% of the patients converted to sinus rhythm from atrial fibrillation. Prior anticoagulation therapy for at least 3 weeks should be considered for patients with atrial fibrillation of more than 48 hours duration. Anticoagulation therapy for at least 3 to 4 weeks after conversion to sinus rhythm appears to be indicated.

Patients with atrial fibrillation who can be considered for electrical cardioversion have new-onset atrial fibrillation or atrial fibrillation of relatively short duration; recurrent emboli or hemodynamic insufficiency during the atrial fibrillation; or a transient precipitating cause removed, such as thyrotoxicosis or correction of mitral stenosis. Patients who are less favorable candidates for electrical cardioversion have atrial fibrillation of long duration, with easily controlled ventricular rates, and no symptoms; sinus node dysfunction; digitalis toxicity; a large left atrium; a history of short-lasting episodes with a high likelihood of spontaneous reversion to sinus rhythm; a history of early reversion to atrial fibrillation after previous electrical conversion attempts; cardiac surgery planned in the near future; and antiarrhythmic drug intolerance.

IMPLANTABLE ELECTRICAL DEVICES FOR TREATING ARRHYTHMIAS

Pacemakers and Defibrillators

AV Conduction	Atrial Rhythm		
	Normal	Bradycardia	Bradycardia-Tachycardia
Normal	None	AAR	AAR
AV block, normal retrograde conduction time	DDO	DDOR	DDOR
AV block, prolonged retrograde conduction time	DDI	DDR	VVR, DDIT
AV block without retrograde conduction	DDO	DDOR	DDOR

^a Depending on the individual patient and clinical circumstances, other modes of pacing may be preferable to those shown here, such as pacemakers with mode switching. AV, atrioventricular.

TABLE 67.4. PREFERRED PACING MODES^a

All permanent pacemakers have programmable capabilities. That means that the electronically controlled features of the pacemaker can be altered in a noninvasive, reversible fashion using an external programmer. Rate, stimulus output, amplitude or duration, amplifier sensitivity, amplifier refractory period, pacing mode, and other functions are programmable. Thus, pacemaker function can be optimized for specific patient needs, malfunctions can be corrected, and the system can be revised to accommodate changing clinical situations.

Because many patients cannot increase their heart rates with exercise due to sinus node dysfunction or the presence of atrial fibrillation and AV block, several physiologic variables, independent of sinus node function, have been used to alter the pacemaker rate according to physiologic needs. Such approaches for so-called rate-adaptive pacemakers include monitoring changes in the QT interval, respiratory rate, ventricular pressure, and body activity. The activity-sensing pacemaker uses a conventional lead system for sensing cardiac activity and pacing the heart. However, a microphone-like sensor inside the pacemaker pulse generator responds to mechanical vibrations of the body by producing electrical signals proportional to the patient's level of physical activity. As activity increases, the heart is paced more rapidly. Naturally, this pacemaker cannot increase the discharge rate when non-exercise-induced metabolic demands result, such as from mental activity while at rest. A second minor drawback is that the pacemaker produces slight rate increases in the presence of certain environmental noises, such as motion in an airplane. Other pacemakers that measure body temperature or respiratory rate, for example, can respond to metabolic demands. More complex rate-responsive systems incorporate multiple sensors that compensate for the deficits of specific individual sensors.

Treatment of Tachycardia

Pacing to treat patients with tachycardias generally involves three categories of treatment. First, symptomatic bradycardia may result from therapy of a tachycardia. For example, amiodarone results in symptomatic bradycardia in about 2% of patients treated, and these patients may require permanent pacing if they continue to receive amiodarone. Second, pacing can be used to prevent a recurrence of tachycardia. For example, when the tachycardia occurs during the setting of bradycardia, prevention of the latter also may prevent the former. However, this situation does not occur often. By far the most common use of electrical therapy is to terminate the tachycardia already present with an implantable ventricular defibrillator. This can be done with competitive pacing, low-energy synchronous cardioversion (Fig. 67.4), or high-energy defibrillation (Fig. 67.5). These implantable devices monitor the cardiac rate and, when they sense the presence of a tachycardia, deliver competitive pacing stimuli, a synchronized shock, or an asynchronous defibrillation shock. Implantable ventricular defibrillators are the therapy of choice for patients with aborted sudden cardiac death or sustained monomorphic ventricular tachycardia. More recently, implantable atrial defibrillators designed to treat atrial fibrillation have also been developed. These devices are largely investigational.

