Tumors of the CNS are a heterogeneous group of intracranial and intraspinal neoplasms ([Table 423.1](#)). Intracranial tumors are divided into two groups, those that grow within the brain (intracerebral) and those that begin outside the brain (extracerebral). Similarly, intraspinal tumors are divided into two groups, those that arise within the cord (intramedullary) and those that originate outside the cord (extramedullary). Extramedullary spinal tumors are subdivided further on the basis of their intradural or extradural location. Primary CNS tumors are then classified by their presumed cell of origin (astrocyte—astrocytoma; arachnoidal cell—meningioma; Schwann cell—acoustic neuroma). Metastatic tumors can be found in either the intracranial or the spinal space and arise from a variety of systemic cancers, the most frequent being lung, breast, and melanoma.

TABLE 423.1. TUMORS OF THE CENTRAL NERVOUS SYSTEM

EPIDEMIOLOGY

Most primary intracranial tumors are uncommon or rare illnesses. In North America, primary brain tumors occur in eight to ten people per 100,000 population per year. More than 60% of them are gliomas, and two-thirds of these are clinically aggressive and high-grade tumors. Primary brain tumors have a bimodal incidence distribution, with an early peak in childhood and a second peak after age 50 years. The locations and types of tumors also vary with age. Tumors of the posterior fossa predominate in children (medulloblastoma, ependymoma, cystic cerebellar astrocytoma, brain stem glioma), and those above the tentorium predominate in adults (glioblastoma multiforme, anaplastic glioma, astrocytoma, oligodendroglioma, meningioma, pituitary adenoma). Primary spinal neoplasms are rare at any age, arising in one to two people per 100,000 population per year. Most primary CNS tumors develop more frequently in men, but meningiomas are more common in women. Metastatic brain tumors are fourfold more common than all primary brain tumors combined, and metastatic epidural spinal tumors account for most spinal neoplasms.

ETIOLOGY

The cause of CNS tumors is unknown, though environmental and genetic factors contribute to their development. Cranial and spinal irradiation predispose to meningioma, fibrosarcoma, and glioma but account for less than 1% of these neoplasms. Long-term exposure to chemicals in the petroleum industry may predispose to glioma. Long-term parental exposure to toxic compounds may be a risk factor for CNS tumors in children. Severe head injury may be a risk factor for meningioma and glioma. Chronic immunosuppression (organ transplantation, AIDS) is associated with primary cerebral lymphoma. RNA viruses (avian sarcoma virus), DNA viruses (simian vacuolating virus), and chemicals (aromatic hydrocarbons, N-nitroso compounds) cause gliomas, meningiomas, sarcomas, and other tumors in animals, but no virus or specific chemical has been causally associated with human disease. Most CNS tumors develop sporadically, yet familial aggregations have been noted, and several inherited disorders are associated with CNS neoplasms ([Table 423.2](#)).

Disorder	Genetic Locus	Tumor Types
Neurofibromatosis type 1	17q11	Neurofibroma Glioma
Neurofibromatosis type 2	22q12	Acoustic neuroma (bilateral) Meningioma
Tuberous sclerosis	9q34 (50% of families) 16p13 (50% of families)	Gen of astrocyte (subependymal) Glioma
von Hippel-Lindau disease	3p25-26	Hemangioma
Multiple endocrine neoplasia type 1	11q23	Pituitary adenoma
Tourette syndrome	16p11	Glioma
Basal cell nevus syndrome (Gorlin syndrome)	9q33	Medulloblastoma Meningioma
Multiple hamartoma syndrome	Unknown	Meningioma
Neurocutaneous melanosis	Unknown	Leptomeningeal melanoma
Li-Fraumeni syndrome	17q11 (p53)	Glioma Medulloblastoma

TABLE 423.2. DISORDERS ASSOCIATED WITH CENTRAL NERVOUS SYSTEM TUMORS

Brain tumors, like most cancers, arise after mutation or altered expression of several growth-controlling *tumor suppressor genes* and growth-promoting *oncogenes*. The location and nature of these molecular abnormalities are being identified in specific tumor types, especially gliomas and meningiomas. Cytogenetic analyses of high-grade astrocytic gliomas show multiple abnormalities, including extra copies of chromosome 7 and loss of chromosome 10. Genetic losses, identified by Southern blot or polymerase chain reaction–based methods, implicate tumor suppressor gene abnormalities on chromosome 10 in glioblastoma multiforme; chromosomes 9p, 13q, and 19q in glioblastoma and anaplastic astrocytoma; chromosomes 17p (*p53* gene) and 22q in astrocytic gliomas of all malignancy grades; and chromosome 19q in low- and high-grade oligodendrogliomas and mixed gliomas. Studies of gene expression show amplification and rearrangement of several oncogenes in glioblastomas and anaplastic gliomas, notably the epidermal growth factor receptor (*EGFR*) gene, *MYCN*, *MYC*, and *GLI*. Glioma cells release growth factors (platelet-derived growth factor, transforming growth factor α), angiogenic factors (vascular endothelial growth factor), and proteolytic enzymes, which enhance growth and invasiveness and, like specific genetic abnormalities, are possible targets for novel therapies. Cytogenetic studies and loss-of-heterozygosity analyses in

meningiomas point to a critical tumor suppressor gene on chromosome 22, distinct from the bilateral acoustic neurofibromatosis gene.

SYMPTOMS AND SIGNS

Brain tumors produce both generalized and focal neurologic disturbances (see [Chapter 427](#) and [Chapter 430](#)). Generalized findings stem from raised intracranial pressure and include headache, drowsiness, vomiting, transient visual loss, papilledema, and neck stiffness. Tumor, peritumoral edema, and obstruction of cerebrospinal fluid (CSF) pathways with resulting hydrocephalus are the principal causes of raised intracranial pressure. Intratumoral hemorrhage or cyst formation are less common causes. Focal or lateralizing findings indicate regional abnormalities, such as language dysfunction, hemiparesis, or seizures. Not all focal findings accurately locate the tumor, however; raised intracranial pressure may provoke false localizing signs, such as visual loss, optic atrophy, or sixth nerve palsies. Headache occurs in 50% of patients with brain tumor, particularly younger patients; headache may be lateralizing but does not specifically locate the tumor. Headache is most prominent in the morning upon awakening and usually resolves within 1 to 2 hours. Certain constellations of symptoms and signs pinpoint the tumor and suggest a specific tumor type ([Table 423.3](#)). Pituitary and suprasellar tumors also produce non-neurologic symptoms and signs as a result of endocrine dysfunction.

TABLE 423.3. INTRACRANIAL TUMOR SYNDROMES

Brain tumors usually cause subacute or chronic symptoms, but they may take the form of acute symptoms of seizures, intratumoral hemorrhage, or ventricular obstruction. Hemorrhage is more common with metastatic than primary tumors (especially melanoma, hypernephroma, choriocarcinoma, and nonseminomatous testicular cancer), but among the primary tumors, glioblastoma multiforme and oligodendroglioma are most likely to bleed. Intratumoral cyst formation is an uncommon cause of acute worsening (gliomas, craniopharyngioma). The tempo at which symptoms and signs evolve may be a clue to the nature of the tumor. Subacute onset over weeks suggests rapid tumor growth and a malignant histologic type (glioblastoma multiforme, medulloblastoma, metastasis), whereas slowly progressive findings over months or years are indicative of benign tumors (meningioma, pituitary adenoma). The rate of growth and typical locations of common CNS tumors are summarized in [Table 423.4](#).

TABLE 423.4. GROWTH CHARACTERISTICS AND LOCATIONS OF COMMON CENTRAL NERVOUS SYSTEM TUMORS

Pain in the neck or back, which may radiate, is the first symptom of spinal tumor in most patients. Within days to years, pain is followed by weakness, sensory loss, and autonomic dysfunction. The interval between pain and other findings is shorter (weeks) with rapidly expanding tumors, such as spinal epidural metastasis, and longer (months or years) with slowly growing tumors, such as astrocytoma, ependymoma, meningioma, and neurofibroma. Cervical, thoracic, and upper lumbar tumors produce a combination of segmental (local) and long tract findings. Segmental symptoms and signs result from damage to local spinal roots and adjacent spinal cord gray matter. Long tract symptoms and signs manifest below the level of the tumor, reflecting damage to motor, sensory, and autonomic fibers descending or ascending the cord. Tumors below L2 compress the cauda equina, not the spinal cord, producing lower back pain, sciatica, muscle wasting, weakness, dermatomal sensory loss, reflex loss in the legs, and autonomic dysfunction by involving single or multiple lumbosacral spinal roots.

Specific spinal tumor syndromes are recognized. Clockwise limb weakness, loss of position and vibration sense in the arms, and atrophy of the hand muscles are characteristic of high cervical and foramen magnum tumors. Dissociated sensory loss (segmental pain and temperature loss with preservation of posterior column function) and sacral sparing are characteristic of cervical and upper thoracic intramedullary tumors. Ipsilateral pyramidal signs and contralateral spinothalamic disturbance (Brown–Séguard syndrome) are features of lateral cervical and thoracic tumors. Early autonomic dysfunction with relative preservation of leg strength and sensation is characteristic of tumors compressing or invading the conus medullaris. Long-standing lower back and sciatic pain without other neurologic findings is characteristic of slowly growing tumors of the cauda equina. Kyphoscoliosis and deformities of the feet may be the initial features of spinal cord tumors in children. Lumbosacral sinus tract, dimple, tuft of hair, or birthmark may point to an underlying tumor of the conus or cauda equina. A combination of cranial and spinal findings, including headache, mental change, cranial neuropathy, polyradiculopathy, and autonomic disturbance, is the hallmark of diffuse leptomeningeal metastasis (leukemia, lymphoma, and solid tumors).

DIAGNOSIS

Advances in neuroimaging have revolutionized the diagnosis of CNS tumors (see [Chapter 452](#)). Most tumors of sufficient size to cause symptoms can be seen. Magnetic resonance imaging (MRI), alone and with gadolinium, is the best diagnostic test for brain and spinal tumors. It has largely replaced computed tomography (CT) scanning, though CT is still less expensive than MRI. Radiographic characteristics of brain tumors are comparable on both MRI and CT scans ([Table 423.5](#)), except that calcification is better seen on CT. High-grade primary brain tumors and metastases are best seen after the administration of iodinated contrast (CT) or gadolinium (MRI); both CT and MRI locate the tumor precisely, because the blood–brain barrier disruption typical of malignant tumors permits dye extravasation and tumor enhancement. Low-grade tumors (fibrillary astrocytoma) are typically nonenhancing lesions seen as regions of hypodensity on CT or as regions of hypointensity on T1-weighted or hyperintensity on T2-weighted MRI ([Fig. 423.1](#)). They are clearly visible on MRI but can be easily missed on CT. Small tumors near the skull base (frontal, intrasellar, suprasellar, clivus, cerebellopontine angle, foramen magnum) are best imaged by MRI, which eliminates the distortion on CT scan created by adjacent bone. Bone artifact also may obscure small tumors of the brain stem or cerebellum, and MRI may be the only means of identifying tumors in these areas.

Tumor Type	Precontrast	Postcontrast
Astrocytoma	Hypointense (MRI T1)	No enhancement
Oligodendroglioma	Hypointense (CT)	No enhancement
Mixed glioma	Hypointense (MRI T2)	No enhancement
Brain stem glioma		
Secundary glioma		
Primary astrocytoma	Hypointense (MRI T1)	Enhancement
Oligoastrocytoma	Hypointense (CT)	Enhancement
Anaplastic glioma		
Metastasis		
Cystic cerebellar astrocytoma		
Cystic cerebellar astrocytoma	Isointense or hypointense (MRI T1)	Enhancement
Meningioma	Isointense or hypointense (CT)	Enhancement
Macroglioma		
Lymphoma		
Medulloblastoma		
Ependymoma		
Hemangiopericytoma (hemangioma)		
Choroid plexus papilloma		
Paraganglioma		
Colloid cyst	Hypointense (MRI T1)	No enhancement
Sarcoma	Hypointense (CT)	No enhancement

TABLE 423.5. MAGNETIC RESONANCE IMAGING/COMPUTED TOMOGRAPHY SCAN APPEARANCE OF COMMON BRAIN TUMORS

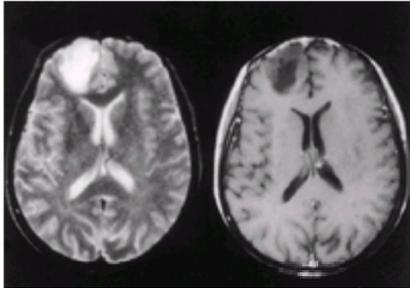

FIGURE 423.1. Magnetic resonance scan of a low-grade right-sided frontal astrocytoma. On the left is a T2-weighted image and, on the right, a T1-weighted image after gadolinium infusion; note the absence of enhancement after gadolinium.

Spine MRI is now the optimal test for evaluating patients with suspected spinal tumors (see [Chapter 452](#)). Tumors that are extradural (metastases) can be seen on MRI without using gadolinium for enhancement; however, intradural tumors (meningioma, spinal cord glioma) often are more easily made visible after gadolinium administration. Plain films show negative results in most patients with primary spinal neoplasms but positive results in 80% to 90% of patients with spinal epidural metastasis. Vertebral collapse and pedicle erosion are the common findings. Myelography also can identify the level, extent, and nature (extradural, intradural, intramedullary) of most spinal tumors, but it is invasive. Complete myelographic assessment may require lumbar and cervical (lateral C1 to C2) dye injections, to ascertain both the rostral and caudal extent of tumor. Spine CT scans done immediately after myelography help find bone destruction, paraspinal tumor, and the location of an intraspinal tumor. Unlike MRI, myelography permits sampling of the CSF, to assess for leptomeningeal tumor, which may be an important issue for some patients.

Analysis of CSF for malignant cells and tumor markers may be helpful in patients suspected of leptomeningeal metastases, or “drop metastases” from a primary tumor (medulloblastoma, anaplastic ependymoma, germ cell tumor, primary cerebral lymphoma). Lumbar puncture may lead to herniation in patients with brain tumor or cause neurologic deterioration in patients with spinal tumor; it should be undertaken only after cranial imaging and only when necessary. The typical CSF picture in patients with leptomeningeal cancer includes pleocytosis, elevated protein level, low glucose level, and a positive result on cytologic examination. CSF levels of human chorionic gonadotropin and α -fetoprotein may be elevated in the context of intracranial germ cell tumors, and other tumor markers (carcinoembryonic antigen, lactate dehydrogenase isoenzymes) may be high with leptomeningeal metastases from systemic cancers.

TREATMENT—GENERAL CONSIDERATIONS

Treatment for brain and spinal cord tumors can be divided into two broad categories, supportive measures and definitive treatment. Supportive measures are directed at symptom control and include emergency management, corticosteroid administration, and antiseizure medications. Definitive treatments, including surgery, radiation therapy, and chemotherapy, are directed against the neoplasm itself, with the goal of reducing tumor size and controlling subsequent growth.

SUPPORTIVE MEASURES

Threatened cerebral herniation and impending spinal cord compression require emergency treatment (see [Chapter 445](#)). Rapid reduction of raised intracranial pressure is the first step in the emergency treatment of patients with brain tumor. Most patients stabilize or improve after intravenous corticosteroids alone, but herniation with coma may require intubation, hyperventilation, intravenous mannitol, and, in some instances, ventricular drainage. Definitive treatment then proceeds under controlled circumstances. Patients with spinal tumors who suddenly have leg weakness, numbness, or urinary retention may improve with intravenous corticosteroid therapy alone, but usually they require urgent surgical decompression or radiation therapy.

Corticosteroids are highly effective symptomatic treatment for patients with intracranial and spinal neoplasms. Neurologic symptoms and quality of life often improve dramatically within 24 to 48 hours. These agents exert their beneficial effect by controlling peritumoral edema. In addition, corticosteroids control postoperative swelling and lessen the incidence and severity of acute radiation reactions due to perilesional edema incited by radiation therapy. Corticosteroids are administered preoperatively, perioperatively, and often throughout radiation treatment. Subsequently, many patients can be tapered off corticosteroids, though some experience exacerbation of neurologic symptoms at this time and require continued treatment. Corticosteroid dependence is often a poor prognostic sign. Long-term use is associated with many side effects, including mental change (ranging from mild agitation to psychotic delirium), hyperglycemia, opportunistic infection, steroid myopathy (which can be confused with tumor progression), and aseptic necrosis of the femoral head. Acute and chronic corticosteroid toxicities improve with dose reduction and resolve when discontinued, but some side effects, such as steroid myopathy, take weeks to months to disappear.

Anticonvulsants, usually phenytoin, carbamazepine, or phenobarbital, are used for the 20% to 25% of brain tumor patients who have seizures. Prophylactic anticonvulsants are useful in the perioperative period for patients who have not had a seizure. Some physicians continue them indefinitely, but randomized prospective studies show that prophylactic anticonvulsants are ineffective. Pain control; hormone replacement; physical, occupational, and speech therapies; and psychosocial support are other important aspects of treatment.

DEFINITIVE TREATMENT

Surgery and radiation therapy are the principal treatments for most CNS tumors. Surgery, now enhanced by MRI- and CT-guided stereotaxis, is also necessary for diagnosis. Surgery is curative therapy for many, primarily low-grade, tumors (meningioma, pituitary adenoma, acoustic neuroma, cystic cerebellar astrocytoma, choroid plexus papilloma, colloid cyst, neurofibroma). It also plays an important role in the treatment of malignant neoplasms; debulking often improves symptoms, lessens corticosteroid dependence, and prolongs survival. Radiation therapy is standard treatment for most patients with malignant tumors (glioblastoma, anaplastic glioma, primary cerebral lymphoma, malignant meningioma, brain metastasis, germ cell tumor, medulloblastoma, brain stem glioma, epidural spinal metastasis) and may be delivered by external beam, either conventionally or stereotactically (radiosurgery), or by the interstitial technique (brachytherapy). Radiation therapy also may be recommended for some patients with partially resected benign tumors (astrocytoma, oligodendroglioma, ependymoma, meningioma, pituitary adenoma, craniopharyngioma, spinal cord glioma).

Systemic chemotherapy is particularly effective for primary cerebral lymphoma, anaplastic oligodendroglioma, medulloblastoma, and germinoma. Nitrosoureas and procarbazine are the most active drugs for glial tumors, methotrexate for cerebral lymphoma, and the platinum compounds for germ cell tumors and medulloblastoma. Intracarotid chemotherapy is not efficacious and can be neurotoxic. Regional treatment using drug-impregnated, implantable wafers has modest efficacy in the

treatment of recurrent malignant gliomas. Antiangiogenesis and gene therapies are investigational approaches under development for glial neoplasms. Intrathecal chemotherapy, through lumbar puncture or Ommaya reservoir, is an effective treatment for leukemic and lymphomatous meningitis. Some patients with carcinomatous meningitis, especially from breast cancer, also improve. Most chemotherapeutic agents are toxic when given intrathecally, but methotrexate, cytarabine, and thiopeta can be used safely.

TREATMENT—SPECIFIC TUMOR TYPES

This section reviews the current management of common CNS tumors and those less common neoplasms for which treatment is either multimodal, changing, or the subject of controversy. Other CNS tumors treated primarily by surgery are summarized in [Table 423.6](#). For all CNS tumors, prognostic factors have a powerful effect upon outcome. The most important factors that are influential in assessing virtually all tumor types are age and performance status; young adults, in good clinical condition at diagnosis, have a significantly better chance of survival than older patients in poor condition. For glial tumors, histologic features and extent of surgical resection also affect outcome. The factors are independent of treatment and, in the case of glial tumors, exert a more profound influence on survival than any therapeutic method.

Tumor Type	Treatment	Comments
Cerebellar astrocytoma	Surgery	
Hemangioblastoma	Surgery	
Meningioma	Surgery	
	RT	Focal (atypical/malignant)
Acoustic neuroma	Surgery	
	RT	Radiosurgery (selected patients)
Choroid plexus papilloma	Surgery	
	RT	Focal or neuraxis (malignant)
Pituitary adenoma (nonadenoma)	Surgery	
	RT	Incomplete resection (selected patients)
	Bromocriptine	Prolactin secreting
	Octreotide	Growth hormone secreting
Oligiocharyngioma	Surgery	
	RT	Incomplete resection (selected patients)
Dermoid/epidermoid	Surgery	
Chordoma	Surgery	
	RT	Proton beam

RT, radiation therapy

TABLE 423.6. CENTRAL NERVOUS SYSTEM TUMORS PRIMARILY TREATED BY SURGERY

GLIOBLASTOMA AND ANAPLASTIC ASTROCYTOMA

Glioblastomas and anaplastic astrocytomas are the common primary brain tumors of adults. Optimal treatment includes maximum “safe” surgical resection followed by radiation therapy and systemic chemotherapy. The completeness of surgical removal is dictated largely by tumor location; for example, nondominant frontal lobe tumors can be extensively debulked, whereas tumors in the basal ganglia or thalamus can only be biopsied for diagnosis. Radiation is delivered by external beam using x-rays from a linear accelerator or cobalt unit to a local field that includes tumor and peritumoral tissue only. Tumor control may be enhanced somewhat by a radiosurgical boost, but this is limited to small focal tumors, and efficacy has yet to be established. Several alkylating agents have antiglioma activity, but carmustine given intravenously is the standard chemotherapy drug for the initial treatment of glioblastoma. PCV, a combination chemotherapy regimen consisting of procarbazine, lomustine (CCNU), and vincristine, may be superior to carmustine for anaplastic astrocytomas but is more toxic. Treatment prolongs life but is seldom curative; the median survival is 10 to 12 months for glioblastoma and 2 to 3 years for anaplastic astrocytoma. Nonrandomized studies of innovative therapies reporting longer-than-expected survivals must be interpreted cautiously; they may have excluded patients with large tumors and unfavorable prognostic factors, such as older age and poor performance status, which can enhance the apparent benefit of the experimental treatment.

ASTROCYTOMA

Several histologic subtypes of astrocytoma, including pilocytic astrocytomas (cystic cerebellar astrocytomas), pleomorphic xanthoastrocytomas, subependymal giant-cell astrocytomas (of tuberous sclerosis), and gangliogliomas, are circumscribed, indolent neoplasms of children and adolescents, curable by surgical resection; radiation is seldom necessary, and malignant degeneration is uncommon. Fibrillary astrocytomas, on the other hand, are diffusely infiltrating tumors of the cerebral hemispheres and spinal cord in adults, rarely curable by surgery alone. Local-field irradiation by conventional external beam enhances tumor control but may be neurotoxic (impaired cognition, myelopathy) in long-term survivors. For hemispheric tumors, the timing of radiation therapy is debated; some advocate early treatment, particularly for symptomatic patients or after partial resection, whereas others prefer to postpone radiation, especially for asymptomatic patients or after gross total removal. Although fibrillary astrocytomas are relatively indolent initially, many progress to anaplastic astrocytomas or glioblastomas. The median duration of survival is 5 to 10 years for patients with fibrillary astrocytomas of the brain.

OLIGODENDROGLIOMA

Oligodendrogliomas may be low grade and exceedingly indolent or high grade (anaplastic) and moderately aggressive; although it is imperfect, this correlation between histologic type and behavior is helpful prognostically and guides treatment. Oligodendrogliomas, most commonly seen in young and middle-aged adults, are frequently amenable to radical surgical resection and re-resection if necessary, because 50% of them are found in the frontal lobe. After surgery, local-field irradiation by conventional external beam has been the standard treatment for anaplastic tumors and often is recommended for symptomatic, partially resected low-grade oligodendrogliomas. The wisdom of early radiation for oligodendrogliomas, a treatment that can be neurotoxic in long-term survivors, is being reconsidered in light of their unusual chemosensitivity; anaplastic oligodendrogliomas and symptomatic, enlarging low-grade tumors respond predictably to PCV. Chemotherapy may soon be the initial nonsurgical treatment for oligodendrogliomas. After surgery and radiation, the median duration of survival is 3 to 5 years for patients with anaplastic tumors and 10 years for those with low-grade oligodendrogliomas.

EPENDYMOMA

Ependymomas occur at all levels of the neuraxis. Intracranial tumors are frequently found in the posterior fossa and are more common in children. Both low-grade and anaplastic intracranial ependymomas seed the leptomeninges occasionally. Treatment includes complete surgical removal, if possible; disease staging by gadolinium-enhanced spinal MRI and CSF cytologic examination; and limited-field irradiation for tumors that are localized or craniospinal irradiation for disseminated disease. Standard initial treatment for older children and adults does not include chemotherapy, but platinum-based regimens have been effective for recurrences. Chemotherapy is used increasingly to postpone radiation in very young children, because they suffer serious developmental side effects after cranial or spinal irradiation. The median duration of survival is 5 years for intracranial ependymomas; very young age, supratentorial location, incomplete resection, anaplastic histologic features, and early dissemination are poor prognostic indicators. Intramedullary spinal ependymomas are often circumscribed and removable by surgery; radiation is recommended after incomplete resection only. Myxopapillary ependymomas of the conus medullaris are difficult to remove completely and may require radiation; those in the filum terminale that can be resected completely require no further treatment.

MEDULLOBLASTOMA

Medulloblastomas are aggressive cerebellar tumors that primarily affect children. Treatment begins with maximum surgical resection. After surgery, the disease is staged by gadolinium-enhanced spinal MRI, CSF for cytologic examination, and bone scan. The extent of surgical resection and tumor stage are helpful prognostic features and guide treatment. Patients with complete resections and no evidence of dissemination have a more favorable prognosis (low or standard risk) compared with those with subtotal resection, brain stem involvement, leptomeningeal spread, or bony metastases (high risk). Subclinical, undetectable leptomeningeal seeding is common with medulloblastoma; for this reason, all patients, except very young children, receive craniospinal irradiation with a boost to the posterior fossa. Overall, the 5-year disease-free survival rate is 65%. High-risk patients are treated with platinum-based adjuvant chemotherapy in addition to radiation, and very young children receive chemotherapy instead of radiation until the musculoskeletal and nervous systems mature more fully. High survival rates (85%) have been reported for aggressively treated, high-risk cases; in light of this, many physicians have added adjuvant chemotherapy for standard-risk patients.

PRIMARY CENTRAL NERVOUS SYSTEM LYMPHOMA

Lymphomas, usually of B-cell origin, once were considered rare tumors of older adults, but they are seen increasingly in younger patients and in the context of iatrogenic or AIDS-associated chronic immunosuppression. Surgery is important for diagnosis but has little therapeutic value for this diffusely infiltrating, multifocal neoplastic process. Many CNS lymphomas are exquisitely corticosteroid sensitive, a property that is advantageous therapeutically but can complicate the diagnostic process; large tumors may regress in the time it takes to organize a stereotactic biopsy procedure. If lymphoma is suspected (clinically or radiologically), corticosteroids should be withheld until the day of surgery. Primary CNS lymphomas are radiosensitive cancers, and for many years whole-brain radiation therapy was the standard treatment. Although some younger patients may have been cured by radiation alone, most died as a result of recurrent tumor 12 to 18 months later.

CNS lymphomas are sensitive to cytotoxic drugs; the addition of systemic chemotherapy to cranial irradiation has doubled median survival (>40 months). Most effective regimens now include high-dose methotrexate and cytarabine; both cross the blood–brain barrier to reach nonenhancing or microscopic tumor. After barrier disruption, chemotherapy with mannitol is an approach used by some, to ensure adequate drug delivery to occult disease. Chemotherapy is given before cranial radiation to assess response and minimize toxicity; however, methotrexate can cause serious neurotoxicity when combined with cranial irradiation. Chemotherapy alone is being investigated in terms of efficacy and reduced CNS toxicity.

GERM CELL TUMORS

Germ cell tumors of the CNS are rare cancers of children and young adults. There are two categories, germinomas and nongerminomatous germ cell tumors; the latter group includes choriocarcinoma, embryonal carcinoma, endodermal sinus tumors, and teratomas. They occur in the pineal and suprasellar regions, where they can be sampled for biopsy but are difficult to remove. They can seed the leptomeninges, necessitating postoperative staging with gadolinium-enhanced spinal MRI, CSF cytologic examination, and CSF biochemistry for the tumor markers α -fetoprotein and b-human chorionic gonadotropin. Germinomas are highly radiosensitive and curable by radiation alone in more than 90% of patients. In an effort to eliminate brain irradiation because of neuropsychological consequences, recent work has focused on the use of combination chemotherapy as initial treatment for germinomas. Platinum-based regimens similar to those for testicular cancer can effect complete responses in many patients; however, these regimens are toxic, and 50% of patients require radiation therapy within 2 years of diagnosis. Therefore, the superiority of this approach has yet to be established. Those with nongerminomatous tumors always require radiation treatment and chemotherapy but are rarely cured.

METASTATIC BRAIN TUMOR

Treatment for metastatic brain tumor depends on the number of lesions and the status of the underlying malignancy. At diagnosis, 50% of patients have single lesions, and an additional 20% have only two. These patients are candidates for focal treatment, whereas those with many brain metastases need whole-brain radiotherapy. Patients with single, surgically accessible tumors and controlled or limited systemic disease should undergo tumor resection. Occasionally, patients with two lesions and limited systemic disease—particularly from radioresistant cancers, such as renal cell carcinoma—are candidates for surgical treatment. Complete resection followed by cranial irradiation prolongs median survival (10 months) compared with radiation alone (4 to 6 months), and some patients are long-term survivors.

The need for radiation therapy after complete resection of a single metastasis from a highly radioresistant primary has been questioned; some physicians postpone radiation therapy and consider reoperation should the tumor recur. Patients with widely disseminated systemic cancer or many brain metastases are treated with whole-brain radiotherapy; although their median survival is short (4 months) and few survive a year, most stabilize or improve neurologically and die as a result of progressive systemic disease. For these palliative cases, radiation therapy usually is delivered over 1 to 2 weeks using large dose fractions. Surgical candidates with the potential for long survival may have fewer late neurologic residual effects if they are irradiated in a more protracted fashion over 3 to 4 weeks using smaller daily fractions. Some patients with few lesions or with recurrent metastases may be candidates for radiosurgery.

METASTATIC EPIDURAL SPINAL CORD COMPRESSION

Epidural spinal metastasis, a common complication of lung, breast, and prostate cancer, is treated with radiation or a combination of surgery and radiation. The indications for surgery include diagnostic uncertainty, tumor in a previously irradiated field, radioresistant primary, and intractable pain. Laminectomy is the most common surgical procedure; it allows for decompression of the cord, but because metastatic tumors typically are located anteriorly in the vertebral body, relatively little tumor is removed. Definitive surgical management requires resection of the vertebral body through an anterolateral approach, followed by spinal reconstruction and stabilization. Occasionally, definitive resection can be accomplished posterolaterally with only partial removal of the vertebral body. Both are major procedures requiring an experienced surgical team and highly selected patients with localized spinal disease and limited systemic tumor.

After surgery, most patients receive radiation if it has not been administered previously. Radiation alone is the treatment of choice for most patients with spinal epidural metastasis. Once the tumor's rostral and caudal extent are known (by MRI), a treatment field is delineated and radiation given by conventional external beam. Radiotherapy is particularly effective for radiosensitive tumors, such as lymphoma and breast cancer, but also for moderately sensitive tumors, such as lung cancer. Radioresistant tumors, such as renal cancer, often are treated surgically—for hypernephroma, typically after an embolization procedure to minimize hemorrhage. Experts debate the intricacies of treatment, but all agree that early diagnosis is essential to good outcome; those patients who are ambulatory at diagnosis usually remain so, but paraplegic patients rarely walk again.

CHAPTER 424: APPROACH TO THE PATIENT WITH IMPAIRMENT OF CONSCIOUSNESS

JOHN J. CARONNA

[Role of the Brain Stem and the Hemispheres in the Regulation of Consciousness](#)
[Definitions: Coma, Stupor, and the Vegetative State](#)
[Categories of Coma and Differential Diagnosis](#)
[Neurologic Examination](#)
[Management of the Patient in Coma of Unknown Cause](#)
[Outcome of Coma and Cost-Effectiveness of Care](#)

ROLE OF THE BRAIN STEM AND THE HEMISPHERES IN THE REGULATION OF CONSCIOUSNESS

Level of consciousness is defined by both arousal and conscious behavior. Changes in level of consciousness depend on the activities of a brain stem regulatory system called the reticular activating system (RAS). Anatomically, the RAS consists of the paramedian regions of the thalamus, midbrain, and the pons not associated with the cranial nerves or specific ascending or descending pathways. Arousal is a crude function that is simply wakefulness and reflects activation of the RAS by somatosensory stimuli or innate motivational symptoms, such as hunger. In clinical terms, arousal is indicated by eye opening, either spontaneously or in response to stimuli. In some cases, arousal may occur despite complete destruction of the hemispheres. Awareness, that is cognition of self and the environment, implies functioning cerebral hemispheres. Awareness is marked by goal-directed or purposeful motor behavior and the use of language. Mutually sustaining areas of both the RAS and the cerebral hemispheres are required to maintain full consciousness.

DEFINITIONS: COMA, STUPOR, AND THE VEGETATIVE STATE

Coma is a pathologic state in which neither arousal nor awareness is present. The comatose patient maintains a sleeplike unresponsiveness from which he or she cannot be aroused; eye opening does not occur, no comprehensible speech is detected, and the extremities neither move to commands nor respond appropriately to localize or ward off noxious stimuli. Nonpurposeful, reflex movements such as flexor (decorticate) or extensor (decerebrate) posturing may be present. Stupor resembles coma, except that the patient remains arousable if strong external stimulation is provided.

Discrete structural lesions in the paramedian areas of the rostral brain stem make arousal impossible by interrupting impulses from the RAS to the hemispheres. Coma induced by depressant drugs, anesthetics, or endogenous metabolic toxins may result from metabolic depression of the RAS alone or depression of both hemispheres. A unilateral lesion in a cerebral hemisphere does not cause coma until brain swelling and herniation impair function either of the opposite hemisphere or, more frequently, of the rostral brain stem and its reticular formation. In some cases, particularly after anoxic–ischemic injury due to cardiac arrest or after head trauma, both hemispheres are severely damaged, but the brain stem RAS is preserved. After a period of coma lasting hours to days, wakefulness returns without evidence of purposive behaviors or cognition. This functionally decorticate state is distinct from coma and is termed the *vegetative state*.

CATEGORIES OF COMA AND DIFFERENTIAL DIAGNOSIS

All types of coma may be divided into three categories: supratentorial lesions, infratentorial lesions, and metabolic encephalopathy. Each has a characteristic clinical evolution. The key to clinical diagnosis when the history is in doubt is to identify the initial anatomic distribution of the lesion and how it evolves ([Table 424.1](#)).

Symmetrical Signs, Brain Stem Functions Intact
Rule: Cause of coma most likely is metabolic or diffuse. Concentrate on metabolic, toxic, and infectious sources.
Exception: Early central herniation (see text) due to a supratentorial mass lesion may mimic metabolic encephalopathy.

Asymmetrical Signs, Brain Stem Functions Intact
Rule: Cause of coma is probably an acute hemisphere mass lesion. Treat urgently to check further herniation.
Exception: Hypoglycemic and hepatic encephalopathy may produce asymmetrical signs, but usually asymmetries do not persist. Metabolic encephalopathy superimposed on a previous neurological deficit may cause confusion in diagnosis.

Symmetrical Signs, Caudal Brain Stem Functions Impaired
Rule: Cause of coma is most likely intoxication or metabolic encephalopathy.
Exception: A posterior fossa mass lesion causing rostral to caudal deterioration may mimic metabolic coma.

Asymmetrical Signs of Brain Stem Dysfunction
Rule: Cause of coma is most likely a structural lesion of the posterior fossa. Consider basilar artery thrombosis, pontine hemorrhage, and cerebellar infarct or hematoma.
Exception: None.

TABLE 424.1. PHYSICAL DIAGNOSIS OF COMA: RULES AND EXCEPTIONS

SUPRATENTORIAL LESIONS

Mass lesions of the cerebral hemispheres cause coma by herniating beyond the confines of the supratentorial compartment and compressing the brain stem RAS. Two syndromes of herniation associated with supratentorial lesions are recognized.

Central Downward Transtentorial Herniation

Deep midline tumors, large edematous hemisphere infarcts, and subdural hematomas may compress and shift the supratentorial contents downward through the tentorial opening into the subtentorial compartment. Unless herniation is checked by treatment, there is progressive failure of the rostral brain stem and then the pons and medulla. The initial stages of cerebral herniation are marked by symmetrical signs, which may be mistaken for metabolic encephalopathy. The first clinical signs reflect failure of the hemispheres and subcortical structures and include reduced consciousness, small pupils with preserved reaction to light, bilateral signs of corticospinal and extrapyramidal tract dysfunction, grasp reflexes, decorticate posturing, and periodic (Cheyne–Stokes) respirations. At this stage, downward herniation is potentially reversible by osmotic agents and, if a tumor or hematoma is present, by surgery. When signs of midbrain failure appear (fixed, dilated, or midposition pupils and decerebrate rigidity), it is likely that distortion and compression have led to irreversible infarction of the brain stem.

Herniation of the Temporal Lobe

An expanding mass in one hemisphere or in the lateral middle fossa may displace the uncus of the temporal lobe medially over the edge of the tentorial opening and compress the third cranial nerve, the adjacent midbrain, and the posterior cerebral artery. The earliest sign of uncal herniation is unilateral pupillary dilation with a preserved or sluggish light reaction. As the uncus continues to compress the midbrain, the patient becomes deeply comatose and manifests ipsilateral third nerve palsy and contralateral decerebrate posturing. Bilateral decerebrate rigidity develops when the contralateral cerebral peduncle is compressed against the tentorial edge opposite the side of herniation. If treatment cannot halt brain displacement at this point, brain stem dysfunction progresses in a manner clinically indistinguishable from that caused by central herniation. In either type of herniation syndrome, destruction of the midbrain RAS results in irreversible coma.

SUBTENTORIAL LESIONS

Two types of posterior fossa lesions produce coma: lesions intrinsic to the brain stem that destroy the RAS (pontine hemorrhage and paramedian infarction of the midbrain or pons) and lesions extrinsic to the brain stem that compress and distort it (cerebral tumor and hematoma). In addition, unconsciousness follows direct blows to the brain stem reticular formation, as occurs in cerebral concussion and rupture of an adjacent cerebral aneurysm.

Hemorrhage into the pontine tegmentum produces coma accompanied by a distinctive clinical pattern. The pupils are pinpoint; horizontal eye movements are

impaired, but vertical eye movements may be preserved; and ocular bobbing may occur. Decerebrate rigidity or flaccid quadriplegia, hyperthermia, and progressive slowing of respiration are characteristic. Compressive lesions of the brain stem are often difficult to distinguish from intrinsic lesions, and cerebellar hemorrhage may mimic brain stem stroke in its clinical features. In other cases, the caudal-to-rostral evolution of neurologic signs may resemble the patchy brain stem depression of sedative drug intoxication. Asymmetric motor signs and hypertension due to Cushing's reflex usually serve to identify brain stem compression.

METABOLIC ENCEPHALOPATHY

Metabolic encephalopathy refers to changes in level of consciousness that result from diffuse failure of cerebral metabolism. Metabolic encephalopathy develops acutely or subacutely, commonly produces coma, and is often reversible if the underlying systemic disorder is treated. Examples include anoxia, hypoglycemia, uremia, and drug intoxications. The anatomic locus of metabolic brain disease has not been defined with certainty. The traditional view has been that the neurons of the cerebral cortex are affected first; then, as the metabolic defect becomes more severe, the subcortical structures are affected from the rostral to the caudal end. A second concept is that the neurons of the RAS are affected first and cause the cortical neurons to cease functioning by depriving them of stimulation.

Pathophysiology

In most cases of metabolic encephalopathy, cerebral oxygen uptake is depressed. The degree of brain dysfunction that manifests clinically is proportionate to a decline in cerebral oxygen metabolism. For example, the brain normally consumes about 3.5 mL of oxygen for each 100 g of brain tissue per minute. When this rate declines to 2.5 mL, delirium supervenes; rates of cerebral oxygen metabolism below 2 mL per 100 g per minute are incompatible with an alert state. The mechanisms of action by which systemic illnesses interfere with cerebral metabolism are not known in every case. The relationship between systemic metabolic defects and cerebral dysfunction is clear, however, in two commonly encountered conditions, hypoxia and hypoglycemia.

Hypoxia

Under normal conditions, 90% of the cerebral energy needed to transmit nervous impulses and to maintain ionic gradients across cell membranes is derived from the oxidation of glucose. Because it does not store oxygen, the brain can survive for only a few minutes if oxygen is reduced below critical levels. During acute, total anoxia, consciousness is lost within 15 seconds. In humans, the electroencephalogram shows when there is arterial hypoxemia such that the partial arterial oxygen pressure (PaO₂) falls to 35 mm Hg or when the cerebral blood flow is reduced to 40% of normal. Electroencephalographic silence occurs when the cerebral venous partial pressure of oxygen (PO₂) reaches 20 mm Hg or after about 18 seconds of total anoxia. When hypoxia is severe or prolonged, secondary depression of the myocardium supervenes. The clinical importance of hypoxia complicated by hypotension and impaired cerebral perfusion derives from its neurologic consequences; these consequences are more severe than those of uncomplicated hypoxia, perhaps because in the former case the delivery of glucose as well as oxygen is diminished, as is removal of metabolic waste products.

Hypoglycemia

Under physiologic conditions, glucose is the brain's only substrate and crosses the blood-brain barrier by facilitated transport. Each minute, the normal brain uses about 5.5 mg (31 μmol) of glucose per 100 g tissue. The blood glucose level at which cerebral metabolism fails and symptoms develop varies from person to person, but, in general, confusion occurs at levels below 30 mg per deciliter and coma at levels below 10 mg per deciliter. There are about 2 g of glucose and glycogen stores in the brain, so that a hypoglycemic patient in coma may survive for about 90 minutes without suffering irreversible brain damage.

Other Substances Required to Maintain Brain Function

In addition to oxygen and glucose, the brain requires enzymes, vitamins, amino acids, and other substances to function. The functions of the brain include maintaining membrane potentials, transmitting electrical impulses, and synthesizing transmitter substances and structural proteins. Therefore, neuronal excitability may be altered by imbalances in electrolytes and changes in serum osmolality, such as occur in renal disease, diabetic coma, and lithium intoxication. Alterations in the activity of central nervous system biogenic amines, such as happen in cases of psychotropic drug overdose and in hepatic failure, also produce delirium, stupor, and coma.

Clinical Findings

Metabolic encephalopathy is associated with a broad spectrum of disorders of consciousness. Mild metabolic disease can be mistaken for psychiatric disease; severe metabolic brain disease is confused with structural brain damage.

NEUROLOGIC EXAMINATION

The neurologic examination that follows has been derived from the Glasgow Coma Scale developed for head injury by Teasdale and Jennett ([Table 424.2](#)) and the techniques for evaluating brain stem function described by Plum and Posner. The neurologic examination consists of an assessment of the level of consciousness, as determined by eye opening, verbal responses, and reflex or purposive movements in response to noxious stimulation of the face, arms, and legs; neuro-ophthalmologic function, as indicated by pupillary size and response to light, spontaneous eye movements, oculocephalic (doll's eyes) and oculovestibular (ice water caloric) responses; and vegetative function, as reflected mainly by the respiratory pattern. Clinical neurologic signs can be correlated with specific anatomic sites, to establish the severity and extent of central nervous system dysfunction ([Table 424.3](#)).

Parameter	Score
Eye opening	
Spontaneous	4
To speech	3
To noxious stimulation	2
None	1
Best Motor Response	
Obeys commands	6
Localizes stimuli	5
Withdraws	4
Abnormal flexion	3
Extensor response	2
None	1
Verbal Response	
Oriented	5
Confused conversation	4
Inappropriate words	3
Incomprehensible sounds	2
None	1

* The coma score is the sum of individual scores for eye opening, motor, and verbal response of 3-15.

TABLE 424.2. GLASGOW COMA SCALE^a

Structure	Function	Clinical Sign
Cerebral cortex	Cerebral behavior	Speech Pupillary assessment
Rostral brain stem (midbrain)	Vertical eye movements	Eye opening
Midbrain	Reflex eye movements	Deep-phase cycle
Midbrain	Reflex eye movements	Decerebrate floor posturing
Midbrain	Reflex eye movements	Decerebrate extensor posturing
Midbrain	Reflex eye movements	Spillary reactivity
Upper pons	Cerebral innervation	Cerebral reflex-arms
Upper pons	Cerebral innervation	Cerebral reflex-motor response
Lower pons	Reflex eye movements	Doll's eye
Lower pons	Reflex eye movements	Gross response
Medulla	Regulation of breathing and blood pressure	Spontaneous breathing
Medulla	Regulation of breathing and blood pressure	Maintained blood pressure
Spinal cord	Protective responses	Deep tendon reflexes

O, oculovestibular.

TABLE 424.3. CORRELATION BETWEEN LEVELS OF BRAIN FUNCTION AND CLINICAL SIGNS

LEVEL OF CONSCIOUSNESS

Level of consciousness is best determined by the ease and degree, if any, of behavioral arousal. Attempts should be made to elicit a behavioral motor response by verbal stimulation alone. If no response follows even shouted commands, noxious stimulation can be applied to the face by digital supraorbital pressure and individually to the arms and legs by compression of distal interphalangeal joints with a tongue blade or pen.

MOTOR RESPONSE

The absence of motor response, especially if flaccidity and areflexia are also present, indicates severe brain stem depression and is frequently found in terminal coma or in severe sedative intoxication. Decerebrate or extensor responses correlate with destructive lesions of the midbrain and upper pons but also may be present in reversible metabolic states, such as anoxic encephalopathy. Decorticate or flexor responses develop after damage to the hemispheres as well as in metabolic depression of brain function. Withdrawal and localizing responses imply purposeful or voluntary behavior. Obeying commands is the best response and marks the return of consciousness. Generalized or focal repetitive movements, not affected by stimuli, usually represent seizure activity. Focal seizures typically indicate a focal cortical lesion but also may be seen in hypoglycemia, hyperosmolarity, and some drug intoxications (with aminophylline and tricyclic antidepressants).

NEURO-OPHTHALMOLOGIC EXAMINATION

Fundi

The fundus of each eye should be examined for signs of increased intracranial pressure (papilledema and hemorrhage). Subhyaloid hemorrhage indicates the presence of subarachnoid or intracerebral hemorrhage but may follow severe head trauma.

Pupils

In coma due to metabolic brain disease, the pupils as a rule are small but reactive to light. Small, reactive pupils are present in normal people during sleep and are a common finding in elderly people, because of degenerative changes in the iris and ciliary muscles. Small, sluggishly reactive pupils that respond to naloxone administration are characteristic of an overdose of opiates. Pinpoint pupils are seen in pontine hemorrhage.

Bilateral dilated, fixed pupils indicate sympathetic nervous system overactivity because of either an endogenous sympathetic discharge (during anoxia–ischemia) or exogenous catecholamines (dopamine). Similar pupils, dilated or partially dilated, are seen in overdosage with tricyclic antidepressants or other atropine-like agents. In coma due to amphetamine, cocaine, and lysergic acid diethylamide overdosage, the pupils are large but reactive. Midposition, fixed pupils indicate midbrain failure and loss of both sympathetic and parasympathetic pupillary tone, whether caused by structural or metabolic disease. Such fixed and midposition, rather than dilated, pupils are seen in death.

A unilateral dilated, fixed pupil usually means damage to parasympathetic fibers of the third cranial nerve, as described previously in the case of uncal herniation. If the patient has suffered head trauma, an ipsilateral epidural or subdural hematoma is probably present. If there is no evidence of trauma, an intrahemispheric mass lesion (hematoma, tumor, or abscess) is the probable cause of herniation.

Eye Movements

Deeply comatose patients may have no spontaneous eye movements. In such cases, doll's eyes responses and the ice water caloric test can be used to determine the integrity of the eighth, sixth, and third cranial nerves and their interconnecting brain stem pathways. When the cortical influences are depressed but brain stem gaze mechanisms are intact, the eyes deviate conjugately to the opposite side if the head is rotated horizontally to one side. Brisk back-and-forth eye movements, like those of a doll in response to rocking the head to and fro, are characteristic of metabolic coma. Doll's eyes indicate the integrity of proprioceptive fibers from the neck structures, the vestibular nuclei, and the nuclei of the third and sixth cranial nerves. Unilateral lesions of the brain stem eliminate the doll's eyes response to the side of the lesion.

When the doll's eyes responses are absent, it becomes necessary to perform the ice water caloric test. In deep coma, the doll's eyes responses disappear before the ice water caloric responses, because the latter are produced by a stronger stimulus. The caloric response is elicited in comatose patients by irrigating the tympanum with 30 to 50 mL of ice water. When the patient is supine with the head elevated 30 degrees, cold water produces convection currents in the lateral semicircular canal that inhibit the firing of the ipsilateral vestibular nerve. In the absence of cortical influences on the oculovestibular pathways, cold water produces tonic deviation of the eyes to the side of irrigation. Metabolic factors (sedative, hypnotic coma, phenytoin overdose) and structural (brain stem) lesions eliminate the caloric response, as does labyrinthine disease. Dysconjugate ocular deviation implies a unilateral lesion or metabolic depression of brain stem pathways. If one or both eyes fail to adduct, the lesion is in the medial longitudinal fasciculus or third cranial nerve. The distinction between the two can be made by examination of the pupillary size and reaction to light. Failure of abduction indicates a lesion of the sixth cranial nerve.

MANAGEMENT OF THE PATIENT IN COMA OF UNKNOWN CAUSE

The initial management of the comatose patient is directed toward stabilization. The first step is to ensure an adequate airway, by intubation if necessary ([Table 424.3](#)). The respiratory rate and its pattern should be noted before they are obscured by therapeutic measures, such as intubation and mechanical ventilation.

HYPERVENTILATION

In a comatose patient, hyperventilation represents either compensation for metabolic acidosis or a response to primary respiratory stimulation (respiratory alkalosis). In metabolic acidosis, the arterial blood pH is usually less than 7.3, and the serum bicarbonate concentration is generally below 10 mEq per liter. In respiratory acidosis, lactic acidosis in cerebrospinal fluid stimulates medullary receptors in the absence of any systemic acidosis, so that the arterial pH is high (more than 7.45) and the serum bicarbonate concentration is normal or slightly reduced. In both metabolic acidosis and respiratory alkalosis, the arterial carbon dioxide partial pressure (PaCO₂) is often less than 30 mm Hg.

Mixed metabolic acidosis and respiratory alkalosis also can occur, especially in hepatic coma and excessive salicylate ingestion. Metabolic acidosis sufficient to produce coma and increased ventilation is frequently the result of one of the following conditions: uremia, diabetic ketoacidosis, lactic acidosis (anoxic or spontaneous), or ingestion of acidic substances. Diabetes and uremia are diagnosed by appropriate laboratory tests. If acidosis is independent of diabetes and uremia, the patient must have either spontaneous lactic acidosis or poisoning with exogenous toxins, such as methyl alcohol or ethyl glycol. The latter sources of metabolic acidosis can be treated effectively by giving intravenous infusions of sodium bicarbonate to restore the blood pH to normal.

Respiratory alkalosis is found in the context of coma due to salicylate ingestion, hepatic coma, pulmonary disease, and psychogenic hyperventilation. Salicylate poisoning causes combined respiratory alkalosis and metabolic acidosis that lowers the serum bicarbonate level disproportionately to the degree of serum pH elevation. Hepatic coma usually is accompanied by signs of liver dysfunction. Gram-negative sepsis always is associated with hyperventilation, probably because of a direct central effect of the endotoxin. Respiratory alkalosis caused by the pulmonary congestion of pneumonia rarely depresses the serum bicarbonate value. Psychogenic hyperventilation does not lead to coma, but it may be present as a symptom in a patient with psychogenic unresponsiveness.

HYPOVENTILATION

In a comatose patient, hypoventilation means either respiratory compensation for metabolic alkalosis or respiratory depression with consequent acidosis. In metabolic alkalosis, the arterial pH and the serum bicarbonate value are elevated. The Pa CO₂ is high but is usually less than 50 mm Hg. In untreated respiratory acidosis, the arterial pH is low and the serum bicarbonate level is either normal or high, depending on previous treatment and the rapidity of onset of respiratory failure. The Pa CO₂ is typically above 55 mm Hg. Metabolic alkalosis results from either excessive ingestion of alkali or excessive loss of acid through gastrointestinal and renal routes.

Respiratory acidosis is caused either by severe pulmonary or neuromuscular disease (peripheral respiratory failure) or by damage to or depression of the medullary respiratory center (central respiratory failure). Severe respiratory acidosis of any origin is best treated by artificial respiration.

When adequate ventilation has been established, the following procedures are mandatory: blood should be drawn for a determination of blood glucose, routine chemistries, and toxicologic testing. Immediately afterward, 25 to 50 g of dextrose should be administered intravenously. Bedside glucose determinations are valuable in identifying hypoglycemia and hyperglycemia, but they should never delay the administration of dextrose. Even in cases of hyperosmolar coma, the administration of one ampule of dextrose is not harmful. Naloxone, 0.4 to 0.8 mg, and thiamine, 100 mg, should be administered intravenously to all patients, regardless of whether opiate or alcohol abuse is suggested. At this point, arterial blood gases should be analyzed to confirm that oxygenation is adequate.

Placement of a nasogastric tube may be indicated, to examine the stomach contents. This procedure always puts the patient at risk of aspiration, because the nasogastric tube dilates the gastroesophageal sphincter and permits regurgitation of gastric contents around the tube. Therefore, a cuffed endotracheal tube should be put in place for any patient in a coma or with a depressed gag reflex, before passage of nasogastric tube.

The blood pressure often provides the first clue to the etiologic diagnosis of coma. Hypertension can be a reflex response to the increased intracranial pressure (Cushing's reflex) or brain stem ischemia and commonly accompanies an intracranial hemorrhage. Rarely, hypertension per se may cause coma, as in hypertensive encephalopathy. Hypotension may indicate myocardial infarction, hemorrhagic shock, sepsis, or sedative, hypnotic drug overdose. The pulse rate and rhythm may be additional clues to the cause of coma and should be recorded and monitored. Bradycardia associated with an elevated blood pressure is an ominous sign of brain stem compression, and reversible causes of transtentorial herniation (subdural hematoma) should be considered immediately, before cardiovascular collapse ensues.

Measurement of the patient's temperature should not be neglected in the initial evaluation. Hypothermia can stem from Wernicke's disease, exposure, overdose with sedative drugs, near drowning, and hypothyroidism. This important sign often is not detected, because either the rectal temperature measurement is omitted or an ordinary thermometer is used that cannot detect temperatures below 95°F. Hypothermia below 80°F produces coma by itself; therefore, warming and resuscitative measures are indicated for all hypothermic patients, even if all vital signs are absent. Hypothermic patients have recovered after prolonged cardiorespiratory arrests, presumably because of the protective effects of low body temperature and depressed cerebral metabolism.

The presence of fever in a comatose patient demands an investigation for possible meningitis. If there is no history of trauma, the neck should be flexed to assess the presence of meningismus (stiff neck). When head trauma is a possible cause of coma, cervical spine injury should be assumed until the cervical spine can be examined by radiologic methods. Therefore, the neck should not be flexed but instead should be stabilized immediately by sandbags or headboard, to prevent movement during the physical and radiologic examinations.

A stiff neck may indicate bacterial meningitis or subarachnoid hemorrhage, but in the latter case there is often a delay of up to 12 hours before blood in the subarachnoid cerebrospinal fluid pathways has produced enough chemical irritation of the meninges to be detected by neck flexion. In deep coma, meningismus may be absent, despite the presence of bacterial or chemical meningitis. Other causes of fever include intracranial abscess and subdural empyema.

During this initial stabilization and assessment of the vital signs, the patient should be checked quickly for signs of head trauma (scalp laceration, bleeding from the ears, cerebrospinal fluid rhinorrhea) and spontaneous movements (seizures or posturing). On completion of the initial assessment and treatment, the physician may be able to categorize the cause of coma as either toxic, metabolic central nervous system depression or structural cerebral damage. A systemic physical examination with special attention to certain key neurologic signs further delineates the cause of coma.

OUTCOME OF COMA AND COST-EFFECTIVENESS OF CARE

The mortality rate for all patients admitted to intensive care units in the United States is 25%; for patients in coma for more than 48 hours, it is 77%. Brain-dead patients who cannot benefit from intensive care must be identified.

CLINICAL CRITERIA OF BRAIN DEATH

Coma of Established Cause

The cerebral lesion must be structural, bearing in mind that an initially metabolic insult, as occurs in prolonged anoxia, can also lead to irreversible structural damage. Any possibility that the patient has drug poisoning or that hypothermia or an electrolyte abnormality is contributing to the depth of coma must be excluded by appropriate laboratory tests. The patient should have no clinical evidence of cerebral function or brain stem reflexes for a period of at least 12 hours, with no demonstrable improvement whatsoever. This period of observation must be extended to 24 or more hours, or until negative toxicology screen results are obtained, if drug overdosage is a possibility. The period of observation may be shortened to as little as 6 hours if, for example, a competent neurosurgeon explores a head wound and finds the brain transected or if one or more supplementary tests (electroencephalography, angiography) confirms the absence of cerebral circulation or electrical activity.

No Cerebral Function

There must be no appropriate response to noxious stimulation, in that the patient must not arouse, groan, grimace, withdraw the head or limbs from an applied stimulus, or attempt to push away the examiner's hand. Reflex responses, such as decerebrate extension or decorticate flexion of the limbs, which are mediated by subcortical but supraspinal cord pathways, cannot be present if a diagnosis of brain death is contemplated. The spinal cord may be intact; therefore, rudimentary reflex responses, such as muscle stretch reflexes, planar flexion, plantar withdrawal (triple flexion), abdominal reflex, and tonic neck reflexes, all of which depend on functions of the spinal cord, may be preserved.

No Brain Stem Reflexes

The pupils must be fixed to light stimulation. The corneal blink reflex must be absent. Both the doll's eyes and ice water caloric responses must be absent. The patient must be apneic and not recover spontaneous ventilatory function after the respirator has been turned off to allow Pa CO₂ to attain a level high enough maximally to stimulate respiratory drive. Evidence indicates that the threshold for respiratory stimulation may approach a Pa CO₂ of 60 mm Hg in patients with brain damage and the rate of rise of PaCO₂ during respiratory arrest is about 3 mm Hg per minute. The duration of respiratory arrest needed to allow Pa CO₂ to reach or exceed 60 mm Hg is not constant and varies depending on the level of Pa CO₂ before the onset of apnea. Therefore, to confirm absolute apnea, blood gas monitoring is required to verify normocapnia, before beginning apneic oxygenation for 10 minutes, or, if a patient is hypocapnic, Pa CO₂ in excess of 60 mm Hg at the end of apnea. No absolute period of apnea sufficient to establish brain death can be recommended in the absence of blood gas determinations. Brain-dead subjects are easily identified and constitute a small population among comatose subjects. A far larger number of comatose patients are those with severe brain damage in whom the prognosis is in doubt. For some patients, intensive care serves only to promote survival in the vegetative state.

PREDICTION OF OUTCOME IN COMA

Studies indicate that despite the best treatment, about 40% of patients unconscious from head trauma and only 15% of those unconscious from nontraumatic causes make a satisfactory neurologic recovery. Critical care physicians have identified certain features that predict a limited response to intensive care of acute illness (advanced age and chronic poor health), but these features do not indicate outcome in individual cases. Several groups of neurologists and neurosurgeons have tried to identify and quantify early indicators that might correlate with prognosis. The results of parallel collaborative studies of 1,500 head-injured and 500 medical coma patients indicate that within a few hours or days after the onset of coma, many patients show neurologic signs that differentiate, with a high degree of probability, the outcome extremes of death or vegetative state from good recovery.

CHAPTER 425: APPROACH TO THE PATIENT WITH A SLEEP DISORDER

ROGER J. BROUGHTON

[Normal Sleep](#)
[Classification of Sleep Disorders](#)
[Investigation](#)

During the 1980s and early 1990s, the clinical importance of sleep became increasingly evident, with the consequent creation of a field of sleep disorders medicine. Epidemiologic studies have shown that at least 10% of people in all decades of life have clinically significant sleep disorders. There are more than 70 discrete sleep disorders. Conditions with symptoms of excessive daytime sleepiness and irresistible sleep attacks unexpectedly have been more common than types of insomnia in patients referred to sleep disorders clinics. In patients with chronic insomnia not caused by sleep hygiene abuse, pulmonary or other medical conditions have been responsible more often than stress-related and other psychogenetic mechanisms.

NORMAL SLEEP

Defining a sleep disorder requires an understanding of normal sleep. Marked changes of sleep occur as a function of age. Neonates sleep in a polyphasic napping fashion around the 24 hours, obtaining an average of close to 8 hours of sleep both at night and in the daytime. They experience lengthy slow-wave sleep (the deepest stages of non-rapid eye movement [NREM] sleep) and rapid eye movement (REM) sleep, and the NREM/REM sleep cycle shows rapid periodicity at 45 to 50 minutes. In childhood, there is rapid consolidation of night sleep, with reduction of daytime napping to three, then two, and finally to a single (almost always afternoon) nap, typically given up at 5 to 6 years of age, when school is attended for the entire day. By adulthood, mean sleep duration is some 6 to 8.5 hours per night, with NREM sleep representing 75% to 80% (deep slow-wave sleep is 5% to 15%) and REM sleep some 20% to 25%; there is little wakefulness after sleep onset. The NREM/REM cycle period slows to 90 to 110 minutes.

In the elderly, sleep fragments, with frequent awakenings, and lightens, with little slow-wave sleep. A return to daytime napping becomes commonplace. The elderly may misperceive this change in night sleep as insomnia and request hypnotics. The normal elderly, however, feel alert in the daytime, and hypnotics only make the quality of night sleep deteriorate and increase daytime sleepiness. Studies under conditions without time cues (*Zeitgebers*) show that the endogenous period of the circadian sleep rhythm is 24.1 to 25.5 hours. Factors (sunlight, alarm clocks, social noise, and so on) that cause awakening at a regular hour entrain sleep to a 24-hour periodicity and keep us from going to sleep later each day. They also confirm the existence of an endogenous twice-daily rhythm, with major and minor sleep periods. In the entrained condition, the latter occurs around midafternoon (the time of the siesta and the last nap given up in ontogeny).

CLASSIFICATION OF SLEEP DISORDERS

Determining the existence of a sleep disorder is not always easy. It is important to recognize the wide variation of normal sleep patterns at all ages. There are morning people (larks) and evening people (owls), light sleepers and deep sleepers, non-nappers and nappers, and short sleepers and long sleepers, all meeting their sleep need per 24 hours. Moreover, events that can constitute a sleep disorder, such as sleep apnea or periodic limb movements, often occur at low frequency in asymptomatic normal people.

A sleep disorder may be said to exist in the context of long-term excessive daytime sleepiness with or without irresistible sleep episodes, significant problems going to sleep or remaining asleep, an undesired change in the circadian timing of sleep/wake states, and episodic behavioral episodes in sleep that disrupt personal or family life or risk injury to self or others. This tetrad of signs and symptoms has formed the basis of a number of classifications of sleep disorders. It has become evident that a single diagnostic entity may take the form of daytime sleepiness, insomnia, or even parasomnia.

The most recent classification of the American Sleep Disorders Association therefore replaces a structure based on symptomatic differential diagnosis by one of final diagnosis. It distinguishes three main groups: *dyssomnias* (subgrouped according to whether the causes are intrinsic or extrinsic to the body or of circadian rhythm origin), *parasomnias* (subgrouped into those involving arousals, sleep/wake transitions, REM sleep, or other), and *sleep disorders associated with medical or psychiatric conditions*. A fourth group lists those proposed sleep disorders that remain incompletely identified. This classification (simplified in [Table 425.1](#)) has been accepted by the European and Japanese sleep societies, is compatible with international disease classifications (International Classification of Diseases and World Health Organization), and is recommended.

TABLE 425.1. CLASSIFICATION OF SELECTED SLEEP DISORDERS

INVESTIGATION

The value of a careful history for diagnosing sleep disorders cannot be overemphasized. The patient is often unaware of behaviors in sleep, so that information from the sleeping partner is frequently essential. Parents of sleep-disturbed children must be questioned. Sleep-related symptoms must be assessed in terms of intensity and duration. The amount, quality, and temporal stability of nocturnal sleep and of any habitual daytime naps should be documented, as should evidence of daytime sleepiness, brief microsleeps (lapses), amnesic automatic states, and irresistible sleep attacks. Problems getting to sleep both at night and during daytime naps should be sought, to detect sleep-onset forms of insomnia. If awakenings are a problem at night, questions concerning their possible cause (nightmares, full bladder, pain, intense erections, respiratory difficulties) must be posed.

In patients with daytime sleepiness or sleep attacks, questioning for the presence of cataplexy and sleep paralysis is needed, to arrive at a diagnosis of narcolepsy syndrome. Prolonged 1- to 4-hour daytime sleep episodes, chronic sleepiness, deep night sleep, and marked morning sleep drunkenness all suggest either idiopathic or symptomatic hypersomnia. Breathing problems in sleep are often unrecognized by the patient, who may exhibit loud snoring or visible apneic pauses terminated by inspiratory snorting, which are disturbing to the bed partner. Patients are typically unaware of motor disorders taking place during sleep, such as periodic movements in sleep, or nocturnal paroxysmal dystonia, whereas restless legs or intense hypnagogic jerks (sleep starts) at sleep onset are readily perceived.

Information concerning the circadian timing of sleep may disclose a delayed, advanced, irregular, or about 25-hour sleep/wake periodicity. Occupational questions should quickly determine problems due to rotating shift work or frequent jet lag. There may be episodic behaviors during sleep, which require careful interrogation pertaining to the differentiation of sleep terrors, sleepwalking, confusional arousals, REM nightmares, REM sleep behavior disorder, nocturnal epileptic seizures, sleep talking, bruxism, jactatio capitis (rhythmic movement disorder), and other parasomnias. It is always important to obtain information concerning sleep hygiene, including the regularity of retiring and morning awakening, daily exercise habits, and intake of central nervous system active substances, including caffeine, nicotine,

alcohol, and others.

A full physical examination should always be carried out, because a large variety of illnesses may underlie sleep problems. Sleep/wake tests are often indicated for specific diagnosis. Overnight polysomnography combines recording of the electroencephalogram, electrooculogram, and submental electromyogram for sleep/wake state scoring. These variables are combined with leg electromyography to detect movement abnormalities; electrocardiography for cardiac abnormalities; and upper airway airflow, chest and abdominal movement, and transcutaneous oxygen saturation monitoring for (often occult) respiratory problems. Videotaping of behavior is often indicated for analysis of parasomnias and, to permit full movement, preferably is associated with telemetry. Daytime sleepiness and ability to fall asleep can be quantified by the Multiple Sleep Latency Test or Maintenance of Wakefulness Test. Each test has five 20-minute nap periods scheduled every 2 hours across the day. In the former, the subject is requested to fall asleep as rapidly as possible, whereas in the latter, the subject is asked to try to remain awake. Ambulatory monitoring may be indicated for assessment of sleep/wake patterns around the 24 hours. Sleep logs may provide valuable information, especially on sleep timing.

Other laboratory tests are frequently indicated and are tailored to the provisional diagnosis. Daytime pulmonary function tests, though they often show negative results in the context of obstructive and central sleep apnea, may be helpful in chronic obstructive pulmonary disease and other respiratory diseases causing a sleep disorder. Fiberoptic and other examinations of the upper airway for obstruction are often necessary in apneic patients. Radiologic procedures may be needed, including magnetic resonance imaging of the brain stem sleep-regulatory structures. In some patients, metabolic (hepatic, renal) or endocrine (thyroid, hypothalamopituitary) causes may be suggested and assessed by appropriate laboratory tests. Tissue typing of human leukocyte antigen for DR2 and DQW1 haplotypes is helpful to rule out narcolepsy syndrome. Follow-up assessment after some 1 to 2 months of appropriate therapy is important for most sleep disorder patients. Whenever possible, central nervous system active medication should be reduced to the minimal clinically efficacious dose.

CHAPTER 426: APPROACH TO THE PATIENT WITH SEIZURES

ANTONIO V. DELGADO-ESCUETA

[Signs and Symptoms of Seizures](#)
[History and Physical and Laboratory Examination](#)
[Strategies For Optimal Care](#)
[Understand the Clinical Settings Under Which Antiepileptic Drugs Have to be Used](#)

A team approach is vital to the successful treatment of epilepsy. The physician in charge should manage and coordinate the efforts of specialists, including professionals in neurology, pharmacology, psychology, psychiatry, and social services. The physician should foster understanding and support among the patient's family, employer, and school, with the following goals:

1. Verify that seizures are epileptic and differentiate them from syncope, drop attacks, and nonepileptic seizures.
2. Define seizure types and epilepsy syndrome.
3. Determine causes of seizures and block trigger factors.
4. Establish an early treatment plan with choice antiepileptic drugs and understand the clinical context and medical background of the patient.
5. Monitor seizure control and recognize adverse effects on the patient's quality of life; recognize, treat, and hospitalize patients with status epilepticus; advise the patient to seek education and support services from the local chapter of the Epilepsy Foundation.
6. Refer for possible surgical treatment or vagal nerve stimulation when seizures are resistant to antiepileptic drugs.

SIGNS AND SYMPTOMS OF SEIZURES

VERIFY EPILEPSY

When a patient loses consciousness episodically, epilepsy should be distinguished from syncope, pseudoepileptic seizures, drop attacks, and drug-induced or withdrawal seizures. Although closed-circuit television videotaping with biotelemetry of the electroencephalogram (CCTV-EEG) and Holter monitoring of the electrocardiogram have shown important clinical differences among these conditions, the history and context are often the most important determinants of the diagnosis.

Twenty percent of patients believed to have epilepsy actually experience nonepileptic seizures. Four common causes of nonepileptic seizures are hyperventilation, hysteria, alcohol withdrawal, and cocaine use. The provoking factor for hyperventilation is sometimes difficult to discover. Rapid, shallow breathing is present, and the patient feels light-headed, with trembling limbs and often trembling of the whole body. Excessive loss of carbon dioxide produces paresthesias in the hands, face, and feet; carpopedal spasms may develop.

Syncope

Syncope occurs in up to 25% to 30% of young healthy adults. (See [Chapter 69](#) for a more detailed discussion of syncope.) Postural tone and consciousness are suddenly lost, and the patient falls. Most frequently, syncope is due to a temporary decrease in cerebral blood flow, resulting from either a fall in systemic arterial pressure (vasovagal syncope) or a decline in cardiac output (cardiac syncope). The clinical picture of pallor, flaccidity, upward deviation of the eyes, and loss of consciousness in simple syncope is paralleled by the appearance of 2- to 4-Hz high-amplitude slow waves on the EEG. The persistence of cerebral anoxia for more than 15 seconds is reflected by tonic spasms and one or two generalized jerks (convulsive syncope). The EEG becomes slow and low voltage but promptly returns to normal after consciousness is regained. Less often, syncope can be produced by hypoglycemia or hypoxia, characterized by gradual loss and regaining of consciousness. Aortic valvular stenosis, hypersensitive stretch receptors in the carotid sinus, micturition, explosive vigorous coughing, pain, and orthostatic hypotension can all provoke syncope.

Pseudoepileptic Psychogenic Seizures

An audience is usually present during hysterical or psychogenic seizures. Consciousness is preserved, amnesia is absent or patchy, and movements that simulate epileptic convulsions do not have tonic-clonic phases or in-phase clonic movements of the upper extremities. Movements are out of phase, chaotic, and bizarre, without stereotype. Side-to-side head movements are noted in one-third of patients and forward pelvic thrusting in almost half of those experiencing psychogenic seizures. The duration is usually longer than the average 70 seconds of a tonic-clonic convulsion. The attack ends abruptly, with the patient alert and showing no postictal tiredness, sleep, or Todd's paralysis. A psychiatric history is usually present; psychogenic seizures are seldom the sole symptom and sign.

Psychogenic fits and epileptic seizures can exist together in the same patient. The EEG and prolactin levels are especially useful in distinguishing the two. A main indication for CCTV-EEG intensive monitoring is the differentiation of pseudoepileptic from epileptic seizures. During and immediately after epileptic seizures, the EEG almost always shows abnormal results. Between epileptic seizures, the EEG gives abnormal results in 40% to 60% of patients. The EEG is normal between, during, and after hysterical attacks. Serum prolactin levels increase within 20 minutes of a tonic-clonic convulsion or complex partial seizure but do not change with pseudoepileptic hysterical fits.

Drop Attacks

Episodic ischemia of the brain stem, which may occur in elderly patients with insufficient blood flow throughout the vertebrobasilar system, is usually of atherosclerotic origin. Transient ischemic attacks affecting the brain stem can cause episodic loss of tone, with falls. Consciousness usually is preserved, and there are no convulsions. EEGs between episodes show normal results.

Drug-induced or Withdrawal Seizures

A history of psychiatric problems, post-traumatic seizures, and convulsions induced by abstinence is not uncommon in the context of chronic alcoholism. Seizures can be induced by alcohol, but withdrawal seizures are more common. Tonic-clonic seizures appear 24 to 48 hours (up to 7 days) after alcohol withdrawal. Confusion, delusions, and visual, tactile, and auditory hallucinations (alcoholic hallucinosis) accompany agitation and can progress to delirium tremens, lasting up to 5 days. Hypoglycemia can complicate the picture. Subdural or epidural hematoma must be excluded. Smoking of crack or cocaine paste can provoke tonic-clonic convulsions that appear at the height of or immediately after the high. In severe cocaine toxicity, respiratory depression, cardiac dysrhythmias, a hypermetabolic state, and status epilepticus can occur. Alcohol withdrawal convulsions, delirium tremens, and cocaine convulsions are medical emergencies and can be treated effectively with benzodiazepines. Ventricular dysrhythmias in cocaine toxicity can be treated with intravenous propranolol (0.5 to 1 mg).

HISTORY AND PHYSICAL AND LABORATORY EXAMINATION

DEFINE SEIZURE TYPE(S) AND EPILEPSY SYNDROME

A detailed case history and description of the first and subsequent attacks must be obtained from the patient and relatives. [Figure 426.1](#) shows an algorithm for diagnosis and initial management. Are the seizures partial or generalized? Is the epilepsy syndrome idiopathic or symptomatic? In partial epilepsies, the first seizure and its aura can give clues about its site of origin. Changes in character in subsequent attacks may suggest progression of a structural lesion or may reflect the effects of antiepileptic drugs. (See [Table 444.1](#) [Table 444.2](#) [Table 444.3](#) [Table 444.4](#) in Chapter 444.)

seizures. If felbamate is prescribed, the patient should sign a consent form (Fig. 426.1 and Table 426.1).

Syndrome	First-Choice Drug	Second-Choice Drug	Third-Choice Drug
Idiopathic			
Absence only	ETH	VPA or CNZ	LTO
Absence plus grand mal tonic-clonic	VPA	LTO or PHT or ETH + CNZ	TM + PHT or TM + CNZ
Juvenile myoclonic epilepsy	VPA	LTO or PHT	TM + PHT or TM + CNZ
Benign childhood epilepsy, e.g., rolandic epilepsy	CBZ or PHT	VPA or CNZ	LTO or PHT
Symptomatic			
Lennox-Gastaut-Dravet syndrome	LTO or TM	GBP + CNZ or LTO + CNZ or VPA + CNZ or PHT + CNZ	TM
Temporal lobe epilepsy	CBZ or PHT	GBP or LTO or PHT	TM
Frontal lobe epilepsy	CBZ or PHT or VPA	GBP or LTO or PHT	TM
Epilepsy in elderly	GBP	PHT or CBZ	LTO or PHT

TABLE 426.1. COMMON EPILEPSY SYNDROMES WITH CHOICE ANTIEPILEPTIC DRUGS

Valproate is a broad-spectrum agent effective against both genetic and lesional symptomatic epilepsies. Before initiating valproate monotherapy, a complete blood count, platelet count, bleeding time, and liver function tests should be done. The patient should be warned of possible signs of serious hepatic dysfunction, such as loss of appetite, nausea, vomiting, abdominal pain, lethargy, easy bruising, or malaise. A complete blood count and hepatic function tests should be carried out again and valproate plasma levels measured after 10 days. Serial complete blood counts, hepatic function tests, and careful clinical monitoring should be undertaken every month for the first 6 months. Elevation of the serum transaminase level is usually transient and dose-related. In sporadic cases, it may mean serious and even fatal hepatic dysfunction. Hepatic failure seems to be idiosyncratic and related to age: children less than 2 years old, with unusual congenital syndromes, mental retardation, or organic brain disease, seem to be the group at primary risk (one in 7,000 with monotherapy and one in 500 with polytherapy). The rate of hepatic failure declines with age and is rare with monotherapy (11 in 37,000). Rarely, valproate also has produced thrombocytopenia, increased platelet aggregation, and hypofibrinogenemia. Hyperammonemia also has been reported.

The dose of valproate gradually is increased from 125 mg or 250 mg in capsule form daily, to achieve trough plasma levels of 60 to 80 µg per milliliter (usually 250 mg three times daily). The final dosage may be 500 mg taken three times daily. Valproate is quickly absorbed and eliminated and controls attacks at lower dosages (15 to 18 mg per kilogram) when used alone. Nausea and vomiting appear when the dose is increased too quickly. Gastric irritation can be minimized by taking the capsules after meals. Hair loss and tremors are common side effects. Excessive weight gain, hyperandrogenism, and signs of polycystic ovaries warrant discontinuation.

Ethosuximide controls 60% of cases of childhood absence epilepsy not associated with tonic-clonic seizures. It is absorbed quickly (0.5 to 4 hours), and steady state is reached in 1 week. It has an average half-life of 24 to 30 hours in children, with a longer half-life in adults. Dose-dependent side effects include nausea, vomiting, anorexia, dyspepsia, night terrors, motor unrest, agitation, and paranoid psychoses. Rash and thrombocytopenia may suggest uncommon idiosyncratic side effects, such as aplastic anemia and agranulocytosis.

Lamotrigine is also a broad-spectrum agent effective both as monotherapy and as an add-on agent against genetic generalized epilepsies (including JME and absences) and lesional partial, complex partial, and secondary generalized seizures. It is also effective in limiting the atonic drop seizures of Lennox-Gastaut-Dravet syndrome. Sodium valproate inhibits the metabolism of lamotrigine, doubling the elimination half-life from 29 to 60 hours. Cytochrome P450 enzyme-inducing antiepileptic drugs, such as phenytoin, carbamazepine, and phenobarbital, reduce the half-life of lamotrigine by about 50%. Rashes appear in 10% of lamotrigine exposures. Because we are unable to differentiate benign rashes from the rashes of Stevens-Johnson syndrome and toxic epidermal necrolysis, the appearance of generalized maculopapular rashes is a reason for discontinuing lamotrigine. A gradual ascension of dose lowers the incidence of rashes; the dose starts at 25 to 50 mg daily for 2 weeks, rising to 75 to 100 mg daily for 2 weeks until 300 to 500 mg daily is reached.

Topiramate is a novel D-fructose derivative that is useful as monotherapy or as an add-on agent for both genetic and lesional epilepsies, including Lennox-Gastaut syndrome. Topiramate does not change serum carbamazepine or epoxide levels but produces modest to small increases in valproate and phenytoin serum levels. Cytochrome P450 enzyme-inducing antiepileptic drugs accelerate topiramate elimination and decrease its plasma levels. Because it is mostly excreted in the kidneys, renal failure results in higher plasma levels. Adverse effects include nephrolithiasis in 1.5%, depression in 15%, psychoses in 3%, and abnormal cognitive functions in 12% at 200- to 400-mg doses and in 26% at doses over 600 mg. For these reasons, a slow ascension of doses is used, and doses are usually kept between 150 to 300 mg.

Clonazepam can be useful as a third treatment option for atonic drop, myoclonic, and absence seizures. Peak plasma concentrations occur in 1 to 4 hours. The half-life is 20 to 50 hours. Doses start at 0.5 mg daily, increased every 3 to 5 days until seizures are controlled or sedation prohibits further dosage increments. Ataxia and irritability can result. Practitioners should take heed that vigabatrin, gabapentin, and tiagabine, drugs that increase GABA concentrations in the human nervous system, can worsen absences and myoclonias and, in rare cases, produce psychoses.

Symptomatic Partial Epilepsies

Carbamazepine, phenytoin, and valproate are the first-tier monotherapy drugs for partial and secondary generalized epilepsies. The exception is the elderly whose seizures start after 60 years of age; for this group, gabapentin is now recommended. Because of its safety, practitioners favor prescribing gabapentin even in adolescents and young adults, when seizures are mild and infrequent. Gabapentin, lamotrigine, and topiramate are being used earlier in the treatment of symptomatic epilepsy, as monotherapy or as add-on drugs. Thus, they are moving from the group of second-tier drugs to the first tier, depending on the clinical context and coexisting conditions. Because phenobarbital and primidone are less well tolerated and cause ataxia, vertigo, nausea, and drowsiness, these drugs are now prescribed less often.

Drowsiness, dizziness, nystagmus, blurred vision, diplopia, and nausea are pronounced at the onset of carbamazepine, phenobarbital, and primidone therapy and at peak plasma levels (Table 426.2). They can be prevented by starting at lower doses and gradually increasing the dose. Carbamazepine is absorbed slowly, reaching peak plasma levels in 2 to 8 hours (24 hours). Leukopenia occurs in 10% of patients. Idiosyncratic side effects include rash, icterus, anemia, and edema. Bone marrow depression has been reported in rare instances. An incidence of 0.5 cases per 100,000 treatment-years with carbamazepine, or two cases per 75,000 patients, has been reported for aplastic anemia. Hypersensitivity reactions in the form of skin rashes, exfoliative dermatitis, Stevens-Johnson syndrome, and systemic lupus erythematosus occur now and then. It also is important to start lamotrigine and topiramate treatment at low doses and increase them slowly, as indicated earlier.

Drug	Usual Total Daily Dose (mg/kg/d)	Peak Plasma Level (mg/L)	Half-life (hr)	Clearance (mL/min/1.73m ²)	Protein Binding (%)	Toxicity
Carbamazepine	10-15	10-20	10-12	10-15	75	Drowsiness, dizziness, nystagmus, blurred vision, diplopia, ataxia, irritability, rash, icterus, anemia, edema, bone marrow depression, aplastic anemia, hypersensitivity reactions, systemic lupus erythematosus
Phenytoin	3-5	10-20	10-12	10-15	90	Drowsiness, dizziness, nystagmus, blurred vision, diplopia, ataxia, irritability, rash, icterus, anemia, edema, bone marrow depression, aplastic anemia, hypersensitivity reactions, systemic lupus erythematosus
Valproate	15-30	10-20	10-12	10-15	90	Drowsiness, dizziness, nystagmus, blurred vision, diplopia, ataxia, irritability, rash, icterus, anemia, edema, bone marrow depression, aplastic anemia, hypersensitivity reactions, systemic lupus erythematosus
Lamotrigine	2-5	10-20	24-30	10-15	55	Drowsiness, dizziness, nystagmus, blurred vision, diplopia, ataxia, irritability, rash, icterus, anemia, edema, bone marrow depression, aplastic anemia, hypersensitivity reactions, systemic lupus erythematosus
Topiramate	150-300	10-20	10-12	10-15	70	Drowsiness, dizziness, nystagmus, blurred vision, diplopia, ataxia, irritability, rash, icterus, anemia, edema, bone marrow depression, aplastic anemia, hypersensitivity reactions, systemic lupus erythematosus
Ethosuximide	10-15	10-20	24-30	10-15	55	Drowsiness, dizziness, nystagmus, blurred vision, diplopia, ataxia, irritability, rash, icterus, anemia, edema, bone marrow depression, aplastic anemia, hypersensitivity reactions, systemic lupus erythematosus
Gabapentin	1500-3000	10-20	7-12	10-15	30	Drowsiness, dizziness, nystagmus, blurred vision, diplopia, ataxia, irritability, rash, icterus, anemia, edema, bone marrow depression, aplastic anemia, hypersensitivity reactions, systemic lupus erythematosus
Tiagabine	10-15	10-20	7-12	10-15	30	Drowsiness, dizziness, nystagmus, blurred vision, diplopia, ataxia, irritability, rash, icterus, anemia, edema, bone marrow depression, aplastic anemia, hypersensitivity reactions, systemic lupus erythematosus
Vigabatrin	10-15	10-20	7-12	10-15	30	Drowsiness, dizziness, nystagmus, blurred vision, diplopia, ataxia, irritability, rash, icterus, anemia, edema, bone marrow depression, aplastic anemia, hypersensitivity reactions, systemic lupus erythematosus

TABLE 426.2. ANTIEPILEPTIC DRUGS

Ataxia and nystagmus are dose-dependent with phenytoin, but sedation is usually not a problem. Dysmorphic effects, including coarsening of facial features, gum hypertrophy, and hirsutism, appear with long-term use at high doses in children, adolescents, and women. Cerebellar degeneration can develop after long-term high-dose therapy. Stevens–Johnson syndrome occurs in one of 20,000 persons. A lupus-like syndrome, pseudolymphoma, exfoliative dermatitis, and fatal hepatic necrosis also can arise. Exanthema, fever, hepatitis, and lymphadenopathy are indications for withdrawal of the drug. Peak plasma levels appear in 2 to 8 hours; phenytoin has a half-life of 24 hours. Up to 96% is bound to plasma proteins. Phenytoin should not be administered intramuscularly, because it precipitates. Toxic neurologic side effects related to peak plasma levels require reduction of dosage.

Disulfiram (Antabuse), chloramphenicol, sulfamethizole, and phenylbutazone all inhibit the metabolism of phenytoin, increasing the risk of intoxication. Phenytoin accelerates the metabolism of warfarin and dicoumarol. This effect causes a risk of bleeding if phenytoin is withdrawn. Phenytoin lowers serum folate levels, occasionally producing macrocytic anemia. It also interferes with vitamin D metabolism, leading to osteopenia. Antagonism with vitamin K can be important during pregnancy; supplemental vitamin K should be administered to pregnant women and to neonates, to prevent hemorrhagic disease of the newborn. Despite these limitations, 60 years of experience has proved that most adults can use phenytoin safely for effective seizure control.

Gabapentin has an advantage over other antiepileptic agents in that it is not metabolized, is not protein-bound, and does not produce significant pharmacokinetic changes in other antiepileptic agents. For this reason, it has achieved a primary and ideal role in late-onset epilepsy or seizures that start after 60 years of age and in infrequent and mild seizures of young adults. Geriatric patients often are taking various agents for heart disease and hypertension, and thus it is advantageous to prescribe an agent that has little pharmacokinetic effect on other drugs. The sole elimination pathway for gabapentin is renal excretion. As an add-on agent, gabapentin (1,200 to 1,800 mg per day to as much as 3,000 to 4,000 mg per day) lessens the rate of partial, complex partial, and secondary generalized seizures.

Tiagabine is the latest of the new GABAergic antiepileptic drugs developed as add-on drugs. Tiagabine is derived from nipecotic acid, which is a potent anticonvulsant by itself but cannot cross the blood–brain barrier. By inhibiting the reuptake of GABA, tiagabine enhances inhibition and stops seizures. The minimal effective dose is 30 mg daily; higher doses (up to 64 mg) are associated with 50% reduction of seizures in 25% of patients. The most common adverse effects are dizziness, nervousness, tremor, diarrhea, and depression.

Phenobarbital remains useful for nocturnal secondary tonic–clonic convulsions. Because sedation and cognitive impairment can be prominent when the drug is administered in the daytime, it is given as a single dose at the hour of sleep. Sometimes impotence presents a major drawback. Transient sedation is prominent during initiation of treatment, but most patients develop tolerance within a few weeks. Phenobarbital levels of 30 µg per milliliter or higher usually produce drowsiness, but some patients complain of tiredness even at low doses. Hyperactivity, agitation, or sleeplessness can appear as paradoxical reactions, especially in children and the elderly. Systemic toxicity is uncommon.

Primidone may cause listlessness and difficulty in rousing from sleep during the first few months of use. Sixty percent of patients discontinue primidone therapy by the end of the first year. Partial and complex partial seizures are poorly controlled. The initial dose should be low and the dosage increased cautiously. After 1 year, primidone has minimal sedative side effects when used as the sole drug. Patients who remain on the drug successfully for 1 year continue to do so for the next 5 years. It is now considered an acceptable third-tier drug. When primidone is administered in combination with phenytoin, increased biotransformation to phenobarbital can lead to side effects similar to those reported for phenobarbital. Systemic side effects have been rare. Primidone's efficacy may be separate from that of its metabolites. When drugs must be combined, primidone can be used effectively with phenytoin or carbamazepine.

Felbamate should be considered a third-tier agent for symptomatic epilepsy and is recommended as an add-on agent. Felbamate is particularly potent and has a wide clinical spectrum. Felbamate (maximum dose, 45 mg per kilogram per day, or 3,600 mg per day) is particularly effective in limiting atonic seizures, generalized tonic–clonic seizures, and total seizure frequency in the Lennox–Gastaut–Dravet syndrome. Felbamate is also effective as a single-entry drug or as adjunctive therapy in partial seizures. When felbamate is administered with phenytoin, phenytoin concentrations rise. With felbamate administered at 1,800 to 2,400 mg per day, phenytoin should be reduced by 20%; at 3,600 mg per day of felbamate, phenytoin should be reduced by 40%. At 3,600 mg per day of felbamate, mean carbamazepine declines 30%, while carbamazepine epoxide increases 60%. Felbamate given at a dosage of 2,400 mg per day raises steady-state plasma valproic acid concentrations by as much as 50%. Mean felbamate trough concentrations increase with valproate and drop slightly with carbamazepine or phenytoin. Felbamate is limited by hepatic toxicity (one case per 6,000) and bone marrow suppression (one case per 10,000).

UNDERSTAND THE CLINICAL SETTINGS UNDER WHICH ANTIEPILEPTIC DRUGS HAVE TO BE USED

Treatment must start with a careful overall assessment of the clinical situation in which epileptic seizures arise. [Table 426.3](#) recommends initial choices for antiepileptic drugs in the context of various clinical pictures and coexisting medical conditions. The age, sex, seizure type, epilepsy syndrome, and medical background of the patient are all important. Is the patient planning pregnancy? Is the patient already pregnant? Is the patient a female adolescent? Is the patient elderly? Does the patient suffer from repeated tonic–clonic seizures or episodes of status epilepticus?

TABLE 426.3. RECOMMENDATIONS FOR INITIAL ANTIEPILEPTIC DRUG, CLINICAL CONTEXTS, AND COEXISTING CONDITIONS

Parenteral administration of antiepileptic drugs is sometimes necessary because of active, repeated tonic–clonic seizures or status epilepticus or when the patient is unable to take drugs by mouth. Intravenous fosphenytoin (75 mg per minute, to reach a total dose of 750 mg) or intravenous valproate (3 mg per kilogram per minute, to reach a total dose of 25 mg per kilogram body weight) is available for rapid loading through the parenteral route when tonic–clonic seizures are frequent. The protocol for treatment of status epilepticus is given in [Table 426.4](#).

TABLE 426.4. MANAGEMENT OF TONIC-CLONIC AND COMPLEX PARTIAL STATUS EPILEPTICUS

EPILEPSY AND PREGNANCY

Carbamazepine, phenytoin, valproate, primidone, phenobarbital, and all the new antiepileptic drugs are potential teratogens when ingested during pregnancy. Major anomalies, such as spina bifida, rarely occur after valproate monotherapy (1.5%) or carbamazepine (0.9%) exposure of the fetus in utero. Urogenital and congenital heart abnormalities are reported with any of the five older drugs. The incidence of oral palate cleft is increased three- to tenfold after in utero exposure to phenytoin or carbamazepine. Minor craniofacial and limb anomalies, especially epicanthal folds and distal phalangeal hypoplasia, can develop in offspring after use of any of the five drugs during pregnancy. Fortunately, most pregnancies (90% to 95%) in which the fetus is exposed to antiepileptic drugs result in normal offspring. Nevertheless, birth defects are two to three times more common in fetuses exposed to antiepileptic drugs than in those not exposed to antiepileptic drugs. A family history of birth defects should serve as a warning.

If an antiepileptic drug is necessary, monotherapy with the lowest dose that stops seizures should be used. Genetic epilepsy syndromes are best treated with the lowest effective dose of valproate during pregnancy. Lesional epilepsies are best treated with the lowest effective dose of phenytoin during pregnancy. Plasma levels of antiepileptic drugs must be monitored monthly. Vitamins, including folic acid (0.8 to 5 mg per day) and vitamin K, are important supplements. Serum and amniotic fluid α -fetoprotein and acetylcholinesterase detect 78% of cases of open spina bifida, but not closed lesions. Ultrasonography detects 96% of cases of open and closed spina bifida. The newborn should receive 1 mg vitamin K (phytonadione) immediately after birth, and clotting factors should be monitored closely.

EPILEPSY IN THE ELDERLY

Epileptic seizures appear for the first time in 52 per 100,000 persons who are 40 to 59 years of age and in 127 per 100,000 persons age 60 years and older. Epilepsy in persons 65 years and older has twice the prevalence rate of epilepsy in younger adults. The most common identifiable cause of seizures in the elderly is stroke; a silent stroke or an overt completed stroke accounts for one-fourth of all seizures in the elderly. In another one-fourth of patients, no cause can be defined. Less often, a brain tumor, head injury, Alzheimer's disease, or infections are identified. Antiepileptic drug therapy should be initiated at lower doses and at longer intervals in the elderly. Hepatic drug metabolism and the glomerular filtration rate of carbamazepine, phenytoin, valproate, phenobarbital, and primidone decline an average 10% per decade from 40 to 70 years of age, resulting in longer elimination half-lives and diminished clearance. Many elderly have low albumin levels and may require measurements of unbound drug levels. Both therapeutic and adverse effects appear at lower plasma concentrations. Cognitive effects of phenytoin, carbamazepine, valproate, and topiramate appear earlier at lower plasma levels; valproate tremors mimicking parkinsonian tremors occur at relatively low plasma concentrations. Drug interactions are particularly important in the elderly, because these patients often are taking other drugs. Propoxyphene (Darvon) and erythromycin inhibit the metabolism of carbamazepine and phenytoin by the cytochrome P450 system. Carbamazepine and phenytoin can affect cardiac conduction in the elderly.

STATUS EPILEPTICUS

Status epilepticus occurs when seizures persist longer than 30 minutes or when convulsions continue without recovery of consciousness. This medical emergency requires immediate treatment to prevent brain damage or death. There is no single ideal drug for the treatment of convulsive status epilepticus; a step-by-step protocol is given in [Table 426.4](#). Combination treatment with intravenous benzodiazepines (diazepam or lorazepam) and fosphenytoin controls 70% of convulsions and complex partial status. Combination treatment is recommended, because 30% of status recur after either intravenous diazepam alone or intravenous lorazepam alone. Intravenous fosphenytoin (18 mg per kilogram) or intravenous valproate (25 mg per kilogram) is indicated in tonic status or convulsive status associated with subdural hematoma or subarachnoid hemorrhage. If the patient continues to convulse after 60 minutes, general anesthesia with a barbiturate (usually pentobarbital) should be initiated.

METABOLISM OF ANTIEPILEPTIC DRUGS

To predict the time of drug actions and interactions as well as toxic effects, the physician should be familiar with the absorption, distribution, protein-binding, and elimination characteristics and the half-lives of antiepileptic drugs ([Table 426.2](#)). Absorption varies from one drug to another and among patients. Peak plasma concentrations appear most often at 4 to 24 hours. Carbamazepine, primidone, and phenobarbital dosages must be increased slowly, because peak plasma levels may rise quickly. Phenytoin and phenobarbital enhance the metabolism of carbamazepine, reducing its half-life from 20 hours to 10 hours. This may result in early-morning seizures despite drug intoxication in the evening.

Body distribution and full antiepileptic effects depend on plasma protein binding. Only the free, or nonprotein-bound, fraction crosses the blood-brain barrier. Carbamazepine forms an active metabolite (10,11-epoxy-carbamazepine) that may be responsible for some of its clinical action and untoward side effects. Primidone forms two active metabolites, phenylethylmalonamide and phenobarbital. No antiepileptic action of the metabolites of phenytoin has been shown.

The half-life of a drug determines the steady state and the number of doses needed per day ([Table 426.1](#)). All antiepileptic drugs are eliminated by first-order kinetics; that is, there is a direct relationship between dosage and plasma levels. The exception is phenytoin, which saturates liver enzyme capacity at high levels. Metabolism depends on plasma levels, so that at the high end of the therapeutic range, dosage should be adjusted by small amounts (25 mg).

Various conditions modify metabolism or protein binding. Adults older than age 65 metabolize drugs more quickly. The dose may be kept unchanged, however, because the unbound protein fraction is larger. Serious kidney failure raises the free fraction of phenytoin, but the absolute plasma concentration is unchanged. Liver dysfunction also can change protein binding and impair metabolism. During serious illnesses and pregnancy, it is wise to track plasma levels carefully. (Dose adjustments in renal failure are discussed in [Chapter 143](#).) The blood levels in newborn infants of treated mothers are similar to the levels in the mothers themselves. Antiepileptic drugs pass into breast milk, but the concentration is significantly lower than in the mother's plasma.

MONITOR TREATMENT AND ASSESS EFFECTS ON QUALITY OF LIFE

Follow-up should be guided by an understanding of the prognosis and psychosocial complications of epilepsy. The prognosis depends to a great extent on the patient's age at onset. An excellent outcome is seen in idiopathic generalized epilepsies of childhood and adolescence. Generalized seizures caused by progressive brain disease have a poor prognosis. Partial epilepsies with psychomotor symptoms can be difficult to treat and may require surgery. Nocturnal tonic-clonic seizures have a good prognosis.

Among patients with absence seizures, 60% to 79% become free of seizures with ethosuximide or valproic acid therapy. Ninety percent of patients with pure grand mal or primary generalized tonic-clonic seizures become free of seizures with valproic acid or lamotrigine therapy. Ninety-five percent of patients with juvenile myoclonic epilepsy are completely free of seizures when receiving valproic acid.

The stigma often associated with epilepsy is still a concern for patients. The burden of epilepsy is not limited to the medical condition. In a study funded by the Epilepsy Foundation, people with epilepsy reported that limits on lifestyle, schooling, driving, and employment were major barriers in their lives. These economic, social, and educational burdens and barriers negatively influence the quality of life and influence the course of epilepsy. For most patients, the single worst thing about epilepsy is the fear of the next seizure. In the past, epilepsy patients were considered to be at high risk for accidents and were thought to have a special tendency toward crime and aggression, but there is no evidence supporting these assumptions. The national Epilepsy Foundation and its affiliates throughout the country can provide a source of support and service to individuals with epilepsy and provide them with opportunities to connect with others who have epilepsy. Physicians are encouraged to refer their patients to the Epilepsy Foundation affiliate in their region.

Persons with epilepsy are often handicapped by depression or cognitive and behavioral problems associated with their condition or with antiepileptic drugs. Emotional immaturity and personality disorders may develop because of defective rearing, overprotection, and rejection. The physician should act as an advocate for the patient and should formulate a support system that includes family, school, and vocational personnel. A multidisciplinary team is needed. The clinician also must be an educator. The patient should have a calendar for recording seizures and a list of drugs and dosages. Follow-up visits should be scheduled at least every 3 months for the first year and every 6 months subsequently. Patients must understand the need for follow-up examinations, complete blood counts, and liver function tests. In a seizure-free condition, patients should experience no mental or psychiatric abnormalities and can have a normal life expectancy. Death can be caused by suicide, status epilepticus, accidents, or brain tumor.

WITHDRAWAL OF ANTIPILEPTIC DRUG TREATMENT

The prognosis and recurrence of seizures after withdrawal of antiepileptic drugs depend on the specific epilepsy syndrome. The presence of a high rate of seizures, several seizure types, abnormal neurologic signs, abnormally slow EEG background, abnormal mental function during inadequate control of seizures, and repeated tonic-clonic status, as observed in Lennox–Gastaut–Dravet syndrome; severe myoclonic epilepsy of infancy; and the progressive myoclonus encephalopathies all have a poor prognosis. In contrast, 80% of patients whose seizures are completely controlled during the first year of treatment remain free from seizures in the subsequent 3 years. Children older than 5 years who have generalized seizures, such as absence seizures; who have normal neurologic examination results and a normal IQ; and whose seizures have been controlled for 2 to 4 years have a 75% chance of remaining free of seizures after withdrawal of antiepileptic drugs. The exception is the juvenile myoclonic epilepsy of Janz and awakening clonic-tonic-clonic seizures, in which electroclinical traits persist for life. Withdrawal of antiepileptic drugs is not indicated for these patients.

Antiepileptic drugs can be withdrawn gradually after 2 years of complete control in cases of rolandic epilepsy and pure childhood absence and after 4 years of complete control of simple partial epilepsy, complex partial epilepsy, absence associated with tonic-clonic seizures, and grand mal tonic-clonic seizures. A minimum 5-year follow-up is recommended after withdrawal of therapy. EEGs and clinical visits should be scheduled at 6 months and 1 year. CCTV-EEG monitoring also can be used to confirm the absence of seizures.

REFER TO AN EPILEPSY CENTER FOR SURGICAL TREATMENT IN THE CASE OF DRUG RESISTANCE

Of patients with refractory seizures, about 10% can benefit from tailored resections of epileptogenic zones, anterior temporal lobectomy, amygdalohippocampectomy, or cortectomy. Refractory complex partial seizures can be due to noncompliance, inadequate drug dosage, improper choice of drugs, or the presence of precipitating or aggravating factors (a stressful home or workplace, use of alcohol, sleep deprivation, menses). Structural lesions, such as a focal cortical dysplasias, arteriovenous malformation, or occult neoplasm, must be identified.

If none of these factors is present and the patient has had complex partial seizures or secondary tonic-clonic seizures for at least 3 to 4 years, which show no sign of remission and are of such severity and frequency that they interfere seriously with life, surgical treatment should be considered. Evaluation for surgery should be done without undue risk to life and without producing serious neurologic deficits ([Fig. 426.2](#)). Excellent motivation and compliance are essential. The evaluation process is aimed at differentiating temporal from extratemporal epilepsy. The results of surgical resection of epileptogenic zones vary ([Table 426.5](#)).

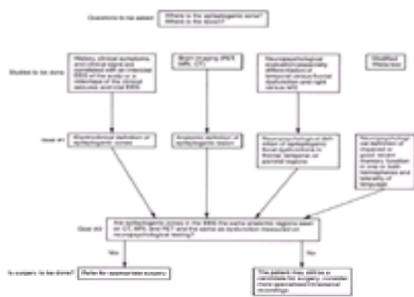

FIGURE 426.2. Presurgical evaluation for medically refractory seizures.

Zone	Complete Elimination or 95% Eradication of Seizures
Temporal lobe epilepsy	
Medial	95%
Lateral	80%
Combined medial-lateral	85%
Combined temporal & frontal	80%
Frontal lobe epilepsy	
Medial	80%
Dorsolateral	
Nondominant hemisphere	70%
Dominant hemisphere	40%
Parietal lobe epilepsy	80%

TABLE 426.5. RESULTS OF TAILORED SURGICAL RESECTION OF EPILEPTOGENIC ZONES

After epileptogenic zones are located, it is determined whether they can be removed without impairing speech or memory. If the focus is within the anterior temporal lobe, the seizure may be arising primarily from medial (hippocampus, amygdala, or both) or lateral structures. If seizures are extratemporal, they may originate from the frontal, parietal, or occipital lobes. An essential test for speech and recent memory is the modified Wada test, routinely carried out for all patients being evaluated for surgery. Sodium amyobarbitone is injected into one internal carotid artery, and tests for speech and memory are conducted during contralateral hemiplegia and in the presence of ipsilateral hemispheric, high-amplitude, 1.5- to 3-Hz slowing on the EEG. Hemispheric lateralization of speech or memory is established by appropriate testing.

The decision to perform selective amygdalohippocampectomy in the context of medial temporal epilepsy or anterior temporal lobectomy in the context of combined medial and lateral temporal epilepsy is based on two conditions. First, focal or regional seizures must originate in one hippocampus or anterior temporal lobe, and there must be no evidence of memory impairment originating in the contralateral temporal lobe. When seizures originate from the lateral temporal or extratemporal cortex, it is especially important to outline the precise site and extent of the seizure focus by chronic stereo EEG, subdural or epidural electrode recordings, and intraoperative electrocorticography. Intraoperative evoked potentials mapping the primary motor cortex and, if necessary, eloquent areas of the hemisphere dominant for language usually precede cortical resection.

distant target in dim light, and the eyes are indirectly illuminated with a hand-held light. The size of the pupils and their shape are noted. The light beam is directed rapidly into the eye, and the speed and completeness of the resulting pupillary constriction are noted for each eye. The patient is asked to fixate an illuminated near target, and the speed and completeness of the resulting pupillary constriction are noted again for each eye. Finally, the light beam is swung rhythmically from one eye to the other. In dim ambient lighting, this usually results in slight dilatation of the pupils in the time between the departure of the flashlight beam from one eye and when it arrives at the other eye, so that a slight initial constriction of the pupils is noted when the flashlight arrives on the new side. A relative afferent pupillary defect (RAPD) is present if there is dilatation of the pupils when the flashlight beam comes to one side, with constriction of the pupils when the other side is illuminated. A RAPD is indicative of a decrease in the pupil-constricting drive to the brain stem from one eye compared with the other and is seen most often in unilateral or asymmetric bilateral optic nerve disease, such as optic neuritis, ischemic optic neuropathy, or compressive optic neuropathy. A RAPD also can be seen in retinal disease but is not present in the context of corneal disease or cataracts.

The external examination of the eyes may reveal a number of important signs. The size of the palpebral fissure and the position of the lids should be noted, and the presence of ptosis (drooping of the upper lid) should be recorded. The ability of the lids to open fully with attempted gaze upward should be evaluated. The conjunctivae and sclera must be inspected for redness due to dilatation of their vessels and for the presence of discharge. The character of any discharge is important; if it is purulent, it should be cultured and a smear examined. Proptosis (bulging of the eye from the orbit) should be noted. The clarity of the cornea should be assessed and lesions recorded. Sensation of the skin of the face and the position and mobility of the facial musculature also must be determined.

An assessment of extraocular movements should be made. The patient should be asked about the presence of diplopia and whether it produces mainly horizontal or vertical separation of the two images. By inspection of the patient, note whether there is an obvious turning of one eye inward toward the nose (esotropia), outward (exotropia), or upward (hypertropia). While the patient is attempting to fixate a distant target, look for any spontaneous movements of the eyes, such as the rhythmic to-and-fro movements of nystagmus (Table 427.1). The patient then should be asked to fixate a small, interesting object in the examiner's hand about three feet away. The examiner should test the range of ocular movements for each eye individually in adduction (toward the nose), abduction (away from the nose), upward, and downward gaze. This is called *testing of ocular ductions* and is a basic part of determining the cause of misalignment of the eyes.

Type	Anatomic Location
Downbeat	Craniocervical junction, cerebellum
Gaze-evoked	Craniocervical junction
Upbeat	Cerebellum, medulla
Seesaw	Diencephalon/mesencephalon
Torsional	Central vestibular
Convergence-retraction	Dorsal midbrain
Rebound	Cerebellum

TABLE 427.1. TYPES OF NYSTAGMUS AND THEIR ANATOMIC LOCATION

Patients with congenital esotropia or exotropia usually will not show significant loss of duction in any direction unless there has been previous eye muscle surgery. On the other hand, patients with acquired eye movement problems often will show a limitation of duction that can help in diagnosis. For example, acquired esotropia may be associated with limited abduction on one side and be due to weakness of the lateral rectus muscle on that side (Table 427.2). Hypertropia may be seen in a patient with limitation of downward duction of the eyes on the side of the higher eye, and this condition most likely will be due to superior oblique paresis, as from fourth nerve paresis.

Muscle (Right Eye)	Type of Deviation	Position of Gaze with Most Separation
Lateral rectus	Esotropia	Right
Medial rectus	Exotropia	Left
Superior rectus	Left hypertropia	Up and right
Inferior rectus	Right hypertropia	Down and right
Inferior oblique	Left hypertropia	Up and left
Superior oblique	Right hypertropia	Down and left

TABLE 427.2. IMAGE SEPARATION IN DIPLOPIA

Finally, careful funduscopic examination should be undertaken. Ophthalmologists usually dilate the pupil with pharmacologic agents to evaluate the ocular fundus easily, but this is not often feasible for the internist in a busy office setting. Through a small pupil, it is usually possible to assess the clarity of the ocular media and determine the presence of a significant cataract obstructing the view of the fundus, which may explain a decrease in VA. The optic disk should be looked at and evaluated for swelling, as should associated hemorrhages, exudates, and so on (Table 427.3). The retinal macula should be inspected for evidence of age-related macular degeneration in the form of pigment deposition, bleeding, exudates, or a macular hole, any of which may explain diminished VA. Retinal detachments are very difficult to see with the usual direct ophthalmoscope through a small pupil; if they are suspected, they must be diagnosed immediately by an ophthalmologist. The retinal arterioles should be assessed for localized or generalized narrowing, presence of emboli, and the amount of light reflex.

Early Papilledema	Pseudopapilledema
Disc color Hyperemic	Pink, yellowish pink
Disc margins Indistinct early at superior and inferior poles, later entire margin	Irregularly blurred, may be lumpy
Disc elevation Minimal	Minimal to marked, center of disc most elevated
Vessels Normal distribution, slight fullness, spontaneous venous pulsations absent	Emanate from center, frequent anomalous pattern, ± spontaneous venous pulsations
Nerve fiber layer Dull due to edema, which may obscure blood vessels	No edema, may glaze with circumcapillary halo of feathered light reflections
Hemorrhages Splinter	Subretinal, retinal, vitreous

TABLE 427.3. DIFFERENTIATION OF PAPILLEDEMA AND PSEUDOPAPILLEDEMA

VISUAL SYMPTOMS THAT DO NOT REQUIRE URGENT EVALUATION

A number of complaints by the patient suggest conditions that should be pursued with the ophthalmologist but do not require emergency referral. A common problem

is the gradual onset of visual blur, often associated with halos around lights at night and often with monocular diplopia. This condition may be monocular or binocular and is most suggestive of development of a cataract or other problem in the ocular media. The examination may show normal results or evidence of an opacity in the lens suggesting a cataract. It is important to know that this is usually correctable by surgery, which leads to a good outcome. Partially or poorly corrected refractive errors, such as astigmatism, can produce similar problems and respond to a simple change in refraction. If the patient reports long-standing strabismus (misalignment of the eyes) or nystagmus (repetitive jerking of the eyes), there may be benefit in nonurgent ophthalmologic or neuro-ophthalmologic evaluation, primarily to explain the problem to the patient and to look for associated treatable problems. The internist's examination of such patients may uncover evidence of strabismus, though sometimes finding evidence of this problem requires more detailed ophthalmologic testing. Nystagmus may be noted.

Long-standing abnormalities of pupil appearance or function usually result from intraocular inflammation, trauma, or other disorders, such as the tonic pupil (called Adie's syndrome when it is associated with decreased tendon reflexes in the lower extremities). The underlying condition may require additional treatment, and nonurgent referral to an ophthalmologist should be considered. A disruption of ocular sympathetic innervation may give rise to Horner's syndrome, with miosis and ipsilateral ptosis. Horner's syndrome can be confirmed by testing with cocaine eyedrops and can be classified further by pharmacologic testing of the pupil using 1% hydroxyamphetamine into involvement of the preganglionic sympathetic fibers and damage to postganglionic fibers. Preganglionic Horner's syndrome is sometimes associated with Pancoast's syndrome of carcinoma of the thoracic apex or with cervical mass lesions. Imaging directed at this area can be reserved for this form of the condition.

The onset of typical migrainous visual phenomena in a person younger than 45, with or without headaches, can be a worrisome symptom, but it is associated only rarely with underlying intracranial or ocular pathologic conditions. The typical visual symptoms include a zigzag bright arc or streak in the peripheral VF bilaterally, of acute onset and usually lasting less than 20 minutes. Other common variants include a central VF defect of similar duration, described as a blurred area or fuzzy spot—like water on glass. This may be followed by some kind of headache, not necessarily severe, in which case the term *classic migraine* is used. Identical symptoms may occur with no associated headache and are called *acephalgic migraine*. A history of headaches, not always identified as migraine, should be sought, and the VF should be carefully examined. If the patient has no persistent VF defect and the description and duration of the symptoms are typical, the main focus should be on screening for underlying medical conditions that may have triggered migraine phenomena, such as uncontrolled hypertension, hypothyroidism, or connective tissue disorders. If the symptoms are persistent or otherwise atypical in any way, or if they are monocular, the patient should be evaluated by a neurologist for an underlying cerebrovascular or intracranial problem.

Age-related macular degeneration can take the form of gradual onset of decreased VA or of a distortion of objects that are being fixated. This distortion can make straight lines show a curved segment, and it may be monocular or bilateral. The examination shows a decrease in VA, possibly a central scotoma, but no RAPD (Table 427.4). Pigmentary changes or hemorrhage may be seen on direct ophthalmoscopy of the macula. There are treatable complications of age-related macular degeneration, but the disease itself is not treatable at present. Nonurgent referral to a general ophthalmologist or retinal specialist is indicated.

Optic Nerve	Macula
Visual acuity	
Reduced	Reduced
Color vision	
Impaired	Preserved
Visual field	
Central scotoma	Normal or small central scotoma
Pupils	
RAPD present	Absent
Photostress test	
Normal	Abnormal
Light brightness	
Reduced	Normal

RAPD, relative afferent pupillary defect.

TABLE 427.4. DIFFERENTIATION OF OPTIC NERVE AND MACULAR DISEASE

Acute unilateral or bilateral conjunctival irritation, discharge, and redness may indicate the presence of viral or bacterial conjunctivitis. Photophobia may be intense, but VA and VF are not impaired. The pupil should function normally, and the lid and eye movement should be normal. The presence of a foreign body should be sought. If any features of the illness are atypical, the patient should be referred immediately to an ophthalmologist. For typical cases of conjunctivitis, a smear and culture of any discharge is essential, and empiric treatment of presumed bacterial conjunctivitis with topical antibiotics may be considered for 7 to 10 days. If at any time VA becomes impaired or other features become atypical, the patient should be referred to an ophthalmologist immediately.

Isolated sudden onset of unequal pupil size, when not associated with any other new visual symptoms or signs is usually not due to a serious underlying disease process. The most common causes are inadvertent or intentional instillation of an anticholinergic agent into the eye, acute tonic pupil, or the transient pupillary dilatation seen in young people, often in association with migraine. More serious pathologic processes almost always also produce other symptoms, such as decreased VA, ocular redness, ptosis, or diplopia and strabismus. Evaluation by an ophthalmologist or neurologist is appropriate but not usually urgently necessary.

URGENT VISUAL SYMPTOMS DUE TO INTRINSIC OCULAR DISEASE

Sudden onset of monocular flashes and floaters is a worrisome symptom, because it may imply a retinal tear or detachment. In middle-aged people, it is more often due to detachment of the posterior face of the vitreous body from the retinal surface, which produces transient traction on the retina and a burst of flashes in the VF from mechanical irritation. Nevertheless, such a posterior vitreous detachment also may cause a retinal tear or detachment, and all patients with this symptom should be evaluated by an ophthalmologist within a few days. The examination outlined earlier usually shows normal results, since a dilated fundusoscopic examination with special instruments is necessary to define most retinal pathologic conditions. A retinal detachment in the macular area will limit VA and may produce other VF and pupillary signs, however. Persistent flashes or a marked increase in floaters are of more concern and should be urgently evaluated by an ophthalmologist.

Sudden onset of monocular or binocular decreased VA is a symptom that should always prompt rapid referral to an ophthalmologist. This may be due to acute glaucoma, retinal or vitreous hemorrhage, retinal infarction, or optic nerve disease. The examination may reveal corneal clouding, abnormal pupil reactions, blood in the vitreous cavity, retinal bleeding, retinal infarction or inflammation, or optic nerve swelling. Other conditions, such as retrobulbar optic neuritis, show normal results on examination, except for decreased VA, VF, and the presence of a RAPD. Sudden awareness of a monocular VF defect may indicate the presence of a vision-threatening process, such as retinal detachment, and should prompt immediate referral to an ophthalmologist. Other possible causes include branch retinal artery occlusion by emboli, ischemic optic neuropathy, or retinal infections. The examination may show retinal detachment, pale swollen infarcted retina, or retinal exudates and hemorrhage.

Ocular pain of sudden onset is frightening to the patient and may imply the presence of a serious pathologic condition. Acute glaucoma can produce intense pain and cause corneal clouding, redness, and pupillary dysfunction, along with decreased VA and VF. Iritis characteristically generates ocular pain, photosensitivity, and ocular redness. VA and VF typically are not affected. Scleritis, episcleritis, and orbital inflammatory syndromes may cause acute ocular and orbital pain, with generalized or localized scleral flushing and overlying conjunctival injection. There may be tenderness to palpation of the ocular globe or orbit. A foreign body in the eye is painful and provokes intense tearing. Foreign bodies must be removed promptly to prevent corneal abrasions and infection. All of these conditions necessitate urgent ophthalmologic referral.

URGENT VISUAL SYMPTOMS OF NEUROLOGIC ORIGIN

The patient who experiences sudden onset of diplopia should be questioned about whether one of the two images disappears upon covering either eye, to distinguish true diplopia from monocular diplopia. It is also useful to know whether the two images are separated horizontally or vertically, because this can help in beginning to determine the weak muscles responsible. The examination should focus on the ocular muscle ductions; on whether there is exotropia, esotropia, or hypertropia; and on whether there is associated ptosis, pupillary abnormality, VF or VA loss, or facial sensory disturbance. One common condition that causes acute diplopia is microvascular infarcts of the ocular motor nerves due to vasa nervorum occlusive disease in patients with hypertension and diabetes mellitus. This process may affect

cranial nerves III, IV, or VI and may be painful.

When the third nerve is affected by a microvascular infarct, the pupil is almost never affected, distinguishing this condition from the most ominous cause of acute third nerve palsy, compression by an enlarging intracranial saccular aneurysm. Both microvascular third nerve infarction and compressive third nerve paresis produce ptosis and weakness of the third nerve–innervated muscles, classically resulting in exotropia and hypotropia of the affected eye. Early in the course of compressive third nerve palsy, the pupil may not be involved; for this reason, all patients with third nerve palsy should be referred immediately to a neurologist or neuro-ophthalmologist for careful assessment and imaging evaluation to help make this distinction.

Another condition causing acute diplopia is myasthenia gravis, which can mimic any ocular motor nerve paresis and can produce findings that fluctuate during the day or even during the examination. A useful fact is that myasthenia gravis never causes abnormal pupillary function. Because of the tendency of myasthenia gravis, left untreated, to generalize to the somatic muscles in up to 80% of patients, prompt referral to a neurologist or neuro-ophthalmologist is essential. Acute diplopia can result from demyelinating disease of the brain stem, causing internuclear ophthalmoplegia, sixth nerve paresis, or other ocular motor disorders. Neurologic evaluation can lead to treatment that shortens the period of disability and helps prevent future episodes.

When a patient has sudden onset of anisocoria in association with ocular pain, diplopia, ptosis, or sensory disturbance on the face, it is more ominous than when anisocoria is an isolated phenomenon. These combinations of anisocoria and other neuro-ophthalmologic signs usually indicate disease in the posterior orbit, cavernous sinus, or brain stem. Such patients need immediate referral to a neurologist or neuro-ophthalmologist.

Acute onset of ptosis of one or both eyelids associated with diplopia, anisocoria, headache, ocular pain, or facial sensory loss has the same implications as other combinations of such findings, usually indicating disease in the posterior orbit, cavernous sinus, or brain stem. Sudden onset of ptosis of one or both eyelids may be an isolated phenomenon, when it generally indicates an underlying condition, such as myasthenia gravis. Acute Horner's syndrome may produce mild unilateral ptosis, typically associated with miosis of the same eye. While acute Horner's syndrome can develop in the course of cluster headache or in a patient with migraine, it also can indicate injury to the internal carotid artery (ICA) with arterial dissection. Thus, a patient with headache, neck pain, and recent-onset Horner's syndrome should be urgently evaluated by a neurologist for internal carotid artery dissection. This evaluation often includes pharmacologic testing of the pupil function and imaging of the ICA with cervical magnetic resonance imaging and magnetic resonance angiography. The danger of an ICA dissection is primarily a risk of distal thromboembolism, especially in the first week; many such patients need short-term anticoagulation, though the natural history is eventual arterial wall healing.

Sudden onset of a binocular VF defect almost always implies an intracranial disease process. Rare exceptions are the acute onset of bilateral demyelinating optic neuritis as well as onset after an episode of systemic arterial hypotension of bilateral ischemic optic neuropathy. Acute onset of homonymous hemianopia usually is caused by ischemia of the occipital cortex, which may be due to atheroembolism to the posterior cerebral artery from the aorta, vertebral arteries, or basilar artery or to cardiogenic embolism. The underlying source must be determined to properly guide therapy. If the patient is examined by the physician within 3 hours of onset of a severe deficit, thrombolytic therapy may be considered. Urgent neurologic referral is indicated. The acute onset of bilateral temporal hemianopia implies acute dysfunction of the optic chiasm. This syndrome is seen in patients with a known or previously unrecognized pituitary macroadenoma that undergoes spontaneous hemorrhage, causing "pituitary apoplexy," and then exerts pressure on the optic chiasm from below. This is a neurosurgical and endocrinologic emergency and requires immediate evaluation.

CHAPTER 428: APPROACH TO THE PATIENT WITH A GAIT DISORDER

STEPHEN G. REICH

[Pathophysiology](#)
[History and Physical Examination](#)
[Differential Diagnosis](#)
[Diagnostic Tests](#)
[Management](#)

Impaired walking, with its associated risk of falling, is one of the most debilitating and demoralizing aspects of aging. It is an important source of morbidity among seniors, a significant contributor to death, and a common reason for nursing home placement. Numerous physiologic changes affect gait and balance with normal aging, yet many of the conditions that cause or contribute to disorders of gait are pathologic. These conditions, often multifactorial, pose not only a diagnostic challenge to the clinician but also a therapeutic imperative, since identifying and treating the cause(s) of impaired gait enhance quality of life and lessen the risk of serious injury.

PATHOPHYSIOLOGY

Although there are undoubtedly centers in the brain and spinal cord where the many discrete contributors to locomotion and maintenance of an upright posture are integrated, they remain largely unknown and currently inaccessible to formal testing. The assessment of gait is approached in clinical terms, by analyzing its various components; this appraisal can be done almost entirely at the bedside. Given the complexity of walking, any scheme attempting to break it down into its parts runs the risk of oversimplification. Nevertheless, when confronted with an elderly patient with a gait disorder, a workable clinical approach is to evaluate four major areas—structural, sensory, motor, and cognitive—since these cover virtually all of the conditions that cause or contribute to impaired walking and balance.

The structural component of gait refers to bones, joints, and ligaments, all of which are frequently diseased in the elderly. Their impairment leads not only to instability but also to pain—itsself a major contributor to gait disorders and one of the causes most amenable to treatment. The sensory components of walking allow for the appropriate assessment and response to environmental and somatic cues. In addition to somatosensory perception (for clinical purposes, largely proprioception), these components also include vision, hearing, and vestibular functioning. The testable motor contributions to gait include strength, coordination, tone, balance, posture, and the presence of bradykinesia, suggesting parkinsonism.

The cognitive contribution to ambulation broadly includes level of alertness, insight into the environment, and judgment. These are all susceptible to medications, orthostatic hypotension, neurodegenerative diseases, and cerebrovascular disease, among other common conditions in the elderly. Last, fear of falling (sometimes for good reason) can be as disabling as physical causes of a gait disorder and contributes to isolation and sometimes causes agoraphobia in the elderly.

HISTORY AND PHYSICAL EXAMINATION

The history and physical examination of an elderly person with a gait disorder should focus on the four areas mentioned earlier that contribute to normal ambulation: structural, sensory, motor, and cognitive. The duration of a gait disorder is best determined by asking the patient to determine the last time his or her walking was normal. Most gait disorders begin and progress insidiously, but an abrupt onset, change, or long periods of stability or even improvement suggest cerebrovascular disease. Patients should be queried about pain in the hips, knees, ankles, neck, or lower back. Inquire about vision, hearing, and vertigo. Previous use of aminoglycoside antibiotics should raise the suspicion of a vestibulopathologic condition. Historical clues suggesting a somatosensory deficit include numbness and tingling in the feet and greater difficulty navigating in the dark.

Motor disorders are suspected when there is a history of weakness. Its distribution provides additional clues: hemiparesis suggests stroke, proximal weakness implies myopathy or a neuromuscular junction defect, and distal weakness usually indicates a neuropathic origin. Weakness confined to the legs, with spasticity, suggests a spinal localization. Motor impairment without weakness denotes parkinsonism or cerebellar disease, though the latter is uncommon in the elderly. Inquire about associated signs that can aid in determining location, including bladder dysfunction, which raises the possibility of spinal cord disease, or hydrocephalus. Additional historical features of importance include medications, use of alcohol, symptoms of orthostatic hypotension, clues suggesting dementia, the patient's emotional state, and the way in which the gait disorder has affected the activities of daily living.

Like the history, the physical and neurologic examination should focus on the four main components of walking. The joints of the lower extremities should be assessed for range of motion and pain. Visual acuity, fields, and hearing should be checked. Vestibular function is evaluated by observing the intactness and symmetry of the vestibulo-ocular reflex. This evaluation can be carried out by having the patient read a near card with the head stationary and then when gently shaking the head from side to side, at a frequency of about 1 Hz. Normally, visual acuity does not decline by more than two lines with head shaking; more than that suggests a vestibular defect requiring further evaluation. The final component of the sensory examination examines proprioception by checking joint position at the great toe as well as vibratory sensation, since they both tend to be affected by disease of large myelinated fibers, dorsal roots, or the posterior columns. A positive Romberg sign also suggests a sensory ataxic component to a gait disorder.

The motor examination begins by testing strength. Mild weakness is rarely the sole explanation for a gait disorder. The cause of weakness is determined by whether it is of upper or lower motor neuron origin and, as mentioned previously, by its topography. In addition to checking strength, the motor examination also should focus on tone and coordination. The gait itself is often diagnostic. Specific types are discussed in the next section, but general features include the patient's ability to arise from a chair; narrowing or broadening of the base; the length, velocity, and regularity of strides; and the ability to turn, stand on toes or heels, and tandem walk. Check the postural righting reflex by determining whether the patient can correct for a pull backward. Watch for diminished arm swing, suggesting either subtle hemiparesis or early parkinsonism. It is sometimes easier to hear a slight asymmetry of gait, by noting a shoe scuff the floor, than it is to see it; this can be confirmed by looking for asymmetrical wear on the soles of the shoes. Final parts of the physical examination should include an assessment of the patient's mental status and a check of supine and standing blood pressure.

DIFFERENTIAL DIAGNOSIS

Most gait disorders in the elderly are chronic and do not require urgent evaluation. Nevertheless, difficulty walking that develops over days to weeks should be considered an emergency. The diagnosis hinges on the specifics from the history and physical examination, but important considerations in this context include stroke; spinal cord compression; a mass lesion, such as a subdural xxxxxx; transverse myelitis, or Guillain-Barré syndrome.

A very different differential diagnosis emerges when one is confronted with a chronic gait disorder. Only the most common types are discussed briefly here. It is easiest to begin with those gait disorders primarily due to pain. When this condition involves one or more joints, the focus is on rheumatologic or orthopedic considerations. Pain limited to the lower back is not dealt with here. Lumbar spinal stenosis is characterized by neurogenic claudication: pain in the lower back, buttocks, and thighs with walking. Unlike vascular claudication, patients with lumbar spinal stenosis do not obtain relief by stopping and standing but prefer to sit. Making this diagnosis relies more on symptoms than signs, yet many patients have mild weakness and depressed deep tendon reflexes in the lower extremities.

Cervical spinal stenosis is another common cause of a gait disorder in the older patient. It is typically the result of hypertrophic degenerative arthritis, with or without frank disk herniation, causing myelopathy. The gait is spastic, with stiff, dragging legs, and aptly has been described as looking as though the patient is wading through waist-high water. There is often surprisingly little leg weakness, but the lower extremities are spastic, with brisk tendon reflexes; when there is a clinically meaningful degree of stenosis, the toes are up. There also may be radicular symptoms and signs in the upper limbs. It is imperative that this diagnosis be based on clinical findings, since plain films, computed tomography, and magnetic resonance imaging (MRI) often show degenerative cervical disk disease in the elderly. When these findings are unaccompanied by myelopathic signs, however, they are practically never a significant contributor to a gait disorder.

When lower motor neuron disorders cause a gait disorder, there is always weakness. A complete differential diagnosis of disorders of the motor unit is beyond the scope of this chapter, but there are general considerations that focus on the elderly. If the weakness is paradoxically admixed with upper motor neuron signs, the most

likely cause is associated cervical stenosis; if this condition is ruled out, then amyotrophic lateral sclerosis should be considered.

Pure lower motor neuron diseases are differentiated by the topography of the weakness and associated symptoms and signs. Multilevel lumbar root disease, in addition to patchy lower extremity weakness, is accompanied by pain, often paresthesias, early loss of deep tendon reflexes, and impaired sensation. A similar picture, evolving over weeks to months in diabetics, is known as diabetic amyotrophy or radiculoplexopathy, but it may be purely motor. Proximal weakness, unaccompanied by sensory symptoms, suggests myopathy or a myasthenic syndrome. Distal weakness is more characteristic of neuropathy, frequently associated with loss of proprioception causing a sensory ataxic gait reminiscent of cerebellar syndrome. A similar picture results from B₁₂ deficiency, an important treatable cause of a gait disorder.

When there is no pain or signs of upper or lower motor neuron disease, consider Parkinson's disease (PD) and related disorders, as discussed in [Chapter 434](#). People with PD are hesitant when arising from a chair; have a narrow base and a flexed posture; take small, shuffling steps; turn en bloc; and evidence decreased arm swing. In the middle to later stages, there is loss of postural righting reflexes. In early PD, the gait is affected only mildly. Therefore, if confronted with a moderate or moderately severe parkinsonian gait in a patient who has not been symptomatic for more than a year or two, consider a parkinsonian mimic. The condition most likely to show signs of significant disorder of gait, with impaired balance and falls, is progressive supranuclear palsy.

The patient who has parkinsonian symptoms from the waist down but not from the waist up has *lower-half parkinsonism*, raising two diagnostic possibilities. The first is normal pressure hydrocephalus. The classic triad is gait apraxia, dementia, and urinary bladder instability. The apractic gait of normal pressure hydrocephalus, like parkinsonism, is characterized by small steps, with failure to pick up the feet—as if they are glued or magnetized to the floor. In contrast to parkinsonism, the base is normal to broad, arm swing is typically preserved, and there are few if any other compelling features of PD.

In some cases of normal pressure hydrocephalus, the gait is affected disproportionately, with relative sparing of cognition. The diagnosis is contingent upon a compatible clinical picture; a scan showing unequivocal hydrocephalus, not accounted for by atrophy; and improvement in gait after a large volume spinal tap. Documenting this improvement is aided by videotaping the patient before and several hours after the lumbar puncture as well as by obtaining before and after lumbar puncture quantitative data, such as the time it takes to walk a specified distance and the number of steps required to turn 360 degrees. At this point, it is appropriate to consider a shunt.

If there is no improvement after a spinal tap, with otherwise typical clinical and radiographic findings, another diagnostic option is more extensive spinal fluid drainage, with placement of a temporary lumbar catheter. Given the challenge of making the diagnosis of normal pressure hydrocephalus and planning treatment, neurologic and neurosurgical consultation are mandatory.

Aside from normal pressure hydrocephalus, the picture of lower-half parkinsonism also suggests microvascular cerebrovascular disease, sometimes called Binswanger's disease. In contrast to a more traditional multi-infarct state, with a history of stroke(s) and signs of hemiparesis, microvascular disease often develops insidiously, with a parkinsonian gait, often unaccompanied by corticospinal signs. The diagnosis is supported by the finding of patchy or confluent areas of increased T2 signal in the periventricular region and subcortical white matter. Given that such findings are nearly ubiquitous in the elderly, it is important not to overdiagnose microvascular disease.

A far more typical scenario than pure Binswanger's disease is a multifactorial gait disorder—arguably the most common condition. These patients rarely have a single overriding abnormality to account for their impaired walking. Instead, they have a little of this and a little of that: mild vestibulopathy, slightly diminished visual acuity, a bit of lower extremity weakness, brisk knee reflexes without significant spasticity, mildly painful hips and knees, some loss of proprioception, and only modest orthostatic hypotension. Although each of these abnormalities is mild, they tend to add up geometrically in the elderly, so that the sum is more than its parts.

Last, as described by Nutt et al., is a group of higher-level gait disorders. These poorly understood but relatively well-described syndromes should be considered in cases where there is neither a singular nor a multifactorial explanation for a patient's impaired walking. They are recognized by their distinctive phenomenological characteristics, for example, isolated gait ignition failure. This rare disorder is distinguished by difficulty initiating gait and sudden hesitation (freezing), reminiscent of advanced PD.

DIAGNOSTIC TESTS

The choice of laboratory tests to evaluate a gait disorder is dictated by the history and physical examination. Practice diagnostic restraint and avoid a “rubber stamp” approach. Most patients should receive a brain scan, preferably MRI, unless there is an adequate alternative explanation, such as marked lower extremity weakness referable to the motor unit. As such, an electromyogram and laboratory studies searching for metabolic sources of myopathy or neuropathy would be most appropriate.

As mentioned, B₁₂ deficiency always should be considered. Since any metabolic disturbance can interfere with the cognitive component of gait, it is reasonable to check liver, kidney, and thyroid function. Symptoms of lumbar spinal stenosis are best evaluated with MRI of the lumbosacral spine, and myelopathy requires the same test of the cervical and sometimes the thoracic spine. It is important to avoid routine tests, which are likely to show abnormal results but are of little clinical relevance and are often misleading (such as plain films of the cervical or lumbosacral spine). Similarly, avoid attaching too much importance to increased T2 signal changes on MRI, unless the clinical picture indicates a multi-infarct state.

MANAGEMENT

Like the choice of laboratory tests, management of a gait disorder is dictated by the underlying cause(s), though there are general principles that can be applied to almost all cases. There are two types of treatment: specific and symptomatic. The former is tailored to curing or improving a specific diagnosis or condition, such as anti-parkinsonian medications for PD or a decompressive laminectomy for lumbar spinal stenosis. This treatment includes optimizing as many abnormalities as possible, even mild ones, such as impaired visual acuity and hearing, orthostatic hypotension, and relief of painful joints—the geriatric equivalent of a “major tune-up.”

Along with specific therapies, patients also should receive symptomatic treatment aimed at improving their general functional status and minimizing the risk of a fall. This is often best accomplished by employing a physical and occupational therapist. Patients should be given an exercise regimen and be cautioned about the deleterious effects of immobility in the context of a gait disorder. Consideration should be given to an assist device, such as a cane or walker, particularly one with wheels. Safety features about the home should be reviewed, including the use of handrails on the stairs, adequate lighting, and removal of throw rugs. The bathroom is a notorious place for falls: aids include a raised toilet seat, shower chair, and, if necessary, supervision in the shower. In anticipation of a fall, patients should have an emergency call device on hand. Finally, medications should be reviewed critically; where possible, eliminate those with central nervous effects or side effects.

CHAPTER 429: APPROACH TO THE PATIENT WITH ABNORMAL MOVEMENTS AND TREMOR

STEPHEN G. REICH

[Pathophysiology](#)
[History and Physical Examination](#)
[Classification and Differential Diagnosis](#)
[Management](#)

Movement disorders are a diverse group of neurologic diseases and syndromes characterized by motor dysfunction not attributable to weakness, cerebellar incoordination, changes in tone, cognitive deficits, or impaired sensory feedback. They often are referred to as *extrapyramidal disorders*, emphasizing their anatomic and clinical distinction from the upper motor syndrome characteristic of disease of the pyramidal tract. They manifest as either a paucity of voluntary movement—the hypokinetic (akineti)c/rigid, or parkinsonian, disorders—or excessive involuntary movement—the hyperkinetic disorders.