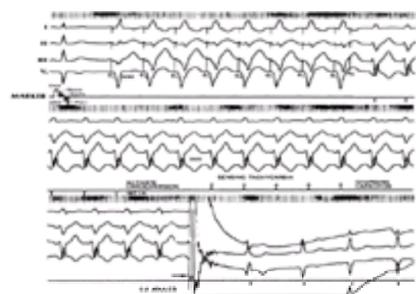

FIGURE 67.4. Implantable transvenous cardioverter. (Top) After a series of eight stimuli (S_1), the S_2 fails to produce a ventricular response. Nevertheless, sustained ventricular tachycardia ensues at a cycle length of 500 milliseconds. The device is activated (middle) to cardiovert the ventricular tachycardia if six sequential cycles of the ventricular tachycardia are sensed (indicated in the marker channel by the small upright square waves). The capacitor then charges and at the horizontal arrow in the bottom panel delivers 0.2 J, which terminates the ventricular tachycardia and restores sinus rhythm.

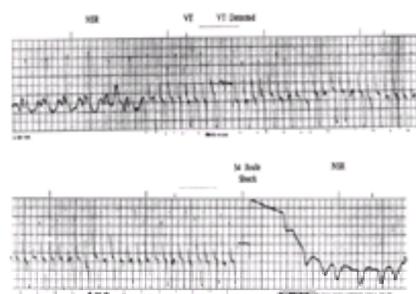

FIGURE 67.5. Cardioversion of ventricular tachycardia. Intracavitary recordings from a cardioverter defibrillator show the transition from sinus rhythm (note negative P waves preceding each ventricular depolarization) to ventricular tachycardia (note change in electrocardiogram and loss of preceding P wave), following a 34-J shock with restoration of sinus rhythm. (From Barold SS, Zipes DP. Cardiac pacemakers and antiarrhythmic devices. In: Braunwald E, ed. *Heart disease: a textbook of cardiovascular medicine*, fifth ed. Philadelphia: WB Saunders, 1996, with permission.)

General Care

Despite the reliability of modern pacemakers and defibrillators, malfunction can result on occasion, and it is important that the patient be followed closely and regularly in an organized pacemaker/defibrillator clinic. In such a clinic, the electrical function of a system is evaluated to detect malfunction or power depletion. The implant site is checked for erosion or infection, and the patient's overall cardiac status is evaluated so that reprogramming or revision of the system or of the concomitant drug regimen can be effected.

RADIOFREQUENCY ABLATION THERAPY

The purpose of catheter ablation therapy is to treat cardiac arrhythmias by destroying myocardial tissue involved in the initiation or maintenance of the tachyarrhythmia. Ablation is most often accomplished by delivering radiofrequency energy through an electrode catheter placed next to the tissue (usually endocardial) to be destroyed. Other energy sources for cardiac ablation, including laser, microwave, and ultrasound, have also been explored.

Radiofrequency catheter ablation is applied in many different clinical situations. The AV junction can be ablated to produce complete or partial block in patients who have recurrent atrial flutter or fibrillation with a rapid ventricular response that cannot be controlled adequately with drugs. Atrioventricular junction ablation that results in complete AV block requires pacemaker implantation but eliminates the rapid ventricular rates during tachycardia (Fig. 67.6). The atrial flutter or fibrillation still occurs but cannot conduct to the ventricles. Modification of the AV nodal area to produce partial block results in slowing of the ventricular rate without the need for a pacemaker.

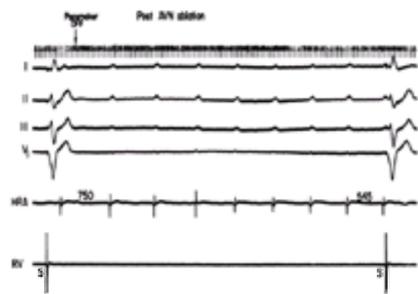

FIGURE 67.6. Ablation of the atrioventricular (AV) junction. Complete AV block follows catheter ablation of the AV junction.

Radiofrequency catheter ablation has been used to interrupt the accessory pathway in patients with the WPW syndrome (Fig. 67.7) and to eliminate AV nodal reentry, which is the most common mechanism of paroxysmal supraventricular tachycardia. Other supraventricular tachycardias that can be eliminated with ablation include atrial flutter and atrial tachycardia. For patients with ventricular tachycardia, sites of origin or reentrant pathways can be identified electrophysiologically and eliminated with radiofrequency catheter ablation. Success rates are highest in patients with no or minimal structural heart disease and can exceed 95%. In patients with monomorphic ventricular tachycardia due to coronary disease, the ablation success rate is about 80% (Fig. 67.8). Finally, radiofrequency catheter ablation techniques are being developed to treat, and potentially cure, atrial fibrillation.

FIGURE 67.7. Successful catheter ablation of an accessory pathway in a patient with the Wolff–Parkinson–White syndrome. The arrow denotes the onset of the application of radiofrequency energy. Accessory pathway function, and the delta wave, is eliminated at the asterisk. Standard ECG leads I, II, and III are shown.