PATHOPHYSIOLOGY

Movement disorders generally localize to the basal ganglia. These large, paired nuclei at the base of the brain include the caudate nucleus and putamen, known collectively as the striatum, and the globus pallidus, which, when combined with the putamen, is referred to as the lentiform nucleus. Most of the understanding of the basal ganglia comes from observations made in the diseased state. Although movement disorders are the most obvious abnormality, it is now clear that the basal ganglia are involved, either directly or indirectly, through their extensive connections, in myriad other functions. These functions include normal motor planning and execution, behavior, mood, cognition, sensation, and ocular motor functioning, among many others. The basic organization of the basal ganglia is that of a circuit, with functionally and somatotopically segregated parallel pathways connecting the basal ganglia to the thalamus to the cortex and back to the basal ganglia. This complex circuitry is controlled by many neurotransmitters and modulators acting upon a dizzying array of receptors. Lesions anywhere in this circuit, either structural or functional, have the net effect of increasing or decreasing cortical activity, producing a clinical picture of either diminished or excessive motor activity.

HISTORY AND PHYSICAL EXAMINATION

When confronted with a patient with a movement disorder, the diagnostic approach begins with accurate classification of the movement(s) based on clinical phenomenology, thus reversing the usual progression from history to physical examination. Information from the patient's history is most helpful when moving from the type of movement disorder to a specific diagnosis. It should focus on the age and tempo of onset, medication exposure, exacerbating and relieving factors, family history, and the effect of the movement disorder on the activities of daily living.

The physical examination is the cornerstone of the phenomenological diagnosis. As is discussed further later herein, the first step is to determine whether the disorder is hypokinetic (parkinsonian) or hyperkinetic. Between the two, the hyperkinetic disorders typically cause the most confusion. This confusion can be minimized by taking a rather simple and orderly approach to the examination. The key questions include whether the involuntary movements are rhythmic; if they conform to a pattern (stereotyped) or are random and unpredictable from one movement to the next; and their speed and anatomical distribution.

CLASSIFICATION AND DIFFERENTIAL DIAGNOSIS

The prototype *hypokinetic disorder* is Parkinson's disease (PD), characterized by bradykinesia and either tremor at rest or cogwheel rigidity. The latter symptom produces a ratchet-like feeling as a joint is moved and is detected most easily with flexion and extension of the neck or at the elbow or wrist. Additional features seen in the early to middle stages of PD include micrographia, difficulty arising from a low chair, trouble turning in bed, drooling, a stooped posture, decreased blink rate and facial expression (hypomimia), a soft and monotone voice, and decreased arm swing while walking. As the disease advances, bradykinesia often gives way to akinesia in the form of difficulty initiating movement (start hesitation), and freezing—the sudden cessation of movement. There is loss of postural righting reflexes such that the patient cannot correct for even a slight loss of balance, resulting in falls. Because PD and related parkinsonian syndromes are discussed more extensively elsewhere in this volume, the remainder of this chapter focuses on the hyperkinetic disorders.

Tremor is defined as a rhythmical oscillation of a body part. It is the rhythmicity that distinguishes tremor from other hyperkinetic movement disorders. A tremor is classified by its position of maximal activation. A tremor at rest is typical of PD. A postural tremor suggests essential tremor (ET)—enhanced physiologic tremor—and may sometimes accompany PD. Synonyms for ET include benign ET, senile tremor, and familial tremor. A tremor maximally activated with purposeful movement is referred to as a kinetic tremor, replacing the former term *intention tremor*. Although this type traditionally suggests a cerebellar tremor, in clinical practice, cerebellar disease rarely manifests in the form of tremor; instead, an isolated kinetic tremor is usually essential tremor. The frequency of tremor is somewhat helpful in distinguishing different types, but owing to overlap and the challenge of estimating frequency accurately at the bedside, this feature is less reliable than the position of activation. The slowest tremor is seen with cerebellar disease: 3 to 5 Hz. This rate overlaps with the 3 to 6 Hz parkinsonian tremor, and both are slower than ET, at 6 to 12 Hz.

Enhanced physiologic tremor (ET) is a high-frequency, low-amplitude postural tremor encountered in the context of metabolic derangements, drug and alcohol withdrawal, medications, fever, and fatigue. Because it is usually transient, disappearing after the provocation has resolved, it rarely provokes symptoms. There are two exceptions: hyperthyroidism and drug-induced tremor. A list of drugs known to enhance physiologic tremor is included in [Table 429.1](#)

Parkinsonism	Dystonia	Tremor
Antipsychotics	Antipsychotics	Lithium
Metoprolol	Metoprolol	Antipsychotics
Albendazole	L-dopa	Valproic acid
Amiodarone	Mydriatics	Glucocorticoids
Dopamine depletors	Almost any drug at toxic doses	Tryptic antidepressants
Chorea	General (especially in the context of renal insufficiency)	β -adrenergic agonists
Phenytoin		Tics
L-dopa	Tricyclics	Antipsychotics
Antipsychotics	Phenytoin	Amphetamines
Metoprolol	L-dopa	L-dopa
Estrogens		Carbamazepine

TABLE 429.1. DRUG-INDUCED MOVEMENT DISORDERS (INCOMPLETE LIST)

In clinical practice, once an enhanced physiologic tremor has been ruled out, the differential diagnosis almost always boils down to either PD or ET. A few key features from the history and physical examination can make this distinction. Most patients with PD are seen within 1 year of onset of tremor, whereas ET is often present for many years, and sometimes decades, before it comes to attention. A small amount of alcohol often transiently suppresses ET but has little effect on PD. At least 60 percent of patients with ET have a positive (autosomal dominant) family history, whereas PD is usually sporadic.

Features from the examination that distinguish ET from PD include the position of activation and frequency, as mentioned earlier. The tremor of PD has a pill-rolling morphologic appearance, whereas ET is typically flexion/extension. Both tremors most commonly affect the upper limbs, but ET sometimes affects the head and voice, which practically never occurs with PD. One of the most helpful differential diagnostic points is whether the tremor begins uni- or bilaterally. Early PD is classically *hemi*-PD, whereas ET is almost always bilateral at onset. A handwriting sample in ET shows the rhythmical oscillation of tremor; in PD the tremor often attenuates with purposeful activities, but there is micrographia. Unlike ET, which is a monosymptomatic disorder (nothing but tremor), PD is characterized not only by tremor but also by the other associated signs mentioned previously. (Note, however, that as many as 30% of PD patients experience no tremor.) Finally, the natural history is

different: ET is an insidiously progressive disorder, whereas PD is more noticeably progressive.

There are many other tremor types (see Deuschl), but two deserve brief mention because they are underrecognized. Primary writing tremor is a task-specific movement disorder, meaning that the tremor occurs exclusively or at least disproportionately often with writing. An equally unusual tremor is primary orthostatic tremor, characterized by a fine tremor of the lower extremities upon standing that disappears with walking. Often the diagnosis is made from the history alone: the typical patient is an older man or woman who complains of the inability to stand still but has no difficulty walking.

Next among the hyperkinetic disorders is dystonia: a syndrome of sustained muscle contractions causing stereotyped, repetitive movements or abnormal postures, generally of a twisting or turning character. Dystonia is distinguished from other hyperkinetic disorders by the sustained and stereotyped nature of the movements. There are several ways to classify dystonia. The first is the age of onset, whether in childhood, adolescence, or adulthood. The younger the age at onset, the more likely dystonia is to be secondary and to spread to other body parts, even becoming generalized. Dystonia is classified as secondary (symptomatic) when there is an identifiable underlying cause and primary (idiopathic) when no cause is found. The majority of adults have primary dystonia. Dystonia can be sporadic or hereditary, and all forms of inheritance have been described. The prototype is seen in Ashkenazic Jews (*DYT1*) on chromosome 9. This is autosomal dominant but has a penetrance of only 30 percent; it typically takes the form of generalized dystonia with onset in childhood, though there is quite a bit of heterogeneity.

The most helpful way to classify the adult-onset dystonias is by their topography. The most common are the focal dystonias, affecting one body part, with a predilection for craniocervical muscles. Segmental dystonia involves two or more contiguous body parts, multifocal dystonia affects two or more noncontiguous body parts, hemidystonia affects an ipsilateral arm and leg, and generalized dystonia involves the lower extremities and another region. As briefly mentioned earlier, dystonia may manifest only during certain tasks, the most common being writing or playing a musical instrument.

The most well-recognized focal dystonia is torticollis, or cervical dystonia, which is characterized by involuntary turning of the head. Similar spasmodic movements involving the orbicularis oculi are known as blepharospasm. The lower portion of the face may be affected (oromandibular dystonia) as well as the vocal cords. The latter condition, known as spasmodic dysphonia, produces a strained quality to the voice, as if being strangled.

Chorea is characterized by brief, nonsustained, nonstereotyped, low-amplitude movements that tend to flow irregularly from one body part to another. It often has a predilection for distal limbs but can affect the trunk and face. The lack of rhythmicity distinguishes chorea from tremor, and the absence of a pattern and its faster frequency separate it from dystonia. Patients with chorea often look fidgety. The prototype choreiform disorder is Huntington's disease (HD), characterized by the clinical triad of chorea, dementia, and an autosomal dominant family history. The gene, located on chromosome 9, causes an expanded trinucleotide repeat (CAG), and there is an inverse correlation between repeat length (over 40 is always pathologic) and age at onset. It typically develops in the third or fourth decade of life, with varying combinations of chorea or psychiatric manifestations, including dementia, impulsively poor judgment, or an affective disorder. Depending on the length of the repeat, it can manifest as early as childhood and well into advanced age.

The differential diagnosis of chorea is long, including other degenerative disorders; such developmental abnormalities as cerebral palsy; drug effects ([Table 429.1](#)); metabolic disorders, such as hyperthyroidism; chorea gravidarum; lupus and the antiphospholipid antibody syndrome; and infectious disorders, such as HIV and Sydenham's chorea, among many others. Acute hemichorea is typically due to a stroke or other lesion in or close to the subthalamic nucleus of Luys. Such a lesion also causes acute hemiballismus, which is similar to chorea but is distinguished by its larger-amplitude, more violent, flinging movements, with a tendency to affect proximal muscles. The dramatic picture of acute vascular hemichorea or hemiballismus is contrasted to its usually benign course, with spontaneous resolution in several weeks or months, though there are exceptions.

Similar to chorea in its random spread from one muscle group to another is myoclonus, distinguished from chorea and other hyperkinetic disorders by its lightning-like speed. Myoclonus can be physiologic in origin, such as the jerks many of us experience when falling asleep, or part of a pathologic process. It may be epileptic or part of a degenerative disease (Alzheimer's disease or Creutzfeldt–Jakob disease) but is most commonly encountered in the context of a metabolic, toxic, or hypoxic/ischemic encephalopathy. The same setting causes the related movement, asterixis, sometimes called *negative myoclonus*, in which there is a sudden lapse of posture of the dorsiflexed hands, producing the classic liver flap.

Motor tics are abrupt, focal movements that burst forth on the background of normal motor activity. Tics may be simple and limited to one body region, such as the shrug of a shoulder, or complex, such as touching the nose or clapping the hands. Unlike chorea, patients usually have a limited repertoire of tics. Additional unique features include a buildup of inner tension before the tic and the ability of patients to suppress tics briefly, but they are not otherwise under voluntary control. Tics also may be vocal, ranging from simple sounds, such as sniffing, grunting, throat clearing, or clicking, to complex vocalizations, including the utterance of obscenities, known as coprolalia. The prototype tic disorder is Tourette syndrome, characterized by the combination of motor and vocal tics beginning in childhood or adolescence. Tics may be accompanied by behavioral disturbances, such as obsessive/compulsive disorder. Less severe than Tourette syndrome are transient tics of childhood and chronic mono- or oligo-symptomatic tics.

All of the above-mentioned movement disorders may be induced by drugs ([Table 429.1](#)). In most cases, they resolve completely when the offending medication is withdrawn. Drug-induced parkinsonism may take as long as 1 year to disappear, and some drug-induced movement disorders may be permanent. Such is the case with tardive dyskinesia, typically manifested by stereotyped chewing movements. It is now well recognized that the same offending medications also can cause permanent dystonia, akathisia, tics, or myoclonus.

The appearance of any movement disorder, either hypokinetic or hyperkinetic, before the age of 50 should prompt consideration of Wilson's disease. This rare autosomal recessive disorder is due to a defect in copper transport, leading to its toxic accumulation. The workup includes measurement of serum ceruloplasmin, which is usually low, and urinary excretion of copper, which is high. A slit-lamp examination should be performed to search for a Kayser-Fleischer ring in Descemet's membrane of the cornea.

MANAGEMENT

A complete review of the complexities of managing movement disorders is beyond the scope of this chapter, but general guidelines can be provided. Since PD is covered in Chapter xxx, this discussion focuses on the hyperkinetic movement disorders. The presence of a movement disorder by itself does not necessitate treatment; treatment is necessary only when the disorder interferes with the patient's functioning or causes significant embarrassment. Likewise, the benefit of therapy is gauged by its effect on the activities of daily living. Education and reassurance are an essential part of therapy, particularly since many patients with hyperkinetic movement disorders feel freakish and unique and are often labeled as having *psychogenic* problems before the proper diagnosis is reached. There is a large and active network of support and advocacy groups for each of the hyperkinetic movement disorders, and patients should be encouraged to seek them out.

When treatment of ET is required, the first-line medications are propranolol and primidone. Each is started at a low dose and escalated gradually, until there is either sufficient functional improvement or clinical signs of toxicity. For the small percentage of patients with disabling tremor unresponsive to medical therapy, surgical therapy, including either stereotactic thalamotomy or deep brain stimulation of the thalamus, is available.

The treatment of dystonia depends on its cause. Although some secondary dystonias are amenable to specific therapy, such as penicillamine for Wilson's disease, most treatments focus on symptom management. The mainstay of therapy for the focal dystonias is local injection of botulinum toxin, which produces sufficient weakness to suppress the spasms but not so much as to impair functioning. The toxin generally wears off in 3 to 4 months, and repeated injections are required. A variety of oral medications provide some relief for dystonia, including anticholinergics, benzodiazepines, antispasticity agents, and sometimes dopaminergic or antidopaminergic agents, among many others. Lacking an understanding of the pharmacology of dystonia, the use of oral medications has been guided largely by empiricism and serendipity. Surgery is available for some types of dystonia, such as selective denervation for cervical dystonia. There is a resurgence of interest in stereotactic procedures for the treatment of dystonia, including both lesioning and, more recently, deep brain stimulation of the thalamus and globus pallidus.

Like dystonia, the treatment of chorea depends on its underlying cause. It is surprising that many patients with HD are not particularly bothered by chorea; if they are, it responds best to antidopaminergic agents, such as haloperidol. These agents should be used cautiously in light of their potential to provoke additional movement disorders. For acute vascular hemichorea or hemiballismus, a short-term course of haloperidol is the treatment of choice; other options are clonazepam or valproic acid. The latter two agents also can be used to treat myoclonus when the underlying cause cannot be reversed.

When motor and vocal tics necessitate treatment, they occasionally respond to clonidine. If not, antidopaminergic agents are the mainstay of therapy, and the preferred drug is pemozide. The treatment of Wilson's disease is aimed at removing accumulated copper with a chelator, such as penicillamine, or preventing the

absorption of copper by zinc. A more extensive discussion of treatment for Wilson's disease and other movement disorders is included in the bibliography.

CHAPTER 430: APPROACH TO THE PATIENT WITH DISORDERS OF SENSATION

JOHN W. GRIFFIN

[Sensory Loss](#)
[Neuropathic Pain](#)

SENSORY LOSS

PRESENTATION

The healthy sensory system functions so effortlessly and silently that it is invisible. The gibe “He can't walk and chew gum at the same time” is posited on the assumption that ambulation is a commonplace and trivial accomplishment rather than the wonder of sensory and motor integration that is recognized by physiologists. Happily, at present the elegant mechanisms required for both unconscious sensation and perceived sensation are being demonstrated dramatically by new advances in functional imaging, electrophysiology, and psychophysics.

The ubiquitous role of afferent signaling in neurologic function leads to manifold vulnerabilities in disease. For the clinician, disorders of sensation are prevalent and wide ranging in both origin and significance. For example, carpal tunnel syndrome, spinal disease, and stroke may all be accompanied by initial complaints of numbness in one hand. The patient's description of his or her subjective sensory experience may not translate easily into medical terms that have specific physiological or anatomic implications. These difficulties are compounded by the inherent subjectivity of the examination and the poor interinterval and interexaminer reproducibility of findings (one evening's sensory findings often cannot be shown the next morning on rounds). Successful differential diagnosis requires avoiding distraction by small and inconstant sensory findings, understanding the basic pathophysiologic patterns, and using applied neuroanatomy, as outlined herein.

PATHOPHYSIOLOGY

Disorders of both the central and peripheral nervous systems can produce sensory loss. The various anatomic sites that can be affected each generate patterns of clinical findings that allow for localization, which is the first step in differential diagnosis.

Peripheral Transducers

Somatosensory transduction occurs at cutaneous receptors that have specific modalities but whose functional roles often are not related intuitively to these modalities. For example, Merkel cells at the dermal–epidermal junction are slowly adapting receptors of pressure and are necessary to making the distinction between various textures. Nociceptors, which cause painful sensation, include the nonensheathed “free” sensory endings within the epidermis.

Peripheral Nerves

Pain and temperature sensibility is conveyed by small-caliber nerve fibers, termed C and Ad fibers. The former are not myelinated and conduct a few meters per second, whereas the latter are larger and myelinated, achieving velocities of up to 30 m per second. The distinction in fast Ad pain and slow C fiber pain is familiar to anyone who has touched a hot stove and reflexively withdrawn the hand before the lingering burning pain was perceived. Joint position sensibility (*proprioception*), the location of the limb in space (*kinesthesia*), and vibratory sensibility are conveyed by larger myelinated fibers (Aa,b) with velocities of 40 to 100 m per second. Similarly, the afferent limb of the tendon reflex utilizes the large muscle stretch receptors designated *Ia fibers*.

Dermatomes

Each spinal segment has a distinctive area of the body for which it provides sensory innervation ([Fig. 430.1](#) and [Fig. 430.2](#)).

FIGURE 430.1. Anterolateral view of the dermatomes according to Foerster. (From Foerster O, Haymaker W, Woodhall B. *Peripheral nerve injuries*, second ed. Philadelphia: WB Saunders, 1953, with permission.)

FIGURE 430.2. Posterior view of the dermatomes according to Foerster. (Adapted from Foerster O, Haymaker W, Woodhall B. *Peripheral nerve injuries*, second ed. Philadelphia: WB Saunders, 1953, with permission.)

Spinal Pathways

Within the spinal cord the large fibers ascend ipsilaterally within the dorsal column to reach their first synapse near the cranial–cervical junction in the gracile (legs) or cuneate (arms) nuclei ([Fig. 430.3](#)). In contrast, the small fibers synapse ipsilaterally in the dorsal horn (substantia gelatinosa) near the segmental level where they enter, and the second-order neuron crosses in front of the central canal of the cord to ascend in the anterior spinothalamic tract.

of the distribution of the sensory symptoms or signs and the modalities involved. The list of etiologic possibilities is then narrowed from the historical information, including the time course, associated diseases, and so on. With regard to localization (distribution plus modalities affected), several patterns have special localizing value.

Polyneuropathic Patterns

Peripheral neuropathies typically produce loss of sensation in the toes and feet initially; with progression, the level of numbness ascends the leg and comes to affect the fingers (Fig. 430.4). On the trunk, the parasternal region represents the region innervated by the longest intercostal axons (Fig. 430.4). This pattern reflects the tendency of the first nerve fibers affected to be those that are longest in length, with the distal regions degenerating and with progression from distal to proximal with time. Patients may complain of a dead feeling, as with receiving lidocaine. More often they describe a positive sensory symptom—tingling or a pins-and-needles sensation (paresthesia) or painful burning (neuropathic pain), described in detail later in this chapter.

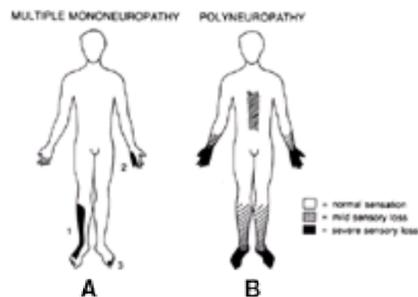

FIGURE 430.4. Contrast between mononeuropathy and polyneuropathy. The figure to the left has three individual nerve lesions (multiple mononeuropathies). Number 1 reflects sensory loss in the distribution of the superficial peroneal nerve; number 2, the distribution of the ulnar nerve; and number 3, the distribution of the deep peroneal nerve. These discrete nerve regions contrast with the distally predominant symmetrical sensory loss found in a patient with polyneuropathy. Note that there is mild sensory loss in the sternal and parasternal regions of the chest; these areas represent the sensory fields of the longest axons in the intercostal nerves. (From Griffin J. Diabetic neuropathies. Medical Grand Rounds of the Johns Hopkins Hospital, 1987, with permission)

The modalities involved in neuropathies may call into play functions of the large nerve fibers (proprioception and vibration with loss of tendon reflexes, usually occurring first at the ankle) and functions of the small (pain, temperature) nerve fibers, or they may be relatively selective. Prominent involvement of small nerve fibers is, for example, seen in the most prevalent neuropathy, diabetic polyneuropathy. The clinical picture can include both loss of pain sensibility, with consequent predilection to painless injuries, and at the same time spontaneous neuropathic pain, usually most severe in the feet, as considered under the heading Neuropathic Pain. Autonomic functions also are mediated by small fibers, so that impotence, orthostatic hypotension, reduced sinus arrhythmia in response to breathing, and diminished sweating also can be seen.

Individual Nerve Injury Patterns

Single-nerve injury, or mononeuropathy, provokes sensory symptoms related to the cutaneous distribution of the sensory component of that nerve. Such isolated peripheral nerve lesions develop most often as a result of trauma or mechanical compression. For example, compression of the median nerve at the wrist, as in carpal tunnel syndrome, produces paresthesias and sensory loss in the first three fingers of the affected hand, and the loss of pain sensibility lies in the median distribution, typically affecting the medial but not the radial side of the fourth digit. Mononeuropathies also can affect the small vessels, as seen in diabetic third nerve palsies.

Multiple Mononeuropathies

This pattern affects several individual nerves (Fig. 430.4). For example, a patient may have numbness in the median distribution in one hand and in the peroneal distribution in the opposite leg. Multiple mononeuropathies are usually due to small-vessel disease, such as vasculitis or diabetes.

Radicular (Dermatomal) Distributions

Nerve root lesions generate symptoms related to the dermatomal distribution of that nerve root (Fig. 430.2). Mixed spinal root lesions, such as those caused by herniated intravertebral discs, typically lead to reflex loss and, if severe enough, weakness characteristic of their distribution. One disorder produces a distinctive picture of widespread selective dorsal root degeneration. This disorder, tabes dorsalis due to tertiary syphilis, is seen rarely now, but it remains important to recognize. It provokes sensory ataxia and loss of protective sensibility (Charcot's joints were first described in tabes), but the peripheral nerves are normal in terms of electrodiagnostic and biopsy parameters, because the lesion is confined to degeneration of the dorsal roots.

Intraspinal Lesions

A sensory level below which sensation is altered or lost is most helpful in delineating the level of spinal cord involvement. Lesions of the spinal cord produce sensory signs and symptoms below the level of involvement that are ipsilateral for touch, vibration, and proprioceptive-type sensation and contralateral for pain and temperature. Following segmental transection of one lateral half of the cord, pain and thermal sensibility are lost on the contralateral half of the body below the level of the lesion, whereas proprioception and vibratory sensibility are lost on the side of the lesion. The pattern is the consequence of the crossing of pain and temperature fibers at or near the segment where they enter the spinal cord, as first identified by the French physiologist Eduard Brown-Séquard.

Dissociated sensation refers to loss of pain and temperature sensibility with preservation of vibration and proprioception. When found to be present over several spinal levels—for example, in the hand and a region of the thorax on one side—dissociated sensation suggests a central intraspinal lesion interrupting the second-order pain and temperature fibers decussating near the central canal. A notorious cause of this picture is syringomyelia, a fluid-filled cavity in the central cord.

Supraspinal Lesions

Central lesions above the spinal cord cause contralateral involvement of limbs and trunk. The disproportionate loss of discriminative abilities suggests involvement of the parietal cortex.

STRATEGIES FOR OPTIMAL CARE

Treatment of sensory loss begins with identification and treatment of the underlying disease. For example, it is increasingly clear that in diabetes, approaching euglycemia lessens both the likelihood and the severity of diabetic polyneuropathy. The management of positive sensory symptoms is discussed in the section Neuropathic Pain. Two aspects of management of sensory loss that require specific comment are management of the insensitive limb and management of sensory ataxia.

Management of the Insensitive Limb

Patients with loss of protective sensibility from disorders as diverse as diabetic neuropathy, leprosy, tabes, and syringomyelia share the need for special education to prevent painless injuries with consequent Charcot joints, ulcers, infections, and amputation. In both the hands and the feet, the keystone is regular careful examination. Because it is important to see both the top and the bottom of the foot, another household member often can perform this task better than the patient. Redness, heat, swelling, calluses, ingrown nails, or redness around the nails are all important warning signs. Development of skin breakage or ulcers should trigger

prompt consultation.

Shoes that fit well are essential. Calluses are a sign of long-standing excessive pressure on the skin and thus signal badly fitting shoes. Calluses usually are found on the balls of the feet, the sides of the feet, or the tops of the toes. They should be treated as soon as they begin to form by finding where the shoe is rubbing and removing the pressure from the foot. Patients must avoid using a knife or razor to cut into a callus, because any cut in the skin can result in infection. A persistent or growing callus needs to be examined and treated by a medical professional.

Every time a shoe is put on, the inside of the shoe should be felt with the fingers (assuming they are normally sensitive), and the shoe should be shaken to make sure that there are no protruding nails or stones inside. Similarly, the foot of the socks should be felt to make sure that no foreign objects are within the sock. Shoes must always be worn with socks, and individuals with insensitive feet must *never* walk barefooted.

Management of Sensory Ataxia

In all the ataxic disorders, the most important principle is to avoid falls and injuries. Continued walking provides an important form of physical therapy and continuous relearning. Patients who are in bed for long periods because of broken hips, for example, have a great deal of difficulty returning to walking and regaining their previous level of function. Several strategies are helpful.

- Review safety in the home. The bathroom is the most dangerous room, with many hard surfaces, small space, and sometimes slick footing.
- Handrails placed in the joists of the wall are essential in the bath.
- A chair in the tub or shower also increases the level of safety while the eyes are closed (for example, when washing the hair), except in the mildest cases.
- Touching while walking increases stability.
- When required, canes and walkers are important tools, expanding the range of activities and the accessibility of places.
- Gait training with a physical therapist who understands the nature of the gait disorder can be invaluable.
- Drivers should carry a card indicating that ataxia is due to a neurologic condition and not to intoxication.
- Finally, driving must be frequently reassessed. Sometimes having fluorescent tape or fluorescent paint on the gas pedal and brake makes it easier to see out of the corner of the eye. In more severe instances, hand controls should be considered. In an emergency situation, it is very easy to catch the foot underneath the brake or to misjudge the amount of force applied to the brake or the gas pedal. In such instances, it is the patient's responsibility to notify the Motor Vehicle Administration about the issue.

NEUROPATHIC PAIN

PRESENTATION

Neuropathic pain represents one of the most prevalent classes of chronic nonmalignant pain. Causes included painful peripheral neuropathies, such as diabetic polyneuropathy; postherpetic neuralgia; neuroma pain from traumatic nerve injury; and the complex problem of causalgia (reflex sympathetic dystrophy or complex regional pain syndrome). Compared with other nonmalignant sources, such as chronic musculoskeletal pain, neuropathic pain is less responsive to nonsteroidal anti-inflammatory agents and to opiate analgesics and thus represents a major challenge in management.

PATHOPHYSIOLOGY

The peripheral nociceptors include the polymodal C nociceptors, which end in the dermis and epidermis. These nociceptors respond to a variety of noxious agents. Among these are capsaicin, a vanilloid extracted from peppers that activates the VR₁ receptor on nociceptors, producing firing and, with sufficient doses, destruction of the fiber. As described earlier, the central processes of Ad and C fibers extend from the dorsal root ganglia to synapse primarily in the superficial dorsal horn of the spinal cord. The neurotransmitters released at these central synapses include the amino acids glutamate and aspartate and the neuropeptide substance P. The second-order pain neurons in the substantia gelatinosa express the substance P receptor NK1. Most nociceptive dorsal horn neurons ascend in the opposite anterolateral quadrant of the spinal cord, known as the spinothalamic tract. The neospinothalamic tract projects, through a synapse in the ventral posterior nucleus of the thalamus, to the somatosensory areas I and II of the neocortex. The major role of the neospinothalamic projection is to localize pain precisely and gauge its intensity and character. The phylogenetically older paleospinothalamic tract, or spinoreticular tract, projects to the reticular formation of the brain stem and thalamus and then diffusely to the limbic cortex to subserve the arousal and affective components of pain.

The mechanisms of neuropathic pain are manifold, and the relative contributions of the different types are uncertain. The C and Ad fiber nociceptors are hyperactive in some contexts and can express new sodium channels that may contribute to hyperexcitability. Transmitter release is amplified in the dorsal horn in some models of pain, and the levels of the substance P receptor NK1 are also increased, suggesting that each stimulus produces a heightened response. Finally, there are a series of structural changes in the dorsal root ganglion and dorsal horn that include sprouting of Ab afferents into the region of the dorsal horn normally occupied by nociceptive afferents, so that stimulation of a hair sensor, for example, triggers a painful sensation.

The brain also contains powerful descending pathways that modulate nociceptive input. The periaqueductal gray region of the midbrain projects to the midline raphe nuclei of the medulla. These nuclei are serotonergic and project in turn to the dorsal horn of the spinal cord, where they suppress nociceptive transmission. Opioid receptors in the region of these brain-stem nuclei allow for the action of opioid analgesics by way of this descending inhibitory pathway, in addition to their direct action on opioid receptors in the dorsal horn. Another major inhibitory pathway is noradrenergic and originates in the pons. Combined with the serotonergic projection from the medulla, these monoaminergic pathways provide one rationale for the analgesic effects of the tricyclic antidepressants that inhibit the reuptake of serotonin and norepinephrine.

HISTORY AND PHYSICAL EXAMINATION

Neuropathic pain often has a burning quality. In painful neuropathies and in tabes, a characteristic description is of lightning pains—sudden stabbing jolts in, for example, one foot. On examination, the threshold to pain may be normal, or there may be sensory loss, even in areas where the perception is of severe pain to a normally non-noxious stimulus once the threshold for perception is reached (allodynia). Hyperesthesia may be reflected in the description of pain produced by the bedsheets touching the feet, for example. As noted previously, painful neuropathies, such as those associated with diabetes, often are accompanied by a predisposition to painless injuries, such as foot ulcers.

DIFFERENTIAL DIAGNOSIS

Painful peripheral neuropathies are seen in most of the disorders listed in [Table 430.1](#). Trigeminal neuralgia, also known as tic douloureux, is the most common cranial neuralgia. This is really an acute recurring pain syndrome in the sense that the patient is seized by episodes of sudden, lightning-like stabs of pain typically involving the second or third divisions of the trigeminal nerve. Each burst of pain lasts a matter of seconds, but they tend to occur in clusters, which are commonly triggered by tactile stimulation in the maxillary or perioral region. Infrequently, the pain is symptomatic of multiple sclerosis or a tumor along the course of the trigeminal nerve. In idiopathic trigeminal neuralgia, the neurologic examination gives negative results. One or more medications provide effective pain relief in 80% of patients with trigeminal neuralgia. Carbamazepine is the drug of choice. Baclofen, in divided doses up to 80 mg daily, may also be effective and sometimes works synergistically with carbamazepine. If medical treatment fails, a percutaneous radiofrequency lesion of the trigeminal ganglion often provides relief, and the procedure can be repeated if necessary. Vascular decompression of the trigeminal sensory root by a posterior fossa craniotomy is also very effective.

Diabetic polyneuropathy
Amyloid
Sensory neuropathy of AIDS
Idiopathic small-fiber sensory neuropathy
Fabry's disease (β -D-glucuronidase deficiency)
Some cases of leprosy
Tabes dorsalis (a dorsal radiculopathy)

TABLE 430.1. SOME PAINFUL NEUROPATHIES

Postherpetic neuralgia manifests as severe burning pain, with superimposed shocklike pains along one or more dermatomes after an attack of herpes zoster. Hyperpathic phenomena are common. It tends to be a disease of the elderly, and the pain can be intractable. Tricyclic agents can be helpful. An oral opioid analgesic, such as oxycodone (starting at 5 mg every 3 or 4 hours) or morphine (starting at 10 mg every 3 or 4 hours), can make the difference between bearable and unbearable pain and carries a low risk of psychological dependence or addiction.

Causalgic pain syndromes are characterized by severe burning pain in an extremity after major or minor injury. If the injury involves a peripheral nerve, particularly the sciatic or median nerve, the syndrome is called *causalgia*. If the injury involves soft tissue or bone, the usual term that is applied is *reflex sympathetic dystrophy*. The pain is continuous, is exacerbated by emotional stress, and usually is associated with hyperpathia. The limb becomes glazed and swollen, with vasomotor and sudomotor changes and atrophy of the subcutaneous tissue and muscle. The pain probably is generated by excess sympathetic activity acting on damaged nerves or nerve endings and by deafferentation after nerve transection.

STRATEGIES FOR OPTIMAL MANAGEMENT

Neuropathic pain responds in part to opioid analgesics. The best responses are obtained with the tricyclic antidepressant and anticonvulsant drugs.

Tricyclic Agents

Amitriptyline has been shown in double-blind crossover studies to benefit patients with painful diabetic neuropathy. The mechanism of action remains the subject of controversy; tricyclic agents may affect descending serotonergic pathways or may have direct effects on sodium channels in the peripheral nervous system. In any event, the effect on neuropathic pain appears to be independent of any effect on mood. Amitriptyline, nortriptyline, or desipramine can be started at 25 mg daily and increased, if needed, to 75 to 100 mg daily. The role of serotonin uptake inhibitors has not been defined.

Anticonvulsants

The first anticonvulsant found to have some benefit for neuropathic pain, the sodium channel blocker phenytoin, largely has been supplanted by carbamazepine and gabapentin. Carbamazepine has the advantage of lower cost. Therapy usually is started at 100 mg once or twice daily, with doses gradually increasing to 200 to 400 mg three times daily. In the United States, gabapentin has achieved great popularity for use in the context of painful diabetic neuropathy, in part because of the paucity of side effects, and its efficacy has been demonstrated in controlled studies. Its superiority over the less-expensive agent carbamazepine has not been established. Gabapentin also is administered in incremental doses, beginning with 100 mg daily and increasing to 900 to 1,200 mg three times a day if required.

Other Agents

In a few patients topical capsaicin preparations may be beneficial, and some patients feel better with topical application of local anesthetic creams, such as lidocaine. Opioids are last resorts, both because of their potential for dependence and because they are less efficacious, in general, than in other pain states.

CHAPTER 431: APPROACH TO THE PATIENT WITH SUSPECTED INFECTION OF THE CENTRAL NERVOUS SYSTEM

ANTHONY W. CHOW AND DONALD W. PATY

[Presentation](#)
[Pathophysiology](#)
[History and Physical Examination and Physical Examination](#)
[Laboratory Studies and Diagnostic Tests](#)
[Differential Diagnosis](#)
[Strategies for Optimal Care Management](#)

Infections of the central nervous system (CNS) continue to have high rates of mortality and morbidity. Early diagnosis and effective therapy are the only means of preventing death and long-term neurologic adverse effects, yet the necessary diagnostic measures and therapeutic interventions often are delayed. This delay may be related in part to the complexity of the clinical problem: a crucial medical history may be unobtainable for a comatose patient, and the differential diagnoses can be numerous. A systematic approach and rapid mobilization and assistance from various specialists (such as neurologist, neurosurgeon, neuroradiologist, infectious disease specialist, microbiologist) are often essential for optimal management. Rapid and irreversible brain damage may occur unless decisive therapeutic measures are implemented quickly.

In approaching the patient with a suspected infection of the CNS, the first step should be directed at localizing the site of infection. Based on the history, a general examination, and a comprehensive neurologic assessment, the predominant clinical syndrome should be characterized (acute, chronic, or recurrent meningitis; brain abscess or encephalitis; parameningeal infections, such as sphenoid sinusitis, subdural empyema, or epidural abscess—see [Chapter 441](#)). In addition, the possibility of a distant source of infection, such as the lungs, heart valve, or pelvis, should be sought rigorously. This first step greatly assists in planning the best strategy for diagnostic procedures and in formulating appropriate initial empiric antimicrobial therapy.

PRESENTATION

The cardinal signs and symptoms of CNS infections include fever, severe or persistent headache, nuchal rigidity, focal neurologic deficit, and changes in mentation, affect, or personality ([Table 431.1](#)). Although most patients experience typical symptoms and signs suggesting infection in the CNS, findings in the very young, the elderly, and the immunocompromised host can be quite subtle or varying. Thus, fever and neck stiffness may be absent in such patients, even in the context of overwhelming infection. Absence of such findings should not preclude the diagnosis of meningeal involvement. Likewise, the presence of an unexplained or subtle change in mentation, arousal, or personality may be sufficient to warrant a systematic investigation.

Complication	Clinical Signs	Cerebrospinal Fluid	Computed Tomography	
			No Contrast	With Contrast
Meningitis	Headache, fever ±; stiff neck, lethargy ±; rapid course ± ±	High WBCs and protein, low sugar	Normal	Diffusely enhanced
Brain abscess	Convulsions ±, headache ±, personality change ±	Lymphocytes, normal sugar	Lucency with mass effect	Capsule
Subdural empyema	Headache ± ±, convulsions ± ±, lethargy ± ±, rapid course ± ±	High WBCs and protein, normal sugar	Lucent area	Dissect-shaped enhancement
Epidural abscess	Headache ±, fever ±	Normal	Lucent area	Extrameningeal
Paranasal sinusitis (sphenoidal)	"Hot seat" fever ± ±, rapid course ± ± (orbital edema ± ±) (orbital pain ± ±)	Normal or high WBCs	Non-specific	Enhancing lesion
Osteomyelitis	Pott's puffy tumor ±	Normal	Ring defect	Ring defect

±, May or may not be seen; ±±, frequently seen; ±±±, characteristically seen; WBCs, polymorphonuclear leukocytes.

TABLE 431.1. THE CLINICAL SPECTRUM AND INVESTIGATION OF INTRACRANIAL COMPLICATIONS

PATHOPHYSIOLOGY

The pathogenesis and clinical manifestations of nervous system infections are critically influenced by the anatomic considerations and host responses to injury of the specific affected neural tissues. The brain, spinal cord, and cauda equina are normally quite resistant to infection. Even when cranial bone flaps become infected after surgery, intracranial extension of infection through the dura is relatively rare. Similarly, abscess in the brain is difficult to induce experimentally, even after direct bacterial inoculation. This is because the host defenses of the nervous system in the normal host are extraordinarily effective. Both complement- and antibody-mediated bacteriolysis or opsonophagocytosis, as well as cell-mediated immunity, appear to be important defense mechanisms in the CNS. Specific antibodies, which may be produced locally or transported passively across an impaired blood–brain barrier, are particularly important for opsonic and bactericidal activity against encapsulated bacteria (*Streptococcus pneumoniae*, *Neisseria meningitidis*, and *Haemophilus influenzae*). After splenectomy, patients and people with deficient terminal components of the complement cascade are particularly susceptible to severe and recurrent meningitides associated with these organisms. In contrast, cell-mediated immunity is the major host defense against mycobacterial, fungal, viral, and certain parasitic infections of the CNS. In the absence of immunologic aberrations, infections of the nervous system are often preceded by disruptions of the dural sheath (post-traumatic or postoperative), congenital defects (spina bifida or myelomeningocele), or preexisting ischemic injury (septic emboli, cerebrovascular disease, or tumor necrosis).

Despite the multitude of microorganisms that can infect the nervous system opportunistically, only limited histopathologic responses result from such injury. Thus, acute infections associated with most bacteria tend to elicit a polymorphonuclear inflammatory response associated with infiltration of microglial cells and proliferation of astrocytes. Subacute or chronic infections associated with mycobacteria and fungi usually provoke a suppurative, granulomatous response. Intracerebral granulomas, with or without calcification, may develop. Parasitic infections, such as cysticercosis, paragonimiasis, or echinococcosis, may elicit a eosinophilic response in the cerebrospinal fluid (CSF). Abscess formation in the brain is accompanied by encapsulation, which takes place by gliosis rather than by fibrosis. In the CNS, secondary effects of infection, such as cerebral edema, hemorrhage, infarction, and hydrocephalus, often are more dramatic and damaging than the primary effects of microbial invasion. Injury to neural tissue also may occur indirectly, because of an exaggerated immunologic response against basic myelin protein after certain infections, such as the multifocal axonal degeneration and demyelination observed in the course of postinfectious encephalomyelitis or Guillain-Barré syndrome.

Knowledge of the anatomic relationship of the cranium and adjacent structures to the underlying brain and spinal cord also is essential for early recognition and management of infections caused by contiguous spread of a parameningeal focus (see [Fig. 441.1](#)). The lower structures of the brain rest within the anterior, middle, and posterior cranial fossae. The anterior fossa forms the roof of the frontal and ethmoidal sinuses; infection within either sinus may cause a frontal epidural abscess, subdural empyema, or a frontal lobe brain abscess. Infection originating in the sphenoid sinus may extend into the anterior fossa to involve the frontal lobe or into the middle fossa to involve the temporal lobe. Infections of the middle ear or mastoid within the petrous bone may extend into the middle fossa to involve the temporal lobe or into the posterior fossa to involve the cerebellum or brain stem. The skull overlying the dura of the cerebrum is covered extracranially by the galea aponeurotica. Pericranial infections, stemming from either head trauma or a craniotomy, may result in subgaleal abscess and cranial osteomyelitis, with possible retrograde spread through the emissary veins to the epidural, subdural, and subarachnoid spaces.

HISTORY AND PHYSICAL EXAMINATION AND PHYSICAL EXAMINATION

Because the brain and spinal cord have only limited means of response to different modes of injury, the neurologic manifestations of infection often are indistinguishable from those of other pathologic processes, such as malignancy, autoimmune diseases, or degenerative disorders. For this reason, the complete history, including considerations of age, epidemiologic associations, immunologic status, and precipitating events, is particularly important in raising the suspicion of an infection of the nervous system. A careful history, paying particular attention to epidemiologic considerations, associated disease states, and the specific nature of

underlying immunodeficiencies, often provides important clues to the etiologic agents of nervous system infections (Table 431.2). The physical examination should include a careful search for any evidence of a pericranial or parameningeal focus of infection (ear, mastoid, sinuses) or of a systemic infection arising from a distant focus (endocarditis, pneumonia, or pelvic infection).

Clue	Etiologic Agent
Acute onset	Bacterial, Mycobacterial, Fungal, Viral
Subacute onset	Bacterial, Mycobacterial, Fungal, Viral

TABLE 431.2. EPIDEMIOLOGIC AND CLINICAL CLUES TO ETIOLOGIC AGENTS IN NONVIRAL NERVOUS SYSTEM INFECTION

LABORATORY STUDIES AND DIAGNOSTIC TESTS

LUMBAR PUNCTURE AND CEREBROSPINAL FLUID EXAMINATION

The lumbar puncture (LP) is the most important diagnostic procedure in the evaluation of a patient for suspected CNS infection, particularly bacterial meningitis. Appropriate cytologic, biochemical, and microbiologic studies of CSF are essential. However, the potential risk of brain herniation must be assessed individually before the diagnostic LP. The fundi should be examined carefully for evidence of markedly increased intracranial pressure, such as papilledema or cessation of venous pulsations. The ready availability of computed tomography (CT) scanning should minimize this complication.

The usual CSF profiles in cases of bacterial, fungal, mycobacterial, and viral meningitis are summarized in Table 431.3. Normal CSF contains fewer than five leukocytes per milliliter, a protein content typically less than 40 mg per deciliter, and a CSF/serum glucose ratio greater than 1:2. Measurement of the chloride concentration in CSF is not useful. In the case of acute bacterial meningitis, the cell count is usually greater than 500 per microliter and is frequently polymorphonuclear (more than 90% polymorphonuclear leukocytes). Nevertheless, patients with viral aseptic meningitis also may show signs of polymorphonuclear pleocytosis in the CSF early in the course, falsely suggesting a bacterial or fungal origin. A second LP carried out 12 to 72 hours later often clarifies the diagnosis and obviates unnecessary antimicrobial therapy.

CSF Profile	Bacterial	Viral	Mycobacterial or Fungal
Total cells (per μL)	Usually >100	Usually <100	Usually >100
White blood cells	Predominantly polymorphonuclear	Predominantly mononuclear	Predominantly mononuclear
Glucose (% of serum)	<40%	>40%	>40%
Protein (mg/dL)	>45	<45	>45
Clamp test	Positive (50–90%)	Negative	Negative

Differential diagnosis of CSF pleocytosis:
Brain abscess or subdural empyema with rupture
Central nervous system vasculitis, tumor

Predominantly Polymorphonuclear (> 90% PMNs)
Bacterial meningitis
Early viral meningitis
Early tuberculous or fungal meningitis
Brain abscess or subdural empyema with rupture into subarachnoid space
Chemical arachnoiditis
Brain abscess of subdural empyema

Predominantly Mononuclear (< 90% PMNs)
Viral meningitis or encephalitis
Tuberculous or fungal meningitis
Atypically treated bacterial meningitis
Brain abscess or subdural empyema
Lymphocytic meningitis
Neurocysticercosis (eye disease)
Neosporosis
Primary amoebic meningoencephalitis
Guinea worm infection
Central nervous system vasculitis, tumor, hemorrhage
Multiple sclerosis

PMNs, polymorphonuclear leukocytes.
DIFFERENTIAL DIAGNOSIS: B, tuberculous meningitis; V, viral meningitis; M, mycobacterial meningitis. Clinical epidemiologic and laboratory investigation during the first year period 1970–1974. New Engl J Med 1974;291:1111–1116.

TABLE 431.3. CEREBROSPINAL FLUID (CSF) FINDINGS IN BACTERIAL AND NONBACTERIAL MENINGITIS

Partially treated bacterial meningitis generally is associated with lymphocytic predominance in the CSF. In bacterial and fungal meningitis, the CSF glucose is low (CSF/serum ratio of less than 1:2). Viral, mycoplasmal, treponemal, rickettsial, and carcinomatous meningitis show a normal or only slightly depressed CSF glucose level. The very lowest levels of CSF glucose are seen in tuberculosis, fulminant bacterial meningitis, primary amoebic meningoencephalitis, and neurocysticercosis. Hypoglycorrhachia (low CSF glucose) is not caused by cells and organisms consuming glucose; instead, it is caused by changes in the transport of glucose between serum and CSF. Thus, the persistence of a relatively low CSF/serum glucose ratio after bacteriologic cure of suppurative meningitis often is associated with evidence of chronic inflammation and neurologic adverse effects. Hypoglycorrhachia also may be caused by subarachnoid bleeding, chemical arachnoiditis (as a complication of radionuclide or metrizamide myelography), sarcoidosis, neoplasms, and certain viral agents (mumps, enteroviruses, herpes simplex, and varicella-zoster).

The CSF should be cultured for both aerobic and anaerobic bacteria as well as mycobacteria and fungi, and the cell pellets should be examined by Gram stain. A Ziehl-Neelsen stain for acid-fast bacilli and an India ink preparation for cryptococci also should be made routinely. Serologic testing for syphilis should be carried out. In very ill patients, a second LP should be made at a different spinal level in 6 to 8 hours if the first LP was inconclusive. Another LP may be considered within the first few days of empiric antimicrobial therapy, to monitor the microbiologic response.

Several rapid methods of CSF examination appear promising for the presumptive diagnosis of infectious and noninfectious causes of meningitis. The acridine orange stain may be more sensitive than Gram stain for rapid identification of microorganisms in the CSF. Use of cytospin centrifugation for examination of cellular elements facilitates the detection of eosinophils, atypical lymphocytes, choroidal and arachnoidal epithelial cells, or neoplastic cells. C-reactive protein, an acute-phase reactant, is elevated markedly in CSF from patients with bacterial meningitis but not in those with viral or noninfectious forms. The CSF lactate and total lactate dehydrogenase isoenzyme levels have a similar correlation. The limulus amoebocyte lysate assay, used to detect the presence of endotoxin in the CSF, also appears valuable for the rapid diagnosis of gram-negative bacterial meningitis. Finally, gas-liquid chromatographic analysis of the CSF for microbial metabolic products may aid in the rapid identification of certain bacterial, mycobacterial, and fungal causes of meningitis. These tests are particularly helpful for patients who had been started on empiric antimicrobial therapy before CSF examination.

ANTIGEN AND ANTIBODY DETECTION AND MOLECULAR DIAGNOSIS IN CEREBROSPINAL FLUID

In addition to nonspecific methods, several techniques for rapid detection and quantitation of specific microbial antigens in the CSF are available. These immunologic techniques include counterimmunoelectrophoresis, latex particle agglutination, staphylococcal protein A coagglutination, and enzyme-linked immunosorbent assays for the detection of microbial polysaccharide antigens of *H. influenzae*, *S. pneumoniae*, *N. meningitidis*, *Streptococcus agalactiae*, and *Cryptococcus neoformans*. An added advantage of these quantitative techniques is that the concentration of microbial antigens detected in the CSF appears to correlate well with the outcome of meningitis and can provide some prognostication of the therapeutic response. A new, rapidly evolving diagnostic technique is the application of DNA probes and polymerase chain reactions to amplify and detect genetic fingerprints of microbial pathogens in the CSF. This powerful technique offers the prospect of rapid diagnosis with improved sensitivity over conventional methods, though the specificity of these assays still requires critical evaluation.

Specific antibody to microbial pathogens is normally excluded from the CNS. During infection, antibody may be detected in the CSF either because of local production or by passive diffusion across an impaired blood-CSF barrier. The serum/CSF antibody ratio in the presence of a normal blood-CSF barrier is usually greater than 200:1. This ratio against the causative agent may be significantly diminished after a CNS infection, compared with antibody ratios against other organisms. Apart from viral diseases, detection of specific antibodies in the CSF has been most valuable in the diagnosis of coccidioidomycosis, toxoplasmosis, cysticercosis,

schistosomiasis, borreliosis, and mycoplasmal infections involving the CNS.

NEURORADIOLOGY AND NEUROIMAGING

Plain radiographs and tomograms of the paranasal sinuses, skull, and vertebral column may furnish invaluable clues to suppurative foci and contiguous infections of the nervous system. Nevertheless, CT scanning and magnetic resonance imaging (MRI) have improved significantly the diagnostic accuracy of intracranial infections, such as brain abscess, subdural empyema, and epidural abscess. The advent of CT scanning and MRI also has permitted nonoperative treatment of selected patients with cerebritis or early brain abscess. The typical CT finding in brain abscess is an area of decreased attenuation surrounded by a “ring” of enhancement. CT also can detect cerebral edema, hydrocephalus, an associated mass effect, and the presence of extracranial infection. MRI appears to be more sensitive than CT in ascertaining early cerebritis and in identifying abscess fluid, which is isodense relative to CSF on CT but hyperdense by MRI.

In subdural empyema, CT shows inward displacement of cerebral substance due to an extracerebral mass. In epidural abscess, CT shows a thick and circumscribed area of diminished density associated with extracerebral displacement. For both conditions, MRI is the diagnostic procedure of choice, since it can detect empyemas not seen on contrast-enhanced CT and also will identify contiguous cranial osteomyelitis. Radionuclide brain scans and cerebral angiography remain useful as complementary procedures for the localization of certain CNS infections, particularly posterior fossa lesions, and for pinpointing evidence of mycotic aneurysms. Metrizamide or radionuclide ventriculography, cisternography, and myelography are useful for studies of CSF dynamics, hydrocephalus, spinal epidural abscess, and localization of CSF leak. These neuroimaging techniques, however, do not readily distinguish infectious processes from malignancy or vascular lesions. It remains to be seen whether newer techniques, such as positron emission tomography, will improve the diagnostic yield further in the case of early infections (see [Chapter 452](#)).

NEUROELECTROPHYSIOLOGY

Electroencephalography may be the earliest laboratory test to show localizing or lateralizing abnormalities in encephalitis. It can detect subclinical seizure activity and provide an early view of the location of cerebral cortical injury. It is neither as specific nor as sensitive as CT, however, in the diagnosis of focal structural disease. Electroencephalography is a useful noninvasive tool to monitor the progress of the disease once the diagnosis is established. Electromyography is appropriate for nerve conduction studies of infectious neuropathies. Slowed conduction is found in the peripheral nerve lesions of Guillain-Barré syndrome, leprosy, and diphtheria. Repetitive nerve stimulation shows an incremental response in muscle contraction, which is characteristic in botulism but not in Guillain-Barré syndrome (see [Chapter 451](#)).

HISTOPATHOLOGY

Patients with chronic meningitis, solitary intracranial mass lesions, encephalitis, or puzzling, atypical neurologic syndromes may benefit from histopathologic studies of brain or meningeal biopsy specimens (see [Chapter 453](#)). Aspirates of abscess walls should be cultured simultaneously for isolation of aerobic and anaerobic bacteria, fungi, and mycobacteria. Special histochemical and immunofluorescent stains can be prepared to identify various fungal and parasitic agents. Histopathologic studies often are required, to resolve the differential diagnosis between infection and other processes, such as malignancy, demyelination, and connective tissue disorders of the nervous system.

DIFFERENTIAL DIAGNOSIS

MENINGITIS

The hallmark of meningitis is a stiff neck that is rigid for forward flexion and subtle to lateral movement. The presence of either Kernig's sign (involuntary flexion at the contralateral knee with hip flexion and knee extension) or Brudzinski's sign (flexion at both hips with passive flexion of the neck) suggests meningeal inflammation. The “aseptic meningitis” syndrome, characterized by lymphocytic pleocytosis and a normal glucose level in the CSF, with negative results on Gram stain and bacterial cultures, typically is associated with viral agents. Nonetheless, it is important to recognize a number of other conditions that may require specific antimicrobial therapy, surgical intervention, or both. These include partially treated bacterial meningitis, parameningeal suppurative foci, infective endocarditis, and a wide variety of meningitides caused by mycobacteria, fungi, *Mycoplasma* species, *Treponema* species, *Borrelia* species, rickettsiae, and parasites. In recurrent meningitis, the neurologic findings completely subside between acute attacks. The differential diagnosis is broad, but bacterial causes usually are related to post-traumatic or postoperative defects of the cribriform plate, the orbital roof, the paranasal sinuses, or the petrous bone. Infected congenital defects, such as spina bifida, dermoid cyst, and meningocele, are other sources. Noninfectious causes include intracranial tumors, sarcoidosis, Mollaret's and Behçet's syndromes, and Vogt-Koyanagi-Harada syndrome.

BRAIN ABSCESS, SUBDURAL EMPYEMA, AND CRANIAL EPIDURAL ABSCESS

These intracranial or parameningeal infections usually result from a contiguous focus of infection, such as the paranasal sinuses, mastoid, or middle ear; from cranial trauma or surgery; or from hematogenous spread of a distant infection, especially the lung and heart valves. The clinical pictures of brain abscesses vary greatly and appear to be influenced primarily by their anatomic location and proximity to the ventricles, cisterns, or dural sinuses and by major alterations in the intracranial pressure dynamics stemming from the mass effect ([Table 431.1](#)). The presence of focal neurologic signs or seizures is particularly suggestive of mass lesions or vascular abnormalities. Papilledema, a finding pathognomonic of increased intracranial pressure, may be present, along with vomiting or impaired consciousness.

Other neurologic findings, such as cranial nerve palsies, may be a manifestation of inflammatory infiltration (third, seventh, and eighth nerves) or increased intracranial pressure (sixth nerve). Sixth cranial nerve palsy developing in the course of bacterial meningitis is considered a false localizing sign, because it is usually the result of increased intracranial pressure rather than a mass lesion and is often bilateral. In subacute cases of brain abscess, a persistent headache and subtle personality changes may be the only clues of CNS infection. Fever is present in only 45% to 50% of patients; therefore, absence of fever should not be used to exclude the diagnosis of brain abscess. Patients with a subdural empyema often complain of an acute flare-up of chronic sinusitis, otitis media, or mastoiditis with an increase in local pain and in purulent nasal or aural discharge.

The onset of generalized headache and high fevers may be the first indications of intracranial spread, followed within days by focal neurologic findings, such as unilateral motor seizures, hemiplegia, hemianesthesia, or aphasia, and signs of increased intracranial pressure with progressive lethargy and coma. The neck is stiff, but CSF examination is more consistent with an aseptic meningitis syndrome. Cranial epidural abscess typically is associated with a postcraniotomy infection or cranial osteomyelitis stemming from chronic sinusitis or middle ear infection. The onset of symptoms may be more insidious and often is overshadowed by the localized inflammatory process. Focal neurologic findings are less common than in subdural empyema. Rarely, fifth and sixth cranial nerve palsy may develop in association with infection of the petrous portion of the temporal bone (Gradenigo's syndrome).

SEPTIC INTRACRANIAL THROMBOPHLEBITIS AND MYCOTIC ANEURYSM

Septic intracranial thrombophlebitis most frequently follows infection of the paranasal sinuses, middle ear, mastoid, or oropharynx. If collateral venous drainage is adequate, septic venous thrombosis may produce only transient neurologic findings or may be silent. If the thrombus outstrips collateral flow, however, progressive neurologic deficits result, with impairment of consciousness, focal or generalized seizures, and increased intracranial pressure. The clinical findings vary with the location of involved cortical veins or dural sinuses. Cavernous sinus thrombosis is characterized by abrupt onset, with diplopia, photophobia, orbital edema, and progressive exophthalmos. Involvement of the third, fourth, fifth, and sixth cranial nerves causes ophthalmoplegia, a midposition fixed pupil, loss of corneal reflex, and diminished sensation over the upper face. Obstruction of venous return from the retina results in papilledema, retinal hemorrhage, and visual loss.

Thrombosis of the superior sagittal sinus leads to bilateral leg weakness and may cause communicating hydrocephalus. Occlusion of the lateral sinus produces pain over the ear and mastoid and may cause edema over the mastoid (Griesinger's sign). Involvement of the fifth and sixth cranial nerves elicits ipsilateral facial pain and lateral rectus weakness (Gradenigo's syndrome). Intracranial mycotic aneurysms usually result from septic embolization as a complication of bacterial endocarditis. They are often multiple and usually are found on distal branches of the middle or anterior cerebral arteries. The early clinical manifestations are similar to those of cerebral emboli and infarction.

ENCEPHALITIS, MYELITIS, AND RADICULITIS

Encephalitis is characterized by diffuse involvement of the brain parenchyma. The most characteristic clinical feature is impairment of mental status, with progression

to stupor and coma. Seizures, cranial nerve palsies, and other focal neurologic abnormalities are less common. Because the meninges almost invariably are affected, the term *meningoencephalitis* may be more appropriate for this entity. Although a viral source is most common (see [Chapter 442](#) and [Chapter 443](#)), nonviral causes of meningoencephalitis are not rare. They are important, because most require specific antimicrobial therapy. These infections include Rocky Mountain spotted fever, typhus, mycoplasmosis, borreliosis (Lyme disease and relapsing fever), leptospirosis, neurosyphilis, invasive mycosis, cerebral malaria, primary amoebic meningoencephalitis, trypanosomiasis, and toxoplasmosis. Nonviral conditions causing meningoencephalitis, including toxoplasmosis, cryptococcosis, and atypical mycobacteriosis, are particularly important complications of the acquired immunodeficiency syndrome.

Myelitis can develop either with or without associated encephalitis. The infectious causes are similar to those of encephalitis, and both can develop as a postinfectious complication due to an exaggerated immunologic response to central myelin (postinfectious encephalomyelitis). In transverse myelitis, the neurologic manifestations resemble those after acute transection of the cord, with rostral limb weakness, decreased sensory level, and loss of bowel and bladder control. In ascending myelitis, there is ascending flaccid paralysis, rising sensory deficit, and early bowel and bladder involvement. As with encephalomyelitis, radiculitis or neuritis also can result from postinfectious sensitization to peripheral myelin (Guillain-Barré syndrome). The patient has clinical symptoms of subjective paresthesias and weakness, progressive flaccid paralysis, and loss of deep tendon reflexes. The onset of poor ventilatory effort and severe autonomic dysfunction with lability of blood pressure may require respiratory support and intensive care monitoring.

PERIPHERAL NEUROPATHY

Leprosy is the only bacterial disease known to result in direct infection of the peripheral nerves, leading to clinical signs of peripheral neuropathy. The cutaneous nerves are destroyed owing to segmental demyelination and axonal degeneration, producing anesthesia. Cranial and peripheral neuropathy also can be caused by bacterial toxins, either directly (diphtheria) or indirectly (tetanus and botulism). Diphtheria toxin provokes noninflammatory demyelination of both cranial and peripheral nerves. The earliest neurologic sign in pharyngeal diphtheria is paralysis of the palate, which imparts a nasal quality to the voice and an increasing tendency to regurgitate fluids through the nose. Other cranial nerves (particularly third, sixth, seventh, ninth, and tenth) may be affected. Later in the course, motor polyneuropathy with symmetrical flaccid paralysis of the distal extremities may evolve. Tetanus toxin binds to the presynaptic endings of motor neurons in the anterior horns of the spinal cord, resulting in uncontrolled motor input and sustained muscle spasms, particularly around the jaw (trismus) and facial muscles (risus sardonicus). Botulinum toxin binds to the presynaptic axon terminal of the neuromuscular junction, preventing release of acetylcholine. The illness manifests within 12 to 36 hours after ingestion of the toxin, with weakness, dizziness, and dryness of the mouth, followed by neurologic symptoms of blurred vision, diplopia, dysphonia, dysphagia, muscle weakness, and flaccid paralysis.

STRATEGIES FOR OPTIMAL CARE MANAGEMENT

MANAGEMENT

Antimicrobial Therapy

Early institution of effective antimicrobial therapy is the single most important factor in the favorable outcome of CNS infections. For this reason, establishing the precise etiologic and anatomic diagnosis is of paramount importance in the selection of the most appropriate antimicrobial regimen. Apart from the antimicrobial spectrum, other important considerations for the choice of effective therapeutic agents in CNS infections include penetration into CSF, bactericidal efficacy, mode of antibiotic administration, and the “postantibiotic” effect. All β -lactam antibiotics penetrate into CSF poorly (about 0.5% to 2% of peak serum concentrations) when the blood–brain barrier is normal, but penetration is enhanced in the presence of meningeal inflammation. Penetration also is augmented by high lipid solubility, a low degree of protein binding in serum, and a low degree of ionization at physiologic pH. Rapid bactericidal activity is clearly desirable for sterilization of the CSF. In general, CSF concentrations of the drug should exceed its minimal bactericidal concentration for the causative organism by five- to tenfold.

Based on the most common causative organisms encountered, the choices for initial empiric antimicrobial therapy for acute purulent meningitis in patients of different age groups are shown in [Table 431.4](#). A third-generation cephalosporin (cefotaxime or ceftriaxone) is recommended as initial empiric therapy for young children and adults, and vancomycin should be added if penicillin-resistant *S. pneumoniae* is suspected. These agents are ineffective against listerial infection. Immunocompromised and elderly patients, who are at increased risk for *L. monocytogenes* infection, should be treated with high-dose ampicillin. The recommended dosages are given in [Table 431.5](#). The final antibiotic selection should be guided by culture results and susceptibility data. The recommended regimens for specific bacterial pathogens in purulent meningitis are outlined in [Chapter 441](#) (see especially [Table 431.2](#)). Although the optimal duration of therapy varies with the offending organism, treatment usually is continued for 10 to 14 days for most pathogens, approximately 3 weeks for staphylococci, and 3 to 6 weeks for enteric gram-negative bacilli.

Age	Common Organisms	Recommended Therapy
0-4 wk	<i>Escherichia coli</i> , <i>Streptococcus agalactiae</i> , <i>Listeria monocytogenes</i>	Ampicillin plus third-generation cephalosporin ¹ or ampicillin plus amoxicillin
4-12 wk	<i>E. coli</i> , <i>S. agalactiae</i> , <i>L. monocytogenes</i> , <i>Haemophilus influenzae</i> , <i>Streptococcus pneumoniae</i>	Ampicillin plus third-generation cephalosporin ¹
3 mo to 18 yr	<i>Neisseria meningitidis</i> , <i>S. pneumoniae</i> , <i>H. influenzae</i>	Third-generation cephalosporin or ampicillin plus chloramphenicol
18-50 yr	<i>S. pneumoniae</i> , <i>H. meningitidis</i>	Third-generation cephalosporin ¹ or ampicillin
>50 yr	<i>S. pneumoniae</i> , <i>H. meningitidis</i> , <i>L. monocytogenes</i> , gram-negative bacilli	Ampicillin plus third-generation cephalosporin ¹

¹Patients without underlying illness.

²Chloramphenicol, rifampin—vancomycin should be added if penicillin or cephalosporin-resistant *S. pneumoniae* is suspected.

TABLE 431.4. INITIAL EMPIRIC ANTIMICROBIAL THERAPY FOR ACUTE PURULENT MENINGITIS^a

Antibiotic	Daily	Dosing Interval (h)
Penicillin G	20–24 million units	4
Ampicillin	12 g	4
Nafcillin, oxacillin	9–12 g	4
Piperacillin	8–12 g	4
Imipenem	4–6 g	6
Cefotaxime	8–12 g	4
Ceftriaxone	4–6 g	12
Ceftazoxime	4–6 g	8
Ceftazidime	6–12 g	8
Chloramphenicol	4–6 g	6
Vancomycin	2 g	12
Gentamicin, tobramycin	3–5 mg/kg	8
Amikacin	15 mg/kg	8
Ciprofloxacin	200–400 mg	12
Metronidazole	30–60 mg/kg	6
Trimethoprim-sulfamethoxazole	5–10 mg/kg	12
	25–50 mg/kg	12

EVIDENCE LEVEL: C. Reference: Expert Opinion.

TABLE 431.5. RECOMMENDED DOSES OF ANTIBIOTICS FOR SUPPURATIVE INTRACRANIAL INFECTIONS IN ADULTS

The choices for initial empiric antimicrobial regimens for other suppurative intracranial infections (including brain abscess, subdural empyema, and cranial epidural abscess) are shown in [Table 431.6](#). These regimens are based on the suspected source of infection and the most likely causative organisms. Maximum doses of systemic antimicrobials are required, to optimize penetration of the blood–brain barrier. Therapy should be continued for at least 6 to 8 weeks, and the patient should be carefully monitored both clinically and by repeated CT scans until complete resolution of the infection. Follow-up is necessary for up to 1 year, to ascertain nonrecurrence. Similar regimens with maximum doses and prolonged antimicrobial therapy (6 to 8 weeks of intravenous antibiotics) are recommended for intracranial vascular or bone infections.

Source of Infection	Antimicrobial Regimens	
	Normal Host	Compromised Host
Cranial parenchymal infection		
Dissect	Ampicillin 2-4 million units i.v. q4-6h + ceftriaxone 2 g i.v. q12h or meropenem 2 g i.v. q8h	Ceftriaxone 2 g i.v. q12h or cefepime 4 g i.v. q12h or meropenem 2 g i.v. q8h
Ring-enhancing	Ampicillin 2-4 million units i.v. q4-6h + meropenem 2 g i.v. q8h	Same as ring-enhancing
Dissecting	Same as ring-enhancing	Same as ring-enhancing
After craniotomy	Ampicillin 2 g i.v. q4-6h + ceftriaxone 2 g i.v. q12h or cefepime 2 g i.v. q12h	Vancomycin 30 g i.v. q12h + ceftriaxone 2 g i.v. q12h or meropenem 2 g i.v. q8h
Hemorrhage from distant site	Choice based on suspected organism from primary site	Vancomycin 30 g i.v. q12h + ceftriaxone 2 g i.v. q12h or cefepime 2 g i.v. q12h
Spinal epidural abscess	Ampicillin 2 g i.v. q4-6h + rifampin 600 mg i.v. q12h or ceftriaxone 2 g i.v. q12h	Vancomycin 30 g i.v. q12h + ceftriaxone 2 g i.v. q12h or cefepime 2 g i.v. q12h

*Include brain abscess, subdural or spinal epidural abscess and optic chiasm abscess.

TABLE 431.6. EMPIRIC ANTIMICROBIAL REGIMENS FOR SUPPURATIVE INTRACRANIAL INFECTIONS^a

Surgical Drainage or Extirpation

The treatment of cerebritis typically does not require surgical drainage if appropriate antibiotic therapy is instituted early. Brain abscesses that are encapsulated are best treated by surgical aspiration. Complete surgical excision or extirpation of the abscess cavity usually is not required. Early surgical evacuation is the cornerstone of therapy for both subdural and cranial epidural empyema. Similarly, because the clinical course of a mycotic aneurysm varies widely and the risk of rupture with catastrophic cerebral hemorrhage cannot be predicted even after successful therapy of the underlying endocarditis, early surgical intervention is advised in patients with an intracranial mycotic aneurysm.

Other Adjunctive Measures

In addition to antimicrobial therapy, concomitant administration of anti-inflammatory agents, such as dexamethasone, oxindanac, or indomethacin, may be useful in reducing subarachnoid space inflammation. Corticosteroids and osmotic diuretics frequently are used to decrease intracranial pressure and cerebral edema. Use of monoclonal antibodies directed at lipopolysaccharides of gram-negative bacilli and at inflammatory cytokines, such as interleukin-1 and tumor necrosis factor, is being evaluated in animal models and in early clinical trials of sepsis syndrome and purulent meningitis. It remains to be seen whether such measures will improve the outcome substantially and prevent chronic neurologic side effects after these devastating CNS infections.

COMPLICATIONS AND PITFALLS

Brain herniation is the most dreaded complication after LP and in any patient with increased intracranial pressure. CSF is formed by the choroid plexus in the cerebral ventricles (chiefly in the lateral and third ventricles) and flows through the third and fourth ventricles into the subarachnoid space through the foramina of Magendie and Luschka. From the subarachnoid space, CSF is resorbed by arachnoid granulations, primarily in the dural venous sinuses. Any obstruction in the flow of CSF results in increased intracranial pressure, leading to communicating or obstructive hydrocephalus. In communicating hydrocephalus, the increased intracranial pressure usually results from an impairment of CSF reabsorption across the arachnoid villi, such as during basilar meningitis or after occlusion of the superior sagittal or lateral sinuses. In such instances, even though the intracranial pressure is high, it is transmitted through the entire subarachnoid space around the brain and cord, and unless concomitant abscess or severe cerebral edema is present, there is relatively low risk of brain herniation after LP. Thus, in most patients with acute meningitis who are alert and without papilledema or focal neurologic signs, an LP can be carried out safely without an initial CT scan.

In obstructive hydrocephalus, on the other hand, increased intracranial pressure typically stems from an interruption of CSF circulation within the ventricular system, either directly because of ventriculitis or indirectly because of external compression by an abscess, mass, or hemorrhage. In such instances, the risk of brain herniation after LP is particularly high. For this reason, LP is contraindicated as part of the initial evaluation of a patient with acute head injury, suspected mass lesions in the brain, or increased intracranial pressure, as evidenced by rapid onset of obtundation, papilledema, abducens paresis, split-skull sutures, or an eroded sella turcica. If CSF examination is deemed critical and CT or MRI is unavailable, a cisternal tap undertaken by an experienced neurologist is the preferred alternative. During LP, one must always measure the CSF pressure. If the intracranial pressure is greater than 300 mm H₂O, care must be taken, and the patient must be kept supine. If cerebral edema is suspected, intravenous corticosteroids (1 g methylprednisolone) are indicated, to diminish brain swelling. External or ventriculoperitoneal shunting may be required in the context of hydrocephalus.

Indications for HOSPITALIZATION

All patients with a suspected infection of the CNS should be hospitalized and appropriate investigations promptly initiated.

Indications for REFERRAL

A careful and systematic neurologic evaluation is paramount for localizing the site of infection. A multidisciplinary approach with assistance from various specialties, particularly neurology, neuroradiology, neurosurgery, infectious diseases, and microbiology, is often essential for optimal management.

COST-EFFECTIVENESS

By far the most cost-effective strategy for the management of infections of the CNS is prevention of infection. In the case of bacterial meningitis, this can be achieved either by postexposure prophylaxis or by active immunization.

Postexposure Prophylaxis

Household contacts of patients with acute meningitis due to *N. meningitidis* or *H. influenzae* infection should receive prophylaxis with rifampin (600 mg daily for 2 days for contacts with meningococcal meningitis and for 4 days for contacts with *H. influenzae* meningitis). Postexposure prophylaxis also is recommended during epidemic outbreaks and for close contacts, such as the other children in nursery schools, and for medical personnel who have had mouth-to-mouth or other direct contact with infected respiratory aerosols.

Vaccines

Effective vaccines for the prevention of meningococcal disease due to serotypes A, C, Y, and W-135 are available and are recommended for use in potentially epidemic situations, for people with terminal complement component deficiencies, and for those with anatomic or functional asplenia. The pneumococcal polyvalent vaccine should be administered to all people with CSF leak, sickle cell disease, asplenia, and other immunodeficiencies, to prevent recurrent bacteremia and meningitis. Similarly, a safe and effective conjugated polysaccharide vaccine against *H. influenzae* type b is readily available and should be administered to all persons at risk. More recently, a Lyme disease vaccine (LYMERix, SmithKline Beecham) has been released. It contains an immunodominant outer surface protein (OspA) of *B. burgdorferi*. The vaccine has been shown to be safe and effective for the prevention of Lyme disease, but three intramuscular doses, at 0, 1, and 12 months, are required. It is indicated for individuals 15 to 70 years of age who are at high risk for Lyme disease owing to frequent and prolonged exposure to *Ixodes* ticks. Its safety and efficacy in children have not been established.

CHAPTER 432: CEREBROVASCULAR DISEASES

JOHN J. CARONNA

[Atherosclerotic Disease of Cerebral Arteries](#)
[Categories of Ischemic or Thromboembolic Stroke](#)
[Common Clinical Syndromes of Ischemic Stroke Associated with Occlusion of Specific Vessels](#)
[Vascular Syndromes Caused by Hypertension](#)

Each year in the United States, 500,000 persons suffer a stroke, and 150,000 of them die from the stroke or its complications. The overall mortality rate from stroke is about 25% in the first month and approaches 50% at 5 years. Neurologic complications account for most deaths in the first week; later deaths usually are due to heart disease and intercurrent infection. There are about two million stroke survivors living in the United States today. The sources of stroke in older patients are primary atherosclerosis in 10%, small-vessel occlusion due to lipohyalinosis or vasculitis in 8%, hematologic or cardiac conditions in 48%, and undetermined causes in 34%.

ATHEROSCLEROTIC DISEASE OF CEREBRAL ARTERIES

The importance of atherosclerosis of the major neck vessels (the carotid and vertebral arteries) as a cause of transient ischemic attacks (TIAs) and embolic or thrombotic strokes is well understood. Transient symptoms of cerebral ischemia are often due to microemboli that break off from ulcerated plaques and are carried distally into the brain. Platelet microemboli and cholesterol-lipid emboli that obstruct flow in the ophthalmic artery cause sudden, fleeting ipsilateral monocular blindness; those that lodge in the distal branches of the middle cerebral artery provoke contralateral hemiparesis, hemianesthesia, and homonymous hemianopia. Microemboli carried elsewhere in the carotid and vertebrobasilar distributions cause other symptoms and signs, depending on the vessel obstructed. If a larger thrombus breaks off, embolic stroke results. Occlusion at the site of atherosclerosis results in a thrombotic stroke if the collateral circulation distal to that occlusion is inadequate.

Cerebrovascular syndromes fall into two categories: disorders in which hypertension is one of several possible causes and disorders that occur primarily in the context of hypertension. Atherosclerosis of the large extracranial arteries in the neck and at the base of the brain is the basic pathologic process in the first category. Although hypertension is a prominent risk factor for atherosclerosis, other factors, such as diabetes, elevated serum cholesterol and triglyceride levels, cigarette smoking, hereditary predisposition, and use of oral contraceptives, may be important causes. Extensive atherosclerosis can develop in the absence of hypertension. TIAs and thrombotic and embolic strokes are the clinical syndromes in this category.

Hypertension damages small arteries deep in the brain and produces two clinical syndromes almost exclusive to hypertension: lacunar infarction (small subcortical strokes) and hypertensive hemorrhage (see later discussion). In the Framingham study, the relationship between hypertension and stroke was analyzed epidemiologically. More than 5,000 symptom-free men and women between 30 and 60 years of age were classified according to the initial level of blood pressure. A blood pressure of 160/95 mm Hg during any clinic visit tripled the risk of stroke and justified a decision to begin antihypertensive treatment.

CATEGORIES OF ISCHEMIC OR THROMBOEMBOLIC STROKE

Strokes due to ischemia may be divided clinically into three categories: TIAs, stroke in evolution (also called progressing stroke), and completed stroke. TIAs are ischemic episodes of focal cerebral dysfunction lasting less than 24 hours—typically only a few minutes—followed by complete recovery, with absence of neurologic deficit on neurologic examination. Modern imaging techniques, such as magnetic resonance imaging (MRI), can detect evidence of cerebral infarction in a high percentage of cases of TIA. Therefore, TIAs are small strokes with transient signs and symptoms, especially in patients with symptoms of long duration (hours). TIAs provide a warning of a possible impending permanent neurologic deficit and are a risk factor associated with both stroke and myocardial infarction.

Stroke in evolution describes ischemic signs and symptoms that worsen while the patient is being observed. The pathogenesis of this type of stroke is usually propagation of a thrombus in the carotid or basilar arteries. It is the least common clinical picture. Completed stroke denotes a relatively stable neurologic deficit resulting from a cerebral infarct. The infarcts in patients with completed stroke may vary from tiny necrotic areas that are barely detectable by neurologic testing to massive lesions with secondary edema of the cerebral hemisphere that mimic brain tumors.

TRANSIENT ISCHEMIC ATTACKS

Pathophysiology and Classification

Whenever the cerebral blood flow (CBF) of a region declines to a point low enough to impair neuronal function, clinical symptoms of focal ischemia can appear. If the supply of oxygen and glucose is restored before permanent damage has taken place, the focal neuronal dysfunction is reversible, and the associated clinical symptoms are transient.

TIAs comprise a diverse group of pathologic conditions that result in intermittent focal interruptions of CBF. The causes of TIAs can be divided into three pathophysiologic categories: abnormalities of the blood vessels themselves, including the heart and extracranial and intracranial vessels; alterations in the composition of the circulating blood; and changes in the manner in which the blood circulates ([Table 432.1](#)). The major theories advanced to explain TIAs are vasospasm, hemodynamic factors, and thromboembolism. Vasospasm of an intracerebral or extracerebral artery is an unlikely cause of transient ischemia, except in cases of hypertensive encephalopathy, subarachnoid hemorrhage, or migraine. Hemodynamic factors, such as reduced perfusion pressure distal to a severely stenotic or occluded cerebral artery, account for a small proportion of TIAs.

TABLE 432.1. CONDITIONS PREDISPOSING TO TIA AND STROKE

The most common mechanism producing alterations in CBF is probably platelet embolization from atherosclerotic extracranial or intracranial cerebral arteries. The evidence for this action is mainly clinical. In patients with transient monocular blindness, the passage of emboli through the retinal circulation has been witnessed. Cerebral arteriography has shown occlusion of small intracranial arteries in the vascular distribution of diseased carotid arteries of patients with TIAs. Pathologic examination of carotid arteries obtained at the time of endarterectomy from patients with TIAs has found ulcerated atheromatous plaques with an adherent fresh thrombus. TIAs often cease when the source of microemboli is removed by carotid stenosis progressing to complete occlusion. Surgical elimination of carotid stenosis

lowers the incidence of TIAs and stroke. TIAs often cease in patients treated with anticoagulants or antiplatelet aggregation drugs.

The history of TIA in the carotid artery territory is generally typical. The most common symptom is sudden onset of weakness, paralysis, or clumsiness in one or both extremities on the same side. Sensory symptoms may be present, including a feeling of numbness or paresthesias involving one or both extremities on the same side. If the TIA involves the hemisphere dominant for language function, dysphasia is present. Another potential component of a carotid system TIA is transient loss of vision in one eye or part of one visual field.

In vertebrobasilar TIAs, the most common symptom is a motor defect, such as weakness, clumsiness, or paralysis of any combination of extremities up to quadriplegia. Sensory phenomena include numbness, loss of sensation, and paresthesias in any combination of extremities. The patient may complain of unsteady gait, disequilibrium, and vertigo. There may be loss of vision, varying from complete blindness to partial blindness in homonymous fields. Diplopia is another characteristic visual symptom in vertebrobasilar TIAs.

Diagnostic Evaluation

Rarely does a physician actually observe a patient during a TIA, so he or she must rely on the patient's account of the attack. The examiner should inquire into the patient's lifestyle (cigarette and alcohol use, use of oral contraceptives, illicit drug use), any recent purulent infections or dental work, any neck pain or neck trauma, and family history of cerebrovascular disease. The evaluation is directed toward detecting evidence of vascular disease. Attention should be given to heart rate, rhythm, and size; heart sounds; blood pressure in both upper extremities; and peripheral pulses. There should be a search for audible bruits over various arterial sites.

Cranial arteritis, an unusual cause of TIA, may be detected by palpating the involved temporal artery. Absence of temporal artery pulses also can indicate occlusive disease of the ipsilateral external carotid artery. It is impossible to palpate accurately the internal carotid artery in the neck; what one feels is the common carotid or the bifurcation of the internal carotid. Bruits often can be heard by auscultating over the carotid artery as it passes up the neck; alternatively, they can be heard over the vertebral artery just above the clavicle and sometimes over the back of the neck or head. When present in a patient with TIAs, a bruit strongly suggests that the cerebral vessels are affected by atherosclerosis.

The cause of the TIA generally can be limited to one of three broad categories: vascular, cardiac, or hematologic. Abnormalities in the vascular system can be detected by ultrasonography. Duplex scanning incorporates B-mode scanning, which images the vessel under study, and Doppler techniques, which determine the velocity of blood flow. Extracranial and intracranial vessels can be imaged. Magnetic resonance angiography (MRA) noninvasively delineates the cervical and cerebral circulation. Ultrasonography and MRA have replaced cerebral arteriography in most situations. Nevertheless, transfemoral cerebral arteriography remains the most definitive test for evaluating the cerebral circulation, especially when more qualitative tests, such as ultrasonography and MRA, give conflicting results. The increased availability of new technologies, such as transesophageal echocardiography, has made commonplace the identification of subtle cardiac lesions, such as patent foramen ovale. Routine testing for coagulopathy and blood testing for antiphospholipid antibodies and for deficiency of protein C, protein S, and antithrombin III have widened the diagnostic possibilities in the patient with TIA and minor stroke.

Differential Diagnosis

The differential diagnosis of TIAs includes classic migraine with scintillating scotomas, hemiplegic migraine, focal convulsive events, Ménière's disease, and peripheral vestibulopathy. TIAs can be distinguished from migrainous accompaniments in that TIAs are generally maximal at onset or evolve all at once, whereas migrainous phenomena build up or progress for several minutes. Headache may accompany TIAs, but it is typically brief and not severe. Focal seizures progress from the distal to the proximal portions of an extremity and produce persistent neurologic deficits on physical examination (Todd's postictal paralysis). Isolated vertigo without other motor and sensory phenomena rarely is caused by a TIA.

Management

Control of systemic hypertension that accelerates atherosclerosis is the mainstay of the medical treatment of the stroke-prone patient. Dietary modification by lowering the consumption of cholesterol and saturated fatty acids in younger patients may retard or reverse the atherosclerotic process but is less beneficial in elderly patients. Modification of lifestyle through the elimination of smoking, increasing exercise, and reducing stress may be helpful.

Randomized trials of anticoagulants (heparin given immediately, followed by warfarin) indicate some decrease in the frequency of TIAs and a small decline in the incidence of completed stroke and of stroke-related death in the treated group but no difference in total mortality rates between treated and untreated groups. The latter finding is not unexpected, because the major cause of death among patients with cerebrovascular disease is cardiovascular disease (myocardial infarction). Most of the beneficial effect of anticoagulants is seen in the first 3 months after the first TIA; thereafter, there is little difference between treated groups and untreated groups in terms of the probability of stroke. Anticoagulants must be continued indefinitely in patients with TIAs due to cardiac-origin emboli or in patients with the antiphospholipid antibody syndrome.

The most popular form of therapy for TIAs is treatment with antiplatelet drugs, such as aspirin (one to four 325-mg tablets daily). Several studies have shown a reduced incidence of TIAs and stroke in patients treated with aspirin. The combined use of aspirin and dipyridamole has the theoretical advantage of blocking both platelet aggregation (aspirin) and adhesion to a damaged surface (dipyridamole). One study has shown an enhanced clinical benefit of low-dose aspirin (50 mg) and dipyridamole (400 mg in a delayed-release form) compared with low-dose aspirin alone. Clopidogrel or ticlopidine, antiplatelet agents more potent than aspirin, may be used in patients with recurrent TIAs who are taking aspirin but who are not candidates for anticoagulation or surgery.

Surgery in the form of endarterectomy remains the treatment of choice for patients with TIAs in the carotid arterial territory who have either high-grade stenosis or stenosis and ulcerated plaques but do not have complete occlusion of the carotid artery on the side appropriate to their symptoms. Extracranial-intracranial bypass of an occluded carotid artery did not prove beneficial in a prospective study of patients with TIAs. Balloon angioplasty with stenting of arteries is a promising therapy for carotid stenosis.

CEREBRAL ISCHEMIC INFARCTION

Pathophysiology and Classification

An ischemic cerebral infarct is an area of brain in which blood flow has fallen below the level necessary to maintain the viability of the tissue. Ordinarily, the CBF, which is about 55 mL/100 g per minute, delivers oxygen and glucose in concentrations exceeding the brain's needs. If there is a threat of insufficiency of substrate (hypoxia, anemia, hypotension, hypoglycemia), homeostatic mechanisms induce cerebral vasodilation. Total deprivation of substrate cannot be compensated for, so when occlusive cerebrovascular disease renders a region completely ischemic, infarction occurs.

Cerebral infarcts may enlarge for 4 or 5 days, because of the development of cerebral edema. The degree of edema is roughly proportional to the amount of brain infarcted. Most deaths occurring within a week after massive hemisphere infarction can be attributed to cerebral edema, with swelling of the affected hemisphere causing herniation of the ipsilateral cingulate gyrus across the midline beneath the free edge of the dural falx, followed by downward displacement of brain through the tentorial incisura.

The pathophysiologic picture of ischemic stroke involves several factors that affect, to varying degrees, the extent of brain infarction. These include propagation of thrombus distal and proximal to an arterial occlusion, the effectiveness of collateral circulation, possible vasospasm, development of brain edema, leakage of blood from damaged arterioles, different metabolic requirements in different areas of the brain, and congenital abnormalities in the cerebral arterial system. Systemic factors, such as hypotension, hyperviscosity of blood, and hyperglycemia, also promote more extensive brain infarction. The differential diagnosis of a worsening neurologic deficit includes cerebral hemorrhage, subdural and extradural hematoma, primary or metastatic brain tumor, cerebral abscess, and focal encephalitis. A computed tomographic (CT) scan of the head usually excludes a mass lesion and should be done on an emergency basis before anticoagulation is instituted.

Diagnostic Evaluation

When a stroke patient is seen by a physician, the initial neurologic examination defines the nature and severity of the neurologic deficit. Reexaminations at intervals

of 30 to 60 minutes indicate whether the deficit remains the same (completed stroke), is improving (TIA), or is becoming more widespread (progressing stroke). When the area of ischemic infarct is supplied by the carotid arterial system, 48 hours without progression is needed to ensure that further progression is unlikely (less than 5% of patients). Patients who improve and then relapse are considered to have progressing strokes. Patients with hemiplegia due to internal or proximal middle cerebral artery occlusion who are stable for 24 to 48 hours but then become lethargic or comatose have brain swelling and brain herniation rather than progressing stroke.

The evaluation of a patient with an acute ischemic stroke is similar to that described for patients with TIAs. CT scan or MRI of the brain should be carried out as soon as possible after admission, to rule out cerebral hemorrhage and tumor. In many instances, the CT scan shows normal results even when the patient has a severe clinical deficit. For these patients, immediate MRI with diffusion-weighted sequences or another CT scan in 24 to 48 hours will reveal the area of infarction. Cerebral arteriography usually is not required for patients with acute strokes unless vasculitis or a cerebral aneurysm is suspected. Ultrasonography of the cervical and intracranial vessels may be used to define the site of vascular occlusion. In patients without evidence of atherosclerotic disease of the cervical carotid arteries, a thorough search should be made for a cardiac source of emboli.

Management

All patients with acute ischemic strokes and negative results of CT scan who are seen within 3 hours of the time of onset of stroke should be evaluated for treatment with intravenous tissue plasminogen activator, a thrombolytic agent. Thrombolytic therapy in one clinical trial produced a 12% increase in the number of patients with a good clinical outcome when assessed at 3 months after stroke. This improvement was gained at the price of a 6% incidence of cases of cerebral hemorrhage, almost half of which were fatal. While thrombolytic therapy is beneficial in selected patients, it is not a panacea for ischemic stroke, since only a small percentage of patients with ischemic strokes qualify for therapy with this agent.

Anticoagulation with intravenous, unfractionated heparin or with subcutaneous low-molecular-weight heparins and heparinoids may be used to treat un- or under-anticoagulated patients with acute ischemic cardio-embolic strokes. The use of heparin in patients with ischemic strokes, even progressing strokes, remains the subject of controversy, since it is not always effective and can cause serious bleeding. An international stroke trial showed a modest effect from subcutaneously administered heparin in preventing recurrent ischemic stroke within 2 weeks of onset but no improvement in eventual outcome. Nevertheless, there may be a role for intravenous heparin or subcutaneous heparinoids in progressing strokes and perhaps also in acute partial infarcts, to prevent progression. Nevertheless, the use of anticoagulants for acute stroke is associated with an increased risk of intracranial hemorrhage.

Even at present, the mainstay of treatment of patients with acute ischemic stroke is good nursing care to prevent pneumonia and deep venous thromboses in paralyzed or paretic limbs. Medical care is directed at the maintenance of circulation by the judicious treatment of hypertension, dysrhythmias, and cardiac failure. Any seizures should be controlled to avert further cerebral damage from seizure-induced hypoxia and hypertension. Pneumonia and urinary tract infections should receive appropriate antibiotic treatment. Fluid and electrolyte balance should be restored by intravenous fluids.

Recovery and Rehabilitation from Stroke

There is extreme variation in outcomes from stroke. Most patients show some improvement after 14 to 21 days, when the cerebral edema of infarction has resolved. In general, the temporal profile of recovery is that 50% of the potential recovery is attained at 1 month after onset, 75% at 3 months, 90% at 6 months, and almost 100% at 1 year. Rehabilitation after stroke should begin early (days after onset), at first to ensure that paralyzed parts do not develop fixed joints and muscle tendon contractures. After the acute phase, physical and occupational therapy can be used to help the patient regain and sustain independence. Cognitive therapy and speech therapy are also of major importance. Dementia, receptive aphasia, and major impairment in sensory perception are important factors limiting rehabilitation potential.

COMMON CLINICAL SYNDROMES OF ISCHEMIC STROKE ASSOCIATED WITH OCCLUSION OF SPECIFIC VESSELS

Knowledge of individual syndromes associated with occlusion of specific vessels helps the clinician localize a lesion, determine that the deficit is of vascular origin rather than due to a mass lesion, decide on appropriate treatment, and establish a prognosis. Nevertheless, syndromes of specific vessels do not localize the site or nature of the occlusion. For example, infarction in the territory of the middle cerebral artery often is the result of occlusion of the internal carotid artery. Occlusions of individual branches of the middle cerebral artery are usually embolic, but the source of emboli may be either a stenotic internal carotid artery or the heart.

OCCLUSION OF THE INTERNAL CAROTID ARTERY OR PROXIMAL MIDDLE CEREBRAL ARTERY

Sudden occlusion of the internal carotid artery or of the proximal stem of the middle cerebral artery results in devastating infarction of the ipsilateral hemisphere. The area infarcted often is coextensive with the entire cortical and subcortical distribution of the middle cerebral artery. Cortical branches of the middle cerebral artery supply the entire motor and sensory cortex controlling the face, hand, arm, and expressive speech area (Broca's area) of the dominant hemisphere (arterial territory of the superior division of the middle cerebral artery) as well as the visual radiation and macular cortex at the tip of the occipital lobe and the receptive speech area (Wernicke's area) of the dominant hemisphere (arterial territory of the inferior division of the middle cerebral artery). Subcortical or lenticulostriate branches of the most proximal position of the middle cerebral artery supply the basal ganglia and motor fibers to the face, hand, arm, and leg in the genu and posterior limb of the internal capsule.

The presence of paralysis of the face, arm, and leg as part of the syndrome of hemisphere infarction is characteristic of occlusion of the proximal middle cerebral artery. Infarction of the cortex supplied by the superior and inferior divisions of the middle cerebral artery results in contralateral hemiplegia involving the face, hand, and arm, sparing the leg. There is a hemisensory deficit, homonymous hemianopia, and, if the dominant hemisphere is affected, total (expressive and receptive) aphasia. Infarction of motor fibers of the internal capsule supplied by the lenticulostriate branches of the proximal middle cerebral artery leads to contralateral hemiplegia, including paralysis of the lower extremity. Infarctions of the conjugate gaze area of the frontal lobe result in deviation of the eyes toward the site of damage.

OCCLUSION OF DISTAL BRANCHES OF THE MIDDLE CEREBRAL ARTERY

Occlusion of the superior division of the middle cerebral artery produces infarction of the anterior portions of the cerebral convexity but spares deep structures and the posterior portions of the hemisphere. Weakness and sensory loss are greater in the face and arm than in the leg, and no visual field defect is present. If the dominant hemisphere is involved, Broca's aphasia is present, with impaired speaking, naming, and writing ability but with relative preservation of comprehension.

Occlusion of the inferior division of the middle cerebral artery brings about infarction of the posterior portions of the cerebral cortex, including the visual radiation. In this instance, contralateral sensory loss predominates, and weakness may be minimal or absent. If the dominant hemisphere is involved, Wernicke's aphasia is present, with fluent speech output of jargon and paraphasia. Comprehension, naming, reading, and writing also are affected.

OCCLUSION OF THE ANTERIOR CEREBRAL ARTERY

Infarction of the cortical territory supplied by the anterior cerebral artery causes weakness, clumsiness, and sensory loss affecting mainly the contralateral leg and foot.

OCCLUSION OF THE POSTERIOR CEREBRAL ARTERY

Occlusion of the posterior cerebral artery causes contralateral homonymous hemianopia by infarction of the visual or calcarine cortex. If the lesion affects the dominant hemisphere and includes the posterior corpus callosum, there is alexia without agraphia owing to disconnection of the intact nondominant visual cortex from the dominant hemisphere language area. Unilateral proximal posterior cerebral artery occlusion may cause a transient disturbance of memory as the result of infarction of the medial temporal lobe.

BRAIN-STEM STROKE DUE TO VERTEBROBASILAR OCCLUSIONS

Occlusion of the Basilar Artery

Occlusion of the basilar artery is a serious event that often leads to death. Obstruction of flow in both vertebral arteries or in a lone, unpaired vertebral artery produces a syndrome similar to basilar artery occlusion. The clinical features of basilar artery occlusion differ, depending on whether the cause of occlusion is embolism or thrombosis in situ. Embolism tends to involve the distal portion of the basilar artery; in contrast, atheromatous occlusion affects the proximal and middle portions of the vessel.

Emboli small enough to pass through the vertebral arteries into the larger basilar artery usually are arrested at the top of the basilar artery at its bifurcation into the posterior cerebral arteries. Loss of consciousness occurs immediately because of obstruction of the blood supply to the mesencephalic ascending reticular activating system. Unilateral or bilateral palsies of the third cranial nerve are characteristic. Hemiplegia or quadriplegia ensues, with decerebrate or decorticate posturing. In fact, the "top of the basilar syndrome"—coma, unequal pupils both fixed to light, and bilateral corticospinal tract dysfunction—resembles and may be confused with midbrain failure caused by transtentorial uncal herniation. A history of vertebrobasilar TIAs or coma that came on suddenly accompanied by bilateral oculomotor dysfunction from its onset serves to distinguish acute brain-stem dysfunction from slowly evolving brain-stem compression due to downward transtentorial herniation.

Smaller emboli that occlude the rostral basilar artery only transiently before fragmenting and passing into one or both posterior cerebral arteries either do not result in permanent neurologic deficits or cause infarction of portions of the midbrain, of the thalamus, and of the temporal and occipital lobes. Thrombosis in situ occurs in the proximal and middle portions of the basilar artery. Pontine infarction due to basilar thrombosis is associated with unilateral damage to the sixth cranial nerve or nucleus. Horizontal eye movements are impaired, but vertical nystagmus and ocular bobbing may be present. The pupils are constricted and may be pinpoint, but they remain reactive to light. Hemiplegia or quadriplegia is usual.

In unconscious patients, the syndrome of basilar occlusion can be confused with pontine hemorrhage. A CT scan of the brain can differentiate between ischemic infarction and hematoma. Coma caused by occlusion of the basilar artery carries a poor prognosis for survival. In some cases, the basis pontis is injured permanently, but not the tegmentum of the brain stem. Such patients regain consciousness if they have lost it, but they remain quadriplegic. The term locked-in state has been applied to this condition. Locked-in patients may be able to signify that they are conscious by blinking to command. For patients who lack any clinical signs of consciousness, a conventional electroencephalogram with stimulation or cortical evoked responses may be needed to distinguish the locked-in state from the vegetative state.

Occlusion of the Vertebral Artery

Many syndromes of partial brain-stem infarction have been described after occlusion of the vertebral artery or of branches of the basilar artery. In general, brain-stem infarcts produce bilateral clinical signs. Ipsilateral signs reflect damage to the cranial nerves, their nuclei, and the uncrossed cerebellar pathways. Contralateral signs result from damage to the motor and sensory pathways that cross below the level of the infarct to the opposite side of the body. Occlusion of one vertebral artery when the other is patent causes the relatively benign syndrome of lateral medullary infarction. This syndrome is the most common of brain-stem infarcts and is prototypical.

Lateral medullary infarction takes the initial form of severe vertigo, nausea, vomiting, and nystagmus as a result of involvement of the lower vestibular nuclei. The descending tract and nucleus of the fifth cranial nerve are affected, with loss of pain and temperature sensation over the face on the side of the lesion. Damage to the inferior cerebellar peduncle causes ataxia of the limbs on the side of the lesion. Ipsilateral Horner's syndrome (miosis, ptosis) and loss of pain and temperature sensation on the contralateral side of the body are found. In addition, if the ninth and tenth cranial nerves are affected, there will be hiccups and difficulty swallowing. In general, ischemic brain-stem syndromes caused by occlusion of individual branches of the vertebral or basilar arteries have a benign prognosis and do not require anticoagulation or vascular surgical intervention. When brain-stem infarction is complicated by extensive cerebellar infarction, however, a life-threatening situation can develop.

CLINICAL SYNDROME OF CEREBELLAR INFARCTION

The symptoms of cerebellar infarction in conscious patients are consistent and resemble those of cerebellar hemorrhage. Common complaints include difficulty standing and walking, headache, nausea, vomiting, dizziness, clumsiness, and slurred speech. The onset of symptoms is abrupt in one-third of patients. With progression of infarction or swelling, most patients show signs of lateral gaze palsy or nystagmus toward the side of infarction. Facial palsies are common, but dysfunction of other cranial nerves and corticospinal and sensory defects typically are absent unless lateral medullary infarction has occurred coincident with cerebellar infarction. As edema develops around the infarct, hydrocephalus and impaired cognitive function or depressed consciousness appear.

When a cerebellar infarct increases in size from edematous swelling, the underlying pons and medulla are compressed against the clivus. The fourth ventricle is distorted, and obstructive hydrocephalus may arise. Brain-stem infarction and hemorrhage may be a late and fatal result of compression of the vessels on the ventral surface of the brain stem. Rapid descent of the cerebellar tonsils and impaction of the medulla cause sudden apnea and circulatory collapse. If tonsillar herniation is not fatal, increasing pressure in the posterior fossa effects upward herniation into and through the incisura or opening of the tentorium. As upward herniation develops, the displaced cerebellum distorts the midbrain. Hemispheric branches of the superior cerebellar arteries may be compressed by upward herniation of the cerebellum against the free edge of the tentorium. In some cases, this results in further infarction of the cerebellar hemispheres. In a review of the literature, my colleagues and I found 39 cases of upward herniation confirmed by postmortem examination. A cerebellar lesion caused upward herniation most frequently (65%) and was most often a hemorrhage (10 cases). Upward herniation followed cerebellar infarction in five patients. Lesions in the cerebellopontine angle (13%), in the pons (11%), and in the fourth ventricle (11%) also were associated with upward herniation.

DIAGNOSIS

An expanding cerebellar mass produces a characteristic syndrome of coma, small reactive pupils, abnormal doll's-eye responses, abnormal ice-water caloric responses, and corticospinal tract dysfunction. These initial signs of pontine compression are followed by signs of midbrain dysfunction, as already described in the context of transtentorial herniation. The gradual caudal-to-rostral progression of brain-stem dysfunction identifies the cause of coma as cerebellar herniation. CT examination of the posterior fossa shows a large area of decreased density in the cerebellum and hydrocephalus.

SURGICAL TREATMENT

Small infarctions of the cerebellum do not lead to coma and can be managed without surgery. Some patients stabilize after ventricular decompression to relieve hydrocephalus. When an extensive cerebellar infarction is recognized, surgical exploration of the posterior fossa and resection of the necrotic cerebellar tissue may be required. The surgical mortality rate is 50% if the patient is operated on while still conscious, but it approaches 80% if the patient becomes comatose or stuporous.

PROGNOSIS

Death from tonsillar herniation and cardiorespiratory failure is a typical outcome of massive, untreated cerebellar infarction. Not all cases of extensive cerebellar infarction are fatal, and patients who remain conscious 1 week after the onset of symptoms are unlikely to deteriorate from brain swelling or to require surgical decompression of the posterior fossa.

VASCULAR SYNDROMES CAUSED BY HYPERTENSION

Lacunar infarction and hypertensive intracerebral hemorrhage differ in clinical characteristics, but the site of the underlying pathologic process uniformly is in the small-resistance cerebral arteries. Before considering the clinical features of hypertensive strokes, we review the normal physiologic responses of the cerebral arteries to changes in systemic blood pressure.

CEREBRAL AUTOREGULATION

Whenever the systemic blood pressure rises too high or falls too low, the cerebral arteries constrict or dilate, respectively, to ensure a constant CBF. Such

autoregulation occurs primarily at the small-resistance cerebral arteries. As systemic blood pressure rises, the proportion of pressure dissipated across the small arteries increases; thus, these small-resistance arteries bear the brunt of systemic hypertension. The range of blood pressure over which autoregulatory responses can maintain a normal CBF can be only approximated. In a normotensive young person, the lower limit at which autoregulation occurs is near a mean blood pressure of 60 mm Hg. As the blood pressure falls below this level, even maximal dilatation of the vascular bed of the brain cannot compensate for the decreased perfusion pressure, and the CBF declines. In contrast, when the blood pressure exceeds the upper limit of the range of autoregulation (150 to 200 mm Hg), the CBF rises, and hypertensive encephalopathy may result.

LACUNAR INFARCTIONS

Lacunar infarctions are the most common cerebrovascular lesions, seen in roughly 10% of autopsied brains. They are often multiple, with an average of three per brain and, in some cases, 15 or more. Lacunes ("lakes") are healed ischemic infarctions, with minute cavities ranging from 0.5 to 15 mm in diameter; most are 2 to 4 mm in diameter. They are most common in the deep nuclei of the brain (putamen, 37%; thalamus, 14%; caudate, 10%), the pons (16%), and the posterior limb of the internal capsule (10%). They are found in lesser numbers in the deep cerebral white matter, the anterior limb of the internal capsule, and the cerebellum.

In part because of their small size and location in relatively silent areas of the brain, many lacunar infarctions are not recognized clinically. The onset of lacunar stroke is usually gradual, developing over several hours or days. Headache is absent in almost all cases, and consciousness is unchanged. Recognition of the lacunar stroke syndromes is important because the deficits produced are self-limited and relatively benign. Anticoagulation is not required and actually may be dangerous, because lacunar infarction often is associated with microhemorrhages. The prognosis for almost complete recovery is good, and the likelihood of future lacunar strokes is limited by adequate control of blood pressure.

Syndromes of Lacunar Stroke

Four major syndromes of lacunar stroke have been described. Lacunar stroke with pure motor hemiparesis is characterized by weakness of the face, arm, and leg on one side of the body, with no associated sensory, visual, or cortical deficits. Large deficits limited to the motor system can develop only where the motor fibers to one side of the body run close together, either in the posterior limb of the internal capsule or in the pons.

Pure sensory stroke of the face, arm, and leg is characterized by paresthesias and mild sensory loss involving half the body, with no other neurologic deficit. The affected area is often numb, tingling, itchy, or stiff. Sensory loss may be detectable by touching the patient with a light hair. At the onset of the stroke, the paresthesias spread over the involved side in a period of seconds to hours. The syndrome is caused by a lacune in the posterolateral nucleus of the thalamus, the primary sensory relay nucleus. The outlook for complete recovery is good. This stroke must be distinguished from a cortical sensory stroke due to disease of a large branch artery.

Homolateral ataxia and crural (distal leg) paresis is characterized by weakness of one leg, especially the toes and ankle, with a Babinski's sign and striking lack of coordination of the ipsilateral arm and leg. TIAs precede the stroke in more than half of cases. Transient paresthesias may occur at the onset in half the cases, but they do not recur. The patient often cannot walk without support. The lacune is in the contralateral internal capsule or corona radiata. Ninety percent of patients recover almost completely. The lacunar state is the syndrome of pseudobulbar palsy in which lability of affect, dementia, small-stepped rigid gait, dysarthria, incontinence, and bilateral long tract signs are present. Despite the prevalence of lacunes in the basal ganglia, parkinsonian tremor is not a feature of the lacunar state.

Pathogenesis

Lacunes are not old cavitated hemorrhages but are caused by occlusion of small arteries. The essential pathologic process involves arteries with a diameter of 50 to 200 μ m and consists of fibrinoid deposition, mural destruction, and thrombotic occlusion, a process termed *lipohyalinosis* or *segmented arterial disorganization*. This process appears to be a specific result of chronic hypertension.

HYPERTENSIVE INTRACEREBRAL HEMORRHAGE

Hemorrhage is the most lethal complication of chronic hypertension. If cases of trauma and ruptured saccular aneurysm or arteriovenous malformations are excluded, the classic type of intracerebral hemorrhage almost always is caused by hypertension.

Clinical Features

Hypertensive hemorrhage most often occurs in persons older than 50 years. The hemorrhage appears without warning while the patient is awake, often during exertion. Headache may be severe but is absent or trivial in half the cases. Vomiting is common; in the context of thrombotic or embolic strokes, it is rare. The blood pressure almost always remains elevated after onset; if nothing else is known in a particular case, the finding of normal or low blood pressure when a stroke patient is first examined makes the diagnosis of hypertensive hemorrhage unlikely. Once hemorrhage has taken place, the patient's condition worsens steadily over a period of minutes to days, until the neurologic deficit stabilizes or the patient dies. Once the deficit stabilizes, improvement occurs slowly. Because much of the deficit may be caused by an expanding hematoma that compresses rather than destroys the brain, return of neurologic function can be dramatic as the swelling subsides.

Large hypertensive hemorrhages rupture through brain parenchyma into the ventricles. Rupture directly into the subarachnoid space is unusual. When death ensues, it most often is due to herniation caused by the expanding hematoma and surrounding edema. However, hypertensive hemorrhages are not all massive or uniformly fatal, as witnessed by clinical observations, by pathologic studies showing old healed hemorrhages, and by CT, which identifies small, nonfatal hemorrhages.

Pontine Hemorrhage

Hemorrhage into the pons produces a fulminant syndrome in which coma occurs within seconds to minutes and death usually follows within 48 hours. The pupils are pinpoint, and horizontal eye movements are absent or impaired. Vertical eye movements may be preserved, and ocular bobbing, with a distinctive bilateral downbeating, may occur every 5 seconds. Quadriparesis often is present, with bilateral long tract signs and decerebration. Hyperthermia frequently is a feature, because muscular rigidity and shivering increase body heat while interruption of sympathetic pathways in the brain stem prevents sweating. Direct rupture of the hemorrhage into the fourth ventricle is the rule.

Deep Cerebral Hemorrhage

Most hemorrhages above the brain stem develop in the deep nuclear masses of the cerebrum. The two most common sites are the putamen of the basal ganglia and the thalamus, the main sensory relay nucleus. The motor defect is more dense in a putaminal hemorrhage, whereas the sensory defect is more prominent when the hemorrhage occurs in the thalamus. Thalamic hemorrhages often dissect downward and medially, to impinge on the midbrain center for upward gaze; in large thalamic hemorrhages, the eyes look downward and appear to be staring at the tip of the nose. Aphasia may occur if hemorrhage in either nucleus presses laterally on the speech areas. A separate aphasic syndrome has been reported in cases of localized hemorrhage within the thalamus; such patients appear to have an excellent prognosis for full recovery of speech.

Cerebellar Hemorrhage

The onset of cerebellar hemorrhage is sudden, without loss of consciousness. Within several minutes, the patient cannot stand or walk and most vomit repeatedly. Headache and dizziness develop in about half the cases. During the first several hours, most patients are alert, confused, or drowsy. Seventy-five percent become comatose within 12 hours and almost 90% within 24 hours. Conjugate lateral eye movements often are abnormal, with paresis of gaze to the side of the lesion or forced deviation away from the lesion. There may be skew deviation, with depression of the eye ipsilateral to the lesion. The pupils remain small and reactive even with deep stupor. In half the cases, ipsilateral facial weakness of the lower motor neuron type is present. Strength is normal, and appendicular cerebellar function may be intact or minimally impaired. Plantar responses initially are flexor but become extensor as the patient deteriorates. Loss of voluntary or reflex upward gaze is a sign of obstructive hydrocephalus. Rapid diagnosis of cerebellar hemorrhage is crucial. Early surgical decompression is lifesaving and often leads to complete reversal of the neurologic deficit. Surgical results are much better for responsive than for nonresponsive patients. Brain-stem stroke and cerebellar infarction can mimic the

picture of cerebellar hemorrhage but are distinguished by CT.

Pathogenesis of Hypertensive Hemorrhage

Multiple microaneurysms arising in small-resistance arteries were found by microangiography by Russell in 1963. These aneurysms were most common in regions of the brain where hypertensive hemorrhages are also most common, and some were surrounded by small leaks of blood. Changes reflective of lipohyalinosis often were present in the aneurysmal walls. Two theories of the underlying cause of hypertensive intracerebral hemorrhage have developed. Russell maintains that these aneurysms are caused by mechanical distention and that lipohyalinosis then occurs as a secondary change. Fisher considers lipohyalinosis to be the initial process and suggests that an affected resistance artery may rupture whether or not an actual aneurysm develops. It is generally agreed that massive cerebral hemorrhage follows the rupture of either an aneurysmal or lipohyalinotic segment of a small-resistance artery and that the basic lesion is caused by chronic hypertension.

Treatment

The importance of surgical decompression for cerebellar hematoma has been mentioned. Surgery is not indicated for pontine or deep cerebral hypertensive hemorrhages. Surgery may be lifesaving, however, in the case of a superficial hemorrhage in the white matter large enough to cause shift and herniation. Prognosis is directly related to the level of consciousness before the operation, and surgery usually is fruitless in an already comatose patient.

There is no effective medical treatment for intracerebral hemorrhage. Corticosteroids or dehydrating agents have not been of more than temporary benefit. The use of antihypertensive agents for acute cerebral hemorrhage is the subject of controversy. Attempts to lower systemic blood pressure may compromise CBF and lead to infarction, but continued hypertension may cause cerebral edema. One approach to this problem is derived from measurements of the cerebral autoregulation curve after stroke or trauma. Because of vasomotor paralysis, a damaged brain may lose the ability to autoregulate; CBF then follows blood pressure in a linear fashion. In effect, the "breakthrough point" is lowered, leading to a situation analogous to hypertensive encephalopathy in which elevated blood pressure accelerates the formation of edema. On this basis, it seems reasonable to lower blood pressure to normal levels after cerebral hemorrhage. This must be done with great care because the cerebral vasculature may be unusually sensitive to antihypertensive agents; therefore, smaller doses of the milder agents should be tried initially.

CHAPTER 433: DEMYELINATING DISEASES

JOHN R. RICHERT

[Multiple Sclerosis](#)
[Optic Neuritis](#)
[Acute Disseminated Encephalomyelitis](#)
[Adrenoleukodystrophy](#)

MULTIPLE SCLEROSIS

Multiple sclerosis (MS) is an inflammatory, demyelinating disease of the central nervous system (CNS).

INCIDENCE AND EPIDEMIOLOGY

MS prevalence tends to correlate with distance from the equator, being 70 to 100 per 100,000 population in the northern United States and Canada and less than 5 per 100,000 in the tropics. Onset most commonly occurs between ages 20 and 50 years. Women affected outnumber men by about 2 to 1. Epidemiologic studies suggest that exposure to some as-yet-undetermined environmental agent in the mid-teenage years serves as an inciting event in the disease.

There is a clear hereditary predisposition to MS: the concordance rate among first-degree relatives of MS patients is about 25 to 50 times higher than the prevalence in the general population. Furthermore, the concordance rate among identical twins (255 to 50%) is higher than that for fraternal twins (1% to 2%). In addition, certain ethnic groups (e.g., Inuits) exhibit a strong divergence in prevalence from those in the predominant populations living in the same latitudes.

ETIOLOGY

Speculation has centered on two types of processes: direct infection of the CNS with a neurotropic agent and autoimmunity. Although elevated antibody titers in MS cerebrospinal fluid and serum have been described for several viruses, none of these agents has been reliably detected in the CNS of MS patients. Recent reports suggesting a causal role of human herpes virus 6 (HHV-6) or *Chlamydia pneumoniae* remain to be substantiated.

Familial cases of MS do not follow mendelian genetics, and current data suggest a polygenic predisposition. Different human leukocyte antigen (HLA) types predominate in different ethnic populations. The most prevalent HLA haplotype in the MS population of northern European origin includes the DR15 subtype of DR2 and DQA1*0102-DQB1*0602. Extensive linkage studies with panels of microsatellite markers are currently under way in several laboratories.

Indirect evidence for an autoimmune component to the disease comes from an animal model of MS, experimental allergic encephalomyelitis, which can be induced by sensitizing laboratory animals to myelin basic protein, proteolipid protein, or myelin oligodendrocyte glycoprotein. Diminished disease activity during pregnancy, which is associated with a state of relative immune suppression, also suggests an autoimmune cause. This is further supported by the tendency for immunosuppressive treatment regimens to be more effective than immunoenhancing ones. Data from several groups have suggested a defect in suppressor cell function. A number of markers associated with immune system activation have been associated with MS disease activity, but these do not distinguish between a primary autoimmune pathogenesis and a viral cause. Current evidence suggests that MS is precipitated by initial exposure of a genetically susceptible host to a relatively common infectious agent in the mid-teenage years and that this ultimately leads to an autoimmune process that pathologically targets CNS myelin.

PATHOGENESIS

The hallmarks of the microscopic examination are multifocal areas (plaques) of mononuclear cell infiltration and demyelination in a perivenular distribution. The mononuclear cell infiltrate consists of lymphocytes (T cells more than B cells) and lipid-laden macrophages. The demyelination results in slowing/blocking of conduction along the axons. At the hemispheric level, plaques tend to occur in a periventricular distribution. With progression of disease, gliotic (fibrotic) scars form, often with secondary axonal loss. Recent evidence suggests that axonal loss or cerebral atrophy or both may occur early in the course of MS.

CLINICAL FINDINGS

Any region of CNS white matter may be affected. For example, involvement of the cerebral hemispheres may produce a hemiparesis or hemisensory deficit or may lead to cognitive dysfunction. Various brain-stem syndromes (e.g., internuclear ophthalmoplegia) and optic neuritis are common. Cerebellar involvement may result in ataxia or intention tremor. Spinal cord disease may produce a spastic paraparesis/paraplegia with neurogenic bowel and bladder and sexual dysfunction. Dysesthetic pain syndromes may result from the involvement of nerve root entry zones in the CNS; trigeminal neuralgia is the classic example.

MS is somewhat arbitrarily divided into four forms. Approximately 15% of patients exhibit the *primary progressive* form, characterized by gradual accumulation of neurologic deficits without clear-cut exacerbations and remissions. This is seen in many patients with late-onset MS. Approximately 75% of patients begin with a *relapsing-remitting (R-R)* course. These patients tend to return to a somewhat more impaired status after many of their exacerbations, such that the R-R course leads to a progressively worsening baseline. Although most exacerbations have no identifiable precipitating cause, about 30% are preceded by a viral illness. Most patients with R-R MS eventually develop a more gradually progressive course, with or without superimposed exacerbations, referred to as *secondary progressive* MS. A small percentage of patients begin with a gradually progressive course and subsequently experience superimposed exacerbations, hence the term *progressive-relapsing* MS.

The diagnosis rests on well-described criteria for “possible,” “probable,” and “definite” MS. The hallmark of the disease is “dissemination in time and space” (i.e., multiple episodes of dysfunction and multiple areas of involvement within the CNS). Thus, the diagnosis cannot be made with certainty at the time of initial neurologic symptoms. Similarly, the diagnosis of primary progressive MS is difficult to make.

LABORATORY FINDINGS

No laboratory abnormality is pathognomonic for MS. Therefore, after accumulating information that is consistent with the diagnosis, one must rule out other diseases that may mimic MS.

Magnetic resonance imaging (MRI) has revolutionized our ability to make an early diagnosis of MS. Plaques typically appear as areas of increased signal intensity on T2-weighted (Fig. 433.1) and proton density images and sometimes as areas of decreased signal intensity on T1-weighted images. Enhancement after gadolinium contrast administration identifies areas of blood-brain barrier breakdown and therefore detects areas of active inflammation in the CNS. Fluid attenuated inversion recovery (FLAIR) images are helpful in distinguishing cerebrospinal fluid from periventricular plaques. Magnetization transfer technology and MR spectroscopy may soon permit more sensitive detection and further information about biochemical abnormalities in MS.

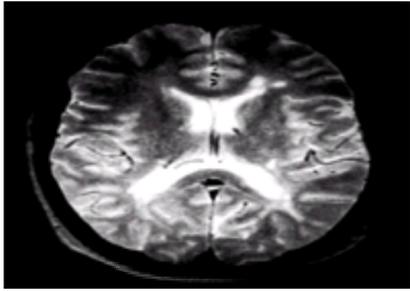

FIGURE 433.1. Magnetic resonance imaging scan of the brain of a 21-year-old patient with isolated spinal cord symptoms showing many deep, white matter lesions.

If clinical and MRI evaluations detect only one involved site within the CNS, evoked potential studies (visual, auditory, somatosensory, and motor) may be used to detect an additional, subclinical area of slowed conduction due to demyelination.

Although the cerebrospinal fluid may be normal, a mild mononuclear cell pleocytosis and modest protein elevation are common. Elevated IgG levels and evidence of increased intrathecal IgG synthesis (IgG index, IgG synthesis rate) are often present. Oligoclonal immunoglobulin bands are found in over 90% of patients.

Other diseases that may resemble MS from clinical, imaging, and cerebrospinal fluid standpoints include syphilis, neuroborreliosis, CNS vasculitis, sarcoid, and HTLV (human T-cell lymphotropic virus)-I-associated myelopathy (tropical spastic paraparesis). Multiple infarcts secondary to small-vessel vascular disease must also be considered. Rarely, the inherited dysmyelinating diseases (e.g., metachromatic leukodystrophy, adrenoleukodystrophy) have their onset in adult life, with MRI appearances that resemble MS. Postviral demyelination in a multifocal distribution may occur as a monophasic illness and may mimic the initial episode of MS. Vitamin B₁₂ deficiency should also be ruled out.

OPTIMAL MANAGEMENT

Treatment regimens can be categorized as being either symptomatic (to ameliorate various physiologic abnormalities) or directed at suppressing CNS inflammation.

Oxybutynin and other anticholinergic agents are useful in reducing bladder spasticity, thereby reducing urinary frequency and urgency. Large residual bladder volumes (usually due to sphincter spasticity) are treated with intermittent catheterization or (less desirably) chronic Foley drainage. Constipation is also related to autonomic dysfunction and is best treated with stool softeners and adequate fiber intake. More potent laxatives and enemas should be used as sparingly as possible.

Spasticity is often well controlled with the use of baclofen, tizanidine, or dantrolene sodium. Diazepam and various anticonvulsant medications are used less frequently. Some degree of spasticity may be necessary to allow patients with severe leg weakness to maintain a reasonable level of ambulation; reducing spasticity may therefore increase the sense of lower extremity weakness. Patients with otherwise refractory severe spasticity may benefit from continuous intrathecal infusion of baclofen by a subcutaneous pump. Rarely, rhizotomy or a tendon-severing procedure is used to reduce severe spasticity.

Trigeminal neuralgia and neurogenic pain secondary to involvement of dorsal root entry zones in the cord can be treated with anticonvulsants or tricyclic antidepressants. If pharmacologic treatment fails to control the pain of trigeminal neuralgia, neurosurgical ablation of the trigeminal ganglion may be considered, particularly if pain is triggered by peripheral stimulation (e.g., chewing or speaking).

Fatigue, characterized by a global inanition of uncertain pathophysiologic cause, is common. Amantadine, pemoline, and afternoon rest periods may be helpful.

Methods for enhancing nerve conduction velocity in demyelinated nerve are being developed. Because elevated body temperature slows nerve conduction and often aggravates MS symptoms, exposure to cold (e.g., a cooling vest) temporarily increases conduction velocity and, for some patients, provides symptomatic improvement. Aquatic exercise programs in cool water allow aerobic exercise with improved dissipation of heat and provide a buoyant density that permits more vigorous exercise than can be achieved on dry land. Experimental agents that block potassium channels and thereby increase conduction velocity (e.g., 4-aminopyridine) are being developed.

Cerebellar tremor is a notoriously difficult symptom to treat. Modest degrees of success have been reported with the use of clonazepam and with isoniazid, both of which may act through the GABA (g-aminobutyric acid) system. Very preliminary attempts to use thalamic stimulation to ameliorate tremor appear encouraging.

Of the treatments aimed at reducing inflammation in the CNS, high-dose intravenous methylprednisolone (0.5 to 1.0 g per day for 3 to 7 days) is most effective at rapidly reversing neurologic deficits associated with exacerbation, although it remains unclear whether the eventual level of recovery is improved with its use. A small percentage of patients experience severe hypokalemia during each course of corticosteroids. Therefore, at least during a patient's initial course of treatment, the physician should have access to the results of each day's serum potassium level on the same day. In some locales, this may require hospitalization. Diabetics may also require hospitalization to control glucose homeostasis.

Recombinant interferon- β is effective in the long-term treatment of both R-R and secondary progressive MS. It is unclear whether the beneficial effect is secondary to its antiviral action or its immunomodulatory function. Glatiramer acetate, a random copolymer of four amino acids designed to inhibit the T-cell response to myelin basic protein (but which may actually have a more general immunomodulatory effect), has been shown to reduce the exacerbation rate in R-R MS.

Progressive forms of MS are often more resistant to treatment, and one often resorts to therapy with chemotherapeutic agents. Mitoxantrone (12 mg/m² intravenously every 3 months) has recently been reported to be effective in a mixed cohort of secondary progressive and relapsing patients who entered the study with a moderate degree of fixed neurologic disability. There is an unknown degree of risk of vacuolar cardiomyopathy with high cumulative doses of mitoxantrone. Low-dose oral methotrexate (7.5 mg week) produces a mild slowing of progression of MS, but most patients appear to eventually require higher doses. Oral azathioprine has been of minimal proven benefit, although it has not been well studied using modern MS clinical trial designs. Its use is particularly popular in Europe. Varied degrees of success have been reported with high-dose intravenous immunoglobulin. Intravenous cyclophosphamide is a controversial form of therapy used by some neurologists in an initial 8- to 14-day course, followed by monthly intravenous pulses. It appears to be most effective in patients with significant recent worsening of neurologic status that has been refractory to treatment with more conventional agents. Monthly pulses of intravenous methylprednisolone (1 g) are widely used and are well tolerated by most patients with MS, although formal proof of efficacy is currently lacking.

OPTIC NEURITIS

Optic neuritis is an inflammatory, demyelinating disease of the optic nerve. Onset is usually acute or subacute and produces diminished visual acuity, scotomata, or color desaturation. Ocular pain with eye movement is a common concomitant. It usually involves the retrobulbar portion of the nerve and therefore is not associated with abnormal funduscopic findings during the acute stage. A papillitis produces papilledema. Over time, optic atrophy may develop, manifested by disk pallor on ophthalmologic examination. An afferent pupillary defect to light stimulation is a common finding on examination. At least 50% of patients eventually develop frank MS, with the highest risk occurring among those with abnormalities on MRI that are suggestive of MS. In one study, treatment with either intravenous corticosteroid followed by a tapering course of oral corticosteroid, or oral corticosteroid alone, produced more rapid recovery from an acute attack than did placebo, although the eventual level of recovery was similar in all groups. Subjects treated with oral corticosteroids alone tended to have a worse relapse record than that of those in the other two study groups. Treatment with intravenous methylprednisolone appeared to delay the eventual development of clinically definite MS.

ACUTE DISSEMINATED ENCEPHALOMYELITIS

Acute disseminated encephalomyelitis (ADEM) is an acute, monophasic, inflammatory, demyelinating disease of the CNS that is most commonly considered to be a

postinfectious process. It is similar to the disseminated encephalomyelitis that occurred secondary to sensitization with CNS antigens found in earlier rabies vaccine preparations. It is the human disease most closely related clinically and pathologically to acute experimental allergic encephalomyelitis, which can be induced in laboratory animals by sensitization with any of several myelin antigens. An elevated T-cell response to myelin basic protein has been reported in those with ADEM.

The clinical manifestations of ADEM may be protean, with involvement of motor, sensory, cerebellar, and cranial nerve function, as well as encephalopathy with mental status changes, sometimes progressing to coma. The mortality rate approaches 30%. Cerebrospinal fluid abnormalities usually include a predominantly mononuclear pleocytosis and elevated protein level. MRI demonstrates extensive areas of increased signal intensity in the white matter on T2-weighted and proton density sequences. Adrenocorticosteroids are often used therapeutically, but their value is uncertain.

ADRENOLEUKODYSTROPHY

Adrenoleukodystrophy is an X-linked recessive disease related to defective peroxisomal β -oxidation of very-long-chain (greater than C₂₂) fatty acids due to either a deficiency of very-long-chain (lignoceric acid) acyl coenzyme A ligase or an abnormality in a peroxisomal membrane protein that is required to transport the ligase into the peroxisome. Childhood and adult forms are recognized; the latter is often referred to as adrenomyeloneuropathy. Both forms occurring within the same kindred suggests that they represent different manifestations of the same mutation. The disease is characterized by CNS demyelination, gliosis, perivascular inflammation, peripheral neuropathy, and adrenal insufficiency. Motor, cognitive, brain-stem, cerebellar, and visual deficits are common. The typical course of adrenoleukodystrophy is one of progressive decline, with death within 5 years. Immunosuppressive therapy has been ineffective. Treatment with a 4:1 mixture of glyceryl trioleate and trierucate oils (Lorenzo's oil) normalized plasma levels of saturated very-long-chain fatty acids but did not prevent progressive loss of neurologic function. There has been a case report of reversal of both neurologic deficits and MRI abnormalities in early disease after bone marrow transplantation.

CHAPTER 434: PARKINSON'S DISEASE AND RELATED DISORDERS

STEPHEN G. REICH

[Epidemiology](#)
[Etiology and Pathogenesis](#)
[Clinical Findings](#)
[Management](#)
[Surgical Therapy](#)

Extrapyramidal disorders, as discussed in [Chapter 429](#) are divided into hypokinetic/rigid and hyperkinetic disorders. The former includes Parkinson's disease (PD) and related conditions and is the focus of this chapter. PD was described in 1817 by James Parkinson, a general practitioner in London. Little has been added to his description of *The Shaking Palsy*: "Involuntary tremulous motion, with lessened muscular power, in parts not in action and even when supported; with a propensity to bend the trunk forwards, and to pass from a walking to a running pace...."

EPIDEMIOLOGY

PD is the second most common degenerative disorder in adults, after Alzheimer's disease. It is estimated that at least 1 million Americans are affected. Both prevalence and incidence rates vary widely, depending on the population surveyed, the methods of case ascertainment, and particularly the definition of PD. A reasonable approximation of incidence, based on studies in the United States, is 20 per 100,000 per year, with a prevalence of at least 100 per 100,000.

ETIOLOGY AND PATHOGENESIS

The pathologic hallmarks of PD are degeneration of the dopaminergic neurons of the substantia nigra and the presence of eosinophilic, cytoplasmic inclusions known as Lewy bodies. What incites the death of nigral neurons is not clear: current hypotheses implicate varying combinations of genetic susceptibility, exogenous or endogenous toxicity, and aging. One of the most important breakthroughs came from identifying MPTP, a meperidine-like drug, as the cause of a small epidemic of parkinsonism in intravenous drug abusers. MPTP is selectively toxic to nigral neurons, producing not only a clinical picture of PD, but also a pathologic picture, and serves as an animal model. Its main effect appears to be on the respiratory chain in mitochondria, particularly complex I, which has been demonstrated to be low in patients with PD. Although it is still not clear what starts the cascade of events leading to the death of nigral neurons, key elements are likely to include energy depletion and oxygen toxicity with the formation of free radicals.

CLINICAL FINDINGS

PD is a clinical diagnosis dependent on recognizing the characteristic features. The sine qua non is bradykinesia—slowness of movements—with either a rest tremor or cogwheel rigidity. Most patients have all three diagnostic signs, but approximately 30% do not have tremor. The signs typically affect one side at presentation (hemiparkinsonism) unrelated to dominant handedness, before eventually becoming bilateral within several years. Additional symptoms and signs encountered early in PD include micrographia; impaired dexterity, especially for rapid repetitive movements such as shampooing or brushing teeth; slowness when arising from a deep chair, the toilet, or car; trouble turning in bed; slight drooling; a soft, monotone voice; diminished facial expression (hypomimia) and blink rate; and diminished arm swing while walking or dragging a foot. In the middle to latter stages of the disease, other motor problems emerge, including impairment of postural righting reflexes, leading to loss of balance with falls, and bradykinesia gives way to akinesia, with difficulty initiating and maintaining movements.

In addition to the motor findings of PD, there are a number of nonmotor symptoms and signs as well, reflecting the diverse functions of the basal ganglia as reviewed in [Chapter 14](#). PD sometimes begins with pain leading to the diagnosis of arthritis or fibromyalgia. Autonomic problems are common, both from the disease itself and from its treatment. These include constipation, impotence, impaired sexual arousal in women, orthostatic hypotension, impaired thermoregulation—sweating or feeling warm or cold in contrast to the temperature—and urinary bladder instability.

Depression is so common in PD that it is safe to assume that all patients with PD are depressed until proven otherwise. Anxiety, embarrassment, and panic attacks are also encountered. With advancing PD (after 10 years), dementia often appears, but it is important to appreciate that *most* patients with PD *do not develop dementia* and it is not an inevitable consequence of the disease. Therefore, treatable causes need to be ruled out, especially pseudodementia due to depression, and the effects of medications, particularly those with anticholinergic activity.

In most cases, the diagnosis of PD is straightforward, but there are some pitfalls to be aware of. PD may be confused with essential tremor as discussed in [Chapter 11](#). When PD presents in a person younger than age 45, which happens in 5% of cases, the diagnosis is often not considered. Likewise, PD tends to be overdiagnosed in the very elderly because it often merges with features of "normal" aging. Dementing illness, like Alzheimer's, are often accompanied by parkinsonian features. The motor signs, rather than dementia, may prompt medical attention, since the former is often unrecognized because of its insidious onset or mistakenly attributed to normal aging by family members. Parkinsonism may also be drug-induced.

The most common pitfall is failure to recognize *mimickers* of PD ([Table 434.1](#)). Up to 25% of diagnoses of PD during life have been shown to be wrong at autopsy; the most common correct diagnoses are parkinsonian syndromes: related degenerative diseases with more extensive clinical and pathologic involvement. The three most reliable clinical features distinguishing PD from related disorders include classic rest tremor, unilateral or asymmetric onset, and a beneficial, sustained response to levodopa. Clues that suggest a cause of parkinsonism other than idiopathic PD include failure to respond to levodopa; symmetric onset; early dementia; early dysphagia; early falls; early and prominent dysautonomia; impaired vertical eye movements; cerebellar, pyramidal, or lower motor neuron signs; and rapid progression, among others. It is not uncommon for features of a parkinsonian syndrome to emerge only after several years; therefore, the diagnosis of PD should be scrutinized at each visit.

TABLE 434.1. DIFFERENTIAL DIAGNOSIS OF PARKINSONISM

In this chapter, the most common parkinsonian syndromes are discussed briefly. All are characterized by a limited or absent response to levodopa and a more rapid course than PD. *Progressive supranuclear palsy* is further distinguished from PD by early falls, vertical ophthalmoparesis, including down gaze, greater axial (neck and trunk) than appendicular rigidity, and early dysphagia. *Multisystem atrophy*, comes in three overlapping forms, all of which include at least two of the following: autonomic dysfunction, parkinsonism, cerebellar, or pyramidal signs. Today, the umbrella term multisystem atrophy is preferred, but older names still survive. When parkinsonism predominates, it is referred to as *striatonigral degeneration*; when combined with dysautonomia, it is the *Shy-Drager syndrome*; and *olivopontocerebellar*

degeneration is the moniker used when cerebellar and pyramidal signs are dominant.

Corticobasal degeneration is recognized by the onset of unilateral dystonia or a “useless” (alien) limb, combined with parietal signs, parkinsonian features, and myoclonus. *Lewy body dementia* can be considered an overlap between PD and Alzheimer’s disease with the more-or-less simultaneous onset of dementia and symmetric parkinsonism, with early hallucinations and delusions. This can be difficult to distinguish from *Alzheimer’s disease*, which is often accompanied by parkinsonian features.

MANAGEMENT

A full discussion of the complexities of treating PD is beyond the scope of this chapter, but some general guidelines are presented. The pharmacologic treatment of PD follows directly from the pathologic finding of dopamine depletion. Almost all the current therapies are directed at either directly or indirectly increasing dopamine in the striatum.

Before commencing therapy, patients need extensive education about the disease and reassurance that the prognosis is likely to be better than they have imagined. Today, with treatment, most people with PD can have a normal life expectancy and, with some limitation, generally lead a fairly good lifestyle. Some people with PD do have a poor prognosis, but this tends to be the exception rather than the rule. Patients should also be counseled that the goal of treatment is not to alleviate all the symptoms and signs of PD and restore them to a normal level of functioning, but instead to improve the symptoms and allow them to function at an acceptable level.