FIGURE 67.8. Successful catheter ablation of sustained hemodynamically tolerated ventricular tachycardia that occurred in a patient with a previous myocardial infarction. The ventricular tachycardia terminated approximately 5 seconds after the onset of radiofrequency energy delivery through an endocardial catheter, restoring sinus rhythm. Standard EKG leads V₁, I, and II are shown.

SURGICAL THERAPY OF TACHYARRHYTHMIAS

The objective of surgery is to excise, isolate, or interrupt tissue in the heart that is critically responsible for the initiation, maintenance, or propagation of the tachycardia while preserving or even improving myocardial function. Indirect approaches have been used to improve cardiac hemodynamics and myocardial blood flow. They may be effective if, for example, ischemia is a cause of the arrhythmia. These include ventricular aneurysmectomy, coronary artery bypass grafting, or relief of valvular insufficiency or stenosis. In the main, however, direct approaches that are focused on myocardial tissue critically involved in the tachycardia are most successful. For instance, the MAZE procedure, in which multiple surgical incisions are made throughout the atria, can be an effective therapy for atrial fibrillation in patients undergoing mitral valve surgery. Other procedures include ventricular endocardial resection in patients with coronary artery disease and ventricular tachycardia. However, implantable ventricular defibrillators have generally replaced surgery for the treatment of ventricular tachycardia. Ablation of monomorphic ventricular tachycardia, when needed, is usually achieved with radiofrequency catheter ablation. Accessory pathway interruption in patients with the WPW syndrome, and AV nodal isolation in patients with AV nodal reentry can also be performed surgically. As with the surgical treatment of ventricular tachycardia, radiofrequency catheter ablation has replaced surgery for most supraventricular arrhythmias. Refer to [Chapter 76](#) and [Chapter 90](#).

CHAPTER 68: APPROACH TO THE PATIENT WITH HEART MURMURS

JONATHAN ABRAMS

[Basis of Heart Murmurs](#)
[Murmur Identification](#)
[When to Order a Doppler Echocardiogram](#)
[Types of Murmurs](#)
[Further Evaluation of Presumed Organic Murmurs](#)

Evaluation of heart murmurs is one of the most common tasks that an internist or primary care physician must perform in daily practice. It is therefore important that physicians develop basic skills in cardiac physical diagnosis as well as a good understanding of cardiac murmurs. Heart murmurs are ubiquitous in the population, but abnormal or organic murmurs are relatively uncommon. Most persons with heart murmurs do not need referral or further noninvasive cardiac evaluation. With well-developed physical diagnosis skills, identifying a normal murmur, the cause of an abnormal murmur, and the severity of cardiac structural abnormalities is relatively straightforward.

This chapter provides an approach to murmur analysis for the noncardiologist. Although the increasing availability and use of cardiac Doppler echocardiographic studies threatens to deemphasize skills in cardiac physical diagnosis, a well-trained physician can detect and evaluate heart murmurs with considerable proficiency, thus avoiding unnecessary testing or enhancing the value of a Doppler echocardiographic examination by facilitating a complete and accurate synthesis of the underlying cardiac abnormality.

BASIS OF HEART MURMURS

Turbulence of blood within the heart or great vessels is the primary cause of audible cardiac murmurs. Turbulence is directly related to intracardiac sound energy, which produces a murmur when the energy reaches an auditory threshold.

A major factor in the genesis of turbulence and heart murmurs is the velocity of blood flow. Normally, the velocity is maximal in early systole during rapid ejection of blood from the left and right ventricles; innocent or physiologic murmurs and pathologic ejection murmurs tend to be loudest in early systole to midsystole ([Fig. 68.1](#)). Because blood velocity is directly related to the pressure difference across a valve, turbulence and murmur intensity usually are greater with increasing degrees of obstruction to blood flow across stenotic valves. Conversely, when cardiac pump function is abnormal or when blood flow is diminished because of other causes, murmurs may become attenuated or even disappear.

FIGURE 68.1. Pressure–flow relationships of the normal or innocent systolic ejection or flow murmur. In early systole, blood velocity and flow are maximal; the resultant turbulence produces audible cardiac sound vibrations or a heart murmur. The innocent or functional systolic ejection murmur ends within the first 60% to 70% of systole. (From Abrams J. Auscultation of heart murmurs: essentials of cardiac physical diagnosis. *Primary Cardio* 1981;7:21, reprinted with permission from Primary Cardiology, PW Communications International, Inc.)

The presence of cardiac sound or murmur in diastole is always abnormal because normal diastolic blood flow within the heart is low pressure and low velocity; in the normal heart, there is insufficient intracardiac turbulence to produce audible diastolic vibrations.

Loudness or intensity of cardiac sound is usually roughly proportional to the underlying severity of the cardiac abnormality. Noncardiac factors may also play a role in determining the relative loudness of a murmur. In general, cardiac sound is increased in children and young adults, in thin persons, and in hyperdynamic states such as anxiety, fever, and anemia. Conversely, murmurs may be soft in obese or heavily muscled individuals, women with large breasts, or patients with increased lung volume. The experienced clinician takes these extracardiac factors into account during the assessment of a murmur.

MURMUR IDENTIFICATION

IS A MURMUR ORGANIC?

The most critical question that needs to be answered whenever a murmur is heard is whether the murmur is physiologic and normal, or is organic representing intrinsic heart disease. If the murmur is judged to be abnormal, the cause and hemodynamic severity must be assessed. Internists and family practitioners are frequently asked to make determinations about employability, insurability, appropriateness of participation in competitive athletics or recreational sports, the necessity of endocarditis prophylaxis, and the safety of pregnancy and delivery. If a murmur is likely to be pathologic, selection of subsequent cardiovascular testing (e.g., Doppler echocardiography, stress test, cardiac catheterization) and the need to refer the patient to a cardiac specialist are issues that must be confronted by the primary physician. Proficiency in cardiac physical diagnosis is useful because it allows the physician to deal more appropriately with the potential issues raised by detection of a murmur.

The major varieties of cardiac murmurs—systolic, diastolic, and continuous—are diagramed in [Figure 68.2](#). Most murmurs detected by physicians are systolic, and the odds strongly favor a functional or innocent cause. Diastolic and continuous murmurs are always produced by underlying cardiovascular abnormalities. The most important task of the clinician is to determine if a given systolic murmur is suspiciously or definitely organic; nonsystolic murmurs usually indicate organic heart disease.

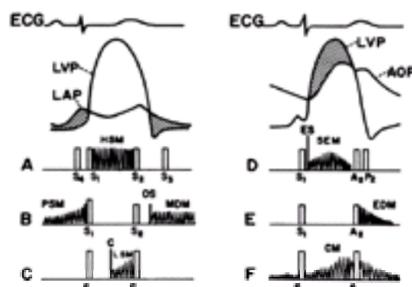

FIGURE 68.2. Intracardiac pressures and heart murmurs in the major cardiac valve abnormalities. **A:** Holosystolic murmur of mitral regurgitation. **B:** Mid-diastolic murmur with late presystolic accentuation of mitral stenosis. **C:** Late systolic murmur of mitral valve prolapse. **D:** Long systolic ejection murmur of aortic stenosis. **E:** Decrescendo diastolic murmur of aortic regurgitation. **F:** A typical continuous murmur, with maximal intensity in late systole spilling over into early diastole. LVP, left ventricular pressure; LAP, left atrial pressure; AOP, aortic pressure; HSM, holosystolic murmur; PSM, presystolic murmur; OS, opening snap; MDM, mid-diastolic murmur; C, midsystolic click; LSM, late systolic murmur; ES, ejection sound; SEM, systolic ejection murmur; EDM, early diastolic murmur; CM, continuous murmur. (From Crawford MH, O'Rourke RA. A systemic approach to the current bedside differentiation of cardiac murmurs and abnormal sounds. *Curr Probl Cardiol* 1979;1:7, with permission.)

EVALUATION OF SYSTOLIC MURMURS

The most critical aspect in auscultation of a systolic murmur is accurate assessment of its length (Fig. 68.3). Because normal ejection dynamics result in markedly reduced blood flow across the aortic and pulmonary valves in late systole (Fig. 68.1), it is abnormal to hear murmur vibrations after the middle third of systole. When there is audible cardiac sound in the last 25% to 30% of systole (a murmur extending up to the second heart sound [S_2]), it almost always indicates underlying abnormality (Fig. 68.2 and Fig. 68.3). In the presence of aortic or pulmonic stenosis at the valvular or subvalvular level, the systolic ejection murmur lengthens in relative proportion to the degree of obstruction to outflow (Fig. 68.3). A long systolic ejection murmur that extends into the last third of systole suggests significant outflow obstruction (Fig. 68.4); see Fig. 68.2D and Fig. 68.3.

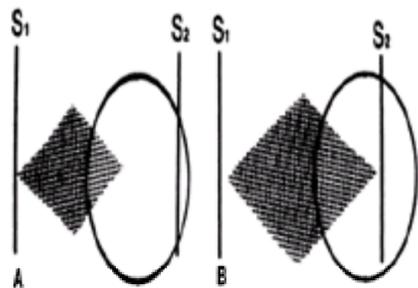

FIGURE 68.3. Importance of assessment of late systole in the evaluation of systolic murmurs. Careful evaluation of the last portion of systole is essential to make a determination as to whether a murmur is ejection in nature or is holosystolic. **A:** An early peaking systolic murmur ends before the last third of systole. This is the usual finding in functional or innocent murmurs, or with mild semilunar valve stenosis. **B:** A long ejection murmur is shown, which peaks late in systole. Sound vibrations extend literally to S_2 , suggesting major obstruction to outflow. In severe aortic or pulmonic stenosis, sound vibrations may extend up to and even beyond S_2 . (From Abrams J. Auscultation of heart murmurs: essentials of cardiac physical diagnosis. *Primary Cardio*. 1981;7:21; reprinted with permission from Primary Cardiology, PW Communications International, Inc.)