The initial step in pharmacologic management is to decide whether symptomatic treatment is necessary; this is determined by the level of activities of daily living (ADLs). If little or no compromise exists, for instance, when PD begins with the nondominant hand, there are three possibilities. The first is to withhold treatment and simply follow along until there is compromise in functioning. The second option for the minimally symptomatic patient, is to consider selegiline, a monoamine oxidase-b inhibitor, for its potential, although controversial, neuroprotective effect. Although selegiline has been shown to delay the time before treatment with levodopa is required, it is no longer clear whether this effect is due to an asymptomatic protective effect on the death of nigral neurons, rather than to its ability to improve the symptoms of PD itself. Because selegiline is very safe, some patients may want to use it despite general skepticism today about its role as a neuroprotective agent. The third option is to refer the patient to a center specializing in PD, since most centers are conducting trials of symptomatic and neuroprotective therapies for patients with early PD.

For the patient who is compromised by the symptoms of PD, the next decision is whether to use levodopa, the mainstay of treatment for PD. However, because of its eventual emergence of treatment-related fluctuations and other problems, the general trend today is to withhold levodopa until significant compromise of the activities of daily living exists. Until that point, there are three treatment options. The first is an anticholinergic, such as trihexyphenidyl (Artane) or benztropine (Cogentin). These agents may be slightly more effective for tremor but do help other features of PD as well. Side effects include dry mouth, constipation, blurred vision, urinary retention, and impaired concentration and memory. Because such side effects increase with age, these agents are generally reserved for patients with tremor-predominant PD who are younger than age 65.

Another option is the antiviral agent, amantadine. Given its anticholinergic side effects, it should also be used cautiously in elderly patients. Amantadine may also cause livedo reticularis, which is not a contraindication to continuing therapy. Recent evidence shows that amantadine may also be helpful for reducing dopa-induced dyskinesias and, as such, there is growing, although cautious, enthusiasm for its use as an adjunct in advanced PD.

The general trend today for the mildly symptomatic patient is to begin treatment with a dopamine agonist. These include bromocriptine and pergolide, as well as the newer, nonergot agents, pramipexole and ropinerole. Although their symptomatic effect is somewhat less than levodopa, they have the potential advantage of delaying the use of levodopa. The more traditional and still important role for agonists, is as an adjunct to levodopa in the middle to later stages of PD.

All patients with PD eventually require treatment with levodopa. This is combined with a decarboxylase inhibitor such as carbidopa to increase absorption into the brain and reduce nausea. Since at least 75 mg per day of carbidopa is required to inhibit dopa-decarboxylase, the 25/100 preparation is usually preferred. The first number refers to the milligrams of carbidopa and the second to the milligrams of levodopa. This is started at a low dose of ½ or 1 tablet per day and escalated gradually using the clinical response as a guide. Most patients improve with 300 mg of levodopa per day. The dose is increased gradually to keep the patient functioning at an acceptable level. The usual approach today is to keep the dosage of levodopa at a modest level, between 600 and 1,000 mg per day, with the early introduction of a dopamine agonist. An alternative therapy to enhance the effectiveness of levodopa and specifically to increase its duration of action, is tolcapone, a catechol O-methyltransferase inhibitor.

During the first 5 years of therapy, most patients with PD experience only mild compromise in their activities of daily living. Thereafter, management becomes more difficult, although there is tremendous variability from patient to patient. With time, the effectiveness of levodopa wanes, but virtually never completely wears off. Some of the most problematic features that emerge with advanced disease do not respond to levodopa, such as impaired postural righting reflexes, falls, akinesia, and dysphagia. Furthermore, the initial smooth response to levodopa begins to be punctuated by motor fluctuations that are initially predictable, such as the reappearance of parkinsonian signs before the next dose, known as end-of-dose wearing off. With time, however, predictable motor fluctuations become admixed with or give way to unpredictable fluctuations (on-off effect) with the appearance of unwanted involuntary movements, known as *dyskinesias*. At this point, the management of PD should be overseen by a specialist.

In addition to the motor complications and response fluctuations that complicate advanced PD, many patients also experience psychological complications. In addition to dementia, as previously mentioned, this also includes acute confusion, hallucinations, and delusions. These can often be managed with a reduction or discontinuation of antiparkinsonian medications, and when that is ineffective, use of one of the new atypical antipsychotic agents, such as clozapine. Traditional antipsychotic agents should be avoided because of their dopamine-blocking activity with the potential to worsen parkinsonism.

SURGICAL THERAPY

With the advent of levodopa in the 1960s, surgical treatment for PD largely fell out of favor. Yet, it is now experiencing a renaissance as a result of drug-resistant treatment complications seen with advanced disease, a better understanding of the pathophysiology of PD, and refinements in surgical and radiographic techniques. For the small percentage of patients with a disabling, medically refractory tremor, options include either thalamotomy or deep brain stimulation of the motor thalamus. For other features of advanced disease, particularly motor fluctuations and dyskinesias, options include either lesioning or deep brain stimulation of the internal segment of the globus pallidus or subthalamic nucleus. Implantation of fetal nigral tissue has demonstrated promising results but is still considered experimental.

PARKINSONIAN DEMENTIAS

DIFFUSE LEWY BODY DEMENTIA

Some elderly present with combinations of parkinsonism and dementia. In some, this is a variant of AD, whereas in others, this is a distinctive parkinsonian–dementia syndrome. Some researchers have coined the term “diffuse Lewy body dementia” (DLBD) to describe these patients. With DLBD, the acute onset of delirium with visual hallucinations is a common mode of presentation, and dopamine agonists or anticholinergics can precipitate or exacerbate DLBD. Often, autopsy shows plaques, but few neurofibrillary tangles. Lewy bodies are found throughout the cortex. The substantia nigra loses dopaminergic cells, and basal forebrain cholinergic cells are similarly depleted. Treatment is difficult because dopamine agonists can exacerbate hallucinations. However, recent work suggests that anticholinesterases can ameliorate the psychiatric symptoms associated with this disorder.

HUNTINGTON'S DISEASE

Patients with this autosomal dominantly inherited disease manifest dementia, chorea, and psychiatric symptoms ([Chapter 418](#)).

PROGRESSIVE SUPRANUCLEAR PALSY

Progressive supranuclear palsy is an idiopathic disorder characterized by frequent falling, axial rigidity, supranuclear gaze palsy, dysphagia, and frontal deficits. The pathologic process is localized to the midbrain, where gliosis and neurofibrillary tangles occur. Like the frontotemporal dementias, the pathology of this disorder has been increasingly linked to τ .

CORTICOBASAL DEGENERATION

This disorder is associated with a combination of focal parietal and focal basal ganglia deficits. Unlike the other degenerative dementias, focal motor and sensory deficits are common, even early in the course of the illness. Alien hand, severe apraxia, and visuoconstructive deficits are common. Focal dystonias emerge, as does generalized parkinsonism. The pathology overlaps with what is seen in frontotemporal dementia, and marked gliosis, abnormal neuronal inclusions, and accumulations of τ are seen.

NONDEGENERATIVE DEMENTIAS

MULTI-INFARCT DEMENTIA

MID is an etiologically and anatomically diverse group of disorders caused by brain infarction. Hypertension, heart disease, family history, hypercholesterolemia, cocaine abuse, and smoking are risk factors. Carotid and cardiac emboli, arterial or venous thrombosis, and vasculitis cause MID. Patients with multiple cortical embolic infarcts have an abrupt or stepwise deterioration; focal neurologic symptoms and signs are present. Mental slowing, pseudobulbar affect and dysphagia, shuffling gait, urinary incontinence, and bilateral motor abnormalities are hallmark findings of MID. In patients with subcortical white matter or lacunar infarctions, a progressive deterioration in cognition without focal deficits can occur. Infarcts on CT or MRI are necessary for a diagnosis of MID. Typically, patients show at least 100 mL³ of infarcted tissue, although “critical infarcts” in a single location like the left angular gyrus are more likely to produce a dementia syndrome than are similarly sized strokes in other brain locations. Many patients diagnosed with MID have AD or a mixture of AD and MID at autopsy. With diagnosis, the stroke mechanism must be determined to prevent further injury. Treatment with aspirin or ticlopidine can preserve function.

NORMAL-PRESSURE HYDROCEPHALUS

Normal-pressure hydrocephalus causes the triad of memory loss, gait disturbance, and urinary incontinence. Apathetic frontal syndromes are common. Prior subarachnoid hemorrhage or meningitis predispose to normal-pressure hydrocephalus by altering cerebrospinal fluid absorption; yet most cases are idiopathic. The pathophysiology of normal-pressure hydrocephalus is poorly understood. MRI shows periventricular edema and ventricular enlargement. Some diagnosed with normal-pressure hydrocephalus have MID or AD, and even when patients are well selected for surgery, many do not respond.

METABOLIC/TOXIC CAUSES

Anemia, electrolyte abnormalities, hypothyroidism, vitamin B₁₂ deficiency, and medications should be considered potential causes for dementia. Adult-onset variants of metachromatic leukodystrophy should be considered in dementia patients with white matter lesions. Defects in mitochondrial metabolism lead to a group of disorders, *mitochondrial encephalopathies*, in which muscle dysfunction, dementia, myoclonic epilepsy, or parkinsonism occurs. Two variants are MELAS (mitochondrial encephalopathy, lactic acidosis, and stroke) and MERFF (myoclonic epilepsy, ophthalmoplegia, and myopathy [ragged red fibers]).

INFECTIONS/PRION DISEASES

The most common infectious cause of dementia is the AIDS ([Chapter 344](#)). Neurosyphilis, now rare, causes dementia with cerebrospinal fluid pleocytosis, or Argyll–Robertson pupils. Dementia is rare with infectious meningitides but does occur with Lyme disease or fungal meningitis. In patients with dementia, diarrhea, or arthritis, Whipple's disease should be considered. It is caused by infection with periodic acid-Schiff–positive organisms and is responsive to antibiotics. Jakob–Creutzfeldt disease, kuru, and Gerstmann–Straussler–Scheinker syndrome are diverse disorders with genetic or infectious transmission modes. Like the animal disease scrapie, infections/prion diseases are caused by the accumulation of prion proteins in the brain ([Chapter 446](#)). Jakob–Creutzfeldt disease causes a rapidly progressive dementia, extrapyramidal findings, and myoclonus, although some cases are slowly progressive.

TRAUMA

Multifocal deficits characterize trauma. Frontal and temporal regions are particularly vulnerable and delayed normal-pressure hydrocephalus or subdural hematoma can follow head injury.

TUMOR

Tumors can lead to symptoms suggestive of dementia, which is why an imaging test such as CT or MRI should be performed in the setting of dementia.

CHAPTER 436: CEREBELLAR DEGENERATION

GING-YUEK ROBIN HSIUNG AND OKSANA SUCHOWERSKY

[Anatomy and Physiology](#)
[Clinical Findings](#)

ANATOMY AND PHYSIOLOGY

The cerebellum and its connections are involved in the maintenance of muscle tone, equilibrium, and coordination of voluntary movement. This is accomplished by receiving inputs from the spinal cord, brain-stem nuclei, and motor cortex and sending efferents back to these structures.

Structurally, the cerebellum is composed of cortex, white matter, and deep nuclei. The cerebellar cortex consists of three layers: molecular, Purkinje, and granular. All afferent fibers, which synapse on one or more of these layers, are of two main types: (1) mossy fibers, originating in the spinocerebellar tracts and brain-stem nuclei and projecting to the granule cell layer, and (2) climbing fibers, originating in the inferior olivary nucleus and projecting to Purkinje's cells. Dopaminergic and serotonergic fibers also arise in brain-stem nuclei and project to Purkinje's and granule cells. Efferents from the cerebellar cortex consist entirely of axons of Purkinje's cells projecting to the deep cerebellar nuclei—the dentate, fastigial, globose, and emboliform (interposed)—and project through the superior cerebellar peduncle to the contralateral motor cortex by way of the thalamus. The fastigial nucleus sends fibers to the vestibular nuclei, other brain-stem nuclei, and spinal cord neurons. All efferent Purkinje fibers are inhibitory, using g-aminobutyric acid, whereas fibers projecting from the deep nuclei are excitatory. Cortical interneurons consisting of basket cells, stellate cells, and Golgi cells modulate the activity of afferent fibers and Purkinje's cells.

Anatomically, the cerebellum is divided by fissures into anterior, posterior, and flocculonodular lobes. However, a functional division dividing the cerebellum longitudinally is much more useful clinically:

1. The flocculonodular lobe is phylogenetically the oldest structure and is involved in control of equilibrium. It receives afferent impulses from the vestibular nuclei and projects primarily back to the vestibular system.
2. The midline zone, composed of the vermis, is located medially in the cerebellum and projects to the fastigial nuclei. It is involved in control of gait; lesions result in poor balance and wide-based, staggering gait.
3. The intermediate zone, composed of the paravermal area and projecting to the interposed nuclei, controls limb postures and tone.
4. The lateral zone, composed of the cerebellar hemispheres, projects to the dentate nuclei. Dysfunction results in ipsilateral limb incoordination with dysmetria, dysdiadochokinesis, intention tremor, dysarthria, and eye movement abnormalities.

CLINICAL FINDINGS

Signs of cerebellar disease include wide-based gait ataxia, dysarthria, dysphagia, intention tremor, dysmetria, past-pointing, dysdiadochokinesis, and eye movement abnormalities such as nystagmus and ocular dysmetria. The particular combination of signs depends on extent and location of dysfunction (e.g., lesions involving the midline structures result in a disorder of gait, whereas those in the hemisphere result in limb ataxia). It is also important to differentiate ataxia due to noncerebellar disorders, such as sensory ataxia of peripheral neuropathy ([Chapter 429](#)) and apraxic gait ataxia of normal-pressure hydrocephalus. A large number of medical conditions can result in cerebellar degeneration ([Table 436.1](#)). Only primary genetic or idiopathic forms that result in slowly progressive ataxia are discussed in this chapter. Classification of cerebellar degenerations had been confusing in the past and was predominantly based on pathologic or phenotypic presentations. With advances in molecular research, the genetic classification is becoming clearer. However, it is still convenient to approach the problem with classification by the age of onset ([Table 436.2](#)).

Endocrine/metabolic
Hypothyroidism
Hyperparathyroidism

Cyclosporine
Toluene

TABLE 436.1. SOME CAUSES OF SECONDARY CEREBELLAR DEGENERATION

Condition	Mode of inheritance
Predominant Childhood Onset	
Friedreich's ataxia	Autosomal recessive
Ataxia telangiectasia	Autosomal recessive
Keroidema pigmentosum	Autosomal recessive
Ataxia polyneuritis	Autosomal recessive
Leukodystrophies	Autosomal recessive or X-linked
Refsum's disease	Autosomal recessive
Storage diseases (i.e., GM ₁ gangliosidosis, sphingomyelinase deficiency)	Autosomal recessive
Inborn errors of metabolism (i.e., Hartnup disease, maple syrup urine disease, phenylketonuria, type I)	Most are autosomal recessive
Predominant Adult Onset	
AICA (i.e., SCA 1, SCA 4)	Autosomal dominant
AICA II (SCA 5, SCA 6)	Autosomal dominant
AICA III (SCA 7)	Autosomal dominant
Dentatorubralpallidum degeneration	Autosomal dominant
Cerebellar atrophy	Autosomal dominant
Cerebellar atrophy—Schönberg disease	Sporadic (not genetic)
Cerebellar atrophy—idiopathic	Sporadic (not genetic)
Idiopathic	Mitochondrial
Neurodegeneration with iron metabolism defects	Sporadic (not genetic)

TABLE 436.2. CLASSIFICATION OF PRIMARY CEREBELLAR DEGENERATION BY AGE OF ONSET

PREDOMINANTLY CHILDHOOD ONSET

Friedreich's ataxia is the most common cause of progressive ataxia in childhood with autosomal recessive inheritance. The classic syndrome manifests in prepubertal children with gait ataxia, dysarthria, lower limb areflexia, and proprioceptive sensory loss. Nystagmus and extensor plantar responses are also seen. In later stages, the patient cannot walk and has gross limb ataxia and weakness, head tremor, incomprehensible speech, and ataxic respiration. Cognitive abilities are preserved, but emotional lability may be present. Cardiomyopathy is seen in at least 50% of cases, resulting in arrhythmia or congestive failure. Ten percent have insulin-dependent diabetes. Death usually occurs in the third or fourth decades of life. With genetic testing now available, adult-onset Friedreich's ataxia is not uncommon. These atypical adult cases are usually less severe, may have retained reflexes or hyperreflexia, and progress more slowly. Pathologically, degeneration is seen in the posterior columns, corticospinal tracts, spinocerebellar tracts, peripheral nerves and nuclei of cranial nerves VII, X, XII, and myocardial muscle fibers. The genetic defect is an expanded GAA trinucleotide repeat in the first intron of the X25 gene on chromosome 9. The protein product, named *frataxin*, is believed to be a

mitochondrial protein, and its deletion may lead to accumulation of iron in the mitochondria, compromising mitochondrial function.

Abetalipoproteinemia (also known as Bassen–Kornzweig syndrome) is a disorder of lipid metabolism transmitted by autosomal recessive inheritance. Apolipoprotein B, which is essential for synthesis and transport of low-density lipoproteins and very-low-density lipoproteins, is absent from the serum resulting in malabsorption of fat-soluble vitamins. Steatorrhea is present early in life, and cerebellar ataxia develops in the first or second decade of life with loss of tendon reflexes. Proprioceptive loss in hands and feet appear later, whereas pinprick and temperature are mildly reduced. The sensory changes are a result of demyelination in the posterior columns and the peripheral nerves. Diagnosis is made by presence of acanthocytes in the peripheral blood smear and absent serum betalipoprotein. Treatment with vitamin A and E supplementation may slow down the development of neurologic sequelae and reverse the neuropathy.

Ataxia-telangiectasia, *xeroderma pigmentosum* and *Cockayne syndrome* all may present as cerebellar ataxia and are all thought to result from defective DNA repair.

PREDOMINANT ADULT-ONSET ATAXIA

Autosomal dominant cerebellar ataxias (ADCA) are a heterogeneous group of disorders described by Harding based on clinical features. Currently, at least eight genotypes of spinocerebellar ataxias (SCA) have been identified, which fit into this category. SCA 1, 2, 3, 6, and 7 are due to CAG repeat expansions within the protein coding region of the gene that encodes an expanded polyglutamine region in the disease protein. Paternal anticipation is present, resulting in disease being more severe with earlier onset when it is inherited from the father. SCA 8 has recently been identified as a CTG repeat expansion in the noncoding region of the gene.

In ADCA type 1 (SCA 1, 2, 3, 4, 8), there is progressive gait ataxia, dysphagia, dysarthria, and variable degree of ophthalmoplegia, extrapyramidal signs, dementia, optic atrophy, amyotrophy, and peripheral neuropathy. Significant overlap of symptoms is present, making it difficult to distinguish the SCAs clinically. In all the SCAs, cerebellar and brain-stem atrophy may be seen on brain imaging. Pathologically, prominent atrophy of the cerebellum and pons with loss of Purkinje's cells is found. A variable amount of atrophy is found in the inferior olivary nucleus, brain-stem nuclei, basal ganglia, dorsal columns and pyramidal tracts of the spinal cord, and the peripheral nerves. The cerebral cortex is usually spared.

ADCA type 2 (SCA 7) is characterized by ataxia with retinal degeneration.

ADCA type 3 (SCA 5, 6) is characterized by a pure cerebellar syndrome, although some patients at a late stage may show pyramidal and peripheral signs. The genetic defect of SCA 5 is unknown. SCA 6 is due to a CAG expansion in the gene encoding a voltage-sensitive P/Q type calcium channel on chromosome 19. It is interesting that point mutations in the same gene may lead to episodic ataxia type 2 and familial hemiplegic migraine.

Up to 40% of patients with a clinical syndrome of ADCA type 1 do not have the latter mutations; type 1 probably represents other forms of SCAs yet to be identified. Other sporadic cases may be autosomal recessive cases or may represent new mutations. *Multiple-system atrophy* is a sporadic neurodegenerative disease that may manifest as a predominant olivopontocerebellar atrophy syndrome.

No satisfactory treatment is available for any of the adult-onset cerebellar ataxias.

CHAPTER 437: AMYOTROPHIC LATERAL SCLEROSIS

ANDREA M. CORSE

[Presentation](#)
[Pathophysiology](#)
[History and Physical Examination](#)
[Laboratory Studies and Diagnostic Tests](#)
[Strategies for Optimal Care](#)

Motor neuron diseases are a group of sporadic or, rarely, inherited neurodegenerative disorders characterized by progressive paralysis. *Amyotrophic lateral sclerosis* (ALS), the most common motor neuron disease, involves both upper and lower motor neuron symptoms and signs. Other motor neuron diseases include *primary lateral sclerosis* with symptoms and signs limited to upper motor neuron dysfunction and progressive *spinal muscular atrophy* (SMA), which includes strictly lower motor neuron disorders.

ALS affects primarily adults of all ages with a mean age of onset in the sixth decade. The incidence is 1 or 2 per 100,000. Roughly 35,000 persons have ALS in the United States. It is slightly more common in men with a male to female ratio of 1.5:1.

PRESENTATION

The clinical presentation of ALS can be very different among patients, making early diagnosis difficult. Patients can present with upper or lower motor neuron symptoms involving bulbar or limb musculature. Presenting symptoms are as varied as hoarseness, difficulty turning a key or buttoning buttons, or foot drop. Other symptoms might include dysarthria, dysphagia, atrophy in the limbs, fasciculations, cramps, or gait instability. The limb weakness is typically painless and asymmetric. Early involvement of the small muscles of the hand is frequently seen, and atrophy may be apparent before functional loss is recognized. Bulbar onset occurs about 10% of the time, more often in women than men. Rarely, ALS can present as respiratory insufficiency. Control of bladder and bowel function, as well as other autonomic activities, usually is spared, as are the extraocular movements. The presence of any sensory symptoms or signs that cannot be explained on the basis of a coexistent condition, such as unrelated neuropathy, should cast doubt on the diagnosis of ALS.

By far most ALS cases are sporadic, and no definite risk factors have been identified other than age. Age-specific incidence rises with age. Roughly 5% to 10% of ALS cases are inherited as an autosomal dominant trait, so-called familial ALS (FALS). Generally, FALS cases are clinically indistinguishable from sporadic cases.

PATHOPHYSIOLOGY

The pathogenesis of ALS is unknown. However, a mutation in the Cu/Zn superoxide dismutase 1 gene on chromosome 21 has been identified in a small percentage of FALS families. The lack of this gene defect in most FALS families indicates that there is genetic heterogeneity among FALS cases. This has led to increased enthusiasm for multifactorial theories of pathogenesis in familial and sporadic ALS related to oxidative injury and excitotoxicity. Other theories include immune-mediated pathogenesises.

The most prominent neuropathologic change is anterior horn cell loss: the remaining motor neurons appear small and pyknotic. There is degeneration of the lateral corticospinal tract and atrophy of ventral but not dorsal spinal roots. In the brain, the motor and premotor cortex are mildly atrophic, and the number of Betz cells is reduced. Lesser neuron loss also occurs more generally throughout the brain. In the brain stem, motor neuron loss occurs especially in the facial and hypoglossal nuclei. There may be very late involvement of the oculomotor and sacral motor nuclei only in patients who have survived long-term with ventilation. Studies have also demonstrated ubiquitin-positive inclusions and proximal neurofilamentous axonal swellings in anterior horn motor neurons primarily. Motor nerves show axonal degeneration with reduced numbers of large myelinated fibers, and skeletal muscle reveals neurogenic atrophy.

HISTORY AND PHYSICAL EXAMINATION

The diagnosis is based on the history and examination, which must demonstrate progressive upper and lower motor neuron involvement in at least three body regions (bulbar, cervical, thoracic, or lumbosacral) for definite ALS or in two regions for probable ALS, according to the World Federation of Neurology criteria. Upper motor neuron signs include spasticity, hyperreflexia, and Babinski responses; lower motor neuron signs include weakness, wasting, hyporeflexia, and fasciculations.

ALS is typically a relentlessly progressive disease with a mean survival of 3 to 5 years. Shorter survival correlates with bulbar symptoms, older age, respiratory involvement, and rapid course. The rate of disease progression is, however, highly variable among patients. In an individual patient, the rate of progression tends to be fairly linear such that the course is best predicted by the rate of change over the preceding months.

The relative contribution of upper motor neuron and lower motor neuron involvement is also widely variable among patients with ALS and other motor neuron diseases. At one extreme is primary lateral sclerosis, a rare disorder in which the degenerative process is confined to the upper motor neuron and corticospinal tracts. At the other extreme is progressive SMA, in which the neurodegeneration is limited to the lower motor neurons. In contrast to ALS, both primary lateral sclerosis and progressive SMA are typified by a more chronic, insidiously progressive course, and the limbs are predominantly affected. However, distinguishing these disorders from ALS is not always possible early in their course, since ALS can present with *isolated* upper or lower motor neuron signs for up to 2 years or more. The relation between ALS and these other forms of motor neuron disease remains to be clarified.

In patients who present with bulbar symptoms alone, there is typically a combination of both upper and lower motor neuron involvement. Some patients present with strictly upper motor neuron signs in the bulbar region, a condition termed *pseudobulbar palsy*. Such symptoms include spastic dysarthria, slow and weak tongue movements, and emotional lability (pseudobulbar affect). In contrast, a presentation with strictly lower motor neuron brain-stem signs is termed *progressive bulbar palsy*, manifested clinically by slurred speech, tongue atrophy and fasciculations, and swallowing difficulties. Generally these conditions will progress to ALS within 2 years or, rarely, longer.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

ALS has no specific biochemical features. The serum creatine kinase level can be elevated, although not usually more than 1,000 IU per liter. The cerebrospinal fluid is normocellular with normal or mildly elevated protein levels. A cerebrospinal fluid protein over 70 mg% increases the likelihood of myeloma or lymphoma; more than 100 mg% is virtually unheard of. Electromyographic examination reveals acute denervation potentials (fasciculations, fibrillation potentials, and positive sharp waves) together with chronic reinnervation, as shown by motor units with increased durations and reduced recruitment. Imaging of the neuroaxis is critical to rule out disorders that could mimic ALS.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis can be broad at the time of the initial presentation but becomes increasingly limited as the disease progresses. Magnetic resonance imaging of the brain and spine excludes a number of disorders that could mimic motor neuron disease, that is, spinal arteriovenous malformation, syringomyelia or syringobulbia, ischemic or demyelinating disease, tumor, or spondylotic myelopathy with polyradiculopathies. The finding of a hyperactive jaw jerk on examination is particularly helpful in this regard, suggesting upper motor neuron involvement that cannot be explained by a cervical myelopathy alone.

In cases with predominantly lower motor neuron signs and equivocal upper motor neuron involvement, an acellular cerebrospinal fluid excludes polyradiculopathies due to malignancies or other meningitides. Multifocal motor neuropathy can be investigated with nerve conduction studies directed at identifying partial motor conduction block and features of multifocal demyelination and with serologic testing for antiganglioside antibodies. There are also familial forms of progressive SMA, including autosomal recessive and sex-linked diseases to consider. In addition to *SMA type I* (Werdnig—Hoffmann disease), the infantile autosomal recessive form in which death occurs before the age of 3 years, both juvenile *SMA type II* and adult-onset *SMA type III* have been described. Some patients with progressive SMA have

been found to have a deficiency of hexosaminidase A, which is also inherited as an autosomal recessive trait. A sex-linked form of adult-onset SMA with gynecomastia and reduced fertility (*Kennedy's syndrome*) is associated with abnormalities in the androgen receptor gene, with increased numbers of tandem trinucleotide repeats in the coding region of the gene.

Other diseases that can occasionally mimic a motor neuron disease–like syndrome and cause confusion include autoimmune myopathies (polymyositis, dermatomyositis, or inclusion body myopathy); autoimmune neuropathy (chronic inflammatory demyelinating polyneuropathy); myasthenia gravis; postpolio amyotrophy; endocrinologic disorders (hyperthyroidism or hyperparathyroidism, diabetic amyotrophy); heavy metal intoxications (lead or mercury); postradiation or paraneoplastic motor neuronopathies (most commonly reported with lymphoma); and rare familial spastic paraplegias.

STRATEGIES FOR OPTIMAL CARE

In the absence of a cure, treatment of ALS is directed at slowing disease progression, enhancing muscle strength, and specific multimodality symptom management. Riluzole (Rilutek) is the only medication approved specifically by the Food and Drug Administration for the treatment of ALS. It is an antiglutamate agent proven to prolong survival in ALS to a marginal degree (on the order of months). It appears to be well tolerated and safe. Liver transaminase levels should be checked periodically, since a reversible chemical hepatitis has rarely been reported. A disadvantage of riluzole is its expense; however, the drug manufacturer Rhone-Poulenc Rorer in cooperation with the National Organization for Rare Diseases provides the drug at reduced cost, depending on a financial needs assessment. Gabapentin (Neurontin), originally approved as an anticonvulsant and available by prescription, is another antiglutamate agent that may slow the rate of decline in strength in ALS based on preliminary clinical trial data.

Numerous clinical trials are ongoing for potential new therapies in ALS. A list of trials is available from the Amyotrophic Lateral Sclerosis Association and the Muscular Dystrophy Association. Providing a patient with such clinical trial information gives the patient the added sense of accessibility to the ongoing efforts of clinicians and scientists involved in the search for the cause and a cure for ALS.

Recent data suggest that the over-the-counter bioenergetic supplement creatine monohydrate (5 g daily) enhances creatine phosphate levels and may improve strength to a minor degree in a number of neuromuscular disorders. Many patients combine riluzole, gabapentin, and creatine, although data on combination therapy are lacking.

Symptomatic management is predominantly directed at the dysarthria, dysphagia with sialorrhea, spasticity, and respiratory insufficiency. In patients with dysarthria, consultation with a speech consultant who has expertise in a wide range of communication devices is recommended relatively early because some devices may take months to obtain. Swallowing function can be enhanced with specific dietary recommendations and head positioning technique. Gastrostomy tube (G-tube) placement is particularly beneficial in patients in whom bulbar dysfunction is affected out of proportion to limb function. For sialorrhea, glycopyrrolate (Robinul) is a very effective drying agent without central nervous system side effects. Alternatively, a scopolamine patch may be preferred for its ease of administration. Tricyclic antidepressants can be useful in minimizing the emotional incontinence typical of pseudobulbar affect while also reducing sialorrhea, although their other side effects can be dose-limiting.

As respiratory involvement progresses, periodic discussions regarding long-term ventilatory options and advanced directives are a logical progression and are essential. Many patients appear to benefit from noninvasive respiratory assistance (e.g., nasal BiPAP [bilevel positive airway pressure] at night) for treatment of dyspnea or as a “bridge” to mechanical ventilation. Only about 4% of patients opt for tracheostomy and invasive mechanical ventilation. Coordinated care with a pulmonologist with expertise in neuromuscular diseases can be very helpful. Finally, hospice services have played an increasing role in the care of the terminal ALS patient in recent years, in many instances providing an invaluable resource and support structure enabling a patient to stay in the comfort of his or her home when it may not have previously been possible.

CHAPTER 438: HUNTINGTON'S DISEASE

MICHAEL R. HAYDEN AND BLAIR R. LEAVITT

[History](#)
[Epidemiology](#)
[Natural History](#)
[Clinical Findings](#)
[The Gene Defect and Pathogenesis of Huntington's Disease](#)
[Predictive Testing](#)
[Special Investigations](#)
[Optimal Management](#)

HISTORY

George Huntington was only 8 years old when he first observed patients with Huntington's disease (HD) as he rode with his father on his professional rounds around East Hampton, Long Island, between 1885 and 1870. At age 21, he presented his paper on chorea, which appeared in the *Medical and Surgical Reporter* in Philadelphia on April 13, 1872. The name Huntington quickly gained acceptance as the eponymic designation of the disorder.

EPIDEMIOLOGY

The prevalence of HD in populations of northwestern European ancestry is approximately 1 in 10,000. There is no decrease in the reproductive fitness of people with HD. There is a 10-fold reduced prevalence rate for HD in people of Japanese, Chinese, and African black descent.

NATURAL HISTORY

The mean age at onset is about 40 years, with considerable distribution around this mean. About 5% of affected people have onset of symptoms before age 20, and 5% have onset after age 60 years. Onset of HD symptoms in the 10th decade has been recorded. The likelihood of having inherited the gene for HD in an asymptomatic person at risk decreases from 50% at birth to about 40% at age 40, 25% at 50, 15% at 60, and 2% at 70 years.

The duration of HD varies between 14 and 18 years. Patients whose onset is before age 20 years usually have a more rapidly progressive course, with mean duration around 12 years. The most common cause of death is pneumonia secondary to aspiration after difficulties with swallowing.

CLINICAL FINDINGS

The clinical diagnosis of HD depends on establishing a positive family history for the disorder and on a detailed neurologic assessment. The clinical diagnosis can be confirmed by diagnostic testing for the gene mutation causing HD. The cardinal clinical features of HD are abnormal involuntary movements associated with cognitive impairment, but disorders of voluntary movements often precede the choreiform disorder. Furthermore, affective disorders and frank psychosis may also herald the onset of HD. This broad spectrum of clinical features may result in misdiagnosis in the early stages of the illness.

SIGNS AND SYMPTOMS

Close questioning of the spouse of a patient with HD frequently reveals that the disease presents as subtle mental changes, including irritability, irascibility, impulsiveness, and depression. In the earliest phases, before frank chorea, significant alterations in voluntary movements are common. Impairment of eye movements with impairment of pursuit movements and slow saccades are common. Many people with early signs of HD are unable to keep their tongue protruded for 10 seconds without choreiform movements. Rapid alternating movements of the hands can also be impaired. Some patients also have arrhythmic speech and are unable to repeat sounds such as "la-la-la" with fluency. Tandem walking may evoke mild ataxic movements. Although signs may be minimal, an obvious disturbance of functional ability may be present. As the disease progresses, the single most common complaint is jerkiness, clumsiness, or mild uncoordination. Chorea becomes obviously apparent in most patients and progresses inexorably with eventual ceaseless writhing, jerking, and twisting. Usually, the face, trunk, and extremities are affected, although to varying degrees.

Facial features are common and present a typical appearance with pouting of the lips, together with twitching of the cheeks and irregular elevation of the eyebrows. When sitting, constant movement of the hands and legs is common. The legs are alternatively crossed and uncrossed. In contrast to other choreiform movement disorders, the chorea in HD is usually slower and more athetoid.

Signs of increased muscle tone become more frequent as the disease progresses. In a small number of patients, hypertonicity with minimal choreiform movements may predominate. Pathologically, brisk reflexes occur in at least 50% of patients in the early years. Over the next decade, however, signs of pyramidal dysfunction, including hyperreflexia, extensor plantar responses, and clonus, become more prominent. Bradykinesia with a masklike facies and a positive glabellar reflex are also more common with longer duration. There is a progressive evolution toward a rigid state. Dystonic posturing is a common sign, usually affecting the hands, head, and trunk.

Slowness of speech occurs early. Eventually, gross disorganization of speech and finally mutism supervene. Dysphagia is a late sign and occurs in patients with predominant chorea or rigidity.

The gait is characteristic. At rest, patients stand on a broad base, and involuntary movements are contained. On walking, the patient has an increasing unsteadiness, and walking is characterized by large lateral deviations from the midline and precipitous advances. Tandem walking becomes difficult. In the terminal years of the illness, incontinence of urine and, later, feces is common.

A striking disparity exists between the features of HD in children and adults, with particular regard to motor abnormalities, rate of progression, and occurrence of epilepsy. Juvenile-onset HD, a rapidly progressive form of the disease sometimes termed the Westphal variant of HD, occurs in about 5% of patients who have a predominantly akinetic-rigid presentation with spasticity, bradykinesia, dystonia, and rapid intellectual decline often complicated by myoclonus and seizures. Chorea occurs early and usually is superseded by rigidity, which is the predominant abnormality in affected people younger than age 20 years. Intellectual deterioration with failure at school is a common presenting finding. Seizures occur in about one third of young people with HD, but with no increased frequency in adults. The earlier the time of onset, the more likely that rigidity will be the major neurologic feature.

In people older than 60 years of age, a milder disease is common, with less obvious chorea and mild intellectual dysfunction.

MENTAL DISTURBANCE

Depression in HD is common, as witnessed by the increased frequency in suicide. In the early phases, a limitation in acquiring new information is evident. With disease progression, spatial and arithmetic functions decrease and memory loss is common. Despite these focal cognitive deficits, perceptive functions remain relatively intact until late in the illness. Occasionally, a schizophreniform psychosis precedes or accompanies the neurologic features of HD. The psychosis is often characterized by paranoid features.

THE GENE DEFECT AND PATHOGENESIS OF HUNTINGTON'S DISEASE

The underlying genetic defect in HD is the expansion of a CAG trinucleotide repeat in the first exon of the HD gene that produces a functional protein with an expanded polyglutamine tract. The HD gene (*IT15*) comprises 67 exons and spans a genomic size of approximately 210 kb, with a predicted protein product of 348 kd.

The gene product, huntingtin, is ubiquitously expressed in tissues throughout the body. The CAG repeat, located in the 5' region of the HD gene, is highly polymorphic in the general population, ranging from 8 to 35 copies, with most (99%) having less than 30 repeats. In contrast, patients with HD have a trinucleotide repeat size ranging from 36 to 121, with a median of 44 repeats. An inverse relation exists between the CAG repeat size and the age of onset of HD (i.e., larger repeat expansions are associated with earlier age of onset).

Molecular analysis of sporadic cases of HD revealed that new mutations for HD are not as rare as previously thought. The length of the CAG repeat is unstable during vertical transmission of the gene from parent to child. Analysis of parental DNA of people who represent new mutations has identified intermediate alleles, which are CAG alleles with repeat size greater than that usually seen in the general population (more than 29), but less than the range seen in patients with HD (less than 36). These intermediate alleles may be unstable in passage through the male germline and, in sporadic cases, expand to the full mutation associated with the clinical phenotype of HD. These findings have significant genetic implications for family members of patients with sporadic HD. Larger CAG repeat sizes exhibit greater instability, and paternal transmission of the CAG repeat allele is more likely to result in expansion rather than contraction of the CAG repeat length. The unstable nature of the CAG expansion in HD provides the molecular basis for the clinical phenomenon of anticipation. Anticipation is defined as increasing severity of disease or decreasing age of onset of disease in successive generations.

These results further support the importance of the CAG repeat in the pathogenesis of HD. Likely, the expanded stretch of polyglutamine residues within huntingtin cause a toxic "gain of function" of the mutated protein, which modulates the selective neuronal cell death seen in this disease. Recent studies have implicated the formation of neuronal intranuclear inclusions (ubiquitinated aggregates containing truncated polyglutamine fragments) in the pathogenesis of HD and other CAG trinucleotide diseases. Transgenic mice expressing a small fragment of huntingtin with a very large CAG expansion develop neuronal intranuclear inclusions. Subsequent immunohistochemical analyses have demonstrated neuronal intranuclear inclusions in postmortem material from HD patients. In vitro models of HD demonstrated that cells transfected with mutant forms of huntingtin undergo cell death and also develop aggregates of truncated huntingtin. Despite the observed correlation of aggregates with neurodegeneration, it appears that aggregates may not play a causal role in the initiation of HD, but rather may be cellular markers for the generation of toxic protein fragments containing the polyglutamine residues.

Truncated huntingtin fragments containing expanded polyglutamine repeats are known to be toxic to neurons and N-terminal htt fragments can be identified in the brains of HD patients. Because small protein fragments containing an expanded polyglutamine are both particularly neurotoxic and prone to aggregation, proteolytic cleavage of the full-length huntingtin protein and generation of a toxic truncated product may be a critical step in neuropathology of HD the other CAG trinucleotide repeat diseases.

PREDICTIVE TESTING

The question for people at risk for HD is whether they will manifest signs and symptoms similar to those seen and diagnosed as HD in the parent. If the affected parent has an known expanded CAG repeat in the HD range, this confirms the family history of HD. Therefore, the presence or absence of the CAG expansion in the proband determines whether or not this person has inherited the mutation and whether or not he or she will develop the signs and symptoms of HD. If the affected person in the family does not show CAG expansion in the HD gene, then the disorder in this family, while phenotypically similar, is not HD. Failure to detect a CAG expansion in the proband in this case does not mean that HD-like symptoms will not develop in the future, and the person at risk may still have a 50% chance of developing the same illness as his or her parent.

Current recommendations for predictive testing include the provision of pretest and post-test counseling, the opportunity to withdraw from testing, the need for voluntary participation, and the recognition of the particular vulnerabilities of people presenting to a predictive testing program who are found to be symptomatic.

SPECIAL INVESTIGATIONS

The hallmark neuropathologic feature of HD seen at autopsy is early and selective neuronal loss in the caudate and putamen (striatum). The medium spiny neurons of the striatum are selectively vulnerable to neurodegeneration in HD, and this selective neuronal degeneration leads to loss of caudate volume and ventricular dilation during the course of the illness. Computed tomography often reveals caudate atrophy in patients with well-established signs and symptoms, but can be normal in early disease. Positron emission tomography with fluorodeoxyglucose is often abnormal early in the course of HD, even in patients without any evidence of caudate atrophy on computed tomography.

OPTIMAL MANAGEMENT

No therapy significantly alters the natural progression of HD. Nevertheless, numerous aspects of this disorder may be improved by appropriate intervention. In the early phases of HD, many depressed patients respond to antidepressant medication. As chorea increases, antidepressants with antidopaminergic effects may be helpful. Treatment of the movement disorder is best undertaken once the chorea significantly limits functional activity. Drugs such as haloperidol, tetrabenazine, or substituted benzamides such as sulpiride that act functionally to decrease dopaminergic effect can significantly reduce chorea. However, careful balancing of the risks of reduced mental activity versus decreased movements must be determined. Phenothiazines are indicated only in the presence of significant associated mental disturbance.

In the later phases of the illness, as the movements decrease as part of natural progression, it is often possible to reduce or stop medication. In severely handicapped patients, medication may actually exacerbate difficulties in swallowing and may best be discontinued.

The benzodiazepines are useful adjuncts in anxious patients. Rigidity may show mild improvement with administration of drugs such as baclofen, which moderate glutamate release. Most HD patients also benefit from physical, speech, and occupational therapy. Supportive counseling may be helpful. People at risk and the unaffected spouse often have significant problems that require specific interventions and support.

CHAPTER 439: CENTRAL NERVOUS SYSTEM POISONING

J. WILLIAM LANGSTON, IAN IRWIN AND SARAH A. JEWELL

[Metals](#)
[Industrial and Agricultural Chemicals](#)
[Drugs](#)

True neurotoxins are substances that are biologically elaborated (e.g., botulin and diphtheria toxin), in contrast to neurotoxicants, which are synthetic or naturally occurring substances. In this chapter, neurotoxicants that affect the central nervous system (CNS) as their primary target are discussed.

The clinical presentation after acute exposure to a neurotoxicant often differs from that induced by chronic exposure, and the effects of acute exposure are rarely restricted to the CNS. Although acute poisoning typically occurs as the result of accidental or deliberate (e.g., homicidal or suicidal) exposure to massive amounts of a substance, the abrupt onset of symptoms may also reflect chronic exposure that has finally resulted in sufficient body burden to produce sudden, sometimes life-threatening, symptoms. Chronic exposure to many CNS toxins, however, results in subtle or nonspecific neurobehavioral effects such as mood disorders.

Because neurotoxicants mimic the signs and symptoms of other diseases, they should always be considered in the differential diagnosis. When exposure to a neurotoxicant is suspected, evaluation should include a complete and detailed history and physical examination, along with a careful assessment of the work and home environment and a thorough social history. Laboratory investigations are required and may provide vital diagnostic clues. For example, radiologic evaluation may suggest heavy metal poisoning, as many metals (e.g., lead, mercury, thallium) are radiopaque and can be observed on abdominal radiography after ingestion. Poisons may also be detected in body fluids or in environmental samples. Ultimately, neuropathologic evaluation may be required to characterize the effects of a neurotoxicant. When exposure to unusual neurotoxic agents has occurred, clinical information resources may be inadequate or contradictory. In this case, animal toxicity studies can provide valuable information, although extrapolation to human illness can be difficult.

Many neurotoxicants exist in the environment, and only a few are discussed here. Identifying and eliminating exposure before irreversible damage is the essential theme in the treatment of all types of CNS toxicity.

METALS

Because of the importance of mining, metals are the earliest-recognized and most extensively studied of the neurotoxicants. With the advent of organic chemistry, many new metal compounds were created by combination with an organic moiety. The resulting increase in lipophilicity increased their access and hence toxicity to CNS structures.

LEAD

Lead is widely distributed in the environment. Industrial workers in smelting, storage battery, and paint factories have a great risk for exposure. Environmental sources of exposure include older building paints, ceramic cookware glazing, and solder; lead-containing fuels are increasingly restricted.

Absorption, Distribution, and Mechanism of Action

Ingestion and inhalation are the primary routes of absorption of lead. Intestinal lead absorption is influenced by particle size and chemical state and by host factors such as age (children will absorb more than five times more lead than adults) and nutrition (low dietary levels of calcium, iron, zinc, copper, and selenium and increased levels of vitamin D enhance the gastrointestinal absorption of lead). Absorbed lead is initially distributed to soft tissues. Its half-life in blood is 1 to 2 months, and it is excreted in the urine, with small amounts eliminated in sweat, hair, and breast milk. Soft-tissue lead is slowly redistributed to bone, a relatively inert compartment (half-life, 10 to 30 years) that represents more than 90% of the total body burden. Bone lead is nontoxic but is mobilized by low phosphate or high calcium intake. The toxicity derives primarily from lead's ability to bind protein sulfhydryl groups, such as those in heme synthetic enzymes.

Clinical Features and Laboratory Diagnosis

In adults, excessive exposure to lead (blood concentrations more than 50 to 100 μg per deciliter) can be accompanied by pallor, gingival lead line, and gastrointestinal, hematopoietic (anemia), renal, and neurologic symptoms, including peripheral neuropathy (e.g., wrist drop). The gravest CNS disorder is lead encephalopathy, with early signs of irritability, decreased alertness, loss of orientation, and lethargy. With severe intoxication, symptoms progress over hours or weeks to seizures, coma, and death. Signs attributable to increased intracranial pressure include papilledema, blindness, and seizures. Neuropathologic findings include cerebral edema with focal hemorrhages throughout the brain. Massive lymphocytic infiltration and microglial proliferation in cerebral and cerebellar cortices suggest a direct toxic action of lead.

Plumbism is confirmed in the laboratory by showing increased blood lead concentrations (more than 25 μg per deciliter should warn of possible toxic exposure in adults). Blood levels of heme precursors such as zinc protoporphyrin may be elevated. Urinary lead higher than 120 μg per 24 hours also indicates recent exposure. With chronic exposure, urinary levels may be within normal limits. Hair is rich in sulfhydryl groups, so the hair:blood ratios of lead are high. Large amounts of lead (and other metals) can be found in hair, making it possible to reconstruct a chronology of exposure based on a separated analysis of hair. Cerebrospinal fluid findings include an elevated protein level and pleocytosis.

Treatment

Removal from exposure is adequate treatment for mild cases of lead poisoning. Chelation therapy with CaEDTA (or a newer agent, succimer, currently approved for use in children), should be considered for all patients with significant toxicity (usually associated with blood lead levels of more than 80 μg per deciliter in adults). For acute lead encephalopathy, supportive measures such as diazepam for seizures, maintenance of fluid and electrolyte balance, and corticosteroids or osmotic agents to manage cerebral edema are used to treat the acute phase of poisoning.

MERCURY

Occupational exposure to mercury typically occurs in the manufacture of paint and fungicides or in electrical, chemical, mining, and agricultural industries. About 10 million pounds of mercury are used annually, and several disastrous large-scale poisonings have occurred. Inorganic mercury waste disposed of in Minamata Bay, Japan, was converted to methyl mercury by the action of microorganisms and thus gained access to the food chain. Hundreds of humans were poisoned after eating contaminated fish. The inadvertent consumption of seed grain containing methyl mercury as a fungicide has also produced epidemics of poisoning (10,000 cases in Iraq).

Absorption, Distribution, and Mechanism of Action

Absorption of mercury depends on the chemical and physical form; CNS toxicity results primarily from exposure to the elemental and organic forms. When ingested, elemental mercury is poorly absorbed and has low toxicity. However, when inhaled as a vapor, it is completely absorbed and rapidly crosses membranes, reaching the brain with much greater facility (mercury is a liquid at room temperature and has a substantial vapor pressure). Organic mercurials (methyl, ethyl, and aryl derivatives) are absorbed by inhalation, cutaneous absorption, and ingestion. Over 90% of ingested organic mercury compounds are absorbed, and substantial amounts cross into the CNS because of their high lipid solubility. Organic mercury has a half-life of 60 days, is excreted in the urine, and can be found in the hair and nails. Like lead, mercury binds to protein sulfhydryl groups. It also binds to amine and phosphoryl groups, interfering with cellular metabolism.

Clinical Features and Laboratory Diagnosis

Characteristic signs of chronic, low-level exposure to elemental or organic mercury include depression, irritability, forgetfulness, confusion, and tremor (erethism). Methyl mercury is particularly damaging to the CNS, causing sensory disturbances, visual deficits (including blindness), hearing loss, ataxia, movement disorders, and cognitive disturbances. Effects of methyl mercury on the fetus include mental retardation and neuromuscular deficits, and toxicity may occur even when mothers are asymptomatic.

Both organic and elemental mercury concentrates in erythrocytes because of the high lipid solubility; therefore, whole blood should be analyzed. Blood levels above 4 µg per deciliter are considered highly indicative of toxicity and correlate with clinical symptoms after methyl mercury exposure. Urinary mercury determination is less useful, but levels over 50 µg per gram creatinine are significant. Hair: blood ratios may be as high as 300.

Treatment

Elemental mercury poisoning is treated by chelation. In symptomatic patients or those with high blood levels, dimercaprol is the chelator of choice. For low-level exposure, penicillamine can be administered. Poisoning by organic mercurials responds poorly to chelation therapy, and dimercaprol, which may actually increase methyl mercury in brain tissue, is contraindicated. Experience with the Iraqi epidemic suggests that penicillamine combined with an oral, nonabsorbable thiol resin (which interrupts enterohepatic recirculation of organomercurials) can lower blood levels.

MANGANESE

Manganese is widely distributed in nature and is present in coal and crude oil. Intoxication was first observed in miners and millers of manganese-containing ores. Manganese is used in the making of steel, machinery, electrical equipment (batteries), fertilizers, animal feeds, dyes, wood preservatives, glass, and ceramics.

Absorption, Distribution, and Mechanism of Action

After inhalation or ingestion, manganese rapidly accumulates in the liver, kidney, and brain. It is excreted in the urine, feces, and bile. Manganese is a required trace element and serves as a cofactor for many enzymes. Its role in metabolism and its putative mechanism of toxicity (oxygen radical-mediated) are derived from its ability to assume multiple oxidation states.

Clinical Features and Laboratory Diagnosis

An acute syndrome occurs after exposure to high levels of manganese. Hallucinations, memory impairment, disorientation, and emotional instability ("manganese madness") occur. Symptoms similar to those seen in Parkinson's disease may appear after weeks or years of exposure and include bradykinesia, rigidity, and tremor. Prominent dystonia may help identify manganese toxicity. Extensive changes in the basal ganglia occur, including cell loss and gliosis in the striatum, globus pallidus, and substantia nigra.

There are no specific laboratory tests for chronic manganese intoxication; blood and urine levels do not correlate reliably with exposure nor with clinical manifestations. The diagnosis rests on the history of chronic exposure and the physical examination.

Treatment

Chelating agents such as CaEDTA may have some benefit if used early. However, significant parkinsonism is not reversible. Therapy with levodopa has been reported to be of benefit in some cases.

INDUSTRIAL AND AGRICULTURAL CHEMICALS

Advances in synthetic organic chemistry over the past century have brought an explosion of activity in the chemical, electronics, textile, petroleum, plastics, and agricultural industries. CNS toxicity has been described for many of the compounds used in these industries. Among these chemicals, organophosphorus compounds and organic solvents are some of the more common causes of human poisoning.

ORGANOPHOSPHORUS COMPOUNDS

Organophosphorus compounds comprise one or more hydroxylated organic moieties (e.g., phenol) connected via an ester linkage to a phosphoric acid derivative. Many of these are highly toxic and have been used as war gases and pesticides. They are also used as flame retardants, lubricants, petroleum additives, and plasticizers. Over 50,000 such compounds are known, and many have toxic effects on the CNS and peripheral nervous system. Several outbreaks of poisoning have occurred from the ingestion of these compounds, usually from contaminated food or beverages. The largest exposure, involving as many as 20,000 cases, occurred in the United States in the 1930s and resulted from the consumption of illicit alcohol ("Ginger Jake") flavored with an oil containing triorthocresolphosphate (TOCP).

Absorption, Distribution, and Mechanism of Action

Organophosphorus compounds can be absorbed after respiratory, skin, or gastrointestinal exposure. Lipophilicity and the requirement of some for oxidative activation govern their distribution and the time course of effects. As pesticides, they inactivate acetylcholinesterase. Although this biochemical attribute is responsible for the acute effects of organophosphates, it does not account for the delayed neurotoxic effects, which appear to involve the inhibition of a poorly characterized specific nervous system esterase referred to as neuropathy target esterase (NTE). NTE is found throughout the nervous system and in other tissues, including lymphocytes.

Clinical Features and Laboratory Diagnosis

Acute organophosphorus poisoning can be life-threatening. Effects include a spectrum of muscarinic (salivation, lacrimation, urination, defecation, bradycardia, hypotension), nicotinic (weakness, fatigability, paralysis), and CNS (confusion, ataxia, loss of reflexes, Cheyne—Stokes respiration, confusion, coma) findings. Acute effects can be attributed to the inhibition of acetylcholinesterase and the consequent overstimulation of cholinergic receptors.

Acute or chronic exposure may result in the appearance of a puzzling array of delayed neurologic effects not related to the inhibition of acetylcholinesterase. TOCP is perhaps the most common offender and certainly the best studied. Acute intoxication is followed 1 to 3 weeks later by the development of a myeloneuropathy resembling motor neuron disease. Initial complaints are of cramps and sharp pain in the calves and paresthesias in the hands and feet. Weakness (progressing to paralysis in the lower limbs), loss of balance, and sensory loss develop over a period of up to 2 months. Ankle and knee reflexes are typically depressed or absent. Wrist drop and weakness in the hands may occur. Neuropathologic findings include degeneration of the pyramidal tracts, usually below the cervical level, and reduced numbers of ventral horn cells, particularly in the lower regions of the spinal cord.

Measurement of red blood cell and plasma cholinesterase may be useful in diagnosing acute intoxication. Measurements of NTE activity are not routinely available. Electrophysiologic tests have been suggested as a way to monitor chronic or delayed toxicity.

Treatment

Acute toxicity should be treated by rapid removal of poison, supportive measures, and administration of atropine and the cholinesterase reactivator pralidoxime. There is no known therapy to prevent the delayed effects. The prognosis for recuperation from the central and peripheral nervous system toxicity depends on clinical severity.

ORGANIC SOLVENTS

Organic solvents are hydrocarbon formulations used in a wide variety of industrial and avocational settings (cleaning/stripping, paint and lacquer, manufacturing). Examples of solvents include turpentine, toluene, acetone, and methylene chloride. Nearly 10 million US workers are occupationally exposed to solvents. Together with home use and, in some cases, recreational abuse (e.g., glue sniffing), the potential public health consequences of solvent toxicity are enormous.

Absorption, Distribution, and Mechanism of Action

Organic solvent compounds tend to be lipophilic liquids with significant volatility, characteristics which facilitate systemic uptake via vapor inhalation and dermal absorption, followed by rapid penetration into the lipid-rich tissues of the CNS. Many solvents are metabolized by hepatic enzymes such as cytochrome P450. Excretion occurs via exhalation of the parent compound or urinary disposition of water-soluble metabolites.

The mechanism by which solvents cause CNS toxicity is not well understood. The clinical picture seen after acute exposure mimics that of ethanol intoxication and is attributed to interactions of the agent with nerve cell membranes. Substantial chronic exposures are associated with irreversible structural changes such as cortical atrophy.

Clinical Features and Laboratory Diagnosis

The hypothesis that organic solvents cause CNS toxicity via direct membrane interactions is supported by the similar clinical features after acute exposure to a variety of hydrocarbon compounds: excitation, euphoria, dysequilibrium, slurred speech, light-headedness, delayed reactions, nausea/vomiting, and severe CNS depression. The acute effects resolve as the agent is eliminated (over minutes to hours). As with excessive consumption of alcoholic beverages, tolerance and withdrawal symptoms can develop with repeated exposure.

Epidemiologic studies of workers exposed to chronic, low levels of solvents seem to indicate that subtle neuropsychiatric abnormalities (e.g., depression, memory deficits) can result. The often vague and nonspecific nature of these abnormalities, and the influence of confounding factors such as socioeconomic status and alcohol consumption, make this a challenging area of research.

In addition to assessing neurologic and cognitive function, clinicians should focus their history and physical examination on other common toxicity manifestations, including hepatic damage, contact dermatitis, history of spontaneous abortion, and cardiac arrhythmia. Some solvent compounds have unique toxicity profiles that may facilitate identification of the causative agent (e.g., peripheral neuropathy caused by hexane and aplastic anemia caused by benzene). Although direct measurement of solvents and their metabolites are sometimes used to monitor worker exposure, these tests are generally not available for diagnostic purposes. Laboratory studies should include hepatic transaminases, blood count, and urinalysis.

Treatment

The mainstay of treatment for organic solvent poisoning is avoidance of further exposure to solvents and other CNS depressants, including alcohol.

DRUGS

Many drugs have a direct effect on the CNS. In most cases, these effects are reversible and thus reflect pharmacologic rather than true toxic effects, but frank neurotoxicity has been associated with several therapeutic agents. The long-term persistence of CNS symptoms after the prolonged use of drugs (e.g., tardive dyskinesia with phenothiazine and butyrophenone neuroleptics) leads one to suspect that recognition of persistent structural or functional alterations of the CNS by other drugs is to be anticipated.

Illicit drug abuse has become a major contributor to the field of neurotoxicology. This problem is due, at least in part, to the clandestine manufacture of analogues of controlled substances. Because these new compounds are rarely tested in animals and quality controls are few, novel and unusual clinical sequelae can occur among drug abusers. Although various new compounds have appeared in the past few years with potentially toxic properties ([Chapter 55](#)), in this section just one of these compounds, MPTP, is discussed. It has proved to be one of the most selective neurotoxicants described to date.

MPTP

1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) was first prepared over 40 years ago in the course of pharmaceutical research. In 1982, this compound was present in batches of a synthetic opioid sold as heroin. Its subsequent intravenous use by a group of addicts in northern California produced an outbreak of neurologic illness characterized by severe and permanent parkinsonism. In retrospect, several episodes of human poisoning by MPTP have almost certainly occurred, and current trends in illicit drug abuse make future repetitions likely. In addition, MPTP and similar compounds are also used as intermediates in the preparation of pharmaceuticals and in basic neuroscience research laboratories, thus posing an occupational hazard.

Absorption, Distribution, and Mechanism of Action

Although the toxic properties of MPTP were first recognized after intravenous exposure, other human cases have been reported after intranasal use and probably after cutaneous absorption and vapor inhalation. Studies in nonhuman primates have shown that MPTP is rapidly distributed to all tissues, with substantial amounts reaching the brain.

The expression of MPTP neurotoxicity is intimately associated with factors determining its biodisposition. MPTP is biotransformed to MPP⁺ by the B form of monoamine oxidase (MAO), an ubiquitous enzyme particularly prevalent in brain tissue. MAO inhibitors completely prevent the development of toxicity. Once formed, MPP⁺ appears to be accumulated into dopaminergic neurons via their reuptake system; blockers of this system prevent toxicity in some experimental models. The mechanism by which MPP⁺ damages neurons is attributed to its ability to act as a mitochondrial poison, blocking oxidative phosphorylation at the level of complex I.

Clinical Features and Laboratory Diagnosis

A history of drug abuse or employment in a pharmaceutical or research laboratory should alert the clinician to the possibility of MPTP exposure. Acute signs and symptoms of MPTP exposure include hallucinations, jerking of the extremities, visual blurring, seborrhea, tremors, and, in addicts, a burning sensation at the site of injection. Chronic features that develop within days to weeks include bradykinesia, rigidity, stiffness, and, in some cases, a typical resting tremor. Almost all the motor features of Parkinson's disease may be seen, including masked facies, drooling, fixed stare, shuffling gait, flexed posture, hypophonia, and loss of postural righting reflexes. Even more subtle parkinsonian features, such as micrographia and seborrhea, are present. In a single human case studied neuropathologically, MPTP produced selective cell loss in the zona compacta of the substantia nigra. Studies in young monkeys have revealed similarly selective cell loss. Older monkeys appear to display a broader array of neuropathologic features, including cell loss in the locus ceruleus and the presence of eosinophilic inclusion bodies in the same sites of predilection for Lewy bodies, a characteristic intraneuronal inclusion body seen in Parkinson's disease.

Patients with MPTP-induced neurotoxicity have few laboratory findings. The cerebrospinal fluid protein level may be slightly elevated in some patients. As a group, the mean concentrations of certain neurotransmitters in the cerebrospinal fluid are altered (3-methoxy-4-hydroxyphenylethylglycol is increased, homovanillic acid is reduced) in MPTP-exposed patients, but many individual values fall within the normal range. With specialized techniques, however, MPTP or MPP⁺ or both are detectable in blood or urine for several days after exposure.

Treatment

Although no clinical data exist regarding the effects of MAO inhibitors after MPTP exposure in humans, animal studies using pargyline and deprenyl suggest that their use should be considered in cases of recent (within 1 to 12 hours) exposure to MPTP. Because results of primate studies of dopamine-uptake blockade are conflicting, these agents cannot be recommended at this time. The development of full-blown MPTP-induced parkinsonism in humans appears to be irreversible; it is

unclear whether milder degrees of exposure eventually lead to a progressive condition. Most patients respond dramatically to treatment with carbidopa/levodopa (Sinemet) and dopamine agonists, but side effects may appear early when compared with the treatment of Parkinson's disease in elderly patients.

CHAPTER 440: THE NEUROLOGIC COMPLICATIONS AND CONSEQUENCES OF ETHANOL USE AND ABUSE

STANLEY A. HASHIMOTO AND DONALD W. PATY

[Acute Intoxication](#)
[Withdrawal Phenomenon](#)
[Effects of Chronic Alcohol Abuse on the Nervous System](#)

Ethanol is consumed by about two thirds of the population of North America, but one third of the population is considered to be moderate to heavy drinkers. About 10% of all drinkers become alcoholics and drink more than 50% of all the ethanol consumed. This makes ethanol use and abuse a major health problem. More than 20,000 deaths per year are directly related to alcohol use in the United States; this rate is related in part to motor vehicle accidents and other types of violence. Alcoholism is a major worldwide problem and an increasing one. The development of alcoholism is a complex phenomenon dependent on genetic, cultural, social, and economic factors. Rarely, an underlying problem such as an alcohol-responsive essential tremor may lead to alcohol addiction.

The acute and chronic effects of ethanol are primarily those that relate to its effect on the central nervous system ([Table 440.1](#)). Other organs are also involved, including the liver, heart, pancreas, and blood; the involvement of those organs subsequently affects the brain, too. The excessive intake of ethanol is in the form of nonnutritional calories, leading to malnutrition. As such, it becomes impossible to separate the effects of chronic alcoholism from the effects of deficiency of nutritional factors, primarily thiamine.

Acute Intoxication
Acute tolerance
Chronic tolerance
Alcoholic blackouts
Withdrawal Phenomenon
Tremors
Seizures
Hallucinations and auditory hallucinosis
Delirium tremens
Sleep disorders
Movement disorders
Neurologic Complications of Chronic Alcoholism
Wernicke's encephalopathy
Korsakoff's psychosis
Dementia
Marsaglia-Bignami disease
Cerebellar degeneration
Central pontine myelinolysis
Polyneuropathy
Myopathy (acute and chronic)
Fetal Alcohol Syndrome
Adverse Consequences
Head injury, subdural hematoma
Compensated myoneuropathy (e.g., radial nerve palsy)
Consequences of liver failure
Impact on stroke

TABLE 440.1. NEUROLOGIC COMPLICATIONS AND CONSEQUENCES OF ETHANOL ABUSE

Ethanol is rapidly absorbed by the gastrointestinal tract, and because of its miscibility in water becomes widely distributed throughout the body. The brain is no exception, and there appears to be no blood–brain barrier to this substance. Ethanol acts on the lipids of the cell membrane and, less likely, directly on the proteins in the cell membrane. Neuronal excitability appears to increase at lower concentrations, and at higher levels neuronal activity progressively decreases. Researchers have studied the impact of ethanol on neurotransmitters, including acetylcholine, serotonin, g-aminobutyric acid (GABA), and catecholamines; the neurotransmitter most consistently involved may be GABA.

ACUTE INTOXICATION

The intoxicating effect of ethanol depends mainly on the blood level but also on the rate of ingestion and the impact of habitual drinking. Because of the development of acute tolerance, ethanol has less of an impact when the level is reached slowly, and the degree of intoxication is less when the level of ethanol is dropping than at the same level when it is rising. Persons who have achieved chronic tolerance through habitual drinking may tolerate very high levels, ones that may be fatal in a novice drinker.

On average, a blood alcohol level of about 25 to 30 mg per deciliter is associated with mood changes and probably a significant decrease in cognition and coordination. This impairment is sufficient to affect the operation of a motor vehicle; current maximums permitted by law for drivers are 80 to 100 mg per deciliter. At 100 mg per deciliter, alcohol's effect on the brain stem causes diplopia, dysarthria, and nystagmus, with added cerebellar dysfunction. At 200 mg per deciliter, the person has marked confusion; at 400 mg per deciliter, most persons become comatose. A level of 500 mg per deciliter is usually fatal owing to respiratory depression, but with chronic tolerance, drinkers have survived levels up to 1,000 mg per deciliter.

In a patient with a high blood alcohol level, hypotension, and coma, the blood alcohol level must be lowered as rapidly as possible. The rate of metabolism of ethanol remains constant; therefore, hemodialysis should be considered if the level is life-threatening.

A “blackout” is said to occur when, after a large intake of alcohol, a person cannot remember what happened during a circumscribed period of time, although there was no loss of consciousness. It is similar to transient global amnesia and always clears spontaneously. Blackouts occur in persons who would not otherwise be considered alcoholics.

WITHDRAWAL PHENOMENON

Withdrawal symptoms occur when alcohol intake is reduced or stopped after prolonged, excessive intake. These symptoms are more likely to occur with increasing duration of excessive intake and with the amount ingested. The adrenergic system is hyperactive, and b-blockers can reduce some of the signs. The most common finding is tremor, which involves mostly the upper limbs; however, the entire body can be tremulous, including the voice. The tremor, which is present both at rest and with action, starts within the first 12 to 24 hours of withdrawal and gradually recedes on its own. The person is usually anxious and agitated. Treatment is usually not required. One third of these patients develop visual hallucinations and more rarely auditory hallucinosis. Auditory hallucinations are usually not associated with confusion, such as that which occurs with delirium tremens. Visual hallucinations usually disappear within a few days, but auditory hallucinosis is a more unpleasant and prolonged disturbance and may resemble schizophrenia.

One fourth of patients have withdrawal seizures within the first 24 to 48 hours, usually generalized tonic–clonic seizures without focal features. These seizures may be associated with myoclonic jerks, and the patient often has a photomyoclonic response to photic stimulation during an electroencephalogram. Anticonvulsant medication is not indicated unless status epilepticus occurs, which is rare. Prophylactic anticonvulsant medication is ineffective. Seizures that vary from this description should be investigated for another cause, such as subdural hematoma or abscess.

Delirium tremens, the most serious withdrawal manifestation, carries a mortality rate of 20% if untreated. It occurs late, after seizures and tremor, usually 3 to 5 days after the patient stops drinking. It is always preceded by restlessness and anxiety, followed by confusion, hallucinations, and insomnia, with added autonomic dysfunctions of tachycardia, fever, and sweating. Occasionally, circulatory collapse occurs. Treatment is primarily sedation and hydration with appropriate doses of benzodiazepines.