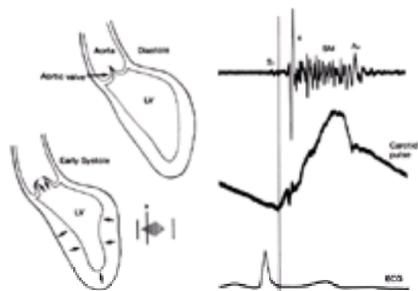

FIGURE 68.4. Aortic stenosis. Note the mechanism for the systolic ejection sound or click (X), which is produced by the maximal excursion or doming of the thickened or noncompliant aortic valve leaflets. This is typical of a congenital bicuspid valve. This systolic murmur (SM) is rather long, lasting throughout systole, indicating significant aortic stenosis. The carotid pulse demonstrates a slowed upstroke with a transmitted murmur or shudder. (From Abrams J. Aortic stenosis. *Primary Cardio*. 1983;9:28; reprinted with permission from Primary Cardiology, PW Communications International, Inc.)

Many systolic murmurs may truly be holosystolic or pansystolic, with the onset of murmur vibrations in early systole (with or just after the first heart sound [S_1]) and continuing to S_2 . The most common cause of such a murmur in adults is mitral regurgitation or insufficiency. In mitral or tricuspid valve regurgitation, the sustained systolic pressure difference between the respective ventricle and atrium provides for continuous retrograde blood flow across the atrioventricular (AV) valve into the respective atrium until the end of systole (Fig. 68.2A). Mitral or tricuspid regurgitation can exist without a holosystolic murmur. For instance, the systolic murmur may taper in late systole, ending before S_2 , or the murmur may be late in starting, extending up to S_2 , as in the classic late systolic murmurs of mitral valve prolapse and papillary muscle dysfunction (Fig. 68.2C).

Doppler echocardiography has revealed that regurgitant flow across the AV valves without an audible murmur is not rare. Although detection of Doppler flow signals suggesting regurgitant flow across the mitral and tricuspid valves without a typical systolic murmur on careful auscultation should raise questions about the physiologic and functional significance of these Doppler "jets," evidence suggests that even the best physical diagnostician occasionally misses organic disease. Whether these flow signals represent Doppler disease rather than true valve abnormality is not always clear. Occasionally, significant AV valve regurgitation can be truly silent to auscultation.

ASSOCIATED CARDIOVASCULAR FINDINGS

Because most pathologic heart murmurs result from hemodynamic perturbations, it follows that evidence of cardiac chamber enlargement, altered carotid arterial pulsations, or abnormalities of the venous pulse commonly are found in patients who have murmurs caused by underlying cardiac disease. Valve opening sounds, normally silent, may be audible when the valvular tissue is thickened, fibrotic, or otherwise abnormal. Table 68.1 lists several associated cardiac abnormalities encountered during physical examination that point to underlying cardiac abnormality; clues to establishing an organic basis of a heart murmur are discussed in a subsequent section. The electrocardiographic or chest radiographic abnormalities may also suggest that a particular heart murmur reflects disease, although the correlation between the murmur and the abnormal test result may be significant or fortuitous.

Cardiac rhythm: atrial fibrillation
 Carotid arterial pulse
 Small volume
 Slow rising
 Increased amplitude
 Double or bifid
 Jugular venous pulse
 Elevated mean pressure
 Very large a wave
 Dominant v wave
 Precordial motion
 Abnormal left ventricular activity: heave, increased forcefulness, palpable a wave (S₁), lifted jugularis, ectopic location
 Parasternal right ventricular lift or heave
 Heart sounds
 Loss of S₁
 Wide, fixed, or paradoxical splitting of S₂
 Loss of P₂
 Prominent S₂
 S₂ on adults (age 40)
 Abnormal heart sounds
 Mitral regurgitant click
 Ejection click
 Opening snap
 Pericardial knock

TABLE 68.1. FINDINGS ON THE CARDIOVASCULAR EXAMINATION SUGGESTIVE OF ABNORMAL HEART MURMUR

CAUSES OF A FALSE-NEGATIVE MURMUR

Occasionally, a patient may have serious cardiac structural disease but an unimpressive or no cardiac murmur when a murmur would be expected. Several factors contribute to this phenomenon (Table 68.2). The most likely and most important reason for a false-negative examination result is impaired cardiac function: a low stroke volume or a decreased left ventricular (LV) ejection fraction. If cardiac flow is reduced for any reason, murmur intensity may also be reduced or absent. Heart failure or a low cardiac output can seriously obscure conventional physical findings in cardiac disorders. Factors exogenous to the heart, such as obesity, a large anteroposterior thoracic diameter, pleural or pericardial fluid, or chronic obstructive lung disease, can decrease murmur intensity and audibility.

Obesity
 Muscular chest
 Large thorax
 Chronic lung disease
 Large breasts
 Low flow
 Low cardiac output or stroke volume
 Heart failure
 Depressed left ventricular systolic function
 Pleural or pericardial fluid or thickening
 Pregnancy
 Decreased systemic vascular resistance may decrease in regurgitant murmur audibility
 Poor stethoscope fit or improper technique (e.g., failure to use the bell and diaphragm appropriately)
 Loud ambient noise interference

TABLE 68.2. FACTORS THAT MIGHT RESULT IN AN UNDERESTIMATION OF MURMUR IMPORTANCE

Intracardiac factors can also decrease murmur intensity. For example, extensive calcification of the mitral valve and chordae is often associated with low flow and can decrease the loudness of the diastolic murmur or opening snap in mitral stenosis. Acoustic factors may play a role in decreasing murmur audibility. Low-pitched sounds or murmurs may not be heard well because the optimal range of hearing for most adults is greater than 1,000 cycles per second. Conversely, many older adults have occult high-frequency hearing deficiency. This can be a problem in murmur detection and identification. The high-pitched “blow” of mild aortic insufficiency is commonly missed, probably because most cardiac events are lower frequency and because persons are not used to listening for cardiac sounds and murmurs with such high frequencies.

It is essential to perform cardiac auscultation in a quiet environment without distractions. The level of noise in hospital rooms, clinics, or physicians' offices can be surprisingly high and usually goes unnoticed. Traffic, construction, and heating and air-conditioning units are common noise pollutants that can subtly interfere with accurate auscultation.

The use of poor-quality or improperly fitted stethoscope ear pieces is a common detriment to good listening. The highest quality stethoscope that a physician can afford is strongly recommended.

CAUSES OF A FALSE-POSITIVE MURMUR

Some murmurs are so prominent that they may result in a diagnosis of a more severe cardiac problem than exists. These can be considered false-positive examination results. Similarly, murmurs that suggest disease despite the absence of an abnormality are false-positive findings.

A common denominator for such murmurs is the presence of a high-flow state, in which the velocity of blood is increased. These individuals often have louder heart sounds and murmurs because of less tissue between the heart and the stethoscope. Children and young adults have prominent murmurs because of the high cardiac outputs in these age groups.

Certain cardiac factors can increase murmur intensity in the presence of organic heart disease and lead to an overestimation of the severity of the valve lesion. A classic example is the enhancement of stenotic murmur audibility in the presence of mixed obstructive and regurgitant lesions of the aortic or mitral valves; the excessive turbulent flow may suggest more serious obstruction than is the case. Even mild degrees of aortic or mitral regurgitation can augment stenotic murmurs.

Pregnancy can produce false-negative and false-positive findings. The enhanced blood volume and cardiac output of middle to late pregnancy typically results in a physiologic ejection murmur or augments the intensity of existing systolic ejection murmurs. Conversely, systemic arterial vasodilatation of pregnancy can diminish the intensity of mitral or aortic regurgitation murmurs, leading to a false-negative impression of the murmur intensity.

Large-volume flow across the AV valves can produce diastolic filling murmurs without valve obstruction. In severe mitral regurgitation, a mid-diastolic flow rumble may be prominent, suggesting coexisting mitral stenosis though none exists. A similar phenomenon can be heard in cases of major tricuspid regurgitation.

CLUES IN ESTABLISHING AN ORGANIC BASIS OF HEART MURMUR

Alert clinicians can take advantage of careful bedside observations that may aid the diagnosis of an abnormal heart murmur. Any cardiac abnormality detectable on examination in addition to the murmur in question increases the likelihood that the heart murmur has an organic basis (Table 68.1). A systematic assessment of the carotid arterial and venous pulsations, as well as the precordial area, is important in the process of murmur identification.

CAROTID PULSATATIONS

Careful attention to the contour and amplitude of the carotid arterial pulse helps to identify an aortic valve abnormality. An increased pulse volume, producing the sensation of a full, briskly rising systolic pulse, should raise the suspicion of aortic regurgitation. A gentle shudder or bifid contour suggests a bisferious pulse, found in pure aortic regurgitation or mixed stenosis and regurgitation. Conversely, a small-volume (hard-to-feel), slow-rising pulse suggests aortic stenosis (Fig. 68.4). In hypertrophic cardiomyopathy, the carotid upstroke is quick and tapping.

JUGULAR VENOUS PULSE

Although less specific than carotid artery findings, alterations in venous pulses may suggest heart disease. An elevated mean venous pressure indicates a high right ventricular (RV) filling pressure, and is consistent with right or biventricular heart failure or with marked pulmonary hypertension. In the latter condition or with a failing right ventricle, the jugular a wave is prominent. If there is associated tricuspid regurgitation, which is often acoustically difficult to detect, there is a dominant V wave in the venous pulse, often transmitted up the external jugular veins to the ear lobes.