Other possible manifestations of withdrawal include transient parkinsonism, other movement disorders, or sleep disorders. All these phenomena probably relate to the adaptive changes that have occurred in the cell membranes during prolonged and excessive ethanol intake that are suddenly no longer compensated by the presence of alcohol.

EFFECTS OF CHRONIC ALCOHOL ABUSE ON THE NERVOUS SYSTEM

WERNICKE'S ENCEPHALOPATHY

Wernicke's encephalopathy is a disorder related to thiamine deficiency. It is not specific for alcoholism and may occur in persons with hyperemesis gravidarum, gastrointestinal cancer, or any other situation leading to inadequate nutritional intake. Alcoholism, however, is by far the most common cause and reflects poor nutrition. There is a genetic component, probably related to abnormalities of transketolase and other carbohydrate enzymes. The problem may be precipitated by the administration of glucose without thiamine. Although most patients present clinically with incomplete syndromes, the triad of encephalopathy, ophthalmoplegia, and ataxia is seen in about one third of all patients affected. Patients may gradually proceed to coma and die if not treated quickly and adequately with intravenous thiamine. The ataxia is identical with that seen in the cerebellar degeneration of alcoholism. The ophthalmoplegia can consist of gaze palsies, including internuclear ophthalmoplegias, third- and sixth-nerve palsies, and pupillary abnormalities and nystagmus; the latter may persist despite treatment.

The pathologic findings, often visible on computed tomography (CT) scanning and magnetic resonance imaging (MRI), are present within the walls of the third ventricle, the periaqueductal gray matter, the floor of the fourth ventricle, and often both mammillary bodies. There is endothelial proliferation, hemorrhage, gliosis, and demyelination in the areas involved.

The treatment is intravenous thiamine (100 mg per day intravenously) until adequate nutrition is established. Improvement can occur quickly.

KORSAKOFF'S PSYCHOSIS

In Korsakoff's psychosis, which is often associated with Wernicke's encephalopathy, retentive memory, both recent and remote, is absent (or almost so), but other cognitive functions remain relatively intact. Confabulation may be present as a manifestation of impaired recall. The problem may be related to mammillary body destruction and diencephalic lesions and possibly to the involvement of the process within both temporal lobes. The prognosis for recovery to normal function is poor: probably 80% of patients are left with a significant memory deficit.

DEMENTIA SECONDARY TO ALCOHOL ABUSE

Controversy exists about whether dementia is a secondary complication of alcoholism separate from Korsakoff's psychosis and head injury. Dementia is, however, generally accepted as a reversible disorder, and, when combined with Korsakoff's psychosis, alcoholism is probably the third most common cause of dementia (after Alzheimer's disease and vascular disease). Alcoholism as a cause of dementia exceeds head injuries, a group to which alcoholism contributes.

Dementia secondary to alcohol abuse (separate from Korsakoff's disease) is usually a mild, primarily amnesic, and potentially reversible disorder. The major supporting evidence for alcohol-related dementia comes from neuroimaging techniques, which show that the brain volume is less in alcoholics than in normal controls. The reduction in brain volume and dementia appears to improve with cessation of alcohol intake; however, patients free of head injury, malnutrition, poor socioeconomic conditions, and other drug use are unusual and difficult to find, making controlled studies difficult if not impossible to carry out.

MARCHIAFAVA-BIGNAMI DISEASE

Marchiafava-Bignami disease, a rare disorder, was initially described in Italy in young men who were extremely heavy red wine drinkers, but it occurs around the world, involves all races, and is not restricted to wine drinkers. The diagnosis is now made premonitory through MRI and CT scanning. The demyelinating pathology, similar to that of central pontine myelinolysis, affects the middle third of the corpus callosum. Terminally, patients become stuporous and seizures are common; this situation is preceded by dementia and gait disorder. The early manifestations are protean, and the disorder can be acute, subacute, or chronic. Patients are usually very heavy drinkers. The underlying cause again probably relates to malnutrition rather than to the direct impact of alcohol on the brain.

CEREBELLAR DEGENERATION

Cerebellar degeneration secondary to alcoholism affects the midline anterior superior vermis. The clinical presentation is therefore that of gait and stance, not functions that relate to the arms. Cerebellar degeneration is similar to the cerebellar ataxia seen in Wernicke's encephalopathy and therefore is probably related to nutritional factors. Alcohol has a direct impact on cerebellar structures, including Purkinje's cells. Cerebellar degeneration occurs in long-term alcoholics, but the problem does not seem to correlate with the amount of alcohol ingested. The problem may recede with abstinence but recurs with drinking and may become irreversible; in rare cases, walking becomes impossible. The treatment is proper nutrition, including thiamine, and cessation of drinking. Genetics probably plays a significant role in the cause of this disorder.

CENTRAL PONTINE MYELINOLYSIS

Central pontine myelinolysis is a disorder consisting of demyelination and at times loss of axons, primarily in the central pons. The disorder also affects both cerebral hemispheres and the cerebellum to a lesser extent. It is usually subacute and often diagnosed after death, but MRI can detect the lesions and brain-stem auditory-evoked responses are also helpful. The prognosis for those with central pontine myelinolysis is poor. In the complete form of the disease, patients have quadriplegia or the "locked-in syndrome." The cause can be the rapid correction of hyponatremia, but the disorder has also been seen in hypernatremia, azotemia, and hyperglycemia. Central pontine myelinolysis is more common in alcoholics, but the mechanism is unknown. It can coexist with Wernicke's encephalopathy. The only treatment is prevention by the slow correction of hyponatremia.

MYELOPATHY

Although most cases of myelopathy in alcoholics are due to advanced cirrhosis of the liver, myelopathy may be secondary to alcohol use alone. This is a progressive disorder with dorsal and lateral column dysfunction.

POLYNEUROPATHY

A diffuse polyneuropathy that involves the lower extremities more than the upper extremities is common in alcoholics. This is one cause of a painful neuropathy, with a burning dysesthesia in some cases. The cause is probably related to malnutrition and thiamine deficiency, and treatment consists of thiamine and cessation of alcohol. The disorder is a sensory motor neuropathy, with weakness and distal sensory loss as well as loss of deep tendon reflexes. The gait may be ataxic secondary to proprioceptive loss.

MYOPATHY

Some cases of proximal muscle weakness are due to hypokalemia, often secondary to diarrhea and vomiting, but both acute and chronic myopathies exist secondary to excessive alcohol intake. Acute myopathy always follows a major alcoholic binge and is a serious disorder, with rhabdomyolysis and renal failure resulting from myoglobinuria. The only treatment is abstinence. These patients may be left with a deficit. Chronic myopathy is more indolent and consists of slowly progressive proximal weakness, with a mildly elevated level of creatine phosphokinase in the blood. Abstinence is the only treatment for this disorder as well.

FETAL ALCOHOL SYNDROME

Ethanol and its metabolite acetaldehyde are both probable teratogens. The full fetal alcohol syndrome of mental and physical retardation, with facial and other congenital abnormalities, is uncommon, occurring in about 6% of children born to alcoholic mothers who maintain a high intake throughout the pregnancy. However, partial syndromes are common, especially with exposure in the first trimester. Low IQ and behavioral and physical changes occur. There is probably no safe level of ethanol ingestion in pregnancy, although lower levels have not been shown to be harmful.

MISCELLANEOUS NEUROLOGIC COMPLICATIONS

Because the alcoholic is subject to falls and assault, head injury is common. Owing to cerebral atrophy, the alcoholic is prone to develop subneural hematoma. Recurrent head injuries can lead to dementia, and seizures secondary to this may develop. Pressure while lying in the stuporous state is a common problem and primarily involves the radial nerve ("Saturday night palsy") and the sciatic and peroneal nerves, although any nerve or plexus can be affected. Finally, meningitis and brain abscess secondary to pneumonia should be considered in all alcoholic patients who are ill and who present with either a depressed level of consciousness or seizures.

The other indirect consequences of alcohol abuse consist of central nervous system problems related to liver failure. Moderate use of alcohol has been the focus of several studies in relation to the development of stroke. There appears to be no difference from one type of drink such as wine compared with another such as beer. There appears to be a U- or J-shaped curve with moderate drinking being protective, whereas higher amounts probably increase the chances of stroke. These results had accounted for other risk factors.

CHAPTER 441: BACTERIAL INFECTIONS OF THE NERVOUS SYSTEM

ANTHONY W. CHOW AND DONALD W. PATY

[Meningitis and Ventriculitis](#)
[Brain Abscess and Cerebritis](#)
[Subdural Empyema and Epidural Abscess](#)
[Septic Intracranial Thrombophlebitis and Mycotic Aneurysm](#)
[Neurosyphilis](#)
[Lyme Disease](#)

Pyogenic bacterial infections of the nervous system can be categorized into distinct entities based on their major anatomical location (i.e., meningitis and ventriculitis, brain abscess and cerebritis, subdural and epidural empyema, septic thrombophlebitis and mycotic aneurysm). In addition to these entities, two other bacterial infections of the nervous system (neurosyphilis and neuroborreliosis [Lyme disease]) deserve special emphasis because of their protean clinical manifestations and the diagnostic challenge that they can represent. In this chapter, the important epidemiologic, anatomical, and etiologic considerations of these conditions are outlined, and their clinical and laboratory findings and optimal management are presented. A more general discussion of the clinical approach to managing the patient with a suspected infection of the nervous system, including specific laboratory investigations and the differential diagnosis, is presented in [Chapter 431](#).

MENINGITIS AND VENTRICULITIS

INCIDENCE, EPIDEMIOLOGY, AND ETIOLOGY

The brain and spinal cord are completely encased by three layers of meninges: the pia mater, the arachnoid (leptomeninges), and the dura mater (pachymeninges). Between the pia and arachnoid is the subarachnoid space, which contains cerebrospinal fluid (CSF). Meningitis develops when the subarachnoid space becomes infected, usually because of hematogenous spread and typically involving the entire surface of the leptomeninges surrounding the brain and spinal cord. Ventriculitis occurs either by contiguous spread of infection from the subarachnoid space through the foramina of Magendie and Luschka, or as direct consequence of a ventricular shunt infection.

Community-acquired meningitis is particularly common in children, young adults, and the elderly, and the causative agents vary greatly among the different age groups ([Table 431.4](#)). In children and young adults, the most common pathogens are the encapsulated bacteria *Haemophilus influenzae* type b, *Streptococcus pneumoniae*, and *Neisseria meningitidis* (75% of cases). However, the wide use of protein–polysaccharide conjugated vaccines has dramatically reduced the incidence of *H. influenzae* type b infections. Patients with splenectomy or sickle cell traits are particularly susceptible to *S. pneumoniae* and *H. influenzae* infection. Bacterial meningitis secondary to head trauma, craniotomy, CSF leak, or congenital defects such as spina bifida, dermoid cyst, or meningocele is most frequently caused by *Staphylococcus aureus* and *S. pneumoniae* infection and less frequently by *Pseudomonas aeruginosa* or other Enterobacteriaceae (e.g., *Klebsiella pneumoniae*, and *Proteus mirabilis*). Patients undergoing cancer chemotherapy or those with underlying immunodeficiency syndromes are more prone to infection with a variety of pathogens, including *Listeria monocytogenes*, Enterobacteriaceae, as well as mycobacteria and fungi. Ventricular shunt infections are most commonly caused by coagulase-negative staphylococci, *S. aureus*, and diphtheroids. Apart from age and underlying conditions, several other epidemiologic associations such as animal exposure and geographic location may provide important clinical clues to possible causative agents in both bacterial and nonbacterial infections of the nervous system ([Table 431.2](#)). An increasing proportion of cases are nosocomially acquired, and approximately one third of such cases are caused by gram-negative bacteria other than *H. influenzae*.

PATHOGENESIS

Purulent meningitis typically occurs after hematogenous dissemination from a distant site of infection, particularly the lung and heart valves. Other sources of purulent meningitis include neurosurgical procedures, basilar skull fractures, congenital neuroectodermal sinus tracts, spontaneous CSF fistulas, and placement of a ventricular shunt for hydrocephalus. In the otherwise healthy host, the subarachnoid space is relatively resistant to microorganisms even during persistent bacteremia. Both complement- and antibody-mediated bacteriolysis and opsonophagocytosis as well as cell-mediated immunity constitute the predominant defense mechanisms in the central nervous system (CNS). Humoral antibodies are particularly important against encapsulated pathogens such as *S. pneumoniae*, *N. meningitidis*, and *H. influenzae*. Once infection in the subarachnoid space is established, the offending microorganism can rapidly multiply to high levels (more than 10^5 colony-forming units/mm³ CSF). This results in the induction and release of several inflammatory and chemotactic cytokines, particularly tumor necrosis factor and interleukin-1, which are responsible for disruption of the blood–brain barrier and the intense inflammatory response in the CNS. These inflammatory changes are directly responsible for various neurologic sequelae, such as hearing impairment, seizure disorders, and hydrocephalus.

CLINICAL FINDINGS

The cardinal manifestations of meningitis are fever, headache, and nuchal rigidity. Other signs of cerebral dysfunction are variable, depending on the onset and clinical course of illness ([Table 441.1](#)). In acute purulent meningitis, most commonly caused by infection with *S. pneumoniae*, *N. meningitidis*, and *H. influenzae*, deterioration in mental status, progressing from confusion and lethargy to coma, may occur rapidly within 24 hours. Weakness, anorexia, shaking chills, profuse sweats, photophobia, vomiting, and myalgias of the lower extremities and back are common presentations. Neck stiffness may be subtle or marked. Cranial nerve palsies (principally third, fourth, sixth, and seventh) occur in 10% to 20% of patients. Seizures are more common in children, whereas focal cerebral signs such as hemiparesis, visual field defects, papilledema, and dysphasia are less frequent (10% to 15%). The presence of focal findings should suggest the coexistence of a brain abscess, subdural empyema, or septic thrombophlebitis. Ventriculitis should be suspected in any patient with an indwelling ventricular shunt or pressure catheter, with an unusual organism, with persistently high intracranial pressure, or with suboptimal response to therapy. In patients with a ventriculoperitoneal shunt, abdominal pain and tenderness may be the initial clinical presentation of a shunt infection.

Condition	Cause	Prevention or Treatment
Acute Phase		
Confusion, depression or level of consciousness	Increased intracranial pressure	Early appropriate antimicrobials
Cerebral edema	Infection, toxic effects of cerebrospinal fluid reabsorption	Early appropriate antimicrobials, corticosteroids
Stinks, aphasia, cortical blindness	Neuroepithelial adhesions	Early appropriate antimicrobials
Cranial nerve palsies	Inflammation, sluggish venous flow	Corticosteroids
Subarachnoid hemorrhage	Mycotic aneurysm	Neurosurgical
Seizure and myoclonus	Cerebritis, vasculitis, venous sinus thrombosis	Anticonvulsants
Late Phase		
Dementia, personality change, gait disturbance, urinary incontinence	Basilar arachnoiditis causing communicating hydrocephalus	Neurosurgical, ventricule shunt
Deafness	Otitis media involvement	Corticosteroids
Optic neuritis	Arachnoiditis, inflammation of optic nerve	Corticosteroids
Seizure	Neuroepithelial adhesions, cerebritis	Anticonvulsants

TABLE 441.1. NEUROLOGIC MANIFESTATIONS OF BACTERIAL MENINGITIS

In subacute or chronic meningitis, the onset is insidious, and neurologic findings may wax and wane. Episodes of acute neurologic deterioration may reflect underlying cerebral edema, cerebrovascular occlusions, hydrocephalus, or seizures. Focal signs are particularly important because they suggest parenchymal mass lesions such as abscess or granuloma. The presence of hydrocephalus in the course of subacute or chronic meningeal inflammation, particularly in association with cranial nerve palsies, is strongly suggestive of basilar leptomeningitis due to tuberculosis, fungi, or parasitic agents. Complications, including cranial neuropathies (ocular, motor, and facial palsies, or deafness), cerebral infarction, and increased intracranial pressure, are common. Myeloradiculitis can occur secondary to inflammatory meningeal exudate involving the spinal roots. Noninfectious causes, such as malignancy, sarcoidosis, and granulomatous angiitis, should be excluded.

usually occurs in the posterior frontal and parietal lobes, which are perfused by the middle cerebral artery. The abscess tends to originate deep in the white matter or gray-white matter junction, where cerebral blood flow is more easily compromised. Inflammation, hemorrhage, edema, and hydrocephalus all may produce displacement of the brain or spinal cord. Displacement of the cerebral hemisphere forces brain tissue beneath the falx cerebri and over the tentorium cerebelli ([Fig. 441.2](#)). Herniation beneath the falx is usually asymptomatic, but herniation of the temporal lobe over the tentorium can cause third cranial nerve palsy and ipsilateral corticospinal tract signs due to compression of the contralateral cerebral peduncle against the tentorium. Onset of coma and progressive loss of brain-stem reflexes culminating in respiratory arrest rapidly ensue. Posterior fossa lesions such as a cerebellar abscess or hemorrhage may produce rapid compression of the medulla and pons and herniation of the cerebellar tonsils through the foramen magnum without antecedent midbrain signs.

CLINICAL FINDINGS

The clinical presentations of brain abscesses are variable and are primarily determined by their anatomical location, proximity to the ventricles or cisternal or dural sinuses, and major alterations in the intracranial pressure dynamics secondary to the mass effect. Four distinctive clinical presentations of a brain abscess can be recognized on the basis of the unique pathophysiologic events implicated: rapid focal mass expansion, intracranial hypertension, diffuse brain destruction, and focal neurologic deficit. In the last category, the temporal progression of infection is so slow that it is often misdiagnosed as a neoplasm. Fever is present in only 45% to 50% of patients; therefore, absence of fever should not be used to exclude the diagnosis of brain abscess. An understanding of the alterations in the intracranial pressure dynamics secondary to the mass effect is particularly helpful in correlating the underlying pathophysiologic process with the clinical presentation. Thus, a pontine abscess may bulge posteriorly and block the aqueduct of Sylvius acutely to cause obstructive hydrocephalus.

An occipital lobe abscess could rupture or leak into the ventricular system, causing ventriculitis, or it could involve the transverse sinus and cause septic thrombophlebitis or a subdural empyema. Both cranial and spinal nerve roots may be involved, either directly because of contiguous infection, or indirectly because of increased intracranial pressure. Of particular importance is the close relation of the third cranial nerve with the tentorium (uncal herniation of the temporal lobe); the third, fourth, fifth, and sixth cranial nerves with the cavernous sinus (septic cavernous sinus thrombosis); the fifth and sixth cranial nerves with the petrous portion of the temporal bone (chronic otitis media and petrous osteomyelitis); and the ninth and eleventh cranial nerves with the jugular foramen (septic jugular thrombophlebitis). Because the second cranial nerve is contained within the subarachnoid space up to its point of entry into the eye, papilledema and optic atrophy may result from a sustained increase in intracranial pressure.

LABORATORY FINDINGS

The diagnosis of brain abscess is no longer difficult with the availability of CT scanning and magnetic resonance imaging (MRI). Such studies should be performed with and without contrast to more easily differentiate early cerebritis from abscess. On a precontrast CT scan, cerebritis is seen as a hypodense area, and abscess is characterized as a low area of density surrounded by a faint ring (capsule). With contrast, both cerebritis and abscess show ring enhancement within 10 minutes of injection, but the ring enhancement does not persist at 60 minutes in cerebritis, in contrast to abscess. In some cases of early cerebritis, the CT may be negative even with contrast. MRI provides more resolution in detecting early cerebritis and the adjacent cerebral edema. MRI is also more accurate than CT in identifying the central liquefactive necrosis of a brain abscess that is hyperintense relative to CSF.

Contrast enhancement with intravenous gadolinium provides even more detail and is the procedure of choice in the evaluation of brain abscesses. Radionuclide brain scans are largely replaced by CT and MRI. Indium-labeled leukocyte scanning may allow differentiation of brain abscess from tumor. A lumbar puncture (LP) is contraindicated if a brain abscess or other mass lesion is suspected. The risk of herniation and death in such patients is high, whereas the potential benefit of obtaining useful information or positive culture from the CSF is relatively low. The CSF cell count is usually normal unless the abscess has ruptured into the subarachnoid space.

OPTIMAL MANAGEMENT

The choice of initial empiric antimicrobial regimens for brain abscess and cerebritis is based on the suspected source of infection, the immunologic status of the patient, and the most likely causative organisms ([Table 431.5](#) and [Table 431.6](#)). The final antibiotic selection should be guided by culture results and susceptibility data. Where anaerobes are implicated, penicillin G remains the antibiotic of first choice. Chloramphenicol or metronidazole are useful alternatives in the penicillin-allergic patient and have the advantage of more effective coverage against b-lactamase-producing anaerobes. Metronidazole is particularly active against *Bacteroides* sp. Its lack of activity against gram-positive anaerobic cocci such as *Peptostreptococcus* sp and facultative organisms such as streptococci, however, is a disadvantage that precludes monotherapy of otogenic or odontogenic brain abscess with metronidazole alone. Combination of penicillin with metronidazole or chloramphenicol is suitable. Clindamycin penetrates the blood–brain barrier poorly and usually is not recommended in CNS infections. For immunocompromised and critically ill patients, broad coverage with extended-spectrum b-lactams (e.g., cefotaxime, ceftizoxime, imipenem) for aerobic gram-negative rods, *S. aureus*, and anaerobes is indicated.

The fluoroquinolones (ciprofloxacin or trovafloxacin) have excellent CNS penetration and antibacterial activity against gram-negative bacilli. If *S. aureus* is suspected,

naftillin, 2 g every 4 hours, may be added. If the *S. aureus* strain is resistant to methicillin, vancomycin is the agent of choice. Brain abscess caused by infection with *Nocardia* sp is treated with intravenous trimethoprim-sulfamethoxazole (5 to 10 mg per kilogram trimethoprim and 25 to 50 mg per kilogram sulfamethoxazole daily in four divided doses). Maximum doses of systemic antimicrobials are required for the treatment of brain abscess or cerebritis to optimize penetration of the blood-brain barrier. Therapy should usually be continued for at least 6 to 8 weeks. Patients should be carefully monitored both clinically and by repeated CT scans until complete resolution of the abscess. Follow-up is required for up to 1 year to ascertain nonrecurrence.

Because of the tendency for recurrence, well-encapsulated brain abscesses are best treated by surgical aspiration. If the focal lesion persists, resection of the abscess capsule may be necessary. In contrast, treatment of early cerebritis does not usually require surgical drainage. Indications for nonoperative treatment of brain abscess include poor surgical candidate; multiple abscesses that are remote from one another; abscesses in deep or dominant locations; a relatively small abscess (less than 4 cm); and partial resolution of the abscess attributable to antimicrobial therapy before surgery. The overall mortality of brain abscess remains high and is dictated by the extent of neurologic compromise at the time of presentation and diagnosis. The mortality is highest among patients with symptoms of short duration, severe mental status changes, and rapidly progressing neurologic deterioration. Among survivors, seizures are the most common complications, occurring in 25% to 50% of cases. Anticonvulsant therapy may be required indefinitely.

SUBDURAL EMPYEMA AND EPIDURAL ABSCESS

INCIDENCE, EPIDEMIOLOGY, AND ETIOLOGY

Subdural empyema and epidural abscess are parameningeal infections that most frequently arise by direct extension from a pericranial focus, such as chronic sinusitis, otitis media, mastoiditis, or petrous osteomyelitis. Subdural empyema or cranial epidural abscesses associated with chronic sinusitis are most commonly caused by anaerobic or microaerophilic streptococci (*Peptostreptococcus* sp, *S. viridans*, *S. anginosus*) and *Bacteroides* sp. In otogenic infection associated with chronic otitis media or mastoiditis, enteric gram-negative bacilli, such as *P. aeruginosa* and *P. mirabilis*, as well as anaerobic organisms are most common. Spinal epidural abscess usually arises hematogenously or by contiguous spread from vertebral osteomyelitis, extension of decubitus ulcers, and infection after epidural anesthesia or penetrating injury. Distant sources of infection include infective endocarditis, pneumonia, intra-abdominal or pelvic sepsis, and urinary tract infection with entry of organisms by way of the paravertebral venous plexus. Epidural abscesses secondary to penetrating cranial trauma or postoperative infection are most commonly caused by infection with *S. aureus* and enteric gram-negative bacilli.

PATHOGENESIS

Subdural empyema is characterized by suppuration located between the inner surface of the dura and the outer surface of the arachnoid. The source of infection is usually in the frontal or ethmoid sinuses. The infection gains entry by direct extension or as a result of thrombophlebitis involving the venous sinuses ([Fig. 441.1](#)). Because the arachnoid and dura are only loosely attached, subdural infection tends to spread rapidly over the entire surface of the cerebral hemisphere. This infection is usually unilateral because further spread is restricted medially by the falx cerebri and inferiorly by the tentorium cerebelli. In contrast, because the cranial dura mater adheres tightly to the periosteum of the skull, except where it invaginates into the cranial cavity to form the falx cerebri, falx cerebelli, tentorium cerebelli, and diaphragma selli, infection in the extradural space tends to be more localized. Cranial extradural abscess is associated with osteomyelitis in a cranial bone and usually originates from infection in the middle ear or the paranasal sinuses, or from a neurosurgical procedure. Spinal subdural empyema is rare both in adults and children. The spinal dura mater and the periosteum are separated by a fat-filled epidural space from the foramen magnum to the level of C7. Thus, both spinal subdural empyema and spinal epidural abscess may extend over many vertebral segments and are usually posterior to the cord.

CLINICAL FINDINGS

Generalized headache, associated with high fevers and malaise, and an acute flare-up of a preexisting parameningeal focus of infection manifested by increased local pain and purulent nasal or aural discharge, are the first indications of a subdural empyema. These clinical features are followed within days by the appearance of focal neurologic findings such as unilateral motor seizures, hemiplegia, hemianesthesia, or aphasia, and signs of increased intracranial pressure with progressive lethargy and coma. The neck is stiff, but CSF examination is more consistent with an aseptic meningitis syndrome. In infants and young children, however, an intracranial subdural empyema is almost invariably a complication of bacterial meningitis. Early signs such as irritability, poor feeding, or increased head size are nonspecific, but hemiparesis, convulsions, stupor, and coma may rapidly ensue. Intracranial epidural abscess is usually associated with a postcraniotomy infection, or a cranial osteomyelitis secondary to chronic sinusitis or middle ear infection. The onset of symptoms may be insidious and overshadowed by the localized inflammatory process. Focal neurologic findings are less common than in subdural empyema. Rarely, a fifth and sixth cranial nerve palsy may develop in association with infections of the petrous portion of the temporal bone (Gradenigo's syndrome).

Spinal epidural abscess may span several vertebrae and may be inadvertently entered during an LP. The abscess may develop acutely or follow a more chronic course. Four stages in the clinical presentation can be recognized. The first phase is usually accompanied by fever and back pain. The second phase involves progression to root pain. If symptoms develop in the cervical or lumbar area, it can suggest nerve root compression due to a ruptured disk. The third phase involves progression to motor weakness, sensory changes, and bowel or bladder dysfunction, signaling spinal cord compression. The fourth phase is total paralysis, which may occur within hours after the onset of motor weakness. If the cervical cord is involved, respiratory function may be impaired.

LABORATORY FINDINGS

CT scanning is the procedure of choice for the diagnosis of both subdural empyema and cranial epidural abscess. In subdural empyema, the CT scan usually reveals a crescent-shaped area of low density directly between the inner table of the skull and cerebral cortex or adjacent to the falx cerebri. With contrast, fine, irregular enhancement of the peripheral margins of the subdural empyema is seen. Occasionally, the CT scan may be inconclusive because density of the subdural empyema may be similar to that of cerebral tissue, and the decreased attenuation may not be evident on CT. MRI may provide an advantage over CT in such cases. Angiography is recommended on an emergency basis if the CT scan is negative and facilities for MRI are not available. As with brain abscess, LP should be avoided in patients suspected of having a subdural or epidural empyema.

MRI has replaced myelography as the diagnostic method of choice for spinal epidural abscess because it is positive early in the course of infection and provides the best imaging of the inflammatory changes. MRI is also superior to CT for visualizing the cord and epidural space as well as in identifying an associated vertebral osteomyelitis. CSF is usually nondiagnostic unless the abscess has ruptured into the subarachnoid space, or if the spinal needle has inadvertently entered the epidural abscess during the LP.

OPTIMAL MANAGEMENT

Early surgical evacuation is the cornerstone of therapy for both subdural and cranial epidural empyema. The incidence of mortality and neurologic sequelae varies directly with the time elapsed before surgical drainage. In addition, the primary focus of infection, such as chronic sinusitis, mastoiditis, or petrous osteomyelitis, should be explored and debrided. The choice of initial empiric antimicrobial therapy is similar to that in brain abscess ([Table 431.6](#)). Intravenous therapy should be continued for 4 to 6 weeks after surgical drainage.

The initial empiric antimicrobial therapy for spinal epidural abscess should be directed at both *S. aureus* (found in approximately 50% of cases) and enteric gram-negative bacilli. Thus, oxacillin or naftillin and a third-generation cephalosporin (e.g., cefotaxime, ceftizoxime, ceftriaxone, or ceftazidime) may be suitable. An extended-spectrum penicillin (e.g., piperacillin, ticarcillin-clavulanate, imipenem, mezlocillin, or azlocillin) plus an aminoglycoside is appropriate if *P. aeruginosa* infection is suspected. Intravenous fluoroquinolone (e.g., ciprofloxacin or trovafloxacin) or trimethoprim-sulfamethoxazole may also be considered in the penicillin-allergic patient.

SEPTIC INTRACRANIAL THROMBOPHLEBITIS AND MYCOTIC ANEURYSM

INCIDENCE, EPIDEMIOLOGY, AND ETIOLOGY

Intracranial thrombophlebitis most frequently follows infection of the paranasal sinuses, middle ear, mastoid, or oropharynx. These catastrophic complications are fortunately rare in the postantibiotic era. *Lateral (transverse) sinus thrombophlebitis* usually follows chronic infection of the middle ear, mastoid, or petrous bone. *Cavernous sinus thrombophlebitis* is usually secondary to infection of the ethmoid, sphenoid, or maxillary sinuses. *Superior sagittal (longitudinal) sinus*

thrombophlebitis usually results from head trauma or postneurosurgical complications. The causative organisms depend on the underlying conditions and are similar to those in subdural empyema and cranial epidural abscess ([Table 431.1](#)).

PATHOGENESIS

The cranium is drained by a network of superficial veins (external portions of the cerebrum and brain stem), deep veins (central white matter, basal ganglia, and thalamus), and venous sinuses within the dura mater. The superficial veins and venous sinuses also communicate extensively with the extracranial venous system through numerous emissary veins that cross the skull and meninges. The intracranial venous system and sinuses lack valves and allow bidirectional blood flow. Because of extensive anastomosis, cortical venous thrombosis or occlusion of venous sinuses often produces only transient neurologic manifestations and at times may be silent. Because the middle cerebral arteries receive the greatest volume of blood, they are more frequently involved in infectious processes such as septic embolization or mycotic aneurysm, compared with other branches of the anterior and posterior circulation. Intracranial mycotic aneurysm usually results from septic embolization as a complication of bacterial endocarditis. This produces infection and necrosis in the arterial wall, which leads to dilation and possible rupture. Mycotic aneurysms can be multiple and are usually found on distal branches of the middle or anterior cerebral arteries. The spinal arteries are seldom involved in infections.

CLINICAL FINDINGS

The clinical manifestations of septic intracranial thrombophlebitis vary with the location and extent of cortical veins or dural sinuses involved ([Fig. 441.1](#)). If collateral venous drainage is adequate, septic venous thrombosis may produce only transient neurologic findings or may be silent. If the thrombus outstrips collateral flow, however, progressive neurologic deficits, including impairment of consciousness, focal or generalized seizures, and increased intracranial pressure, ensues. *Cavernous sinus thrombosis* is characterized by abrupt onset with diplopia, photophobia, orbital edema, and progressive exophthalmos. Involvement of the third, fourth, fifth, and sixth cranial nerves produces ophthalmoplegia, a midposition fixed pupil, loss of corneal reflex, and diminished sensation over the upper face. Obstruction of venous return from the retina results in papilledema, retinal hemorrhage, and visual loss. Thrombosis of the *superior sagittal sinus* usually presents with unilateral convulsions and alternating hemiplegia, monoplegia, or paraplegia due to communicating hydrocephalus. Occlusion of the *lateral sinus* produces pain over the ear and mastoid and may cause edema over the mastoid (Griesinger's sign). Involvement of the fifth and sixth cranial nerves produces ipsilateral facial pain and lateral rectus weakness (Gradenigo's syndrome). The early clinical manifestations of mycotic aneurysms are similar to those of cerebral emboli and infarction. The weakened vessel may be seen to increase in size progressively on serial angiograms. The funduscopic examination is particularly useful for the detection of an embolic source of infection because the ophthalmic artery is a branch of the internal carotid artery, and septic embolization within the anterior circulation may produce characteristic visual field defects and retinal lesions.

LABORATORY FINDINGS

Skull radiographs may also show pineal shift and evidence of sinusitis or mastoiditis. LP reveals increased intracranial pressure, a slight lymphocytic pleocytosis, and slightly elevated protein concentration. The CSF is usually sterile. MRI with angiography is the procedure of choice for the diagnosis of intracranial suppurative thrombophlebitis and mycotic aneurysm because of its ability to distinguish between flowing blood and thrombus. Angiography with close attention to the venous phase for evidence of nonfilling should be considered if venous sinus thrombophlebitis is suspected despite negative CT or MRI. Radionuclide scans may also be helpful. Abscess can be excluded by either CT or MRI. Cavernous sinus thrombosis is readily detected by CT. The definitive diagnosis of mycotic aneurysm requires the combination of both CT or MRI and angiography.

OPTIMAL MANAGEMENT

Treatment of septic cranial thrombophlebitis requires maximum dosages of intravenous antibiotics ([Table 431.6](#)) and surgical decompression of the underlying predisposing infection. Anticoagulation is controversial, and glucocorticoids or osmotic diuretics may be required to control intracranial hypertension. Internal jugular vein ligation has been used in lateral sinus thrombosis, and in a few instances thrombectomy has been successful. Antimicrobial therapy of mycotic aneurysm is directed at the causative organism of the underlying endarteritis, often associated with positive blood cultures. Prolonged treatment with high-dose intravenous antibiotics for at least 6 to 8 weeks is required. Because the clinical course of a mycotic aneurysm is variable and the risk of rupture with catastrophic cerebral hemorrhage cannot be predicted even after successful therapy of the underlying endocarditis, early surgical intervention is advised. Fortunately, these vascular lesions tend to occur in the distal branches of the middle or anterior cerebral arteries and hence are relatively accessible for surgical ligation or resection.

NEUROSYPHILIS

INCIDENCE, EPIDEMIOLOGY, AND ETIOLOGY

The incidence of syphilis has increased since the mid-1980s. It is the most chronic form of meningitis and has become an increasingly important complication in women with AIDS and in their newborn infants. From a preventive standpoint, asymptomatic neurosyphilis is the most important because it is during this phase of the disease that spread mostly occurs.

PATHOGENESIS

Up to 10% of patients with primary syphilis and 30% to 70% with secondary syphilis have pleocytosis of the CSF with a normal or slightly elevated CSF protein concentration, probably as the result of meningovascularitis induced by transient treponemia. In a proportion of such patients, meningovascularitis persists as evidenced by elevated treponemal antibodies in the CSF. This condition, without neurologic signs or symptoms, is called *asymptomatic neurosyphilis*. When not adequately treated, 7% to 9% of patients with asymptomatic neurosyphilis go on to have symptomatic neurosyphilis. Invasion of the CNS occurs from 3 to 18 months after initial infection. The early phases of neurosyphilis usually occur within 5 years after initial infection and are caused by treponemal obliterative endarteritis, meningitis or by meningovascularitis at a cerebral or spinal level. These early syndromes can present as transient ischemic attacks, pachymeningitis, or leptomeningitis. The late parenchymatous syndromes occur 5 to 25 years after infection and are primarily caused by neurovascular involvement. Clinically, these syndromes present as tabes dorsalis, general paresis, taboparalysis, syphilitic optic atrophy, and spinal syphilis. Tertiary granulomatous lesions (gummata) are rare today.

CLINICAL FINDINGS

Patients with meningeal syphilis present with headache, stiff neck, cranial nerve palsies, convulsions, and confusion without fever. Meningovascular syphilis may present 6 to 7 years after infection as a stroke (hemiplegia, aphasia, sensory loss, visual disturbance, or mental confusion). Tabes dorsalis is a degeneration of the afferent fibers of the dorsal spinal roots, the cranial nerves, and the sympathetic fibers. Sensory loss, ataxia, muscle hypotonia, and loss of tendon reflexes in the legs are the hallmarks. Impotence, sphincter disturbances, "lightning" pains in the legs, painful functional disorders of the viscera ("tabetic crisis"), and Argyll–Robertson pupils also occur. In general paresis, intellectual deterioration occurs (memory disturbances, poor judgment, delusions), often accompanied by epileptic attacks, slurred speech, Argyll–Robertson pupils, weakness, and fast tic-like movements in the face (*wetterleuchten*). Tabes and general paresis can occur together as taboparalysis. Partial expressions ("formes frustes") of the classic syndromes occur frequently. Syphilitic optic atrophy produces sequential and progressive blindness. Visual fields are constricted. Spinal syphilis manifests as either syphilitic meningomyelitis (Erb's spastic paraplegia, bilateral corticospinal tract signs) or spinal meningovascular syphilis (anterior spinal artery syndrome).

LABORATORY FINDINGS

Active treponemal infection of the CNS is detected by the local production of specific treponemal antibodies (e.g., *Treponema pallidum* hemagglutination assay [TPHA]) in the CSF. This can be measured either by the presence of CSF antitreponemal IgM antibody (TPHA-IgM) or by determining the CSF:serum ratio of TPHA-IgG titers. In the latter instance, the normal range of the CSF:serum TPHA-IgG ratio is between 0.5 and 2.0. In active neurosyphilis, this ratio is increased to 3.0 or higher. The CSF in neurosyphilis may show lymphocytic pleocytosis, normal glucose, and normal or slightly elevated protein concentration. A negative CSF treponemal antibody test (e.g., fluorescent treponemal antibody unabsorbed or TPHA-IgG) virtually rules out neurosyphilis in patients with late disease, but not in those with early disease.

OPTIMAL MANAGEMENT

The treatment of neurosyphilis is aqueous penicillin G, 0.15 million U per kilogram intravenously per day for 15 days in six divided doses. In patients who are allergic

to penicillin, tetracycline hydrochloride, or erythromycin, 2 g daily for 30 days is required. Follow-up evaluation by repeating the LP at 6 months is recommended.

LYME DISEASE

INCIDENCE, EPIDEMIOLOGY, AND ETIOLOGY

Lyme disease is caused by the spirochete *Borrelia burgdorferi*. The vector is the common ixodid tick. Although Lyme disease occurs in 43 states and in many countries around the world, in the United States the disease is concentrated along the coastal plains of the Northeast and mid-Atlantic regions, in the upper Midwest, and to a lesser degree along the Pacific coast. Exposure is most common in meadows or woodlands, but infection may also occur in suburban settings.

PATHOGENESIS

The precise pathogenesis of Lyme disease, particularly CNS involvement, is not totally clear. In the early stages of infection, within 3 days to 3 weeks after exposure, a typical skin rash (erythema chronicum migrans [ECM]) occurs in over two thirds of cases. This is accompanied by a flulike illness with fever, headache, stiff neck, arthralgia, myalgia, and regional lymphadenopathy in about 50% of cases. Like neurosyphilis, the early neurologic manifestations of Lyme disease are probably secondary to meningovascular involvement. The late stages of Lyme disease include debilitating arthritis; neurologic manifestations such as fatigue, chronic encephalomyelitis, paraparesis, ataxia, polyradiculopathy, depression, and dementia; and cardiac complications such as heart block, myocarditis, or left ventricular dysfunction. It is suggested that the development and deposition of immune complexes in the skin, synovium, or neural or cardiac tissues is the underlying pathogenesis for the multisystem involvement seen in those with Lyme disease.

CLINICAL FINDINGS

The most distinctive clinical feature of Lyme disease is the large, flat, annular skin lesion of ECM. These skin lesions may be single or multiple and often reach a very large size with a zone of central clearing. Arthritis is the most common complication (45% of cases), followed by neurologic (11%) and cardiac (8%) manifestations. The neurologic presentations are protean, including aseptic meningitis, encephalitis, chorea, cerebellar ataxia, cranial neuritis, motor and sensory radiculoneuritis, mononeuritis multiplex, and myelitis, each in various combinations. The usual pattern is a fluctuating meningoencephalitis with superimposed cranial and peripheral radiculopathy. These neurologic findings usually appear early in the course, within days to weeks after the antecedent tick bite, often while the ECM is still present or within 1 to 6 weeks after the skin rash has faded.

The onset of meningitis is suggested by intermittent attacks of severe, prostrating headaches with stiff neck, nausea, vomiting, and photophobia, alternating with periods of mild infrequent headache for another several weeks. Symptoms of encephalitis include somnolence, emotional lability, depression, poor memory and concentration, or behavioral changes. The most common manifestation of cranial neuritis is unilateral or bilateral facial palsy. Radiculoneuritis may be motor, sensory, or both. Shoulder girdle neuritis, indistinguishable clinically from neuralgic amyotrophy, is the most common motor radiculopathy. Sensory symptoms include regional or generalized cutaneous hyperesthesia to touch or temperature.

LABORATORY FINDINGS

Lyme disease is diagnosed primarily by the clinical presentation, the classic ECM skin lesions, a history of tick bite or exposure, and the exclusion of other conditions. Confirmation by laboratory diagnosis requires the demonstration of specific serum antibodies to *B. burgdorferi*, either by enzyme-linked immunosorbent assay or by immunoblot techniques. Unfortunately, interpretation of results may be complicated because of poor sensitivity and presence of cross-reactive antibodies to indigenous or other spirochetes. Elevated CSF antibody titer to *B. burgdorferi* compared with serum levels is probably a more sensitive method for making the diagnosis of Lyme neuroborreliosis than serum antibody titers alone. Polymerase chain reaction (PCR) directed at *B. burgdorferi* DNA in the CSF may be helpful. Unfortunately, since PCR does not differentiate between live and dead organisms, it cannot be used to prove active infection. CSF examination in Lyme neuroborreliosis may reveal variable or minimal inflammation. MRI scans may show areas of increased density that are consistent with demyelination. Although such patients often have specific antibody to *B. burgdorferi* in the CSF, a test that unequivocally indicates active infection in the CNS with this organism is lacking. Direct isolation of *B. burgdorferi* from the blood or CSF is difficult and a low-yield procedure.

OPTIMAL MANAGEMENT

Patients in whom frank meningitis, encephalitis, or cranial and peripheral neuropathies develop may be treated with intravenous penicillin G (20 million U per day for 10 to 14 days in four to six divided doses). Headache, stiff neck, and radicular pain usually begin to subside by the second day of therapy and are often completely resolved by 7 to 10 days. Motor deficits, however, frequently require 7 to 8 weeks for complete recovery. Ceftriaxone, 2 g per day in one or two divided doses for 14 days, has also been used successfully in patients with Lyme neuroborreliosis. Patients allergic to penicillin may be treated with tetracycline (2 g per day in four divided doses) or doxycycline (400 mg per day in two divided doses) for 10 to 20 days. There is no established role for the use of corticosteroids in addition to antibiotic treatment in Lyme neuroborreliosis.

CHAPTER 442: VIRAL INFECTIONS OF THE NERVOUS SYSTEM

JORGE T. GONZALEZ

[Pathogenesis](#)
[Clinical Syndromes](#)

This chapter deals with four neurologic clinical syndromes that can result from a viral process. The first three syndromes, aseptic meningitis, encephalitis, and poliomyelitis, involve the central nervous system (CNS). The fourth syndrome, herpes zoster ganglionitis, primarily involves the peripheral nervous system. Slow virus infections, HIV infection, and other causes of aseptic meningitis are discussed in separate chapters.

Depending on their ability to infect certain cell populations (i.e., meningeal cells, brain parenchymal cells), many viruses that affect the nervous system have a distinct, although not exclusive, predisposition to manifest as a particular clinical syndrome. For example, enteroviruses are the most common causes of aseptic meningitis, but occasionally cause severe encephalitis. Conversely, arboviruses are common causes of encephalitis but sometimes lead to aseptic meningitis. Specific viruses are discussed in association with the clinical syndromes with which they are most commonly associated.

PATHOGENESIS

As a rule, neurologic manifestations of viral infections represent a small percentage of all infections. Most infective viral agents gain access to the CNS through hematogenous spread. The initial viremia usually is transient and is followed by a phase of viral replication in the reticuloendothelial system and sometimes in muscle tissue. The degree of secondary viremia that follows determines whether successful infection of the CNS will continue.

Viral invasion of the CNS can occur by several mechanisms. The virus may cross the blood–brain barrier directly, or it may infect leukocytes initially, which then cross the disrupted blood–brain barrier. It also may infect endothelial cells, adjacent glial cells, and neurons. On histopathology, this is seen as endothelial inflammation and lymphocytic infiltration of the perivascular areas and surrounding gray matter. Some viruses, such as the mumps virus, cross through the epithelium of the choroid plexus before spreading to the ependyma and parenchyma. Once in the subarachnoid space, the organisms can spread contiguously, through infected leukocytes or along axons, dendrites, and other cell processes. Alternatively, there are three known organisms that can penetrate the CNS through peripheral and olfactory nerves. Herpes simplex virus 1 and *Naegleria fowleri* reach the CNS by extension from the olfactory bulbs. In contrast, the rabies virus spreads from the site of inoculation to the CNS along the motor and sensory fibers.

In acute viral encephalitis, the virus produces parenchymal inflammation by cytotoxicity and lysis of infected cells or by initiation of an immunologic reaction against parenchymal cells. With progression of the disease, histopathologic changes include astrocytosis and gliosis. Cowdry type A and B bodies, which are intranuclear inclusions, are associated with herpesvirus, adenovirus, and the measles virus. Intracytoplasmic inclusions are found in cytomegalovirus encephalitis, and Negri bodies are pathognomonic of the rabies virus. The extent of the pathology depends partly on the type of virus involved. For example, infections with herpes simplex virus 1 and eastern equine virus can lead to severe and widespread neuronal dysfunction, whereas infections with viruses such as the LaCrosse virus usually have milder presentations.

CLINICAL SYNDROMES

VIRAL MENINGITIS

Viral meningitis is inflammation of the meninges due to viral organisms. It is the most common cause of aseptic meningitis, which is characterized by cerebrospinal fluid (CSF) lymphocytic pleiocytosis. By definition, there is no evidence of a bacterial, fungal, protozoal, or parasitic organism.

Incidence and Epidemiology

From 1983 to 1993, the yearly incidence of aseptic meningitis ranged from 8,300 to 12,800 cases. Enteroviruses are most commonly associated with this syndrome, accounting for up to 80% of all cases. The mumps virus has been described as the second most common cause, but its incidence has decreased substantially with vaccination.

Factors that influence the epidemiology of viral meningitis include season, geographic location, and climate. Indirectly, these factors provide significant clues to the identity of the causative agent ([Table 442.1](#)). In North America, the enteroviruses and arboviruses are most prevalent in summer and early fall. Between fall and winter, the incidence of lymphocytic choriomeningitis increases, whereas in winter and spring, mumps tends to be more common. In general, viral meningitis is most prevalent during summer, peaking between August and October, which essentially reflects the incidence of the enteroviruses.

Agent	Characteristic Clinical Findings or History	Season/Epidemiology
Enteroviruses	Myalgias, pleurodynia, conjunctivitis, rash	Summer/fall; epidemic and sporadic
Lymphocytic choriomeningitis	Contact with rodents; rash, arthralgia, orchitis, myelomeningocele	Winter; sporadic
Herpes simplex type 2	Primary genital lesions	No seasonality; sporadic
Mumps	Parotitis, orchitis, parotiditis	Spring/summer; sporadic
Herpes simplex type 1	Focal neurologic deficits	No seasonality; sporadic
Varicella zoster virus	Characteristic rash, cerebellar ataxia	No seasonality; sporadic
Human herpesvirus 6	Focal neurologic presentation	No seasonality
Epidemic-bull virus	Mononucleosis syndrome	No seasonality; sporadic
Cytomegalovirus	Immunosuppression	
Eastern equine virus	Mosquito-borne; viremia; encephalopathy	Summer; epidemic, eastern coastal states
Western equine virus	Mosquito-borne; focal encephalitis	Summer; epidemic, western US and Canada
St. Louis virus	Mosquito-borne; dysuria; BAH; myalgia	Summer; epidemic, southeastern and midwestern US
California virus	Generalized and focal seizures	Summer; epidemic, north central states
Rabies	History of animal bite, dysphagia	No seasonality; sporadic

BAH: syndrome of inappropriate antidiuretic hormone secretion.

TABLE 442.1. CLINICAL EPIDEMIOLOGY OF VIRAL MENINGITIS AND ENCEPHALITIS

Specific Viruses That Cause Meningitis

Enteroviruses

Enteroviruses are RNA viruses that belong to the picornavirus group. They have a worldwide distribution and humans are their only natural hosts. They inhabit the gastrointestinal tract and are spread by the fecal–oral route. Enterovirus infection is most common during summer and fall in temperate countries but has no seasonal prevalence in the tropics. It accounts for 80% to 92% of all cases of aseptic meningitis. Epidemics of aseptic meningitis have been described in young infants.

Because patients with enterovirus infection present with a nonspecific aseptic meningitis picture, evidence of its presence may circumstantially depend on the season, associated signs and symptoms, and knowledge of an ongoing epidemic. The organism may be cultured from any specimen (i.e., CSF, nasopharyngeal swab). However, growth from stool specimens may not be causally related because the organism can stay in the lower gastrointestinal tract for as long as 8 to 12 weeks. Thirty-one serotypes of echovirus, 23 serotypes of coxsackievirus A, six serotypes of coxsackievirus B, and three serotypes of poliovirus have been identified as pathogens in human CNS infections.

Examination of the CSF usually reveals a leukocyte count of less than 500 cells per microliter, with lymphocytic predominance in 48 hours, although up to two thirds of

patients have polymorphonuclear predominance initially. The protein level is mildly elevated and the glucose level usually is normal but may be low in up to 18% of cases. Polymerase chain reaction (PCR) techniques are currently available to detect enteroviruses in the CSF with a sensitivity of 85%.

Encephalitis, ataxia, paralysis, and learning disabilities in children are rare complications. In children with agammaglobulinemia, a complication consisting of a dermatomyositis-like syndrome and edema may develop and responds to treatment with intravenous g-globulin.

Mumps Virus

Mumps is caused by a single-stranded paramyxovirus. Similar to the enteroviruses, the mumps virus has a ubiquitous distribution, but it occurs more commonly during late winter and spring in temperate areas. The mumps virus is spread by respiratory droplet infection or direct contact with saliva and infects primarily the parotids, testes, ovaries, mammary glands, pancreas, and, occasionally, CNS. Involvement of the CNS may be manifested as a meningitis, encephalitis, or meningoencephalitis. Mumps meningitis usually is a benign syndrome with a male:female ratio of 2 to 5. In a few cases, it causes unilateral deafness from cochlear inflammation. Other rare complications include polyradiculitis, cranial nerve palsy, and seizures. The diagnosis is based on the clinical picture of parotitis (50% of cases) or other glandular involvement. This can be confirmed by isolation of the virus from CSF, saliva, or urine. Serologic diagnosis of a recent infection can be established by complement fixation or by documentation of fourfold rise in antibody titers. The CSF leukocyte count is predominantly lymphocytic, ranging from 5 to 500 cells per microliter. The CSF protein level is mildly increased and the glucose level is normal; however, in 5% to 15% of cases, hypoglycorrhachia may be observed. Although 50% to 90% of patients with mumps parotitis have CSF pleocytosis, only 1% to 10% have symptomatic meningitis.

Lymphocytic Choriomeningitis Virus

The virus that causes lymphocytic choriomeningitis is an arenavirus that is transmitted to humans through the inhalation or ingestion of food or particles contaminated with the urine, feces, and other secretions of infected rodents. It does not have any seasonal prevalence, although the incidence is increased slightly during winter, which may reflect increased contact with the common house mouse that typically enters the warmer environment of a household. During the early stages, the patient experiences a nonspecific viral prodrome with fever, retro-orbital headache, myalgia, arthralgia, rash, and respiratory symptoms. As in mumps, parotitis with or without orchitis may occur. The disease course usually is self-limited, especially if the infection is confined to an aseptic meningitis; however, a severe encephalitis may be part of the clinical picture. Other complications at later stages include orchitis, arthritis, myocarditis, and alopecia.

Examination of the CSF may reveal an unusually high leukocyte count (more than 1,000 cells per microliter) with lymphocytic predominance. Hypoglycorrhachia also may be seen in 25% of cases, and a complete blood count may demonstrate leukopenia and thrombocytopenia.

The virus can be cultured early from blood and CSF and at later stages from urine. Commonly, a fourfold rise of titers in the serum has been used to confirm the diagnosis. The presence of IgM antibody in the blood and CSF may indicate recent infection.

Herpes Simplex Virus

Herpes simplex meningitis usually is caused by herpes simplex virus type 2 that has spread hematogenously from a primary infection, often of the genitourinary tract. Typically, herpes simplex type 2 meningitis is a benign, self-limited disease that affects young, sexually active adults. An active genital lesion often is present. Occasionally, herpes simplex virus type 1 causes aseptic meningitis, but it has a much greater predisposition for meningoencephalitis.

In a few reported cases, a recurrent meningitis has been associated with a sacral radiculitis and low segment myelitis. Similar complications have been observed in patients with AIDS.

Examination of the CSF reveals lymphocytic pleocytosis, which may be as high as 2,600 cells per microliter; a protein level greater than 110 mg per deciliter in more than 50% of cases; and, occasionally, hypoglycorrhachia. A definitive diagnosis can be established by CSF culture, although isolation often is unsuccessful. A fourfold rise in titers can help confirm the diagnosis. If available, use of the PCR test can be sensitive and specific.

Treatment with acyclovir is not necessary unless a primary genital infection is evident.

Mollaret Meningitis

Herpes simplex virus has been detected by PCR in Mollaret meningitis, which is characterized by recurrent benign episodes of meningitic symptoms and fever lasting 1 to 3 days. An initial CSF pleiocytosis with predominance of polymorphonuclear neutrophils and endothelial leukocytosis on the first day is followed by CSF lymphocytosis. With an active primary genital infection, intravenous acyclovir is recommended. If none, oral acyclovir 200 mg five times per day for 5 days may suffice.

Other Herpesvirus Meningitides

Varicella-zoster virus and Epstein–Barr virus have been associated with aseptic meningitis and have a benign course if the infection remains limited to the meninges. Epstein–Barr virus meningitis usually occurs in the setting of infectious mononucleosis, and also may have features of encephalitis. The CSF profile is characterized by atypical lymphocytes, mononuclear cells, an increased protein level, and heterophile antibodies. Cytomegalovirus meningitis is common in immunocompromised patients.

Clinical Findings

In general, patients with viral meningitis present with a sudden or gradual onset of headache, low- to moderate-grade fever, and mild neck stiffness. Malaise, myalgia, nausea, and vomiting may occur. Photophobia and, occasionally, mental confusion may be present. Although the clinical presentations may be similar, certain findings are associated with specific viral agents (i.e., parotitis with the mumps virus, cutaneous genital lesions with herpesviruses, conjunctivitis with enteroviruses).

The differential diagnosis of viral meningitis includes all other causes of aseptic meningitis ([Table 442.2](#)). Nonviral infections, such as partially treated bacterial infections, parameningeal processes, Lyme disease, tuberculosis, and *Mycoplasma*, fungal, parasitic, and protozoal infections, may have similar clinical and CSF presentations. In addition, noninfectious causes, such as neoplastic processes, connective tissue diseases, sarcoidosis, and various drugs, should be included in the differential diagnosis. Appropriate testing should be performed based on the overall assessment to exclude the treatable causes.

Leptospirosis (Weil's disease)
Tuberculosis
Toxoplasmosis
Rocky Mountain spotted fever
Mycoplasma infection
Lyme disease
Cryptococcosis
Coccidioidomycosis
Histoplasmosis
Amebic meningoencephalitis
Cysticercosis
Parameningeal processes
Paragonimiasis
Toxocarasis
Schistosomiasis
Systemic lupus erythematosus/Jorgensen's syndrome
Uveomeningoencephalitis (Vogt-Koyanagi-Harada syndrome)
Behçet's disease
Whipple's disease
Sarcoidosis
Mollaret's disease
Granulomatous angitis

TABLE 442.2. NONVIRAL CAUSES OF ASEPTIC MENINGITIS AND ENCEPHALITIS

Laboratory Findings

The primary objective of the laboratory evaluation is to confirm the clinical diagnosis of a meningitic process and, if possible, identify the causative agent. However, in many cases, the diagnosis of an aseptic meningitis is made, but the agent cannot be identified.

The CSF examination is the most important step in establishing the presence of a viral meningitis. Typically, CSF findings include lymphocytic pleocytosis with a leukocyte count of less than 1,000 cells per microliter, a normal glucose level, and a slightly to moderately elevated total protein level (usually less than 80 to 100 mg per deciliter). Transient polymorphonuclear cell predominance may be seen in the initial stages but soon shifts to a lymphocytic predominance. Up to 14% of all patients with acute bacterial meningitis present with this picture. In addition, some cases of enterovirus meningitis are associated with a persistent polymorphonuclear cell predominance. Certain unique findings also are associated with some virologic agents, such as hypoglycorrhachia in some cases of mumps, herpes virus infection, or lymphocytic choriomeningitis.

Culturing the virus from a reliable source, preferably the CSF, is the most definitive way of identifying the agent involved. The usefulness of this test depends on the rapidity with which results can be obtained and on the sensitivity, which can range from almost nil for herpes simplex virus type 2 to between 40% and 80% for the enteroviruses.

PCR testing, when available, is being used increasingly to identify many organisms, including herpes simplex virus types 1 and 2, varicella-zoster virus, Epstein-Barr virus, cytomegalovirus, enteroviruses, HIV, and JC virus. PCR has been performed on human herpesvirus 6, lymphocytic choriomeningitis virus, measles, mumps, and adenovirus. This technique allows rapid and accurate diagnosis of an organism with results potentially available in a few hours. Moreover, it avoids unnecessary investigation or antibiotic treatment and may lead to early discharge of the patient.

The results of other routine laboratory tests usually are normal. However, these tests still should be performed because some abnormalities may occur that are characteristic of specific viruses, such as thrombocytopenia and leukopenia with the lymphocytic choriomeningitis virus.

Neuroradiologic imaging does not play an important role in meningitis unless there is parenchymal involvement. However, with the improved resolution achieved by modern scanners and with the use of contrast agents, meningeal enhancement sometimes can be seen.

Optimal Management

Please refer to [Chapter 431](#) for information regarding the treatment of viral meningitis.

VIRAL ENCEPHALITIS

Viral encephalitis is an inflammation of the brain parenchyma caused by a virus. It manifests as a syndrome that begins with a viral prodrome of fever, headache, nausea, and vomiting, followed by an encephalopathy characterized by altered mental status, behavioral changes, and convulsions. Focal neurologic deficits may occur in the form of aphasia, hemiparesis, partial seizures, ataxia, or cranial nerve palsy. In severe cases, progression to a fatal coma and death may result.

It is not always possible to differentiate viral encephalitis from viral meningitis based on the physical examination alone. Moreover, nuchal rigidity and photophobia may be present, giving credence to the term *meningoencephalitis*.

Incidence and Epidemiology

According to the Centers for Disease Control and Prevention, the reported yearly incidence of viral encephalitis in the United States has ranged from 800 to 1,700 cases over the past 10 years. Postinfectious encephalitis accounts for an additional 100 cases per year. However, these figures may represent only 18% to 60% of the actual number of cases. Furthermore, a specific virus is identified in only 25% of the reported cases.

Herpes simplex virus is the most common cause of sporadic encephalitis, accounting for about 10% of all reported cases. Collectively, the arboviruses account for another 10% of cases, and for as many as 50% during epidemics. In the United States, California encephalitis and St. Louis encephalitis are the most common forms of the disease. However, Japanese B encephalitis is the most common epidemic viral encephalitis worldwide. In immunocompetent patients, other viral agents, such as the rabies virus, enteroviruses, the mumps virus, the rubella virus, Epstein-Barr virus, and the measles virus, cause encephalitis much less commonly.

Specific Viruses That Cause Encephalitis

Herpes Simplex Virus

Herpes simplex encephalitis is a potentially devastating and often fatal disease with an estimated incidence of 1 per 250,000 to 500,000 population per year. Most cases in older children and adults are caused by herpes simplex virus type 1, but in neonates, herpes simplex virus type 2 is involved. The initial presentation usually is a nonspecific fever, headache, and lethargy progressing to a more profound altered mental status. In more than 85% of cases, focal neurologic deficits such as cranial nerve palsy, autonomic dysfunction, hemiparesis, and focal seizures are observed. Untreated, patients quickly deteriorate into a coma and 60% to 80% of them die.

Much of the pathology is in the orbitofrontal and temporal lobes, where localized or widespread hemorrhagic necrosis can be found ([Fig. 442.1](#)). Microscopically, neuronal necrosis, polymorphonuclear cells, hemorrhage, and intranuclear Cowdry type A inclusions in neurons and glial cells are evident. Based on animal models, in 30% of cases, primary infection is hypothesized to occur as the virus spreads along olfactory nerve fibers to the CNS after intranasal inoculation. In most cases, it is postulated that latent virus in the trigeminal ganglia from a previous infection is reactivated and spreads anterogradely to involve the temporal and orbitofrontal lobes.

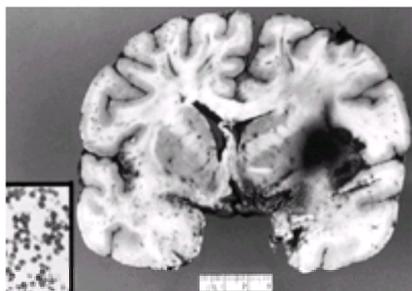

FIGURE 442.1. Gross appearance of a brain infected with herpes simplex virus type 1. Note the multiple hemorrhagic encephalomalacia with mass effect involving the temporal and insular lobes on the right. The inset depicts the typical viral nucleocapsid of the herpesvirus.

The CSF leukocyte count usually is less than 500 cells per microliter with lymphocytic predominance, and red blood cells are seen in 80% of cases. The protein level commonly is elevated and the glucose level is normal, although hypoglycorrhachia occasionally is observed. However, CSF findings initially are normal in almost 10% of cases. Culture of the virus from the CSF is difficult and other serologic methods, such as immunoblot assay, immunofluorescence, and enzyme-linked immunosorbent assay, usually are not helpful early in the disease course, when a definitive diagnosis is crucial. Neuroimaging studies, particularly magnetic resonance imaging (MRI), can demonstrate the lesions in characteristic areas, but are nonspecific ([Fig. 442.2](#)). The finding of focal slowing or epileptiform discharges

on electroencephalography is fairly sensitive and has been shown to correlate in 80% of cases.

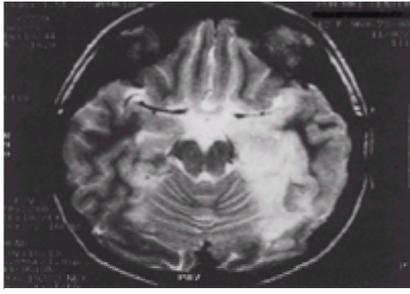

FIGURE 442.2. Herpes encephalitis. The T2-weighted magnetic resonance image shows multiple foci of increased signal primarily in medial aspect of the left temporal lobe with extension to the inferior occipital lobe. There is also some lesser involvement on the right side in similar areas.

In current practice, PCR testing for the detection of herpes simplex virus in the CSF is the norm. False-negatives, however, can occur very early in the course; thus, a second lumbar puncture may need to be considered 24 to 48 hours later in suspected cases. PCR is usually negative 2 weeks after onset of symptoms. Determination of herpes simplex virus antibody in serum and CSF may also be helpful in the diagnosis, especially if the PCR result is not convincingly positive. A serum to CSF ratio of less than 20:1 of herpes simplex virus antibody implies intrathecal synthesis. This process occurs in the first week of onset of symptoms up to the fourth week. Brain biopsy has been advocated as the gold standard for the diagnosis of herpes encephalitis but is now rarely performed. Specimens should be evaluated by electron microscopy, antigen testing by immunofluorescence, and, most important, viral culture, which is 90% sensitive and 100% specific.

Herpes simplex virus encephalitis is treated with intravenous acyclovir 10 mg per kilogram (ideal body weight) every 8 hours for 10 to 21 days.

Arboviruses

The arboviruses that commonly cause viral encephalitis in humans include the togaviruses (alphavirus), flaviviruses, bunyaviruses, and reoviruses. The most commonly encountered arbovirus infections in the United States are California encephalitis (bunyavirus), St. Louis encephalitis (flavivirus), western equine encephalitis (alphavirus), and eastern equine encephalitis (alphavirus). Venezuelan equine encephalitis, Powassan encephalitis, and Colorado tick fever are reported less often. These viruses are most prevalent during the summer months, just after the mosquito population peaks. In most cases, the clinical and CSF findings are similar and nonspecific. However, serologic testing, especially complement fixation antibodies, is useful in establishing the diagnosis. For some of these viruses, inapparent infection may account for up to 90% of cases.

Western equine encephalitis usually occurs in the western United States and Canada during the summer months, following the geographic distribution of its vector, the *Culex tarsalis* mosquito. Young children and inhabitants of rural areas are at higher risk for infection with this virus. The incubation period lasts 5 to 20 days and is followed by a prodrome of nonspecific fever, general malaise, vomiting, and myalgia. The severity of the disease ranges from a mild febrile illness to a severe encephalopathy with a mortality rate of 5% to 15% in some series. Full recovery is the rule, although developmental delay, seizure disorder, and paralysis have occurred in children. In adults, postencephalitic parkinsonism after the acute phase has been described.

Eastern equine encephalitis occurs primarily in eastern coastal states, particularly in New England. The virus is transmitted to humans by *Aedes* mosquitoes. Although the disease is not as prevalent, it can cause widespread parenchymal destruction involving whole lobes, similar to herpes simplex virus type 1 encephalitis. This is in contrast to the microscopic lesions caused by other arboviruses. Reportedly, up to one third of patients die and another third have serious morbidity, such as mental retardation, seizures, and hemiplegia.

St. Louis encephalitis has been an important cause of epidemics in the midwestern and southeastern United States. Depending on the region, the virus is transmitted by different *Culex* mosquitoes. The illness is most severe in patients older than 60 years of age. An influenza-like prodrome of fever, headache, and malaise occurs initially, followed by symptoms of encephalitis. Occasionally, severe muscle aches, dysuria, and pyuria are observed. The syndrome of inappropriate antidiuretic hormone secretion also is encountered in up to 25% of cases. More than 90% of patients recover without any sequelae, although some, especially the elderly, are prone to complications such as behavioral disorders, memory loss, and seizures. The elderly also have a higher risk for increased mortality, with rates up to 19.5%.

California encephalitis (LaCrosse virus) is the most common viral encephalitis in the United States. Similar to the other arbovirus infections, it is more common during the summer months and has a propensity for rural areas in which the mosquito vector, *Aedes triseriatus*, inhabits stagnant water. In addition to the usual prodrome and encephalitic picture, generalized and partial seizures occur in 60% of infected children but are less common in adults. Mild variants of the disease are associated with full recovery, but severe infections lead to focal neurologic findings such as aphasia and hemiparesis in up to 25% of cases.