PRECORDIAL MOTION

The presence of an LV or RV lift or heave (a sustained impulse that is palpable into the second half of systole) indicates an abnormality of the respective cardiac chamber. This may be a result of concentric hypertrophy or ventricular dilatation; it suggests that the murmur is likely to have a pathologic basis. Such findings increase the likelihood that an aortic ejection murmur has true hemodynamic importance (LV heave) or that mitral valve disease is severe enough to produce pulmonary hypertension (RV heave). Volume overloading of the heart, as in aortic regurgitation, may produce an apex impulse that is increased in amplitude but normal in contour. When the left ventricle is dilated, the point of maximal impulse of LV apical impulse is displaced leftward and downward from the normal middle left chest fourth and fifth interspaces; RV enlargement produces a parasternal or RV impulse.

ATRIAL FIBRILLATION

Atrial fibrillation is often seen in chronic mitral valve disease, and its presence should increase suspicion of mitral stenosis or insufficiency.

CLICKS AND SNAPS

Audible sounds of valve opening are always abnormal and represent helpful clues to the astute examiner. An opening snap is almost pathognomonic of mitral stenosis. Audible ejection clicks or sounds should focus attention on the aortic valve, usually indicating a bicuspid valve or possibly a dilated aortic root. Aortic ejection clicks are best heard at the apex, not at the aortic area. These sounds are usually loud, occur immediately after S₁, and radiate to the base ([Fig. 68.4](#)). Pulmonic ejection sounds are much less common. They should be suggested if the examiner detects an early systolic click at the upper left sternal edge that decreases with inspiration. Pulmonic stenosis (rare in adults) and pulmonary hypertension produce these sounds.

Midsystolic clicks are the hallmark of mitral valve prolapse and may be heard even if there is no systolic murmur. These are high-frequency popping sounds, best heard near the apex in midsystole to late systole. They are frequently accompanied by a late or, less often, holosystolic murmur ([Fig. 68.2C](#)), indicating associated mitral insufficiency.

HIGH-FREQUENCY DIASTOLIC MURMUR

The detection of a high-frequency diastolic decrescendo murmur along the left sternal border indicates aortic or pulmonic insufficiency and confirms an abnormality of one of the semilunar valves. A systolic ejection murmur at the base associated with a blowing diastolic murmur beginning with S₂ is probably caused by an aortic valve abnormality. Severe pulmonary hypertension with functional pulmonic insufficiency is virtually identical on auscultation.

Optimal detection of these murmurs, which are often difficult to hear, occurs with the patient sitting up and leaning forward, with the breath held in end expiration. Firm pressure on the diaphragm of the stethoscope is necessary to bring out the high-frequency vibrations of these murmurs.

WHEN TO ORDER A DOPPLER ECHOCARDIOGRAM

CONFIRMATION OF A DIAGNOSIS

If the examiner is not confident about her or his diagnostic skills in cardiac auscultation, obtaining an echocardiogram (with or without Doppler) is an obvious solution to assessing a heart murmur. The tendency to routinely order an echocardiogram is increasing, and this is unfortunate. It is appropriate for experienced physicians to use echocardiography, but this technology should not be used as a “fishing net” that is cast out indiscriminately. The physician should use Doppler echocardiography to confirm an impression or diagnosis of structural heart disease.

ESTIMATION OF SEVERITY

High-quality Doppler echocardiograms may be useful in helping to determine the severity of a known or suggested cardiac lesion. An approximation of the hemodynamic significance of aortic stenosis or mitral stenosis is reliably obtained by noninvasive study. Echocardiograms are somewhat less useful in assessing the precise severity of valvular regurgitant lesions. The size and status of the various cardiac chambers are readily determined by echocardiography, and this is important in the complete assessment of any structural abnormality.

VENTRICULAR FUNCTION

The status of LV function is a critical factor in the assessment of the organic murmurs of aortic stenosis and mitral regurgitation. In pulmonary hypertensive conditions and in cases of tricuspid regurgitation, RV size and performance must be assessed. Two-dimensional echocardiography is useful in evaluating ventricular size and function.

DETECTION OF OCCULT ABNORMALITIES

Doppler echocardiography is often useful in detecting unsuspected problems in patients for whom the physical examination is confusing or misleading. The occasional identification of acoustically silent mitral stenosis in the presence of major aortic stenosis or the diagnosis of significant pulmonary hypertension by Doppler are examples of the utility of this noninvasive procedure. Similarly, documentation of tricuspid regurgitation, often missed at the bedside but commonly present in persons with mitral valve disease or biventricular failure, is an excellent example of the help that a good-quality echocardiogram can provide.