Rabies Virus

The yearly incidence of human rabies in the United States is none to three cases, comparatively much less than the hundreds of cases reported worldwide. This low rate can be attributed to the standardized vaccination of domestic animals. Wild animals such as skunks, foxes, raccoons, bats, and coyotes remain sources of human infection. The incubation period is shorter for bites on areas of increased innervation, such as the face, fingers, and genitalia, than for bites on the arms and legs. After inoculation, the virus ascends along the peripheral nerves by retrograde axonal transport and reaches the CNS. The two presentations of rabies consist of the more well-known rabid form and a less common paralytic form. The prodromal phase of the rabid form starts with fever, headache, malaise, and sore throat. Subsequently, an encephalopathy characterized by severe agitation, anxiety, and confusional psychosis ensues. In about 50% of cases, the patient has severe throat spasm when swallowing liquid, resulting in the appearance of hydrophobia. The dysphagia also makes the patient appear to be frothing with saliva. Death occurs shortly after this overactive phase or after the patient slips into a coma.

In about 20% of rabies cases, the spinal cord is the primary site of involvement. The infection initially presents as paresthesia and pain of the wounded limb, followed by paralysis. A more diffuse weakness with or without bulbar involvement occurs, mimicking Guillain-Barre(c) syndrome. Little treatment is possible once symptoms develop. Most patients succumb within 1 to 2 weeks, although there have been a few reports of survivors.

Varicella-Zoster Virus

Varicella-zoster virus is a herpesvirus that commonly manifests as yearly epidemics of chickenpox. It also can present as several other syndromes, including cerebellitis, encephalitis, herpes zoster ganglionitis, radiculomyelitis, and isolated myelitis. Cerebellitis from varicella-zoster virus has an incidence of 1 per 1,000 cases and usually manifests in childhood during the second week of illness as a result of an immunologic response to the virus. This is a self-limiting disease that lasts for a few days to a few weeks. Varicella-zoster virus encephalitis is less common, with an incidence of 1 per 2,000 cases. Encephalitic symptoms follow the rash after 5 to 6 days and, despite the self-limited nature of the disease, mortality rates can be as high as 15%. Diagnosis can be established by CSF PCR, viral culture, and increase in antibody titer.

Human Herpesvirus 6

Human herpesvirus 6 is the causative agent of roseola infantum, also known as sixth disease or exanthem subitum, which has been associated with meningoencephalitis and recurrent febrile seizures in children. It has also been identified as another cause of focal encephalitis in adults and may present as partial seizures and focal neurologic deficits similar to herpes simplex virus encephalitis. The course of the illness can be mild and self-limiting, but there have been instances of severe neurologic sequelae and death. Laboratory diagnosis is by viral culture, a fourfold or greater rise in IgG titer or by PCR (preferably by RNA

detection assay). Gancyclovir or foscarnet are the drugs of choice, although their efficacy has not been proved.

Epstein–Barr Virus

Several neurologic syndromes have been described with Epstein–Barr virus infection, including aseptic meningitis, encephalitis, Guillain–Barre(c) syndrome, Bell's palsy, and transverse myelitis. Epstein–Barr virus encephalitis usually occurs in infectious mononucleosis and manifests as a diffuse or focal involvement. Although most patients recover fully, mortality and morbidity rates of 8% and 12%, respectively, have been reported. The diagnosis can be established by testing for the heterophile antibody, by other Epstein–Barr virus serologic tests, by viral culture, and by PCR.

Clinical Findings

The diagnosis of viral encephalitis rests on clinical findings of a febrile illness as part of a viral prodrome and an encephalopathy. The encephalopathy may be diffuse or focal and may consist of other neurologic deficits, such as altered mental status, behavioral or speech disturbances, seizures, or hemiparesis. In most cases, the presentation is mild. However, severe and sometimes fatal infections do occur.

The encephalopathic presentations of the different viruses are generally similar. However, some viruses have certain patterns of clinical manifestations that may be explained partly by their tropism for specific CNS cell populations or regions. For example, rabies has a strong predisposition for the limbic areas, whereas herpes simplex virus invariably involves the temporal lobe.

The physical examination must distinguish between a generalized encephalopathy and a focal process. Herpes simplex encephalitis is the most common cause of focal encephalitis. However, the differential diagnosis for other organisms that can mimic this entity is considerable. For example, tuberculosis, *Cryptococcus* infections, bacterial abscesses, and some viral infections (e.g., Epstein–Barr virus, several of the arboviruses) present similarly.

Laboratory Findings

As in viral meningitis, CSF findings are nonspecific in most cases of viral encephalitis, with predominantly lymphocytic pleocytosis, a moderately elevated protein level, and a normal glucose level. Predominance of neutrophils is common in the initial stages, especially with eastern equine encephalitis, which may produce CSF findings similar to those of a bacterial infection. However, most of the viral organisms that commonly cause viral encephalitis are more difficult to isolate from the CSF or blood. Serologic methods such as hemagglutination inhibition, neutralizing antibodies, or complement fixation tests have been more successful in identifying the offending agents by demonstrating a fourfold or greater rise in IgG titers. However, these tests take weeks to complete and have limited usefulness from a therapeutic standpoint. In a few viral infections, such as western equine encephalitis, St. Louis encephalitis, and Japanese B encephalitis, acute IgM titers can be obtained a few days after onset. In herpes simplex virus encephalitis, a PCR test using CSF has a sensitivity of 75% to 100% and a specificity of 100%, making it useful for detecting the infection early in its course. PCR has also been used in identifying other agents including varicella-zoster virus, human herpesvirus 6, Epstein–Barr virus, cytomegalovirus, and Jakob–Creutzfeldt virus.

Neuroimaging modalities such as computed tomography (CT) and MRI have become important tools in the evaluation of viral encephalitis. Areas of cerebritis appear as poorly defined regions of lower density on CT. On MRI, they appear as hypointense areas on T1-weighted scans and as hyperintense areas on T2-weighted images. The sensitivity of MRI can be increased with the use of contrast agents. Because of its propensity to cause petechial hemorrhage in the temporal lobe and occasionally along the orbitofrontal lobe, herpes simplex virus type 1 encephalitis lends itself to early detection by CT or MRI.

Electroencephalography has proved to be a sensitive test for an encephalopathic process. Findings include focal or generalized background slowing and epileptiform discharges. Findings of focal activity in or near the temporal regions can be assumed to be herpes simplex virus type 1 encephalitis in the appropriate clinical setting, although patients with conditions such as Epstein–Barr virus infection, eastern equine encephalitis, or human herpesvirus 6 may present similarly. The absence of a focal process does not rule out herpes simplex virus infection.

Optimal Management

Please refer to [Chapter 431](#) for information regarding the treatment of viral encephalitis.

POLIOMYELITIS

Before routine immunization became available, the polioviruses types 1, 2, and 3 were chiefly responsible for the syndrome of poliomyelitis, with serotype 1 accounting for epidemics of the disease. Like the other enteroviruses, polioviruses are single-stranded RNA viruses that are transmitted by the fecal–oral route and reach the CNS by hematogenous spread. The incidence of poliomyelitis in the United States between 1984 and 1993 ranged from three to nine cases per year (average 7.5 cases). Most cases are vaccine-associated after exposure to the live attenuated virus. Other enteroviruses, such as certain serotypes of the echoviruses and coxsackieviruses, have been reported to cause paralytic poliomyelitis.

Most cases of poliomyelitis are inapparent or associated with only a mild viral prodrome. About 1% to 2% of patients have neurologic symptoms, which range from an initial aseptic meningitis to severe asymmetric paralysis of the extremities with or without bulbar involvement resulting from inflammation and central chromatolysis of the lower motor neurons in the brain stem and spinal cord. The lumbar segments more commonly are affected clinically, followed by the cervical segments and, to a lesser extent, the brain stem. Muscle weakness peaks in 2 to 5 days. Treatment is supportive, with special attention paid to respiratory failure and swallowing difficulties.

HERPES ZOSTER

Herpes zoster, commonly referred to as shingles, is caused by varicella-zoster virus, which also is responsible for varicella, or chickenpox. In almost all cases, a history of chickenpox precedes the manifestations of varicella-zoster virus infection, and this initial exposure allows the virus to remain latent within neuronal cells in the sensory ganglia for several years. After spontaneous reactivation, an intense inflammatory process begins in the sensory ganglia and extends to the peripheral nerves.

Most affected patients are elderly. The vesicles usually appear along a single dermatomal distribution on one side and are accompanied by severe pain and dysesthesia that can outlast the vesicles by several months. The thoracic levels are involved in about 70% of cases, but lesions also are common in the distribution of the ophthalmic division of cranial nerve V as a result of inflammation of the gasserian ganglion. Ramsay Hunt syndrome is encountered less often and has been described as a unilateral facial palsy with herpetic lesions in the external auditory canal. The inflammation of other cranial nerves also has been reported, including cranial nerves III, IV, VI, IX, and X. Encephalitis, cerebral angiitis, and myelitis are other rare complications of this disease.

Treatment of herpes zoster with oral acyclovir (800 mg five times a day for 7 days) shortens the course in immunocompetent persons with uncomplicated cases, although intravenous therapy may be necessary in patients with widespread disease or severe immunosuppression. Symptomatic therapy for postherpetic dysesthesia is approached best with amitriptyline and carbamazepine.

CHAPTER 443: SLOW VIRUS INFECTIONS IN THE NERVOUS SYSTEM, INCLUDING AIDS

JERRY S. WOLINSKY AND JUSTIN C. MCARTHUR

[Subacute Sclerosing Panencephalitis](#)
[Progressive Rubella Panencephalitis](#)
[Progressive Multifocal Leukoencephalopathy](#)
[Aids Dementia](#)
[Creutzfeldt–Jakob Disease](#)

Slow viral disease is a recent concept in clinical medicine. As human problems, these disorders have prominent examples among neurologic diseases. Much of our understanding of slow virus disease rests on observations from veterinary medicine and animal experimentation. Sigurdsson worked with visna and scrapie, two prototype natural slow virus infections of sheep, and found that these illnesses were characterized by long intervals from exposure to onset of clinically recognized disease, presented with symptoms limited to dysfunction of a single organ system and followed a stereotyped, ingravescent, and fatal course. These features are the highlights of slow virus diseases of the central nervous system (CNS). The importance of involvement of the immune system as a reservoir for virus and as an additional target for viral cytopathic effects is increasingly recognized.

Slow virus diseases can be classified as those caused by conventional viruses (e.g., measles and rubella virus), selected human papovaviruses and retroviruses, or unconventional agents whose chemical characteristics distinguish them from viruses. The latter group includes the prions, which are germ line–encoded, protease-resistant, proteinaceous, infectious particles that lack nucleic acids ([Table 443.1](#)).

Pathogen	Agent Group	Disease	CSF ¹	Pathology ²
Measles virus	Paramyxovirus	Subacute sclerosing panencephalitis	=	L, D
Rubella virus	Rubivirus	Progressive rubella panencephalitis	=	L, D
K virus	Papovavirus	Progressive multifocal leukoencephalopathy	–	N, D
HIV-1	Lentivirus	AIDS dementia	=	L, M
HTLV-1	Oncovirus	Tropical spastic paraparesis	=	L, V
PrP ^{Sc}	Prion	Creutzfeldt–Jakob disease, sporadic	–	N, S
PrP ^{Sc}	Prion	Kuru	–	N, S, A
PrP ^{Sc}	Prion	Creutzfeldt–Jakob disease, familial	–	N, S
PrP ^{Sc}	Prion	Gerstmann-Sträussler-Scheinker syndrome	–	N, S, A
PrP ^{Sc}	Prion	Fatal familial insomnia	–	N, T

HTLV-1, human T-cell lymphotropic virus type 1; PrP, progressive rubella panencephalitis.
¹Typical CSF disease findings: =, variable mild lymphocytic pleocytosis, elevated IgG index and synthetic rate oligoclonal bands; –, normal in all major constituents.
²Typical neuropathologic findings: I, perivascular and parenchymal inflammation; II, no inflammatory change; D, demyelination with relative axonal sparing; M, multinodular; V, vacuolization of myelin; S, spongiform vacuolization of neuropil; A, amyloid plaques; T, selective thalamic atrophy.

TABLE 443.1. HUMAN CNS SLOW VIRUS DISEASES

Slow virus diseases caused by conventional viruses have remarkably common laboratory features when they occur in apparently immunocompetent hosts. The cerebrospinal fluid (CSF) often shows a mild lymphocytic pleocytosis, modest protein elevation, increased g-globulin content, and intrathecal synthesis of oligoclonal immunoglobulins with specificity for the antigens of the causal viral agent. Neuropathologic changes usually include some inflammatory component, suggesting that the disease is at least in part immunologically mediated. Other neurologic diseases with similar features, such as multiple sclerosis, may eventually be shown to be due to conventional viruses. In contrast, slow virus diseases due to unconventional agents show no systemic or intrathecal evidence of host immune recognition of the inciting agent and have neuropathologic features that are noninflammatory and degenerative. Other neurodegenerative diseases might have a similar cause. A representative disease from each major group is discussed in depth, with brief descriptions of the other slow virus diseases of the CNS.

SUBACUTE SCLEROSING PANENCEPHALITIS

Subacute sclerosing panencephalitis (SSPE) is the prototype human slow virus disease due to a conventional virus. Primarily a disease of childhood, it is characterized by progressive cognitive and motor dysfunction with myoclonus, intrathecal synthesis of extraordinary amounts of measles virus-specific immunoglobulin, and a characteristic inclusion body neuropathology.

INCIDENCE AND EPIDEMIOLOGY

SSPE is an uncommon disease that complicates about 1 in 100,000 patients with measles. The disorder is more common when measles occurs within the first 2 years of life. A rural background also predominates. Males are about three times more frequently affected than females. The disease has declined progressively in the United States with the institution of mandatory attenuated live measles virus vaccination programs. The incidence of SSPE attributable to the use of these vaccines is at worst 1 in 1 million.

ETIOLOGY

SSPE was first recognized in 1933. Based on the characteristic inclusions in glial and neuronal cells, it was believed to be of viral origin. The inclusions are composed of paramyxovirus nucleocapsids. Virus isolation requires the cocultivation of infected brain cells with an indicator cell line to rescue defective variants of measles virus.

PATHOGENESIS

Measles is typically a self-limited childhood disease. Significant complications of the acute disease in the immunocompetent host are generally limited to superimposed bacterial infections or postinfectious measles encephalitis. The latter is believed to be an autoimmune disease that is not dependent on direct viral invasion of the CNS. Persons with defective cell-mediated immunity exposed to measles virus may have acute CNS virus dissemination and develop ongoing defective measles virus replication in the brain, with evolution of a subacute measles encephalitis.

Uncomplicated measles ultimately causes SSPE. Whether virus enters the CNS at the time of the initial infection or remains persistent at systemic sites until it later invades the brain is unknown. Measles virus genome may reside latent in otherwise normal adult human brain and is present in circulating lymphocytes and systemic organs of patients with SSPE. Similarly, it is uncertain whether spread of the virus within the CNS and resultant neuronal dysfunction is continuous but clinically evident only after several years or whether it requires an independent activational event. The role of antiviral antibody in the pathogenesis of SSPE has been emphasized, but well-documented SSPE occurs in children with congenital hypogammaglobulinemia. Nonetheless, antimeasles antibody may contribute to the down-regulation of the tempo of disease through antigenic modulation of viral antigens at the surface of infected cells.

Virus rescued from SSPE brain tissue is uniformly defective. This situation probably reflects attenuated transcription of the 3' portion of the measles virus genome in brain cells. Consequently, mRNA for virion matrix (M) and surface (fusion [F] and hemagglutinin [H]) proteins are underrepresented and, when transcribed, are poorly translated. Several metabolic and functional alterations of in vitro persistently infected neuronal cells are described, which could readily account for the clinical expression of disease without cell destruction.

CLINICAL FEATURES

Although predominantly a disorder of childhood, well-documented cases of SSPE are described into the seventh decade of life, so the disorder should be considered in the appropriate clinical setting at any age. Initial symptoms are usually limited to subtle cognitive dysfunction. Accompanying behavioral changes and deterioration

in school performance are frequently mistaken for emotionally based problems, leading to inappropriate counseling or psychiatric referral. With time, motor disabilities develop and characteristic myoclonic spasms and choreoathetosis appear to reveal the neurologic nature of the illness. Generalized dystonia and spasticity progress, and a decerebrate state evolves as the dementia becomes profound; eventually, a vegetative state ensues. The duration of each stage varies. Half of all patients develop visual symptoms, often attributable to direct retinal involvement by the virus. When present, a characteristic maculopathy and chorioretinitis provide direct evidence for the disease.

LABORATORY FINDINGS

The most useful and specific neurodiagnostic findings are provided by the electroencephalogram (EEG) and by detailed CSF examination. In the early phases of the disease, the EEG may be normal or may show evidence of nonspecific cerebral dysfunction by virtue of slowing or disorganization of the normal background rhythm, occasionally with multifocal paroxysmal sharp wave discharges. Characteristic synchronous high-voltage, slow-wave bursts 2 to 3 seconds in duration that occur at remarkably fixed intervals of 5 to 8 seconds eventually develop. The bursts may be temporally associated with the clinically expressed myoclonic activity. Although not pathognomonic, the presence of these rhythmic periodic complexes in the setting of subacutely evolving childhood dementia strongly suggests SSPE.

With no hypogammaglobulinemia or intensive immunosuppressive chemotherapy, the CSF shows a mild mononuclear pleocytosis, a mildly increased total protein content, and a greatly elevated g-globulin content. The IgG index and synthetic rate are increased with oligoclonal immunoglobulins, easily shown by electrophoresis of CSF and serum. The serum:CSF ratio of measles virus antibody is greatly reduced (normal, greater than 200), and CSF immunoglobulins generally react with all structural proteins of measles virus except the M protein. Most authorities consider these serologic findings to be diagnostic of the disease without the need for brain biopsy or virus isolation.

Computed tomography (CT) can document evolving cortical atrophy and ventricular enlargement, and it often shows attenuation of the density of the cerebral white matter; however, single examinations do not correlate well with the clinical disease state. Magnetic resonance imaging (MRI) provides similar evidence of the progressive destructive process, but neither CT nor MRI is diagnostically specific.

The brain biopsy shows inflammatory changes in gray and underlying white matter consisting of mononuclear cells, plasma cells, and microglia. Neuronal loss and astrogliosis can be prominent. Eosinophilic intracytoplasmic and intranuclear inclusions are present in neurons and oligodendroglia and can be shown to be measles virus-specific by immunocytochemistry. Virus isolation by sensitive explant and cocultivation techniques is successful in less than 50% of cases. Evidence suggests that more than one variant of measles virus can be isolated from a single patient at once.

OPTIMAL MANAGEMENT

SSPE's disease course is variable. Patients with acute cases progress from first symptoms to death within a few months. The average patient survives for 1.8 years, and up to 5% of patients survive more than 5 years. Well-defined spontaneous disease remissions are reported but uncommon. Treatment is symptomatic and supportive. Myoclonic seizures can often be controlled with clonazepam, with the dosage titrated to suppress seizure activity and avoid undue sedation. Specific therapy is controversial. Several uncontrolled reports suggest that the putative immunomodulatory drug isoprinosine is effective in prolonging the course of the disease for patients with more slowly evolving disease and may have induced symptom remission. Other uncontrolled reports suggest that intrathecal or systemic interferon has beneficial effects.

PROGRESSIVE RUBELLA PANENCEPHALITIS

Progressive rubella panencephalitis (PRP) is a rare slow virus disease of childhood with features similar to those of SSPE. It follows as a late complication of both the congenital rubella syndrome and typical childhood rubella. Intrathecal synthesis of substantial amounts of immunoglobulin specific for the three structural proteins of rubella virus and successful isolation of virus from brain tissue by cocultivation link persistent viral infection with the clinical syndrome. Immune complex deposition in cerebral vasculature suggests an immunopathologic component to the demyelinating disease. Early cerebellar symptoms and absence of myoclonus may clinically distinguish PRP from SSPE. The course is very protracted and usually fatal, but like SSPE, PRP may spontaneously remit. There is no known treatment.

PROGRESSIVE MULTIFOCAL LEUKOENCEPHALOPATHY

Progressive multifocal leukoencephalopathy (PML), first delineated in 1958, is primarily a disease of the immunocompromised host, although several cases have been reported in patients with no known underlying disorder. JC virus, a human papovavirus, is usually the causative agent. Although infection with JC virus is common, PML is not. Whether defective cellular immunity leads to the activation of a long latent B-lymphocyte reservoir of papovavirus infection or precludes clearance of virus during primary infection is uncertain.

PML has a marked predilection for hemispheric white matter. Individual lesions are characterized by plaque-like concentric zones of central necrosis, surrounded by primary demyelination and loss of oligodendroglia. This is bordered by a sector of hypertrophied oligodendroglia containing basophilic intranuclear inclusions consisting of paracrystalline arrays of virions ringed by normal-appearing white matter. Astrocytes within lesions are morphologically bizarre. Once initiated, the pathogenesis of PML appears straightforward. Infected oligodendroglial cells fail to maintain their myelin sheaths, leading to demyelination of adjacent axons. Eventually, the infected cells lyse and progeny virions are released into the microenvironment to infect adjacent oligodendroglia. Macrophages participate in the clearance of cellular debris, but viral specific immune responses are not mounted. Astrocytes in the midst of this activity undergo transformation to a near-malignant state in response either to released substances or more likely to their own infection by virus. Despite the ease of extraction of virions from infected tissue, successful culture of virus from brain requires the presence of immature human glial cells.

Until recently, most patients with PML had an underlying lymphoreticular malignancy such as Hodgkin's disease or chronic lymphocytic leukemia; now AIDS is preeminent. Presenting symptoms vary but often include confusion and disorientation, visual disturbances progressing to cortical blindness, and ataxia. The onset is usually insidious, but may be explosive. The course is generally fatal within 1 year and can be particularly rapid in AIDS patients. Rare spontaneous remission of symptoms with eventual recurrence is well documented; this complicates the interpretation of anecdotal reports of response to antiviral therapy with cytosine arabinoside, interferon, or both. In PML, the CSF is acellular with little alteration of protein content, but polymerase chain reaction amplification of CSF sediments may disclose diagnostically useful JC virus gene sequences. EEG findings are nonspecific. The MRI displays spectacular high-signal-intensity lesions, predominantly restricted to white matter. Despite typical MRI findings, the differential diagnosis can be trying in AIDS patients and may require brain biopsy. Further, the recognition that herpes varicella-zoster virus can produce similar clinical, neurodiagnostic, and gross neuropathologic changes precludes definitive diagnosis without histology and specific immunohistochemical staining in the non-AIDS patient.

AIDS DEMENTIA

Most AIDS patients develop one or more CNS opportunistic infections ([Chapter 267](#)). In addition, HIV invades the CNS to cause symptoms of neural dysfunction directly. Initial viral invasion of the CNS can occur very early after exposure to the virus and may be marked by a transient, clinically recognizable aseptic meningitis. Chronic asymptomatic CNS infection follows. After a variable and often protracted interval, the first definite progressive neurologic symptoms unfold.

The early symptoms of AIDS dementia (HIV-associated cognitive motor complex) may precede any systemic manifestations of AIDS, but they become more prevalent late in the course of HIV infection. These are usually heralded by an insidious (rarely abrupt) but generally progressive deterioration of cognitive function with behavioral changes. Severe subcortical dementia ensues over a variable interval of several to many months in association with increasing motor impairment. In the late stages, moderate to profound dementia with psychomotor retardation develops, variably associated with pyramidal weakness and hypertonia, ataxia, incontinence, peripheral neuropathy, seizures, and myoclonus. About 15% of persons with AIDS develop this chronic encephalitis. Symptoms of AIDS dementia may be overshadowed by those of opportunistic CNS infections, lymphoma, or the metabolic consequences of systemic disease.

Diagnosis rests on the clinical features, documentation of HIV infection and exclusion of opportunistic infection or neoplasm. MRI commonly documents cerebral atrophy and ill-defined areas of increased signal intensity deep within the cerebral white matter. From diffuse or multifocal areas of hemispheric white matter correlated with AIDS dementia.

Immunohistochemical and in situ hybridization studies document that macrophages and macrophage-derived multinucleate giant cells harbor virus in neural tissues;

these findings are analogous to those in visna. The intensity of the macrophage activation correlates with dementia severity, and it is likely that macrophage secretory products, including proinflammatory cytokines, lead to neuronal dysfunction. There is evidence that these symptoms can be reversed, at least in part, with antiviral therapy, especially since the introduction of combination antiretroviral therapy.

In the spinal cord, spongiform degeneration of the posterior and lateral columns, with vacuoles in the myelin sheaths, can produce progressive spastic paraparesis, a condition termed *vacuolar myelopathy*. The pathogenesis is unknown, and no treatment for this condition has been identified. In the peripheral nerves a dying back axonal degeneration, frequently accompanied by a painful sensory neuropathy clinically, is common late in the course of AIDS. Similar painful neuropathic symptoms are brought out by initiating therapy with some antiretroviral agents, including, ddI, ddC, and d4T. Treatment for these painful neuropathies is symptomatic. Early in the course of HIV infection, usually before immunosuppression, chronic or, less frequently, acute inflammatory polyneuropathy can occur. Immunotherapy for these presumed immune-mediated disorders is the same as in HIV-negative individuals (Chapter).

CREUTZFELDT–JAKOB DISEASE

Creutzfeldt–Jakob (CJD) is the prototype human-transmissible neurodegenerative disorder caused by a prion.

INCIDENCE AND EPIDEMIOLOGY

In its sporadic form, CJD occurs worldwide with an annual incidence of 1 in 1 million. About 10% of CJD cases are familial, autosomal dominant, and due to several well-defined germ line mutations that segregate in families and generally correlate with nuances of disease phenotypes. These cases are also transmissible. Despite the ease of experimental transmission of sporadic CJD, its mode of transmission in nature is unknown. There is no known conjugal or enzootic transmission, and the disease is not more common among medical personnel. There is an increased incidence of prior surgical and particularly neurosurgical procedures for CJD cases compared with matched controls. The disease can occur at nearly any age, with peak incidence in the sixth decade.

ETIOLOGY

In 1921, Jakob differentiated what is now known as CJD from Alzheimer's presenile dementia based on distinctive neuropathologic change. Demonstration of the transmissible nature of scrapie, a disease of sheep, and the subsequent recognition that the clinical course and pathology of kuru, an apparent degenerative disease in an isolated New Guinea tribe, might reflect an analogous disease process culminated in the signal observation that kuru was transmissible to subhuman primates. Classification of CJD among the subacute spongiform encephalopathies opened the way for transmission of this globally distributed sporadic disorder as well. Kuru, once responsible for ataxia, tremor, and death within a year in 1% of all Fore tribe members, has disappeared with the proscription of ritualistic cannibalism. Sporadic, familial, and iatrogenic CJD, the dominantly inherited Gerstmann–Sträussler–Scheinker syndrome, and fatal familial insomnia are the currently known human prion diseases.

The agents that cause scrapie, “mad cow” or bovine spongiform encephalopathy, and CJD are remarkably similar. Scrapie infectivity copurifies with PrP^{Sc}, a hydrophobic, protease-resistant glycoprotein of 27 to 30 kD. PrP^{Sc} rapidly forms higher-molecular-weight, rodlike, birefringent aggregates. The failure to demonstrate a nucleic acid component associated with purified and infectious PrP^{Sc} is convincing. PrP^{Sc} is an abnormal isoform of the normal PrP gene product PrP^C. The *PrP* gene has been cloned and sequenced, is phylogenetically highly conserved, and in humans is localized to chromosome 20. The function of the normal PrP gene product is uncertain, but PrP^C may be involved in synaptic inhibition. Introduction of PrP^{Sc} into normal cells is likely to induce conformational change of PrP^C into PrP^{Sc} through protein–protein interactions. This results in a cascading conversion of PrP^C and accumulating neuropathogenic aggregates of PrP^{Sc}.

PATHOGENESIS

A considerable body of clinical and experimental data is available on the biology of the spongiform encephalopathies. Prions are remarkably resistant to most chemical and physical agents. Transmission can be effected by oral or parenteral inoculation but is most efficient by intracerebral routes. The incubation period depends on the dose and route of inoculation and host genetics and may theoretically exceed the host's life span. Experimentally, replication occurs at many systemic sites; all organs and body fluids from CJD patients must be considered potentially infectious. Symptoms and pathologic change are limited to the CNS. Prion amplification in brain tissue precedes the development of recognizable pathology. Well-developed neuropathologic changes include noninflammatory spongiform degeneration of the neuropil, neuron loss, and marked astrogliosis. The topography of this change is generally widespread but may show regional variation consistent with the patient's clinical symptoms.

Koch's postulates have been fulfilled for CJD by the inadvertent transfer of disease by corneal transplantation, cadaveric dural grafts and inadequately sterilized depth electrodes, and the administration of contaminated growth hormone preparations. Such incidents can be minimized by avoiding organ transplantation from donors with unexplained neurologic disease and by adequate sterilization of all surgical instruments.

CLINICAL FEATURES

Prodromal manifestations occur in about one third of all cases CJD. These symptoms are subtle and varied and often are initially attributed to neurosis or other psychiatric disorders. As cognitive deficits evolve, the dementing nature of the illness becomes evident. Eventually, myoclonus or startle myoclonus becomes a prominent feature in over 80% of all cases; in contrast, in Alzheimer's disease myoclonus is an infrequent and usually late finding. Because of the widespread nature of the underlying pathology, the dementia is usually accompanied or preceded by other neurologic signs and symptoms. The disease can be subclassified into several subtypes. Pyramidal, extrapyramidal, cerebellar, and cortical visual defects are common in either relatively isolated or mixed patterns. The early development of multisystem neurologic deficits in the presence of dementia suggests the diagnosis of CJD even without myoclonus. Usually, the onset of symptoms is gradual (over weeks or months), but an explosive onset over a matter of hours is well chronicled.

LABORATORY FINDINGS

The EEG can be most helpful. Early in the disease, it can be normal or show only nonspecific slowing or disorganization of the normal cortical patterns. Over 80% of all patients exhibit diffusely slowed background activity with periodic, symmetric, high-voltage biphasic or triphasic sharp waves. Although this periodic complex pattern is not pathognomonic of CJD, it is highly suggestive of the disorder in the appropriate clinical setting. CT and MRI can document rapidly evolving brain atrophy but may be normal in the early phases of the disease. Routine CSF studies are normal. Brain biopsy remains necessary for definitive antemortem diagnosis and may be necessary to distinguish atypical cases of sporadic or iatrogenic CJD from other forms of dementia. Unfortunately, the presence of the characteristic spongiform change in the cortex of the biopsy specimen may be subtle or difficult to differentiate from artifact. Diagnosis by transmission studies is no longer essential, because recently developed techniques to detect the presence of PrP^{CJD} by immunoblot using polyvalent and monoclonal-specific reagents are definitive in difficult cases. Molecular genetic analysis of DNA samples derived from peripheral blood leukocytes provides a powerful means of diagnosis of familial cases of CJD, Gerstmann–Sträussler–Scheinker syndrome, and fatal familial insomnia.

OPTIMAL MANAGEMENT

Typically, the signs and symptoms of CJD evolve dramatically over a matter of months, with death occurring in 90% of patients within 1 year. In some patients, the disease reaches a plateau for protracted intervals at a low level of neurologic function. A slower clinical course may be conferred by heterozygosity at codon 129, a normal human polymorphic allele in the *PrP* gene. The apolipoprotein e4 allele may be an additional risk factor. Attempts at treatment with antiviral chemotherapy have been disappointing.

CHAPTER 444: SEIZURES AND EPILEPSIES

ANTONIO V. DELGADO-ESCUETA

[Incidence and Epidemiology](#)
[Classification: Seizures and Epilepsies](#)
[Etiology and Pathogenesis](#)
[Clinical Features: Epilepsy Syndromes](#)
[Common Lesional Epilepsies](#)
[Neurocysticercosis](#)
[Course and Prognosis](#)

The term “epilepsy” is derived from a Greek word meaning a condition of being overcome or seized. The term is used to describe the brain's innate ability to produce paroxysmal depolarization shifts within neurons and recurrent electroencephalographic (EEG) discharges such as focal spikes or diffuse bilateral 1.5- to 6-Hz spike-and-wave complexes ([Chapter 426](#)). Clinically, a person's consciousness and senses may be abruptly suspended, and motor, sensory, or behavioral symptoms result.

An individual seizure is distinguished from epilepsy per se with the latter term being reserved for three or more recurrent seizures. Epileptic seizures should be distinguished from nonepileptic convulsive seizures produced by cerebral ischemia or hypoxia, hypoglycemia, convulsive drugs, such as cocaine, and withdrawal from alcohol, barbiturates, and benzodiazepines. Pseudoepileptic behavior produced by conversion hysteria must not be mistaken for epilepsy.

INCIDENCE AND EPIDEMIOLOGY

Worldwide, the epilepsies, afflicting approximately 40 to 100 million people, are the second most common neurologic disorder, second only to headaches. In developing countries, the epilepsies are the most common serious neurologic disorder, whereas in the United States, the epilepsies are second only to cerebrovascular disease and strokes, affecting at least 2 to 3 million people. Incidences among persons under treatment for recurrent seizures range from approximately 1.5 per 1,000 for Japan, 2.7 per 1,000 in Chile, 4.4 per 1,000 for China, 6 per 1,000 in Rochester, Minnesota, 9 per 1,000 for Sri Lanka and Pakistan, 17 per 1,000 in Ecuador, and up to 16 to 21 per 1,000 in Africa and Panama.

In the United States, at least 105,800 new cases of epilepsy are diagnosed each year. Incidence rates are highest among the very young (especially newborns and infants), drop to a relatively constant rate among those between 10 and 70 years of age, and increase again thereafter. Acquired epilepsies characterized by partial and secondary tonic-clonic seizures are the most common forms. They occur frequently in the first 5 years of life, somewhat less often in persons 5 to 10 years of age, and more often in those older than 20 years. The incidence of genetic epilepsies with grand mal tonic-clonic convulsions peaks during adolescence and early adulthood; juvenile myoclonic epilepsy (JME) is a disease of adolescence. Absence epilepsies are usually childhood disorders and rarely occur before age 3 or after age 20.

CLASSIFICATION: SEIZURES AND EPILEPSIES

[Table 444.1](#) is a classification of epileptic seizures and [Table 444.2](#) is a revised and modern version of the 1989 ILAE Classification of the Epilepsies. It distinguishes genetic epilepsies from acquired epilepsies symptomatic of a neurologic or medical illness.

TABLE 444.1. INTERNATIONAL CLASSIFICATION OF EPILEPTIC SEIZURES

TABLE 444.2. MODERN CLASSIFICATION OF THE EPILEPSIES

Genetic epilepsies are divided into (1) genetic epilepsies whose primary and exclusive symptoms are seizures, either generalized (e.g., benign familial neonatal epilepsies, childhood absence epilepsy, and JME) or partial (e.g., autosomal dominant nocturnal frontal lobe epilepsy, familial temporal lobe epilepsy, Rolandic epilepsy), (2) genetic epilepsies associated with severe neurologic deficits or malformations or both (e.g., cortical dysplasias) or associated with progressive degenerations (e.g., progressive myoclonus epilepsies), and (3) idiopathic epilepsies with generalized seizures suspected to be genetic.

Symptomatic epilepsies are divided into symptomatic epilepsies with mainly generalized seizures and symptomatic epilepsies with partial and secondary tonic-clonic seizures, such as those caused by structural lesions.

Thus, the medical practitioner must first identify the type of seizures the patient has and then determine the epilepsy syndrome and cause of the seizures ([Table 444.1](#)). Are seizures manifestations of a genetic epilepsy, a cerebral cortical dysplasia, a degenerative disorder, or a structural lesion? Genetic epilepsies most often manifest as generalized seizures but can also manifest mainly as partial seizures. Epilepsies symptomatic of structural disease almost always manifest as partial, complex partial, and secondary generalized tonic-clonic seizures.

GENETIC EPILEPSIES

About 40% of adults and children with epilepsy suffer from genetic epilepsies with primary generalized or partial seizures. Intelligence and neurologic examination results are normal in those with the common genetic epilepsies, whereas they are abnormal in cortical dysplasias and progressive myoclonus epilepsies. Generalized seizures are present when epileptogenic discharges involve both cerebral hemispheres from the onset. Early loss of consciousness is the rule. Generalized seizures may involve only loss of consciousness (absence) or convulsive movements (tonic-clonic, myoclonic, tonic, or clonic). Early childhood myoclonic, myoclonic-astatic, absence, benign JME, and tonic-clonic or clonic-tonic-clonic grand mal epilepsies can be best recognized by their onset in childhood and adolescence. Almost all are genetically transmitted. Structural lesions are rare. The EEG shows bilaterally symmetric and synchronous 2.5- to 3.5-Hz or 3.5- to 6-Hz spike- or polyspike-wave complexes. Genetic partial epilepsies have a localized origin and show any of the partial seizure types described in [Table 444.1](#). Between seizures, the EEG can show localized epileptiform spikes.

ACQUIRED OR SYMPTOMATIC PARTIAL, COMPLEX PARTIAL, AND SECONDARY GENERALIZED EPILEPSIES

Symptomatic epilepsies account for 60% of adult and about 40% of childhood epilepsies. The clinical signs of symptomatic partial epilepsies are not different from those of genetic partial epilepsies that have a localized origin. Neurologic signs may be present, and onset can occur at any age. Between seizures, the EEG can show localized epileptiform spikes. During onset of seizures (ictus), the EEG shows epileptogenic discharges related to the lesion. During seizures, the most common EEG pattern consists of localized, rhythmic, low-voltage 16- to 30-Hz rapid potentials, which can propagate and spread.

Partial seizures arise from an anatomical or functional system limited to a part of one or both cerebral hemispheres ([Table 444.2](#), [Table 444.3](#) and [Table 444.4](#)). Localization and preferred routes of spread determine clinical features. Partial seizures are divided into three major subgroups: simple, complex, and secondarily generalized seizures. In simple partial seizures, consciousness is never lost. In complex partial seizures, consciousness is impaired. Synonyms include psychomotor seizures, fugus epileptique, and Damner attacken. Simple or complex partial seizures can develop into secondary tonic-clonic seizures. Complex partial seizures should be differentiated from absence because the choice of drug for each of these disorders differs. Most absence seizures last 10 seconds or less. Complex partial psychomotor seizures last an average of 3 minutes, and most are not longer than 5 minutes. An aura precedes 44% of complex partial seizures. Full consciousness returns slowly. Absence seizures have no aura and start suddenly; full consciousness returns abruptly.

TABLE 444.3. FRONTAL LOBE EPILEPSIES

TABLE 444.4. MEDIAL TEMPORAL LOBE EPILEPSIES

Automatisms in complex partial seizures are more complex than automatisms of absence. Walking or running, perseverative bilateral arm or leg motions such as kicking and defensive flailing, and bimanual, bipedal movements can appear as stereotyped automatisms at the onset of frontal lobe complex partial seizures. Such complicated motor movements have not been reported in absence. Between seizures (interictus), local spikes or spike-wave formations appear in the EEG. If a circumscribed lesion is present, the term focal or partial epilepsy is most appropriate. If the site and side of seizure onset vary (often the case in benign childhood syndromes), the term localization-related is more appropriate.

Acquired generalized epilepsies manifest tonic-clonic seizures, but focal or diffuse cerebral pathology may be recognized by the presence of abnormal neurologic signs, background EEG changes, and brain images. Organic brain disease can also manifest as generalized tonic seizures, myoclonic jerks, infantile spasms, or atonic attacks as in West syndrome of infancy, symptomatic Lennox-Gastaut-Dravet syndrome, and the progressive myoclonus epilepsies.

ETIOLOGY AND PATHOGENESIS

Three factors acting alone or together have long been considered important in the cause and pathogenesis of the epilepsies: (1) an epilepsy gene or gene(s), which predispose persons to recurrent seizures, (2) seizure-generating (epileptogenic) brain lesions; and (3) internal and external stimuli, which affect epilepsy susceptibility genes or epileptogenic lesions and trigger seizures. These three factors contribute to produce the generalized 3- to 6-Hz spike waves of generalized epilepsies or the focal cortical spikes and sharp waves of partial epilepsies.

EPILEPSY GENES

Subvarieties of epilepsies with clear mendelian inheritance such as benign familial neonatal convulsions and forms of epilepsies that are complex genetic diseases such as JME are now being distinguished from multifactorial symptomatic epilepsies. Mutations in potassium channel genes in benign familial neonatal convulsions, in a sodium channel gene in febrile seizures plus, and in a nicotinic ACH b-subunit receptor in autosomal dominant nocturnal frontal lobe epilepsy are examples of monogenic epilepsies. Both 8q24 and 20q loci for benign familial neonatal convulsions are the sites of mutations in two different novel voltage-gated K⁺ channel genes dubbed *KCNQ2* and *KCNQ3*, channel genes involved in neuronal repolarization. The mutation in the neuronal $\alpha 4$ subunit of the nicotinic acetylcholine receptor in autosomal dominant nocturnal frontal lobe epilepsy in chromosome 20q13.2 renders the receptor to be less efficient and less functional reducing permeability to calcium.

More than 20 separate chromosomal loci of mendelian forms of idiopathic generalized and partial epilepsies have been identified, and their mutations surely will be defined in the next decade with the anticipated completion of the human genome sequence ([Table 444.5](#)). Four of these genotypes pertain to common idiopathic generalized epilepsies: (1) JME, which has two chromosomal loci in 6p11 and in 15q14, (2) childhood absence epilepsy, which persists with grand mal seizures in chromosome 8q24; (3) familial febrile seizures, which has three loci in chromosomes 8q13-21, 19p, and 2p. The locus for benign adult familial myoclonic epilepsy is also in 8q23.3-q24.1. A susceptibility locus for idiopathic generalized epilepsies with generalized spike waves is also present in chromosome 3p. The chromosome

locus for childhood absence epilepsy that remits during adolescence has not been defined.

TABLE 444.5. LATERAL TEMPORAL LOBE EPILEPSIES

FOCAL EPILEPTOGENIC BRAIN LESIONS

Three factors contribute to focal epileptogenesis in temporal lobe epilepsy with hippocampal scleroses, post-traumatic epilepsy and cerebral cortical dysplasias. These three key elements are (1) the capacity of membranes in some pacemaker neurons to develop intrinsic burst discharges (e.g., pyramidal neurons in the CA3 region of the hippocampus and in layer 4 of the cerebral cortex), (2) the reduction of g-aminobutyric acid (GABA)ergic inhibition or presence of disinhibition; and (3) the enhancement of synaptic excitation, as in the presence of recurrent excitatory synaptic circuits produced by mossy fiber sprouting. Resected human epileptic hippocampal tissue has consistently shown a pattern of neuronal circuit alteration, namely, neuronal loss, ectopic granule cells, and mossy fiber reorganization and sprouting in the inner molecular layer of the dentate gyrus. These sprouting fibers synapse with proximal apical dendrites of granular cells where more dendritic spines and more branching in apical dendrites are present.

Repeated seizures and prolonged convulsive status epilepticus cause such hippocampal damage that in turn sets up reverberating and recurrent excitatory circuits, focal epileptogenesis, and impaired recent memory. Immunocytochemical studies in human temporal lobe epilepsy also support the notion of reduced GABAergic interneurons as indicated by reduced parvalbumin, calbindin D28k and calretinin, and reduced glutamic acid decarboxylase. Neurotrophin expression, and increased mRNA levels for brain-derived neurotrophic factor, nerve growth factor, and NT-3 also correlate with neuron losses or supragranular mossy fiber sprouting in the chronically damaged and epileptic human hippocampus. These latter growth factors may be the trigger for the structural remodeling of granule cells, their dendritic changes, and axonal sprouting.

Even in epileptogenic cortical dysplasia, reorganization with a reduction of putative GABAergic neurons, increased numbers of balloon cells with NMDAR1 and GluR2-3 subunits of glutamate receptors are present. In the epileptogenic zones adjacent to cortical microgyria and dysplasias, neurofilaments increase in numbers and glutamate staining is more prominent. Furthermore, polysynaptic inhibitory postsynaptic currents are larger in amplitude and their frequency more dependent on glutamatergic input. Mossy fiber sprouting and its recurrent excitatory circuits plus the reduced GABAergic interneurons thus provide the substrate for cortical hyperexcitability and chronic epilepsy.

In post-traumatic neocortical epilepsy, similar mechanisms operate and layer 5 neurons increase input resistance, prolong membrane time constants, reduce slow spike after hyperpolarizations, and fire more rapidly during depolarizations. Axons of injured neurons sprout, double their contacts, and increase recurrent excitation. GABAergic terminals also sprout and increase their innervation of interneurons. Moreover, there is evidence that complex febrile convulsions and status epilepticus in infancy can induce molecular and cellular mechanisms subserving sprouting and reorganization of hippocampal circuits and eventually cause hippocampal scleroses and chronic temporal lobe epilepsy in adolescents and adults. Magnetic resonance imaging (MRI) studies of infants who have complex and prolonged febrile seizures can show acute edematous hippocampi in the hemisphere of seizure origin and the subsequent development of hippocampal atrophy and scleroses.

CLINICAL FEATURES: EPILEPSY SYNDROMES

GENETIC EPILEPSIES WITH BENIGN GENERALIZED SEIZURES

Childhood absence epilepsy, JME, and grand mal epilepsy on awakening are the three most common forms of genetic generalized epilepsies. Together, these three syndromes account for almost half of all epilepsies. Benign familial neonatal convulsions and benign myoclonic epilepsy of infancy and early childhood are rare syndromes with generalized seizures.

Childhood Absence Epilepsy (Petit Mal)

Childhood absence appears in 3% to 4% of all patients with epilepsy. Onset is between 4 and 8 years of age. Absences are the first manifestation. Because seizures occur at least 1 per day or up to several hundred times per day, the absences are called *pyknoleptic* (meaning dense, compact). The child is otherwise neurologically normal. There is sudden interruption of activities, such as walking or talking. Responsiveness is partially or totally lost for a period of less than 10 seconds. A blank stare and a slight upward rotation of the eyeballs is the typical manifestation. Rhythmic clonic movements of eyelids and eyebrows, stereotyped automatisms (lip smacking, chewing movements, blinking), and mild clonic, atonic, or tonic movements may appear. Pupil dilation and changes in facial color, heart rate, and respiration may also occur. The ictal EEG reveals bilateral symmetric and synchronous 3-Hz spike-wave complexes with a normal background. Hyperventilation, photic stimulation, drowsiness, and non-REM sleep activate the 3-Hz spike-wave complexes.

In over 50% of patients with childhood absence epilepsy, absences are the only manifestation. These absences usually resolve during adolescence. Fourteen percent experience both petit mal and tonic-clonic seizures at onset. Tonic-clonic seizures develop after absence in 32% of patients. These forms of absence epilepsy associated with grand mal seizures usually persist longer into adulthood. Another syndrome should be suspected when seizures start as myoclonias or grand mal later to be followed by absences.

A family history of seizures is noted in 40% of patients with absences. Spike-wave complexes of 3 Hz may be inherited as an autosomal dominant trait. Expression declines with age. Siblings and offspring have a lifelong 50% risk for inheriting the spike-wave trait (dominant), a 12% risk for generalized seizures, and an 8% risk for having absence. Diffuse 3-Hz spike-wave complexes are also prevalent in relatives of probands with febrile convulsions or focal seizures.

Other rare forms of absences occur during late childhood and adolescence (juvenile absence epilepsy). The attacks are infrequent and random (spanioleptic) and are usually associated with tonic-clonic seizures; the electroclinical traits persist into later life. Because closed-circuit television with biotelemetry of the EEG (CCTV-EEG) shows that grand mal seizures are often preceded (as much as 45%) by absences, absence epilepsy with grand mal seizures may account for up to 15% of all epilepsies.

Juvenile Myoclonic Epilepsy

JME occurs in at least 10% to 20% and up to 30% of patients with epilepsy. Patients have normal intelligence and an excellent prognosis. JME is extremely sensitive to valproic acid. The syndrome usually starts at 13 to 15 years of age with mild myoclonic jerks of arms and shoulders. Myoclonic jerks may be mistaken for nervousness. Major tonic-clonic convulsions follow myoclonic seizures—usually in 2 to 3 years. Seizures may be induced by lack of sleep, premature awakening, fatigue, or alcohol. In 10% to 37% of patients JME may be atypical and also have absences. Rapid 4- to 6-Hz diffuse polyspike-wave complexes are characteristic. This 10% to 37% of patients also has 3-Hz spike-wave sequences in addition to the fast 4- to 6-Hz polyspike waves. Patients with JME have a high recurrence rate (90%) on withdrawal of treatment.

The genetic locus of autosomal dominant JME with 3.5- to 6-Hz polyspike-wave complexes is in chromosome 6p11. Segregation analysis agrees with linkage mapping

and shows that JME is a heterogeneous syndrome. Autosomal recessive, autosomal dominant, two-loci, and polygenic forms all have been suggested.

Genetic Epilepsy with Clonic–Tonic–Clonic and Tonic–Clonic Seizures (Grand Mal Epilepsy)

Commonly, absences or myoclonic seizures precede grand mal seizures. Hence, pure grand mal epilepsy is rare. Two forms are now recognized: awakening clonic–tonic–clonic grand mal and random tonic–clonic grand mal. Awakening clonic–tonic–clonic grand mal seizures are usually triggered by sleep deprivation, fatigue, and alcohol. The interictal EEG shows the rapid form of diffuse 4- to 6-Hz polyspike-wave complexes. Diffuse 14- to 24-Hz polyspikes fire during brief and violent flexor spasms of the entire body (initial clonic phase). Consciousness is preserved early and, if upright, the patient may fall. Consciousness is abruptly lost with tonic contraction. The tonic phase lasts 10 to 20 seconds, followed by clonic jerks. Sixty-eight percent of cases present at puberty; 85% disappear on treatment with valproic acid. Seizures persist, and 60% to 90% of patients suffer relapse on withdrawal of treatment. Awakening grand mal epilepsy appears to be an allelic form of the chromosome 6p-linked JME syndrome.

Grand mal epilepsy with tonic–clonic seizures is characterized by seizures that occur randomly with no special circadian pattern. Its interictal EEG is more similar to the pattern of childhood absences and consists of diffuse 3-Hz spike-wave complexes or 3-Hz polyspike-wave complexes. Recruiting patterns of 9- to 12-Hz diffuse rhythms herald the tonic phase. Seizures may appear only nocturnally. Up to 70% of seizures disappear with treatment, and 22% decrease in frequency. Eight to 20% of patients suffer relapse after drug withdrawal.

Benign Familial Neonatal Convulsions

Benign familial neonatal convulsions, a rare cause of neonatal convulsions, is an autosomal dominant disorder with favorable outcome. Psychomotor development proceeds normally. In 80% of patients, partial or generalized clonic seizures, sometimes with apneic spells start on the second and third days of life. Seizures usually stop by 6 months without any neurologic sequelae. Childhood or adult epilepsy subsequently develops in about 10% to 14% of patients.

Two genetic loci are responsible—one on chromosome 20q13.2 and another on chromosome 8q. Cosegregation of a nonsense mutation in the $\alpha 4$ subunit of the nicotinic acetylcholine receptor with the chromosome 20q13.2-linked benign familial neonatal convulsions was recently demonstrated. In 1995, the syndrome of autosomal dominant nocturnal frontal lobe epilepsy was shown to be an allelic form of the chromosome 20q13.2 epilepsy gene.

Benign Myoclonic Epilepsy of Infancy

Benign myoclonic epilepsy of infancy is a rare condition characterized by brief bouts of massive or mild generalized myoclonic seizures without loss of consciousness in normal children during the first 3 years of life. The neurologic examination is normal. During drowsiness, there is an increase in the frequency of the myoclonias and during slow sleep they usually disappear. The EEG always shows diffuse irregular 3-Hz spike-wave or polyspike-wave discharges synchronous with the myoclonic muscle activity in the electromyograph (EMG). No other seizure types are involved, although generalized tonic–clonic attacks may occur later in life. Seizures are easily controlled by valproic acid monotherapy. Prognosis is good if treatment is started early. If left untreated, patients may present impaired psychomotor development and behavioral disturbances. A family history of epilepsy or febrile convulsions is present in 31% of the cases.

Benign Myoclonic Epilepsy of Early Childhood

When familial myoclonic epilepsy starts in early childhood (between 1 and 5 years), a combination of myoclonic-astatic, myoclonic, absence and tonic–clonic or clonic–tonic–clonic seizures may occur. The EEG shows bilateral synchronous 2- to 3-Hz spike-wave and polyspike-wave complexes, 4- to 6-Hz polyspike-wave complexes, and bursts of diffuse 4- to 7-Hz rhythms. No evidence of brain damage is present on neuroimaging; the disease does not progress, and no cognitive deficits emerge on neuropsychological tests. A strong family history is present, since 20% of nonproband family members are affected. Most present a primary generalized epilepsy syndrome. Response to valproate monotherapy is good to excellent.

Benign myoclonic epilepsy in infants and young children may be the infantile and early childhood equivalent of JME.

GENETIC EPILEPSIES WITH BENIGN PARTIAL SEIZURES

Even in partial epilepsy syndromes, genetic linkage studies have been successful. Partial epilepsy with auditory symptoms has been linked to chromosome 10q. Two separate loci have been found in Rolandic epilepsy—Rolandic epilepsy with writer's cramps and ataxia in the pericentromeric region of chromosome 16p and Rolandic epilepsy with centrotemporal spikes on 15q14. First-degree relatives of patients with symptomatic partial seizures have an increased incidence of seizures, and genetic susceptibility is important even in partial epilepsies. An environmental insult such as head trauma might not produce seizures in a person with low susceptibility.

The most common form of genetic epilepsy with partial seizures is autosomal dominant benign rolandic epilepsy, which accounts for 15% of all childhood seizures. Less common is benign occipital epilepsy. Seizures develop between 4 and 8 years of age in benign rolandic epilepsy. Most attacks occur at night as secondary tonic clonic seizures preceded by twitching of one side of the face, tongue or hands. Unilateral or bilateral diphasic or triphasic sharp waves over the rolandic regions increase during sleep. Declining in frequency with age, seizures disappear by age 16 years, and are associated with a normal background EEG, positive family history for seizures or rolandic spikes and normal neurologic examination.

GENETIC EPILEPSIES CHARACTERIZED BY A PROGRESSIVE MYOCLONUS EPILEPSY

The progressive myoclonus epilepsies (PMEs) are a rare, heterogeneous group of debilitating, often fatal epileptic encephalopathies characterized by segmental arrhythmic myoclonus, massive myoclonias, generalized tonic–clonic or clonic seizures, with or without absences, dementia, and other progressive neurologic manifestations, especially cerebellar. Unverricht–Lundborg and Lafora types of PME are the most common, relatively speaking. Specific mutations have also been defined among the more than 12 loci of the PMEs. These include Lafora's disease, Unverricht–Lundborg disease, ceroid lipofuscinoses 3 (Spielmeyer–Vogt syndrome) within Batten disease, or sialidosis, dentatorubropallidoluysian atrophy, and the mitochondrial syndrome, MERRF (myoclonic epilepsy and ragged red fibers).

Unverricht–Lundborg or Baltic–Mediterranean PME

This debilitating but not fatal form of autosomal recessive PME was first described in 1891 and 1895 by Unverricht in Estonia and in 1903 by Lundborg in Sweden. The incidence is at least 1:20,000 in Finland. Although rarely seen in North and South America, it is, relatively speaking, the most common form of PME in the Americas. Presenting with severe stimulus-sensitive myoclonias in a person between 6 and 18 years, the disease progresses slowly with cognitive decline and emotional lability. Tendon tapping, or passive joint movements, auditory and light stimuli are common precipitants of myoclonias. Clonic, tonic–clonic, and myoclonic seizures mostly appear on awakening and should be differentiated from JME. Late in the course of illness, motor incoordination, dysmetria, dysdiakinesia, and ataxic gait appear. Valproate, topiramate, and lamotrigine can reduce seizure frequencies, but eventually resistance to antiepileptic drug treatment develops. After a period of approximately 5 years, the patient is usually incapacitated.

Armpit skin biopsy reveals membrane-bound vacuoles in eccrine cells. The genetic mutation for Unverricht–Lundborg Baltic type and Mediterranean type PME are both in chromosome 21q22.3 and consists of a loss of function in cystatin B. Cystatin B is a member of the superfamily of cysteine proteinase inhibitors.

Lafora's Disease

Lafora's disease, a fatal autosomal recessive form of PME, starts with epileptic seizures during early adolescence or as late as 18 years. Patients die 5 to 10 years after the first symptoms—usually by 20 years of age. The disease is relatively common in the Mediterranean countries, the Middle East, India, and other geographical areas where consanguinity occurs. Initial tonic-clonic, partial visual, absence, or drop seizures are followed by myoclonus. Trains of photic-sensitive high-voltage, usually bilaterally synchronous, spike-wave and polyspike-wave complexes interrupt a disorganized slow EEG background. Dementia, apraxia, and visual loss lead to a vegetative state. The hallmark of the disease is a periodic acid-Schiff–positive cytoplasmic inclusion body, originally described by Lafora in 1911. Lafora bodies

contain polyglycosans and are found in the brain, striated muscle, liver, and skin. An axillary skin biopsy is the diagnostic procedure of choice.

The mutated gene for Lafora's disease maps to chromosome 20q and encodes protein tyrosine phosphatase. Based on its sequence analyses alone, protein tyrosine phosphatase probably has dual-specific activities catalyzing the dephosphorylation of glycogen synthase kinase-3B. Glycogen synthase forms and extends outer linear chains, and new outer linear branches (α1 to 6 branches) of glycogen. In the presence of mutations in the protein tyrosine phosphatase, the phosphorylated form of glycogen synthase would remain in an activated form, and excessive glycogen could be synthesized and Lafora inclusion bodies form.

Other rare forms of PME can be caused by the neuronal ceroid- lipofuscinoses: juvenile Gaucher's disease, sialidosis type I, and MERRF. PME can be caused by three types of neuronal ceroid- lipofuscinoses: late infantile (Jansky–Bielschowsky disease), juvenile (Batten disease or Spielmeyer–Vogt–Sjögren disease) and adult (Kufs' disease). The late infantile form (CLN-2) is autosomal recessive, starts in early childhood between 2.5 and 4 years, and is fatal. Myoclonic, generalized tonic–clonic seizures, atonic, and atypical absence seizures cause the disease to be mistaken for Lennox–Gastaut–Dravet syndrome. Intellectual loss, blindness, spasticity, and ataxia lead to a decorticate state and death between 6 and 10 years. Slow irregular spikes and polyspike-wave discharges interrupt a slow disorganized EEG background. Photic stimulation induces posterior high-amplitude, polyphasic spikes, and giant visual-evoked potentials. An autosomal recessive juvenile form of ceroid-lipofuscinosis (CLN-3) is also fatal and starts in early childhood or childhood (4 to 10 years) with loss of central vision that progresses to blindness. Absence seizures and generalized tonic–clonic seizures appear 2 years later with ataxia, dysarthria, and mental deterioration. Death occurs in the late teens or early 20s.

Vacuolated lymphocytes in peripheral blood and characteristic fingerprint profiles and curvilinear inclusions in ultrastructural study of skin biopsy or lymphocytes confirm the diagnosis. The gene locus of CLN-3 is 16p.

Only the juvenile type (type 3) of Gaucher's disease presents as PME in childhood or early adulthood. Severe intention myoclonus, abnormal saccadic horizontal eye movements, and supranuclear gaze paralysis are the first symptoms. Cerebellar deficits, generalized and partial seizures, and some degree of dementia are common. Hepatosplenomegaly is present. Death occurs 10 years from the diagnosis. The EEG shows rapid 6- to 10-Hz diffuse polyspike and rhythmical sharp waves most prominent posteriorly, and 6- to 10-Hz photic stimulation induces a photoparoxysmal or photomyoclonic response. The juvenile type of Gaucher's disease is an autosomal recessive disease caused by a deficiency of glucocerebrosidase. The gene for glucocerebrosidase has been mapped to the q21-231 region of chromosome 1.

Sialidosis type I also known as the *cherry-red-spot myoclonus syndrome* was first described by Guazzi and colleagues in 1968. It causes a PME syndrome in childhood and adolescence, appearing between the ages of 8 to 15 years. Macular cherry-red spots are seen in the fundus with visual failure. These are combined with easily controlled seizures and pains of "burning hand and feet." There is usually no dementia. Stimulus-sensitive myoclonic jerks as well as sporadic, stimulus-insensitive facial myoclonus can be triggered by active and passive movements, the thought of movements, and touch, but not by light or sound. An inherited primary deficiency of neuraminidase is observed in those with sialidosis type I.

MERRF is a tRNA^{Lys} mutation in mitochondrial DNA and can cause a childhood or adult form of PME. Cerebellar ataxia, action myoclonus epilepsy, tonic–clonic seizures, and ragged-red fiber myopathy occur with deafness, dementia, dysarthria short stature, optic atrophy, neuropathy, lactic acidosis, hypoventilation, and migraine. Inheritance is consistent with mitochondrial (maternal) transmission. Muscle biopsy reveals subsarcolemmal aggregates of mitochondria, the so-called ragged-red fibers. Giant visual-evoked potentials are recorded in all cases. Several investigators have demonstrated, in a number of patients with MERRF syndrome, the presence of a disease-related A-to-G substitution at nucleotide 8344 in the mitochondrial DNA, which affects the pseudouridine loop of the mitochondrial tRNA^{Lys}. A causal relation between this genetic mutation and MERRF disease is present, and the A-to-G mutation in the mitochondrial tRNA^{Lys} gene is disease-specific for MERRF.

SEVERE ACQUIRED GENERALIZED EPILEPSIES OF INFANCY AND EARLY CHILDHOOD

The West syndrome and the Lennox–Gastaut–Dravet syndrome are the most common acquired generalized epilepsy syndromes in infancy and early childhood.

West Syndrome or Infantile Spasms

Spasms, arrest of psychomotor development, and hypsarrhythmia begin during the first year of life. Spasms may be flexor, extensor, or mixed and are described as jackknife. In salaam spasms, the arms are abducted. The EEG hypsarrhythmia is defined as grossly chaotic diffuse, asymmetric mixtures of very high-amplitude slow waves, sharp waves, and spikes. Evolution from West syndrome to Lennox–Gastaut–Dravet syndrome is common, and both disorders represent a peculiar response of the brain to an insult at different stages of maturation. Affected patients do not respond to most antiepileptic drugs, but corticotropin (ACTH), corticosteroids, or clonazepam control the spasms.

Most cases are symptomatic and related to one of an innumerable list of diseases. An idiopathic and possibly genetic form of West syndrome is characterized by normal psychomotor development and spontaneous recovery. Probably less than 5% of patients with West syndrome have the idiopathic form.

Lennox–Gastaut–Dravet Syndrome

Atypical absences, atonic seizures, and tonic seizures are common, although partial seizures and myoclonic seizures also occur and may be difficult to distinguish clinically from atonic or short tonic seizures. An EMG recording is essential to determine whether a drop attack is an atonic seizure or a true myoclonic seizure, since both are characterized by a sudden fall of the head or body. The EEG shows slow background and the slow form (less than 2 Hz) of spike-wave or polyspike-wave discharges with no EMG activity during atonic seizures. Diffuse rapid 10- to 20-Hz rhythms fire with EMG muscle activity during myoclonic seizures. Tonic seizures show either desynchronization of background activity or a recruiting 10- to 20-Hz rhythm of increasing amplitude, or both. Myoclonias are rare in the Lennox–Gastaut–Dravet syndrome. A family history has been reported in 3% to 27% of the patients. In 20% to 30%, no underlying cause is found. A cryptogenic form in which a family history of epilepsy was present in 48% of patients has been described.

Early Myoclonic Encephalopathy

Erratic, fragmentary myoclonus, massive myoclonias, infantile spasms, focal motor seizures, and tonic seizures start in the neonatal period. The EEG shows a burst-suppression. Severe neurologic impairment leads to death in the first year of life in 60% of patients. The remaining 40% survive in vegetative states. No obstetric or perinatal complications have been recognized. Although the high incidence of familial cases suggests a genetic cause, most cases of early myoclonic encephalopathy are considered acquired.

Early Infantile Epileptic Encephalopathy

Also called Ohtahara's syndrome, early infantile epileptic encephalopathy appears during the first weeks of life as a subacute condition that progresses over a period of several days or weeks. Flexor, extensor, or asymmetric spasms and tonic–clonic or unilateral seizures characterize the disease and progressively increase in frequency. Normal at onset, the patient deteriorates soon as mental retardation and neurologic deficits appear. Burst-suppression EEG pattern consists of several seconds of flat periods, alternating with high-amplitude spike-wave complexes. The cause is variable and includes brain malformations and diffuse prenatal lesions. The prognosis is poor, and 50% die in infancy or childhood. The rest survive severely incapacitated. The syndrome has been considered an early variant of the West syndrome.

Epilepsy with Myoclonic Absences

Myoclonic absences, which are the only or main seizure type, start from 2 to 12.5 years, usually at 7 years of age. Rhythmic, bilateral, diffuse 3-Hz myoclonias of severe intensity are accompanied by EEG bilateral, synchronous, and symmetric 3-Hz spike-wave discharges identical with those of classic petit mal. Seizures are longer than petit mal absences, lasting 10 to 60 seconds. Impairment of consciousness can range from a complete to a lesser degree of disruption. Myoclonic absences are frequently provoked by hyperventilation and in some cases by photic stimulation. Patients may have associated generalized tonic–clonic seizures. There is a positive family history in 19% of patients. The prognosis is usually poor because of the lack of response to antiepileptic drugs and frequent mental deterioration. The treatment of choice is valproic acid, but a combination of valproic acid and ethosuximide is often necessary to control the seizures. Epilepsy with

myoclonic absences is considered an intermediate syndrome between primary and secondary generalized epilepsies.

Severe Myoclonic Epilepsy of Infancy of Dravet

Severe myoclonic epilepsy of infancy of Dravet, although presently considered an acquired form of epilepsy, presents certain characteristics of a genetic epilepsy: absence of causative factors, high incidence of family history (25%), initial epileptic symptomatology, and photosensitivity. Onset is always during the first year of life as generalized or unilateral febrile clonic seizures. No abnormality in development is apparent before seizure onset. Myoclonic seizures, which develop later in the illness, can induce a fall if severe enough, but subtle, inconspicuous seizures also occur. Consciousness is not disturbed unless the seizures are frequent (one seizure every few seconds). Partial seizures evocative of complex partial and partial motor seizures also form part of this syndrome. Generalized spike-wave or polyspike-wave complexes are seen interictally, and photosensitivity is common. The prognosis for those affected with severe myoclonic epilepsy of infancy of Dravet is poor because of the intractability of the fragmentary and segmental myoclonus seizures, the slow psychomotor development, and progressive neurologic signs.

Acquired Partial Epilepsies with or without Secondarily Generalized Seizures in Children and Adults

Temporal lobe and frontal lobe epilepsies are the most common forms of acquired epilepsies and account for almost half of all epilepsies in children and adults.

Frontal Lobe Epilepsies

In the United States, an estimated 600,000 patients have frontal lobe seizures and epilepsies. Frontal lobe seizures and epilepsies account for 20% to 30% of all partial epilepsies. These seizures are classified according to the dominant region and systems of the frontal lobe involved ([Table 444.2](#)):

Dorsolateral region seizures— anterior polar or frontopolar, frontal operculoinsular, and premotor frontal

Medial frontal seizures— supplementary motor and anterior cingulate.

Orbital frontal seizures— anterior mesio-orbital and posterior orbital frontal—temporal.

A combination of various frontal lobe regions involved by seizures

In general, secondary tonic-clonic convulsions and simple partial seizures with somatomotor or postural signs and contraversive head and eye movements are common in those with frontal lobe epilepsies. When psychomotor attacks appear, motor manifestations are prominent. This contrasts to the paucity of motor signs seen in those with temporal lobe seizures in whom arrest of movements, staring, proptosis, and masticatory oroalimentary automatisms are more common, as in amygdalar-hippocampal-parahippocampal epilepsy. Complex partial seizures, which originate from the frontal basal and anterior cingulate cortex, can begin with extreme fear and terror, bizarre vocalization, bilateral motor automatisms, bipedal movements, frenetic arm- and leg-thrusting behavior, sexual automatisms, and running. The latter motor signs are rare in those with temporal lobe seizures, although fear, bizarre vocalization, and sexual automatisms can appear rarely in temporal lobe opercular seizures. Oroalimentary masticatory automatisms combined with a motionless staring phase may also appear in those with frontal lobe seizures but usually in the middle or late stages of the attack.