TYPES OF MURMURS

SYSTOLIC MURMURS

Functional or Innocent Murmur

A functional systolic murmur is the most common murmur heard in daily practice. These murmurs are typically not loud, usually of grade 1 to 2 intensity. In high-flow states they may be grade 3, and this degree of loudness can mimic an organic murmur. Characteristically, the murmur is relatively pure in frequency or vibratory. The innocent systolic murmur ends well within the first 60% to 70% of the ejection period. These murmurs are typically best heard at the upper left sternal border. Still's murmur, an innocent murmur in children, is best heard just to the left of the lower sternal edge. If a systolic murmur is clearly maximal at the apex, careful scrutiny is necessary to exclude mitral regurgitation.

Functional murmurs are common in young adults and children. They are frequently found in hyperkinetic states. In older adults with stiffening and thickening of the aortic valve (aortic sclerosis), ejection murmurs are common. In these cases, the murmur tends to be more mixed frequency or harsh, and it radiates to the neck. In isolated aortic stenosis of the elderly, there may be few or no helpful associated cardiac abnormalities. In the aging population, electrocardiogram or chest radiographic abnormalities are common, and the correct diagnosis (i.e., aortic sclerosis versus true aortic stenosis) may require echocardiography.

The assessment of a functional or innocent murmur is in part a diagnosis of exclusion. No other suggestive findings are available, and the murmur meets the criteria presented earlier. Unusual loudness or prominent radiation to the neck or apex, or a particularly long systolic murmur, generally requires Doppler echocardiographic

interrogation.

Organic Systolic Murmurs

The major organic murmurs that must be considered in addition to a functional murmur are aortic sclerosis, aortic stenosis, mitral regurgitation, and mitral valve prolapse. A less common systolic murmur is that of hypertrophic cardiomyopathy. These conditions are considered in detail elsewhere in this volume.

In mitral regurgitation or aortic stenosis, a decompensated left ventricle may produce a softer, less impressive systolic murmur, even in the presence of a severe hemodynamic burden. The suggestion of valvular aortic stenosis or mitral regurgitation in a patient with congestive heart failure or a decreased LV ejection fraction mandates a meticulous search for evidence of valve disorder and its severity.

Diastolic Murmurs

The detection of a diastolic murmur virtually always indicates structural heart disease. There are two major variants of diastolic murmurs in the common adult cardiac conditions: the long decrescendo and usually high-frequency murmur of aortic insufficiency (Fig. 68.2E) and the low-pitched rumbling murmur of mitral stenosis (Fig. 68.2B). These murmurs appear at different times in diastole, have markedly different frequency characteristics, and are localized to different areas of the precordium. Occasionally, a mitral stenosis murmur is medium to high frequency and is easily heard close to the sternal border; such a murmur can be readily mistaken for aortic regurgitation.

Nonstenotic Middiastolic Murmurs

Several varieties of *flow rumble* or mid-diastolic flow murmurs are detectable in patients with various cardiac lesions. These murmurs can mimic mitral stenosis, and their presence confirms a significant hemodynamic burden related to the primary valvular abnormality.

In major degrees of mitral or tricuspid regurgitation, when increased blood traverses the respective AV valve during diastolic filling, a mid-diastolic murmur may be audible. These murmurs are relatively short and end well before S₁; they are detected in an apical location, with the patient in a left decubitus position for assessing mitral regurgitation, or located at the lower sternal edge and increasing with inspiration in the case of tricuspid regurgitation. Their presence suggests a big regurgitant leak at the respective valve. A comparable middiastolic murmur can be generated by a large left-to-right shunt at the atrial and ventricular level, when the excessive volume of blood from the shunt returns to the respective ventricle in diastole. A long rumbling diastolic murmur at the apex can simulate mitral stenosis in cases of severe aortic regurgitation. This is the Austin Flint murmur; when diagnosed correctly, the Austin Flint murmur indicates a major degree of regurgitation.

Continuous Murmurs

Continuous murmurs are rare. They indicate blood flow in late systole and early diastole, and result from a communication between a chamber or artery with systemic pressure or resistance with a low-pressure or resistance vessel or chamber, allowing continued blood flow after ventricular ejection has ended. Table 68.3 lists some of the more common continuous murmurs.

Patent ductus arteriosus
Arteriovenous fistula
 Congenital and acquired
 Systemic and pulmonary
Ruptured sinus of Valsalva aneurysm (communication usually into right atrium or right ventricle)
Venous hum (innocent finding in children)
Anomalous origin of coronary artery from pulmonary artery or coronary arteriovenous fistula
"Mammary souffle" of pregnancy
Systemic arterial-pulmonary arterial collaterals or bronchial arterial collaterals in congenital defects
Coarctation of the aorta at coarctation site and collateral vessels
Pseudocontinuous murmur: severe aortic stenosis and regurgitation