Certain characteristics or oroalimentary automatisms can be valuable in differentiating frontal from temporal lobe seizures. Mastication, chewing, smacking, and licking lips are characteristic of amygdalar-hippocampal-parahippocampal seizures with its lateral temporal and subcortical connections. Swallowing, orofacial dyskinesia-like movements of mouth and lips are more suggestive of frontal opercular seizures.

Pseudoabsence attacks lasting 10 to 30 seconds with minimal automatisms are also observed in frontal lobe seizures. Such short attacks occur frequently, often in clusters, and may be associated with sphincter incontinence. These seizures can be associated with drop attacks.

Complex partial seizures of frontal lobe origin very commonly evolve to tonic-clonic convulsions or complex partial status epilepticus. When secondary tonic-clonic seizures appear in 40% of temporal lobe epilepsy, such convulsions appear rarely.

Temporal Lobe Epilepsies

Temporal lobe epilepsies account for approximately 40% to 50% of adult and 25% to 30% of childhood epilepsies. Temporal lobe epilepsies are divided into medial temporal (hippocampal-parahippocampal and amygdalar), lateral temporal neocortical (inferotemporal, superotemporal, and perisylvian— opercular), combined medial-lateral temporal lobe epilepsies, and combined temporal-extratemporal lobe epilepsies ([Table 444.3](#) and [Table 444.4](#)). Hippocampal-parahippocampal epilepsy accounts for 60% of all temporal lobe epilepsies and commonly combines with amygdalar epilepsy.

The classic hippocampal psychomotor attack is preceded by symptoms of an “indescribable strange feeling” and autonomic signs. Fifty-five percent of attacks start with arrest reaction (motionless staring), oroalimentary automatisms, or a single discrete motion. A typical seizure lasts 2 minutes. The motionless stare lasts 5 to 20 seconds and is followed by lip-smacking, chewing, and then lingering confusion for 60 to 90 seconds. Tonic movements, postures, and clonic jerks appear late as a manifestation of seizure spread. The surface interictal EEG commonly shows anterior medial spikes or sharp waves. Sixty percent show hippocampal atrophy on MRI, and 80% show hypometabolic temporal lobe on positron emission tomography. Ninety percent of cases show hippocampal scleroses on pathology; less frequently neuronal migration, hamartoma, ganglioglioma, astrocytoma, and oligodendroglioma are observed.

Rising epigastric discomfort and autonomic symptoms and signs, including borborygmi, belching, pallor, fullness or flushing of face, arrest of respiration, and pupillary dilation, suggest either an amygdalar or a lateral temporal opercular onset. Simple auditory hallucinations, psychical seizures containing illusions or hallucinations of voices, songs, and music, visual perceptual hallucinations, interpretive illusions, the dreamy state and experiential hallucinations (*déjà, jamais vu*, dream-like sequences, memory recording), and vestibular hallucinations can mean lateral superotemporal seizures, including Heschl's gyrus.

Inferotemporal neocortical seizures are usually silent clinically until discharges spread medially to the hippocampal-amygdalar circuit or laterally to the perisylvian opercular regions. The interictal surface EEG shows midtemporal or posterior temporal spikes. Traumatic encephalomalacia, arteriovenous malformations, or gliomas are observed on pathologic study.

Combined temporal lobe extratemporal lobe seizures manifest clinically with the motor signs of frontal lobe complex partial seizures, such as running, bipedal movements, frenetic arm- and leg- thrusting, and sexual automatisms or parietal lobe seizures with body circling.

Parietal Lobe Epilepsies

Localized parietal seizures do not involve changes in consciousness, although changes in perception are expected. They can rapidly spread to subcortical regions, can impair consciousness, and can be mistaken for temporal and frontal lobe seizures. Gustatory hallucinations, pharyngeal automatisms, feelings of uncontrolled movement, body turning, bilateral arm automatisms, primary sensations, and misperceptions can occur. Unformed visual hallucinations, contralateral numbness, vertigo and tinnitus, and speech arrest have been reported.

Occipital Lobe Epilepsies

Occipital lobe lesions produce simple visual hallucinations. Spread of paroxysms can result in urges to urinate, posturing, speech arrest, complex vivid hallucinations, confusion, and automatisms. The initial visual aura can be eclipsed by psychomotor automatisms. Blindness, dim vision, field cuts, visual hallucinations, forced blinking, eye deviations, visual agnosia, or abnormal perception can precede or follow complex partial seizures.

COMMON LESIONAL EPILEPSIES

Age at onset, birth and developmental history, family history, personal and social drug habits, nature of seizures, neurologic signs, and EEG results are important

considerations in looking for epileptogenic brain lesions. In infants, children, and young adults, perinatal lesions, anoxia, neuronal migration disorders, focal cerebral cortical dysplasias, and birth trauma without hemorrhage are observed in 25% of cases. Postnatal trauma causes 20% of simple partial seizures in young adults. Trauma, neoplasm, birth injuries, and arteriovenous malformations are the most common causes when seizures begin in a person between 20 and 35 years of age. Neoplasm, trauma, and infarction or hemorrhages are most common causes when seizures start in a person between 40 and 55 years of age. Cerebrovascular accidents and neoplasms are common causes in seizures starting between 55 and 70 years of age. Neurocysticercosis is a common cause of epilepsy, especially in patients emigrating from Mexico, Central America, Ecuador, Iran, and India.

Asymmetry of extremities and facial and cranial bones may suggest cerebral hemiatrophy and atrophic epileptogenic process. Todd's postictal hemiparesis suggests a focal process.

NEURONAL MIGRATION DISORDERS AND CEREBRAL CORTICAL DYSPLASIAS

In the last decade, a body of evidence, advanced by MRI imaging and neuropathology of surgical specimens, has placed neuronal migration disorders and cerebral cortical dysplasias as crucial in the pathogenesis of familial and sporadic epilepsies. These malformations of cerebral cortical development are classified into two major distinct groups, namely, generalized dysplasias and focal dysplasias. Bilateral and generalized dysplasias include the microlissencephalies, classic and "cobblestone" lissencephalies, heterotopia, periventricular nodular heterotopia, and diffuse polymicrogyria. Focal dysplasias include focal cortical dysplasia of the Taylor type with giant balloon neurons in the temporal lobe, developmental neoplastic lesions, hemimegalencephaly, focal polymicrogyria, and schizencephaly. Dysplasias can also be bilateral and focal, as in the subcortical band heterotopia or "double cortex syndrome," bilateral parasagittal parietooccipital polymicrogyria and, bilateral perisylvian polymicrogyria. Dysplasias can be unilateral and hemispheric, as in hemimegalencephaly. Bilateral generalized dysplasias more often have a genetic basis, whereas environmental causes that impair development are suspected in focal dysplasias.

Seven separate chromosomal loci have now been defined for some of these generalized cortical dysplasias (see Table 21C1). Three specific mutations have been unraveled, one for X-linked bilateral periventricular nodular heterotopia in the form of a 2.25 to 3.25 Mb duplication in chromosome Xq28, one for lissencephaly 1, a deletion in chromosome 17p13.3, and one mutation in a gene that encodes for the protein "doublecortin" in the syndrome of subcortical band heterotopia. The locus 17p13.3 appears phenotypically as a sporadic disorder but actually represents either an isolated autosomal dominant lissencephaly or an isolated autosomal dominant Miller Dieker syndrome. Duplication of 9p was recently implicated in centrosylvian polymicrogyria.

Although most cases of generalized neuronal migration disorders appear to be sporadic, a genetic cause is actually present. Either sex-linked dominant inheritance with male lethality or severe expression in hemizygous males explains the female preponderance, the high frequency of spontaneous abortions, and the abnormal sex ratios in sibships of subcortical band heterotopia or double cortex syndrome and periventricular nodular heterotopia. These X-linked disorders are allelic human disorders, which map to chromosome Xq22.3-Xq23. It is interesting that families typically have females and daughters with subcortical band heterotopia, mild mental retardation, and seizures, whereas their sons have lissencephaly, seizures, and severe retardation. In 1998, mutations of doublecortin were identified in four families and three sporadic cases of the double cortex syndrome. A novel 10-kb brain-specific cDNA interrupted by a balanced translocation was originally observed in an XLIS patient that encodes the novel 40-kd protein called doublecortin. Mutations in doublecortin impair migration and explain the disruption of the six-layered cortex as a failure of early events associated with neuron dispersion.

In contrast to subcortical band heterotopia, periventricular nodular heterotopia appears in persons with normal intelligence who present clinically with epilepsy, often temporal lobe epilepsy. Bilateral perisylvian polymicrogyria is probably also a genetic disorder, having been reported in monozygotic twins and families.

In the 1970s and 1980s, histopathologic abnormalities, such as abnormal distribution of granule cells, focal cortical dysplasia, and forme fruste of tuberous sclerosis, had already been observed in surgical specimens removed from patients with hippocampal temporal lobe epilepsy, frontal neocortical epilepsy, infantile spasms, and Lennox-Gastaut syndrome. Neuronal migration disorders—specifically microdysgenesis—had originally been recognized as important pathological substrates in the autopsy specimens of genetically determined idiopathic generalized epilepsies and symptomatic partial epilepsies, such as West syndrome and Lennox-Gastaut syndrome. More recently, birth defects, such as cleft lip/palate, spina bifida aperta/Yoculta, and other forms of rachischisis, have been reported to be increased in infants of mothers with epilepsy with or without antiepileptic drug treatment.

SEIZURES FROM INTRACRANIAL TUMORS

Epileptic seizures that recur in 5 to 20 years may be the only symptom of a slow-growing neoplasm ([Chapter 426](#)). Seizures are presenting symptoms in 40% of brain tumors and precede focal neurologic signs and increased intracranial pressure in two thirds of these cases. Seizures occur in 37% of patients with glioblastomas, 70% with astrocytomas, 67% with meningiomas, and 92% with oligodendrogliomas.

Five to 10% of patients who undergo anterior temporal lobectomy or cortectomy because of drug-resistant seizures have a cerebral neoplasm. A cerebral tumor should be suspected when seizures increase in frequency or change patterns or when patients develop status epilepticus or new neurologic signs or symptoms.

POST-TRAUMATIC SEIZURES

Trauma is a common cause of symptomatic or acquired epilepsy and accounts for 10% to 20% of seizures overall and up to 50% in the 15- to 24-year age range. Moderate to severe head injury can increase the risk of epilepsy up to 7% and even 34% in patients injured in combat. Seizures that recur within the first week of head injury are called *early post-traumatic seizures*. They occur in 4% of patients with head injuries. Late traumatic epilepsy (seizures occurring more than 1 week after injury) develop in approximately 5% of nonmissile head injuries and in one third of those with gunshot wounds who are admitted to the hospital. The risk for epilepsy rises to 25% if one early seizure has occurred. About one third of early seizures occur in the first hour after injury, a third occur in the next 23 hours, and the rest occur in the next 6 days. However, the risk for late epilepsy is similar whenever early epilepsy has occurred. Almost 25% of late epilepsy develops more than 4 years after injury. Fifty percent of patients with post-traumatic epilepsy recover spontaneously within 8 years.

Risk factors for post-traumatic seizures include post-traumatic amnesia of more than 24 hours, depressed skull fracture, dural tear, and focal neurologic signs. Brief cerebral concussion in closed-head injuries, which is not associated with loss of consciousness, rarely causes seizures. Treatment should be continued for at least 2 years after the last seizure. Early post-traumatic seizures are not likely to persist. Delayed post-traumatic seizures have a less favorable prognosis. Intractable drug-resistant seizures may be expected in 25% to 30% of cases. Onset of seizures 10 years after head injury is extremely rare.

Phenytoin, phenobarbital, carbamazepine, and valproate have all been futile in preventing chronic epilepsy after head injuries.

At the present time, we have no explanation for the "silent period" between traumatic head injury and the appearance of chronic epilepsy months or years after the injury. Intracellular transduction and gene expressions during head trauma, sprouting of mossy fibers, and granule cell dispersion all may have a role in the silent period between trauma and the induction of chronic epilepsy.

NEUROCYSTICERCOSIS

Neurocysticercosis is a major cause of epileptic seizures in areas of the United States, such as Los Angeles, Chicago, New York, and Miami, which have large populations of immigrants from endemic areas in Asia, Africa, Mexico, and South and Central America. In Mexico, cerebral cysticercosis is found in 2% to 4% of unselected autopsies.

Neurocysticercosis is the encystment of the larvae of *Taenia solium*, the pork tapeworm in the brain. Infestation is produced by ingestion of the ova through fecally contaminated food, by autoinfestation via anal-oral transfer, or by reverse peristalsis of proglottids into the stomach. The larvae are not acquired by eating infected pork; the latter results in adult tapeworm infection. Neurocysticercosis occurs even among vegetarians in endemic areas. Central nervous system invasion occurs in 50% to 70% of all cases of cysticercosis. Epileptic seizures occur in more than 50% of patients with neurocysticercosis. Several clinical subtypes of neurocysticercosis exist and determine whether treatment should be done with anticysticercal drugs. Epileptic seizures should be treated with antiepileptic drugs. These clinical subtypes can occur alone but in 50% of patients, they occur in combinations of two or more subtypes in the same patient. Following are the clinical subtypes of neurocysticercosis:

1. Parenchymal—when the cyst resides in the brain parenchyma. No, minimal, moderate, or severe inflammation can exist around the cyst. A fibrous capsule due

to reactive astrogliosis may surround the cyst. Granulomas may form and, over years, be replaced by calcification. The number of cysts vary from one to hundreds.

2. Meningeal—when cysts measuring 0.5 to 1 cm to 10 to 15 cm (giant cysts) reside within the subarachnoid space and cause widespread inflammation and fibrosis of arachnoid membranes. This can lead to hydrocephalus and vasculitis, the most severe and often fatal form of neurocysticercosis syndrome. Severe arachnoiditis at the base of the brain may produce Parinaud's syndrome. Vasculitis and occlusion of vertebral and basilar arteries can lead to death. Multiple vascular occlusion in the cerebral hemispheres causes multi-infarct dementia.
3. Ventricular—when an oncosphere arrives at the choroid plexus of the fourth ventricle through the bloodstream (in 1% of neurocysticercosis), it grows to a size large enough to produce a ball valve that occludes cerebrospinal fluid flow. Hydrocephalus occurs, and episodic intracranial hypertension characterizes the syndrome.

Computed tomography (CT) and MRI, both with contrast enhancement, complement each other in diagnosing the subtypes of neurocysticercosis. When either or both imaging studies suggests neurocysticercosis, cerebrospinal fluid analysis is mandatory to quantify the inflammatory reaction. Enzyme-linked immunosorbent assay (ELISA) for anticysticercus antibodies has 94% sensitivity and 98% specificity. The complement fixation test has 84% sensitivity and 94% specificity for anticysticercus antibodies when cerebral spinal fluid shows inflammation.

Simultaneous administration of albendazole and dexamethasone is the suggested treatment for parenchymal cysticercosis and clumps of cysts in the subarachnoid space. Albendazole (15 mg per kilogram per day in two daily doses for 8 days) destroys 85% of parenchymal cysts. Dexamethasone ameliorates the intense inflammation produced by cysticidal therapy. Three months later, a second CT and MRI should be done to determine whether cysts remain. If so, praziquantel (50 mg per kilogram per day in three daily doses for 15 days) should be given as a second course in all patients. When parenchymal cysts respond to cysticidal treatment without leaving granuloma, withdrawal from antiepileptic drug treatment is usually successful. Inactive forms of neurocysticercosis, such as granulomas and calcifications, do not respond to cysticidal treatment but need antiepileptic drugs to stop seizures. Ventricular shunting is performed when hydrocephalus with or without an obstructing cyst in the fourth ventricle is present. Shunting is usually performed before cysticidal treatment is begun. After intracranial hypertension is relieved, cysticidal and corticosteroid treatments are started.

At present, there is one blinded randomized small study that questions the usefulness of albendazole and praziquantel, in (1) ameliorating acute seizures, (2) preventing epileptogenesis, and (3) interrupting the pathologic consequences of central nervous system invasion by cysts. Unfortunately, such a small study had not been able to separate the various clinical subsyndromes of neurocysticercosis, such as the following:

- Active lesions with edema and enhancement after contrast medium
- Inactive lesions with residual calcification and gliosis
- Perisylvian subarachnoidal cysts
- Basilar subarachnoidal cysts
- Intraventricular cysts

This difficulty included their responsiveness or contraindication to cysticidal drugs or surgical treatment. A prospective double-blind controlled study of a large cohort with long-term follow-up is clearly needed.

SEIZURES FROM CEREBROVASCULAR DISEASE

After a person is 50 years of age, cerebrovascular diseases, especially acute embolic cerebrovascular disease, frequently cause seizures ([Chapter 426](#)). Cerebrovascular arteriosclerosis without cerebral infarction or hemorrhage rarely causes seizures. Twelve percent of patients have seizures 6 to 12 months after cerebral infarction or hemorrhage. Only 2% of stroke patients experience seizures acutely. These usually present as epilepsy partialis continua or partial status with periodic lateralized epileptiform discharges.

COURSE AND PROGNOSIS

GENETIC EPILEPSIES WITH GENERALIZED OR PARTIAL SEIZURES

Almost all genetic epilepsies with primary generalized seizures have an excellent prognosis. Sixty to 95% are stopped by drug treatment. Genetic partial epilepsies, such as rolandic epilepsy are usually controlled by monotherapy, and clinical features usually disappear by age 16.

ACQUIRED PARTIAL EPILEPSIES

Because partial seizures are often due to atrophic nonprogressive structural changes, they stand a good chance of being controlled and even cured. Seizures from tumors, vascular malformation, and cerebral infarctions are unlikely to be cured. Control of attacks should be the goal. Partial seizures occurring early in life and in newborns have a favorable prognosis. Early treatment in adults also produces a favorable prognosis as long as an underlying progressive structural disease is not present.

CHAPTER 445: STRUCTURAL DISORDERS OF THE SPINAL COLUMN

JOHN DEAN RYBOCK

[Myelopathy](#)
[Neurogenic Claudication](#)
[Radiculopathy](#)
[Neck and Back Pain](#)

Spinal disorders probably account for more physician visits than any other group of medical disorders. One of every five to six adults seek treatment for back problems each year, 85% of the population experiences a significant episode of back dysfunction during his lifetime, and 25% of time lost from work is due to spinal problems. The bulk of neurosurgical practice is devoted to spinal diseases, and a large percentage of orthopedic, chiropractic, and physical therapy practices involve spinal problems. Most patients treated in specialized pain programs have spinal disorders.

It is neither reasonable nor practical to create a comprehensive list of all the disorders of the spine. The standard disease processes require multivolume texts for basic coverage; furthermore, the clearly defined diagnoses explain only a limited portion of the spinal complaints seen in daily practice. Fortunately, most complaints encountered in the office result from definable structural problems with straightforward treatment approaches, or they can be grouped into a nonspecific (and nonserious) class, which can be successfully treated empirically. The goal of this section is to differentiate between potentially serious conditions that require specialty referral and the much more common benign spinal problems that are best treated in the primary care setting.

The key to understanding the basic spinal dysfunctions and their significance is knowledge of the anatomy of the spine and how it changes with aging. The spine is a stack of 24 blocks of bone (vertebral bodies) separated by flexible spacers (intervertebral discs) running from the sacrum to the base of the skull. It provides the central support for the body while allowing for a certain degree of motion, and it provides a housing for the spinal cord and its nerve roots (spinal canal). In some sense, this combination of the flexible supporting structure of the body with the passageway for the spinal cord is unfortunate, because the stresses of the upright posture and the increasing human longevity lead to degenerative changes in the supporting structures that make an impact on the spinal cord and its nerve roots.

Most patient complaints are a result of aging processes that progress at various rates in all human spines. In the simplest case, the muscular and ligamentous structures that labor to keep this stack of blocks from toppling are always near the limits of their strength and even minor events can overwhelm them, leading to mechanical pain. As the patient ages, the intervertebral disc becomes less flexible and the muscular and ligamentous stresses increase. Each disc goes through a fairly well-defined sequence of changes, in which it loses its hydration, flexibility, and cohesiveness.

Tears occur in its outer cover, and nuclear disc substance may escape the confines of the disc. This is most likely to occur posterolaterally where the spinal nerve roots pass over the disc, and so nerve root compression may occur. Tears may also occur centrally, impinging on the spinal cord, or, in the lumbar area, the cauda equina. As time goes on, all discs become more dehydrated and narrower. The adjacent bone reacts by thickening, as if to provide the support the disc no longer gives. The facet joints, bordering the spinal canal, hypertrophy, as does the lining of the posterior lining of the spinal canal. The result is progressive encroachment on the spinal canal, progressively reducing its cross-sectional area and therefore the space for the spinal cord and its roots. Depending on where such bony growth and ligamentous thickening occur, the spinal cord, the cauda equina, or individual nerve roots can become compressed and symptomatic.

Most spinal problems by far can be traced to either mechanical stress on a less-than-robust structural assembly, an extrusion of substance from a degenerative disc, or the chronic changes that are an inevitable part of the aging process.

Structural spinal dysfunction can manifest clinically in one of three patterns: (1) encroachment on the spinal canal, with compression of its contents (myelopathy in the cervical or thoracic regions, neurogenic claudication in the lumbar region), (2) focal intrusion on a single nerve root (radiculopathy), or (3) mechanical and soft-tissue dysfunction causing pain (cervicalgia or lumbalgia). Each of these distinct clinical syndromes has characteristic features.

MYELOPATHY

Myelopathy is dysfunction of the spinal cord itself. This can result from intrinsic disease of the spinal cord or extrinsic compression of it. The presentation depends on the rapidity of development, the spinal levels involved, and the portion of the cord (left-right, anterior-posterior) predominantly affected. Intrinsic processes include neural tumors, demyelinating diseases, and syringomyelia; such conditions are beyond the scope of this chapter.

The more common extrinsic compression can occur as an acute event (fracture-dislocation of the spinal column), a subacute event (metastatic carcinoma occupying the epidural space) or an insidious process (gradual compression due to progressive encroachment on the spinal canal by degenerative changes).

The characteristics of myelopathy are long tract signs and motor and sensory loss patterns confined to the regions below a specific segmental level. The most obvious long tract signs are hyperreflexia, including ankle clonus, and "pathologic reflexes" such as Babinski's sign. If the lesion is in the thoracic region, upper extremity function remains intact. As the involvement moves up the spinal cord from C7 to C4, functional loss progresses from hand to arm to shoulder; higher lesions are usually incompatible with survival.

Acute and subacute presentations of myelopathy warrant early neurosurgical referral; diagnosis and treatment are urgent. Insidious onset myelopathy in patients under 50 years of age is uncommon and generally should be evaluated by a neurologist. In older patients, the most common cause of gradual-onset myelopathy is progressive narrowing of the spinal canal (stenosis) due to the chronic degenerative changes (spondylosis) as previously described. This spondylotic stenosis can occur without neck pain; the patient may simply note that his or her sense of steadiness of the legs has declined or that he or she is having increasing difficulty with fine manipulations with the hands. If physical examination reveals signs of long tract dysfunction, cervical spondylotic myelopathy should be suspected. Magnetic resonance imaging (MRI) can confirm the diagnosis. The condition tends to be slowly progressive and can be arrested only by surgery. The appropriateness of surgical evaluation should be based on the patient's level of disability, rate of progression of the impairment, and age and health status.

NEUROGENIC CLAUDICATION

Neurogenic claudication is the primary syndrome resulting from "spondylotic stenosis" at levels of the cauda equina rather than the spinal cord. The spinal cord typically ends at the L1 level, so that stenosis in the lumbar region produces neurogenic claudication rather than myelopathy.

Neurogenic claudication derives its name from its symptomatic similarity to intermittent claudication, the difficulty with walking due to vascular insufficiency. In both conditions, the main symptom is limitation of walking distance by progressive leg fatigue. Whereas intermittent claudication results from ischemia of the leg muscles, neurogenic claudication is probably due to ischemia of the cauda equina as a result of compression. The two syndromes differ in that the neurogenic variety is more quickly relieved by sitting, is not associated with trophic changes in the legs, and can be relieved by lumbar flexion, which reduces the degree of spinal canal narrowing. A report of increased walking distance while pushing (and leaning on) a shopping cart is typical of neurogenic claudication.

A noteworthy aspect of neurogenic claudication is that pain is rarely a major presenting symptom. The presence of significant back pain suggests that spinal stenosis, to whatever degree it is present, is not the primary source of the patient's complaint.

Spinal stenosis is a slowly evolving compression; there is the rare occurrence of acute compression of the cauda equina, usually by a massive lumbar disc herniation. Acute cauda equina compression may produce significant pain, but the main presentation is that of severe sudden bilateral leg weakness and numbness with loss of bowel and bladder control. This event represents a surgical emergency and requires urgent neurosurgical referral.

Spinal stenosis, presenting as neurogenic claudication, is commonplace; the caricature of the elderly figure, bent forward and leaning on a cane, is symbolic of this condition. The diagnosis of spinal stenosis is established by imaging studies of the lumbar spine. Both computed tomography scans and MRI can confirm the diagnosis. In interpreting either scan, it is important to evaluate the cross-sectional area of the thecal sac at each motion segment. The bony canal may appear

adequate, but hypertrophic ligaments lining the posterior canal usually are the main source of thecal compression.

The most effective nonsurgical treatment for neurogenic claudication is regular performance of a specific back exercise program, called *William's exercises*. This program consists of a series of lumbar flexion stretches, which, over time, flatten the degree of lumbar lordosis. In so doing, the hypertrophic ligaments in the posterior canal are stretched out, decreasing their inward buckling, which is a major component of the stenosis. If regular performance of such exercises over a 2- to 3-month period fails to yield an acceptable degree of improvement, surgical intervention should be considered. Removal of hypertrophic bone and ligament yields marked improvement in walking distance in most patients.

RADICULOPATHY

Widespread neural dysfunction (myelopathy or neurogenic claudication) results from major encroachment on the spinal canal by a structural lesion; however, significant focal neural dysfunction can result from small structural lesions in certain critical areas. The critical areas are the far lateral spinal canal and the neural foramina, where the nerve roots pass through confined spaces. The upper portion of this passageway, where the nerve root arises from the thecal sac, overlies the intervertebral disc. Disc protrusion due to bulging as a result of gradual weakening of its outer layers or due to rupture of its inner material (nucleus pulposus) through the outer layers cause nerve root compression (i.e., herniated disc). Degenerative changes causing reactive bone thickening and spur development (osteophytes) can produce root compression in the lower portions of the passageway (lateral recess and neural foramen). Nerve root compression, by either disc herniation or osteophytes, causes radiculopathy, the loss of the root's motor and sensory functions, and pain in its sensory distribution.

There is a characteristic pattern of neurologic deficit for each nerve root ([Chapter 429](#)). Since disc herniation and osteophyte formation are uncommon in the thoracic region, we are usually dealing with cervical or lumbar radiculopathy. Persistent radiculopathy is the main indication for spinal surgical intervention.

Disc herniation is the classic cause of radiculopathy, generally affecting patients in the 30- to 55-year age range. The onset is often sudden, evolving from back or neck pain to the full pattern of radiculopathy over hours to a few days. There may be an episode of trauma causing the onset, but spontaneous occurrence is not uncommon.

Nerve root compression due to osteophyte formation is more common past the age of 50. Onset is less often related to trauma and is often insidious, progressing over months to years. Compared with radiculopathy due to disc herniation, the pain tends to be duller, the weakness less marked, and neck or back pain more significant.

In the cervical area, the most common nerve roots affected by either disc herniation or osteophytic compression are C6 and C7. The C6 root innervates the biceps muscle and carries sensation from the thumb and first finger. Therefore, loss of the biceps reflex and radial hand numbness and paresthesias are characteristics of C6 radiculopathy. The C7 root innervates the triceps and carries sensation from the middle digits, so C7 radiculopathy is characterized by loss of triceps jerk and sensory abnormalities in the central portion of the hand.

In the lumbar area, the L5 and S1 roots account for 95% of radicular loss in clinical practice. The L5 root provides sensation from the medial foot and innervates the dorsiflexors of the ankle; its loss is characterized by numbness of the great toe and partial foot drop. The S1 root serves the lateral foot and the gastrocnemius muscles, so an S1 radiculopathy produces small toe numbness and loss of the ankle reflex.

The diagnosis of radiculopathy is made on clinical grounds. Although imaging studies can clarify the structural cause, such clarification is not initially important. Nonsurgical therapy is initiated, with the expectation that at least 75% of cases can be resolved without surgery. The most important treatment modality for cervical radiculopathy is cervical traction. Although physical therapy modalities appears to help reduce the pain level, it is "over-the-door" cervical traction, done twice daily at home, which appears to most effectively promote resolution. Traction works well even when root dysfunction is due to osteophytic compression, suggesting that radiculopathy is due to more complex pathology than simple impingement. Once an episode of radiculopathy has resolved, physical therapy, stressing neck-strengthening exercises, can reduce the risk of recurrence.

With lumbar radiculopathy, initial treatment depends on the rapidity of onset and the severity of the symptoms. Acute onset with severe radicular pain usually requires several days of reduced activity, occasionally bed rest, until the degree of disability decreases. Pain medication, either a nonsteroidal anti-inflammatory or a narcotic-acetaminophen combination, is prescribed. In the more severe cases, the addition of diazepam provides some muscle relaxation and makes reduced activity more easily tolerated. Prolonged periods of marked inactivity should be avoided. As the degree of pain decreases, activity can be gradually increased; in general, the highest level of activity that does not aggravate the radicular pain should be maintained. Aggravation of nonradicular back pain does not delay recovery.

After the acute episode has settled down or with gradual-onset radiculopathy, physical therapy progressing to a home back exercise program is recommended. Particularly in older patients with probable osteophytic compression of a nerve root, a lumbar flexion exercise program (Williams exercises) can gradually open up the neural foramen and resolve the radiculopathy.

Except in cases of major neural dysfunction, such as a complete foot drop, the described should be undertaken before specialty referral. Since most radiculopathies resolve with such treatment, surgical intervention is seldom a valid consideration before 4 to 6 weeks of conservative therapy. Even if some pain or neurologic deficit persists at that point and the patient is showing any evidence of improvement, conservative therapy should be continued. In some cases, it may take 3 months for complete resolution of the radiculopathy.

NECK AND BACK PAIN

In classic cases of myelopathy, neurogenic claudication, or radiculopathy, nonradicular pain is not a prominent component. When neck or back pain predominates, the causes are usually not stenosis or nerve root compression. Such pain, constituting the bulk of patient spinal complaints, is not well understood. Most cases appear to be a combination of chronic stress on spinal structures, such as facet joints, and acute stress to the paravertebral muscles. Although the intervertebral disc is not highly pain-sensitive, the facet joints are. Considering the typical forces born by these true diarthrodial joints, chronic injury and pain are probably fairly common. Furthermore, maintaining competent body support about a flexible stack of vertebrae requires significant continual muscle tension; fairly trivial movements, particularly when lifting or bending, can require a level of tension that exceeds the strength of some muscle bands. Acute strain can occur without an identifiable event. Once paraspinal muscles are injured and in spasm, the baseline stress level can delay resolution.

If a patient is experiencing predominantly neck or back pain, even if studies demonstrate some spinal stenosis or disc pathology, surgery is generally not beneficial. The initial approach is standard physical therapy, using modalities to reduce the acute discomfort and exercises to restore normal function and strengthen the muscles to minimize future episodes. If the patient fails to respond to a basic course of therapy, referral to a physiatrist should be considered.

RELEVANT ANATOMY AND PATHOPHYSIOLOGY

ANATOMY

The anatomy of the peripheral nervous system (PNS) is complicated by its diverse array of cell types and broad expanse ([Fig. 446.1](#)). The concept of the PNS is itself arbitrary because many of its cells lie in part in the central nervous system (CNS). Cross sections of nerve biopsy specimens reveal only a limited snapshot of the PNS, showing myelinated and unmyelinated fibers of various sizes, but not their orientation or function.

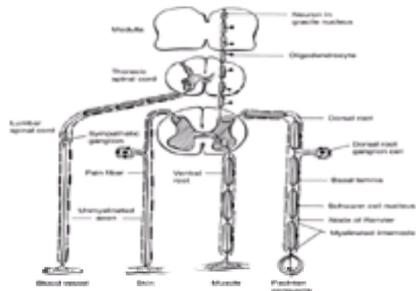

FIGURE 446.1. The principal components of the peripheral nervous system. (Redrawn from Schaumburg HH, Berger AR, Thomas PK. *Disorders of peripheral nerves*, second ed. Philadelphia: FA Davis Company, 1992.)

The alpha and gamma motor neurons lie in the anterior horns of the spinal cord but may extend for up to 1 m in length in the PNS. The cell bodies of the primary sensory neurons are in the dorsal root ganglia (DRG), and their central processes extend into the spinal cord segmentally. They project either up the dorsal columns to the gracile and cuneate nuclei or synapse with second-order neurons in the dorsal horn, which form the spinothalamic tracts. The proximal portions of the PNS are the dorsal and ventral spinal nerve roots, which lie in the subarachnoid space and are bathed in cerebrospinal fluid. Only the postganglionic autonomic neurons lie entirely within the PNS. The long length of PNS axons, their dependence on axonal transport for renewal of structural membrane and cytoskeletal components, and other factors make them especially vulnerable. Retrograde transport is essential for trophic function and recycling.

Schwann cells envelop myelinated and unmyelinated axons in the PNS. The signal for myelination comes from the axon, and myelination occurs in axons larger than 1 to 2 μm in diameter. Each segment of a myelinated axon is the territory of a single Schwann cell, the length of the segments correlating with the diameter of the axon. For unmyelinated fibers, single Schwann cells usually surround multiple axons. The myelin sheath is composed of compacted layers of the Schwann cell membrane. It is predominantly lipid but contains several proteins that have key roles in maintaining the structure and compaction of the myelin and adhesion of the sheath to the axon. Several of these proteins and lipids may be important immunogens in disease.

Peripheral nerves are divided into fascicles surrounded by the perineurium, a connective tissue sheath, and are bound together by the epineurium. The endoneurium surrounding the individual nerve fibers contains collagen, fibroblasts, mast cells, and resident macrophages. The endoneurial arterioles are supplied by a plexus of epineurial blood vessels with multiple systemic feeders. Circulating macromolecules are excluded from the endoneurium by the blood–nerve barrier, which is analogous to the blood–brain barrier and is formed by the endothelial cells and their tight junctions. The blood–nerve barrier is relatively deficient in the DRG and in the preterminal regions of nerves.

PATHOLOGIC FACTORS

The major pathologic reactions of nerve fibers are axonal degeneration and demyelination. Axonal degeneration can be distal, sometimes referred to as dying back or distal axonopathy. This is characteristic of metabolic and toxic neuropathies. Transection of an axon results in complete degeneration of its distal extent, a process known as wallerian degeneration. This occurs in nerve injuries and entrapments. Repair after either of these axonal lesions is by axonal regeneration, a vigorous response that proceeds distally at 1 to 3 μm per day. With distal lesions, regeneration can produce an excellent result, but the likelihood of success is inversely related to the distance to be covered and, in the case of traumatic transection, the timeliness and accuracy of repair. Recovery may be limited in distal axonopathies by the degeneration of the central processes of the DRG cells, which do not effectively regenerate.

Damage to Schwann cells or myelin can result in segmental demyelination or paranodal demyelination. Segmental demyelination results in stripping of the myelin sheath from a complete segment, up to 1 mm in length, whereas paranodal demyelination usually covers less than 50 μm . Macrophages remove myelin debris, and Schwann cells divide after segmental demyelination. Remyelination can begin quickly, within a few days, producing shorter segments of myelin, usually about 300 μm .

PHYSIOLOGY

Conduction in myelinated fibers is saltatory, with the action potential regenerated at successive nodes of Ranvier, the site of sodium channels. During the action potential, sodium flows down its electrical and concentration gradients into the axon through the nodal sodium channels. The action current flows along the core of the axon, confined because of the insulating qualities of the myelin, and depolarizes the next node. The major effect of demyelination is to cause current leakage from the axon, so that not enough current reaches the next node to cause depolarization. This results in conduction block. This failure of transmission produces weakness and sensory loss. However, even minor degrees of remyelination can quickly result in restoration of conduction and recovery of function. The combination of demyelination and remyelination often causes several other characteristic physiologic abnormalities, such as slowed conduction velocity, temporal dispersion of nerve impulses, and reduced ability to conduct impulses at high frequency; however, these defects have only minor clinical effects.

CLINICAL FEATURES OF NEUROPATHY

A thorough history is essential in neuropathy diagnosis. The onset and progression of symptoms vary tremendously, from acute over hours to days, to chronic over many years. The progression may be gradual or stepwise, the latter in multiple mononeuropathy. A history of infections, travel, diet, toxic exposure, alcohol, and medications must be sought. Occupational factors may be important in causation as well as therapy. The family history is often critical. A detailed family tree should be drawn and information sought from key relatives. In cases of doubt, examination and electrophysiologic or genetic testing of family members may be necessary.

Negative symptoms predominate in polyneuropathy (usually weakness and numbness). Positive motor symptoms (cramps and fasciculations) are uncommon, whereas positive sensory symptoms (tingling and pain) occur more frequently. Imbalance, especially at night or in the shower, is a common complaint with loss of proprioception. Signs found on examination correspond closely to the symptoms and are predominantly distal and symmetrical. Weakness is common and wasting, if

present, signifies axonal loss. Loss of superficial pain sensation is found with loss of small myelinated and unmyelinated axons, but loss of vibration sense is more common with large-fiber neuropathies. Sensory loss is usually in a glove-and-stocking distribution. Loss of tendon reflexes is common with all polyneuropathies. Both vibration sensation and tendon reflexes are lost early in demyelinating neuropathies, probably because of desynchronization of afferent nerve impulses produced by the variable slowing of conduction velocities. Automated quantitative sensory testing may improve the reliability of the sensory examination in neuropathy. Autonomic neuropathy can cause postural hypotension, urinary retention and incontinence, constipation, nocturnal diarrhea, impotence, and sweating abnormalities. Nerve hypertrophy occurs occasionally. Ulnar and peroneal nerves can be palpated, and several nerves, including the dorsal cutaneous nerve of the foot, the great auricular nerve, and the distal branch of the superficial radial nerve at the wrist, can be both seen and felt. These nerves must be examined often to establish a sense of normal.

Multiple mononeuropathy differs from polyneuropathy in its distribution. It often affects the territory of individual nerves and is usually asymmetrical. Symptoms are more abrupt in onset. The symptoms may be sensory alone or combined motor and sensory. Pain is often a feature.

LABORATORY INVESTIGATION OF PERIPHERAL NEUROPATHY

Nerve conduction studies and electromyography provide a physiologic nerve "biopsy." The goal is to determine if the predominant pathologic process is demyelination or axonal loss. The pattern of disease can often be discerned, which may be helpful in multiple mononeuropathy.

The major physiologic features are shown in [Table 446.1](#). Demyelination is characterized by slowed conduction velocity, temporal dispersion of the compound muscle action potential, and conduction block. Hereditary demyelinating neuropathies do not usually show the latter two features. Prolonged distal motor and sensory latencies and prolonged F-wave latencies are reflections of slowed conduction velocities in distal and proximal portions of the nerves, respectively. Axonal disease and loss are characterized by modest slowing of velocities, more marked reductions in the amplitudes of the compound muscle action potentials and the sensory nerve action potentials, and evidence of denervation on needle electromyography. The latter includes the presence of fibrillation potentials and positive waves indicative of recent denervation, and enlarged hypercomplex motor unit potentials indicative of chronic denervation with subsequent reinnervation.

Feature	Axonal	Demyelinating
Distal latency	*	---
Conduction velocity	#	###
F-wave latency	\$	---
Conduction block	No	Yes
Temporal dispersion	No	Yes
CMAP amplitude	##	#
SNAP amplitude	#	##
Denervation on EMG	+++	+/-

CMAP, compound muscle action potential; EMG, electromyography; SNAP, sensory nerve action potential.

TABLE 446.1. ELECTROPHYSIOLOGIC FEATURES OF AXONAL AND DEMYELINATING POLYNEUROPATHIES

Nerve biopsy is reserved for difficult diagnostic and management situations in which the information may yield a specific diagnosis or increase diagnostic security before the use of potentially toxic or expensive treatment. Many diseases formerly diagnosed in part by biopsy can now be diagnosed better by genetic analysis, rendering biopsy unnecessary. Suspicion of vasculitis is the most important current reason for nerve biopsy. A sample of an adjacent muscle may increase the diagnostic yield. Biopsy is also valuable in the search for neuropathy due to amyloid, sarcoid, or leprosy. Occasionally, when steroid or immunosuppressive therapy is being considered for an acquired demyelinating neuropathy, a biopsy may be helpful to ease diagnostic uncertainty. There are, of course, exceptions to these guidelines and a variety of research indications for biopsy.

The sural nerve is the usual site of biopsy, and fascicular biopsy is adequate except when vasculitis is a consideration, in which case it is essential to take a segment of the whole nerve so that the epineurial vessels can be examined. When a motor nerve is required, the deep peroneal nerve can be sampled just above the ankle along with the sensory superficial peroneal nerve and the peroneus brevis muscle. In the search for vasculitis, it may be useful to examine all of these nerves electrophysiologically and then select an abnormal one for biopsy.

Toluidine blue-stained plastic cross sections of nerve are the most informative, yielding the best morphologic details. Paraffin-embedded sections stained with hematoxylin-eosin are useful in the search for vasculitis, and Congo red stains are positive for amyloid. Teased-fiber analysis may be useful to distinguish demyelinating neuropathies in questionable cases. Electron microscopy is sometimes helpful.

Patients must be told that the biopsy will result in an area of permanent numbness and that there may be tingling and, occasionally, pain. Meticulous surgical technique is required to yield a biopsy specimen free from artifacts and to ensure good wound healing.

Quantitative autonomic testing may be useful in neuropathies with autonomic features; however, it is not widely available.

CLASSIFICATION OF PERIPHERAL NEUROPATHIES

Anatomical and pathologic classifications of peripheral neuropathies facilitate clinical diagnosis. The two common patterns are a symmetrical, usually distal distribution, and an asymmetrical or multifocal distribution. The former is often usefully termed polyneuropathy and can be divided pathologically (physiologically) into distal axonopathies (axonal neuropathies) and myelinopathies (demyelinating neuropathies). Sensory neuronopathies (diseases of the DRG) may have a similar distribution. Asymmetrical neuropathies may be focal (mononeuropathy) or multifocal (mononeuropathy multiplex). In general, the causes of each of these categories of neuropathy differ, although diabetes is a notable exception. These neuropathies may be further subdivided into acute, subacute, and chronic conditions. A differential diagnosis of common neuropathies based on the temporal course of the illness is given in [Table 446.2](#). Causes of multiple mononeuropathy are listed in [Table 446.3](#). [Figure 446.2](#) outlines a schematic approach to diagnosis of specific neuropathies. Despite extensive investigations, cause may be elusive in up to one-third of the patients.

Acute (days-weeks)
 Acute inflammatory polyneuropathies (Guillain-Barré syndrome and variants)
 Diphtheritic neuropathy
 Porphyric neuropathy
 Diabetic amyotrophy
 Some toxic neuropathies
 Subacute (weeks-months)
 Vasculitic neuropathy
 Nutritional and alcoholic neuropathy
 Most toxic and infectious neuropathies (e.g., HIV)
 Chronic (months-years)
 Diabetic polyneuropathy
 Chronic inflammatory polyneuropathy
 Paraneoplastic and paraproteinemic neuropathies
 Most metabolic neuropathies (e.g., hypothyroidism)
 Idiopathic small-fiber sensory neuropathy
 Very chronic (many years, often childhood onset)
 Inherited neuropathies (e.g., Charcot-Marie-Tooth disease)

(Adapted from Griffin PW, Cornblath DR. Peripheral neuropathies. In: Harvey M, et al., eds. Principles and practice of medicine, 22nd ed. Norwalk, CT: Appleton and Lange, 1988.)

TABLE 446.2. CLASSIFICATION OF NEUROPATHIES BASED ON TEMPORAL COURSE

Vasculitis
 Diabetes
 Sarcoidosis
 Hereditary neuropathy with liability to pressure palsies (tomaculous neuropathy)
 Multifocal motor neuropathy with conduction block
 HIV infection
 Lyme disease
 Leprosy
 Malignant infiltration of nerves
 Lymphomatoid granulomatosis
 Neurofibromatosis

TABLE 446.3. CAUSES OF MULTIPLE MONONEUROPATHY

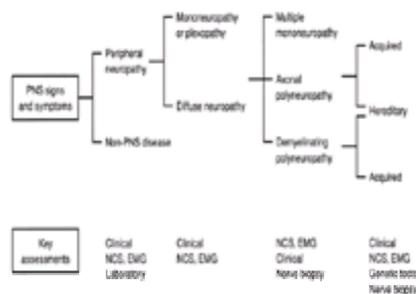

FIGURE 446.2. Stages in the diagnosis of peripheral neuropathy. “Clinical” includes history and physical examination. NCS, nerve conduction studies; EMG, electromyography. (Adapted from Schaumburg HH, Berger AR, Thomas PK. *Disorders of the peripheral nerves*, second ed. Philadelphia: FA Davis Company, 1992.)

SPECIFIC NEUROPATHIES

GUILLAIN-BARRÉ SYNDROME

This dramatic illness is sometimes called Landry's paralysis or acute inflammatory polyneuropathy. It has long been thought to be a classic inflammatory–demyelinating polyneuropathy, but the concept has broadened considerably more recently. The annual incidence is 1 to 2 per 100,000.

The principal symptoms and signs of Guillain–Barré syndrome (GBS) are weakness and sensory loss. The illness typically begins with tingling and numbness in the feet, followed by a gradually progressive, often ascending weakness. Sensory signs are usually minor blunting of distal pain and more marked loss of vibration sensation, but all modalities can be involved. Facial weakness occurs in up to 50% of cases, and bulbar weakness and oculomotor signs in less than 10%. Pain occurs in 70%, usually in the back and upper legs. Respiratory failure requiring mechanical ventilation develops in about 25% of patients. The disease progresses for an average of about 2 weeks, and the arbitrary upper limit for research studies has been set at 4 weeks. The progressive stage is usually followed by a brief plateau; then recovery begins, which may take many months and occasionally 1 to 2 years.

The differential diagnosis includes spinal cord disease and acute motor disorders, such as botulism and myasthenia gravis. Spinal cord disease can usually be excluded on clinical examination by the absence of spasticity, hyperreflexia, and Babinski responses, and often by the presence of facial weakness. Nerve conduction studies may be helpful, but in difficult cases spinal cord imaging may be necessary. Acute motor disorders are usually excluded by the presence of sensory signs. Physiologic studies may again be helpful. Unusual disorders, such as poliomyelitis and porphyria, should be kept in mind.

Cerebrospinal fluid examination and nerve conduction studies often yield characteristic findings. The cerebrospinal fluid protein level is usually elevated without a cellular response after the first few days. The major early electrophysiologic finding is conduction block in motor nerves. This may be very distal or proximal, and multiple stimulation sites must be used to detect it. Distal latencies and F-wave latencies may be prolonged early. Conduction velocity reduction is usually most pronounced after a few weeks, likely reflecting early remyelination.

Pathologic examination of nerves from GBS cases usually reveals perivascular lymphocytic infiltration of the endoneurium, although some biopsy studies have failed to find this. The cardinal pathologic finding is segmental demyelination, best seen on teased-fiber studies. Axonal degeneration is also seen, especially in severe cases, and is thought to be a “bystander” effect of inflammation and demyelination. This secondary axonal degeneration, if marked, is likely to cause a poor outcome.

The pathogenesis of GBS is still unclear. GBS is preceded by an infection in up to 70% of cases, including various viruses, *Mycoplasma pneumoniae*, and *Campylobacter jejuni*. The antigenic heterogeneity of these agents suggests that they may act as nonspecific immunologic triggers. *C. jejuni*, a common intestinal pathogen, may be an exception. It shares epitopes with G_{M1} ganglioside, a component of axonal membranes and myelin. Some series have found up to 40% of GBS patients to have anti-G_{M1} antibodies, but their role in demyelination is not certain. The effectiveness of plasma exchange suggests that antinerve antibodies may be significant. There is also evidence of T-cell activation in GBS, although the administration of anti-T-cell antibodies does not seem to stop progression of the disease.

Complete recovery from GBS occurs in about 70%, good functional recovery with minor residua in 10%, moderate disability in 10%, severe disability in 5%, and death in up to 5%. Death is usually caused by pulmonary embolism, sepsis, or cardiac arrhythmias. There are several useful prognostic factors. Older age, rapid onset, and the need for artificial ventilation all indicate a relatively poor prognosis. A more specific indicator of poor outcome is severe reduction of the compound muscle action potential (less than 20% of the lower limit of normal). This usually indicates severe axonal loss, which might be expected to correlate with poor recovery.

Treatment has an important impact on the outcome from GBS. Excellent nursing care and physiotherapy are essential. Subcutaneous heparin is given to prevent deep venous thrombosis. Careful monitoring of the vital capacity during the progressive phase is necessary to detect the onset of respiratory failure. It is important to provide adequate information to patients and families at the time of diagnosis to prepare them for progression of the disease and its implications.

Two specific treatments speed recovery from GBS. Plasma exchange has been shown in several studies to improve outcome at 6 months. It is started as early as possible in patients who cannot walk without assistance. The optimum schedule is not known, but the usual approach is to give four to five exchanges (200 to 250 mL per kilogram) over 7 to 10 days. Intravenous immunoglobulin (IVIg) in a dose of 0.4 g per kilogram per day for 5 days has been shown to have an equivalent beneficial effect in GBS. Combination of plasma exchange and IVIg does not provide further benefit from either one given alone. High-dose methylprednisolone has been shown to be ineffective.

VARIANTS OF GUILLAIN-BARRÉ SYNDROME

An acute axonal form of GBS (acute motor and sensory axonal neuropathy) has been described. It presents more acutely than typical GBS and is clinically more severe. Milder cases may occur, but the clinical spectrum has not been defined. These patients often reach their nadir in less than 5 days and are frequently quadriplegic. Pathologic examination of nerves early in the course has shown severe axonal degeneration without demyelination or inflammation. The motor nerves are often electrically inexcitable. The prognosis is poor; less than half of reported patients have recovered well. Specific treatment has not yet been developed.

Acute motor axonal neuropathy has been described mainly in northern China, where it has a high incidence in spring and summer, especially in children. Marked

paralysis and respiratory failure are common, but good recovery often occurs. Physiologic studies show marked motor involvement of the axonal type with sensory sparing. Pathologic studies show axonal degeneration with macrophages clustered at the nodes of Ranvier, perhaps causing axonal damage. Many of these patients have preceding infections with *C. jejuni*. Antibodies against G_{M1} ganglioside have been found in some of these cases. Because G_{M1} and *C. jejuni* have common epitopes, *C. jejuni* may trigger an antibody response that targets G_{M1}, which is localized to the nodes. Macrophages then are attracted to the nodes and produce axonal damage.

The Miller Fisher syndrome is a GBS variant with ophthalmoplegia, ataxia, areflexia, and, often, facial weakness but at most minor limb weakness. The onset is subacute and recovery is usually good. Antibodies to the ganglioside G_{Q1B} are found in most cases. These antibodies are capable of blocking neuromuscular transmission in the mouse nerve–diaphragm preparation, and may be active at ocular motor nerve terminals in humans. Mechanisms of ataxia and areflexia are not clear. No good data exist on the usefulness of specific treatments, but the relatively benign prognosis must be kept in mind.

CHRONIC INFLAMMATORY DEMYELINATING POLYNEUROPATHY

Chronic inflammatory demyelinating polyneuropathy is pathologically similar to GBS but is slower in onset, with the lower limit for progression arbitrarily being 12 weeks; however, some patients progress more quickly. Sensory signs are usually more prominent than in GBS and tremor sometimes occurs. There is seldom a history of preceding infection. Electrophysiologic studies are critical in making the diagnosis and typically show slowed conduction velocities, temporal dispersion of the compound muscle action potentials (CMAPs) and sensory nerve action potentials (SNAPs), and conduction block. The pathogenesis is unclear, but evidence favors an immune mechanism, perhaps antibody-mediated. Antibodies to several neural antigens have been reported in chronic inflammatory demyelinating polyneuropathy (CIDP), most recently to tubulin, but the significance is unclear. Nerve biopsy, which is not usually necessary, shows thinly myelinated and occasionally demyelinated fibers. Cross sections may show "onion bulbs" (myelinated fibers surrounded by concentric layers of Schwann cell cytoplasm and basement membranes), indicative of past cycles of demyelination and remyelination.

Several treatments are available. Prednisone produces improvement in most CIDP patients. It is usually started at 60 to 80 mg per day and then tapered slowly with alternate-day dosing after a significant response occurs. Unfortunately, significant side effects occur with prednisone, a complete response does not always occur, and relapse is common as the dose is reduced. Plasma exchange also is effective in many patients. The optimal treatment schedule has not been determined. It is often given intensively, two or three times weekly at the start, and then progressively less frequently. Its main disadvantages are its cost, the need for good venous access, and the risk of relapse as it is withdrawn. Some patients become dependent on plasma exchange, requiring it weekly. IVIG is the newest treatment and works in about 70% of CIDP patients, especially those whose disease is of fairly recent onset and with typical signs of demyelination. The dosage and maintenance schedules must be individualized. Most patients require some type of long-term treatment.

PARAPROTEINEMIC NEUROPATHIES

Monoclonal gammopathy is found in up to 5% of patients with polyneuropathy, particularly in those older than 60 years, in whom it occurs in 3% of normals. The finding of an M protein should always initiate a search for a plasma cell dyscrasia, such as multiple myeloma. Multiple myeloma and Waldenström's macroglobulinemia are frequently associated with an axonal polyneuropathy. Cryoglobulinemia, which may be associated with either of these or occur independently, may be associated with multiple mononeuropathy, usually distal. The mechanism is thought to be deposits of cryoglobulin in the vasa nervorum causing nerve infarction.

There is a specific neuropathy associated with monoclonal gammopathy, usually IgA or IgG and osteosclerotic plasmacytoma. This is often called the POEMS syndrome, the acronym standing for polyneuropathy, organomegaly, endocrinopathy, M protein, and skin changes. The neuropathy is usually chronic, 1 to 2 years in duration, with motor and sensory involvement. Physiologic and pathologic studies confirm its demyelinating nature. There may be hepatomegaly, hyperpigmentation, gynecomastia, testicular atrophy, and, occasionally, pleural effusions and ascites. An osteosclerotic plasmacytoma is best diagnosed by a skeletal survey. It is usually proximal and may have associated lytic areas. It is presumed that the monoclonal protein is an antinerve antibody of some type, but this is unproven. Radiotherapy, the preferred treatment, is effective in most cases, although improvement may be slow. Excision of accessible lesions has proved effective. More extensive disease may respond to chemotherapy.

Another chronic demyelinating neuropathy is that associated with IgM monoclonal gammopathy, with the M protein directed against the myelin-associated glycoprotein of peripheral nerve myelin. This predominantly sensory neuropathy is often of many years' duration. Microscopy shows characteristic widened spacing of the myelin lamellae. Long-term plasma exchange may be helpful, but the results are not dramatic.

The most common paraproteinemia is monoclonal gammopathy of uncertain significance (MGUS), which occurs in up to 5% of patients with neuropathy, especially older patients. About half of patients with IgM gammopathy are in this category, as are most patients with IgG and IgA gammopathies. The pathologic process may be demyelinating or axonal. The demyelinating cases are likely variants of CIDP and differ little in clinical features, course, or response to treatment from those without MGUS. The axonal cases are usually chronic and vary in severity. In some cases, the M proteins seem to be antinerve antibodies, but this has been an inconsistent finding. Treatment of the axonal cases has been unrewarding.

MULTIFOCAL MOTOR NEUROPATHY

Multifocal motor neuropathy is a slowly progressive asymmetrical neuropathy usually presenting in the third and fourth decades. Although minor distal sensory signs may be present, the signature of this neuropathy is marked motor involvement of individual nerves that have normal sensory function both clinically and electrophysiologically. The weakness and wasting are usually much greater in the arms than the legs, especially in the forearms and hands. Although the patients usually remain ambulatory, the hand weakness can result in significant disability. Areflexia is common. Physiologic studies often show motor conduction block, but not at sites typical of nerve entrapment. The few pathologic studies available have shown signs of chronic demyelination.

Anti-G_{M1} antibodies are found in some multifocal motor neuropathy patients. In preliminary studies, these antibodies have produced conduction block in an experimental nerve–muscle preparation. The roles of these and other antibodies and of demyelination remain to be clarified.

Multifocal motor neuropathy usually does not respond to steroids or plasma exchange. Cyclophosphamide is sometimes effective but potentially toxic. IVIG produces a positive response in about 70% of patients. The result is often seemingly modest but may be functionally important if it leads to improved intrinsic hand muscle strength or better extension of wrist or fingers. Maintenance treatment at intervals of 2 weeks to 2 months is often necessary to sustain improvement.

DIABETIC NEUROPATHY

Diabetic neuropathy (DN) is the most common specific diagnosis made in neuromuscular clinics. Its prevalence is directly related to the duration of the diabetes, approaching 50% in those who have been diabetic for 25 years. Two general types of DN occur—symmetrical polyneuropathies and focal or mononeuropathies—each having several subcategories ([Table 446.4](#)).

Mononeuropathies

Cranial neuropathies

Limb and trunk mononeuropathies

Asymmetrical lower-limb motor neuropathy

Polyneuropathies

Distal sensorimotor (+ autonomic) polyneuropathy

Autonomic neuropathy

Acute painful polyneuropathy

TABLE 446.4. CLASSIFICATION OF DIABETIC NEUROPATHY

The pathogenesis is unknown. A metabolic cause is likely for the polyneuropathies, probably secondary to hyperglycemia. The concept of increased sorbitol, reduced myoinositol, and lowered Na⁺,K⁺-ATPase activity in nerve has been popular but remains unproven. Attempts to treat DN by reducing sorbitol levels with aldose reductase inhibitors or by increasing myoinositol levels by dietary supplementation have been unconvincing. The alternative hypothesis is that endoneurial hypoxia is responsible for DN. The common occurrence of endoneurial vascular thickening supports this, but definitive proof in humans is lacking. The presence of vascular thickening and nerve infarcts in the few autopsy studies available of cranial and limb mononeuropathies, and the usually abrupt onset of these disorders, is strong evidence for a vascular cause in these cases.

SYMMETRICAL POLYNEUROPATHIES

Distal sensory and motor polyneuropathy is the most common form of DN. Its onset is usually insidious, sometimes preceding the diagnosis of diabetes in late-onset cases. All fiber sizes are affected, although large- and small-fiber categories have been noted. The former usually presents with distal tingling and numbness and the latter with foot pain, often burning in quality. Rarely, a distal, very painful neuropathy presents acutely and without much sensory loss, and this may have a different mechanism. Mild autonomic features are common. The symptoms of distal sensory DN may remain mild or may produce moderate disability. Progression to severe disability is uncommon. Motor signs are mild.

Strict control of blood sugar is the standard treatment approach and probably slows progression. Pain control may be the major problem. Amitriptyline is the most effective drug, starting at a dose of 25 mg at bedtime and gradually increasing to as high as 150 mg if tolerated. Drowsiness and xerostomia often limit the dose. Gabapentin at a dosage of 900 to 2,400 mg daily in three divided doses may be used as a second-line agent. Carbamazepine and phenytoin are rarely effective. Capsaicin cream can provide short-term relief.

Autonomic neuropathy is part of the spectrum of distal sensory neuropathy, but at times it predominates. The most common symptom is erectile failure, although this may in part be caused by diabetic vascular disease. Incomplete bladder emptying is less common. Cardiovascular reflex abnormalities can be detected but are usually asymptomatic. Occasionally, postural hypotension is disabling. Nocturnal diarrhea and gastroparesis are well known but uncommon. The most common gastrointestinal problem is constipation. Loss of distal sweating is common.

MONONEUROPATHIES

Diabetic mononeuropathies may affect cranial nerves, limb nerves, truncal nerves, or the lumbosacral plexus. These tend to affect older diabetics and may be the first evidence of diabetes. The third nerve is most commonly affected. The onset is abrupt and associated with periocular pain. All divisions of the nerve may be affected, but the pupil is spared in most cases, which helps to differentiate this from intracranial causes. The sixth nerve is less often affected, and rarely the fourth or the seventh nerve is affected. Spontaneous recovery in 1 to 3 months is usual.

Mononeuropathies can affect most major limb nerves. The deficit usually appears suddenly and is often painful. The clinical features resemble those of other “vascular” neuropathies, such as those caused by vasculitis. Recovery is often satisfactory after distal lesions, but proximal lesions do less well. The affected sites in these painful mononeuropathies are usually not common entrapment sites. However, diabetic nerves are sensitive to compression, and entrapment neuropathies, such as carpal tunnel syndrome, occur frequently. They may respond to decompression, but not as well as those in nondiabetics.

Diabetic truncal neuropathy presents in older patients as radicular thoracic pain, often dysesthetic, in one or more thoracic dermatomes. The sensory loss may be strictly radicular or, more commonly, patchy. Hyperesthesia is common. The symptoms usually improve, but the time course is often more than a year. Pain management is the major problem. Amitriptyline and other tricyclics are the mainstays of treatment.

Diabetic lumbosacral plexus neuropathy has also been called diabetic amyotrophy, a useful descriptive term because muscle wasting and weakness are major symptoms and there is usually minimal sensory loss. Typically, the weakness affects the quadriceps, psoas, thigh adductors, and, occasionally, the glutei. Wasting ensues over a few weeks. The quadriceps reflex is usually absent. The onset is sudden but may evolve over a week or two. There is usually deep, aching proximal leg or hip pain that lasts a few weeks, and occasionally much longer. Moderate recovery often occurs but takes a year or more. There is some recent evidence that some of these conditions may be inflammatory in nature and may respond to immunosuppression.

HEREDITARY NEUROPATHIES

This large group of neuropathies is now much better understood as a result of molecular genetic advances. The major disorders are listed in [Table 446.5](#), along with their genetic loci and gene products. Specific diagnosis is now possible by genetic analysis in appropriate phenotypes, obviating the need for nerve biopsy in many cases. Neurologic assessment and counseling of at-risk family members is necessary.

Disease	Locus	Gene	Mechanism
HMSN I			
CMT1A	17q11.2-12	PMP22	Duplication or point mutation
CMT1B	1q22-23	P0	Point mutation
CMT1X	4q13.1	CK2	Point mutation
HMSN II			
CMT2A	1p35-p36	Unknown	Unknown
CMT2B	3q13-q12	Unknown	Unknown
CMT2C	Unknown	Unknown	Unknown
CMT2D	7p14	Unknown	Unknown
HMSN III			
DSDA	17q11.2-12	PMP22	Point mutation
DSDB	1q22-23	P0	Point mutation
HMP			
HMPA	17q11.2-12	PMP22	Deletion or point mutation
HMPB	Unknown	Unknown	Unknown

HMSN, hereditary motor and sensory neuropathy; CMT, Charcot-Marie-Tooth disease; DSD, Dejerine-Sottas disease; HMP, hereditary neuropathy with liability to pressure palsy.

TABLE 446.5. GENETIC CLASSIFICATION OF THE HEREDITARY SENSORI MOTOR NEUROPATHIES

HEREDITARY MOTOR AND SENSORY NEUROPATHIES (FORMERLY CHARCOT–MARIE–TOOTH DISEASE)

Hereditary motor and sensory neuropathy (HMSN) type I is a chronic demyelinating polyneuropathy that presents in the first and second decades with slowly progressive distal weakness, wasting, and sensory loss that is most pronounced in the legs. High arches (pes cavus), hammer toes, ankle instability, and eventually deformity are common. Nerve hypertrophy may be seen. Slowed nerve conduction velocities, usually to 20 to 30 m per second, without conduction block are typical. Biopsies show loss of myelinated fibers, signs of demyelination and remyelination, and onion bulbs. Ankle braces, special shoes, and corrective foot and ankle surgery are often helpful. Most patients remain ambulatory. Types Ia and Ib are similar phenotypically, although they have defects in different myelin proteins (in type Ia the PMP22 protein and in Ib the P0 protein).

Hereditary motor and sensory neuropathy type II is a chronic axonal motor–sensory polyneuropathy, similar phenotypically to HMSN type I. High arches, hammer toes, and a distal predominance of wasting, weakness, and sensory loss are typical. Electrophysiologic studies show signs of chronic distal muscle denervation and minor slowing of nerve conduction velocities. Biopsies show chronic axonal loss without signs of demyelination. The clinical course is quite similar for HMSN I and II. Both conditions are autosomal dominant and common.

Hereditary motor and sensory neuropathy type III (Dejerine–Sottas disease) is a rare and probably genetically heterogeneous group of neuropathies presenting in infancy. There is evidence suggestive of both autosomal dominant and recessive inheritance. Defects in the *PMP22* and *PC* genes have been found. The typical patient shows impaired motor development, weakness, sensory loss, and nerve hypertrophy as well as histologic evidence of chronic demyelination and remyelination. HMSN type IV (Refsum's disease), another hypertrophic neuropathy associated with onion-bulb formation, is caused by phytanic acid accumulation. Other HMSN variants have been associated with spastic paraplegia and optic neuropathy.

Charcot–Marie–Tooth X disease is an X-linked form of HMSN. It is expressed more fully in male subjects who clinically resemble patients with HMSN types I and II. About half of female carriers are mildly affected. There is mild slowing of nerve conduction velocities to 30 to 40 m per second. The pathologic changes suggest an axonal defect, but the abnormal protein, connexin-32, is a gap junction protein found in compacted myelin.

HEREDITARY NEUROPATHY WITH LIABILITY TO PRESSURE PALSIES

Hereditary neuropathy with liability to pressure palsies (HNPP) is a common, dominantly inherited neuropathy that is underdiagnosed. It causes mononeuropathies that usually follow minor compression of a nerve, such as from sleeping awkwardly on a limb. Typical nerves to be affected include the radial nerve in the spiral groove of the humerus, the ulnar nerve at the elbow, the median nerve at the wrist, and the peroneal nerve at the fibular head. Brachial plexus palsies sometimes occur, often after unrelated surgical procedures. The lack of pain in typical cases of this neuropathy helps to distinguish this from inherited brachial plexus neuropathy, which is usually painful. The major symptoms are weakness, tingling, and numbness. Recovery is the rule, but it may take several months and may be incomplete. Major disability is unusual.

Nerve conduction studies reveal focal conduction block at symptomatic sites and slowing across other common entrapment sites. Mild, generalized changes are seen, such as prolonged distal latencies, suggesting that there is also a mild polyneuropathy. Nerve biopsies show sausage-like thickenings of the myelin sheathes, known as tomacula, produced by redundant wrapping of the sheath around the fiber. The genetic defect is a deletion in the *PMP22* gene, the same gene that is duplicated in HMSN type Ia.

HEREDITARY SENSORY AND AUTONOMIC NEUROPATHIES

These rare conditions are classified into four categories. Hereditary sensory and autonomic neuropathy (HSAN) type I is a dominantly inherited sensory neuropathy with predominantly small-fiber loss, resulting in distal pain insensitivity, especially in the feet. It presents in the second decade and progresses slowly. Excellent foot care is the mainstay of treatment. HSAN type II is autosomally recessive, presents in infancy, and progresses slowly. HSAN type III is another autosomal recessive neuropathy presenting in infancy. It is a severe disorder with loss of pain and temperature sensation and autonomic instability. Nerve biopsy shows a near-absence of unmyelinated fibers and depletion of myelinated sensory fibers. HSAN type IV is another recessive condition presenting in infancy. There is loss of pain and temperature sensation, anhidrosis, and mental retardation.

AMYLOID NEUROPATHIES

Amyloid neuropathies may be acquired or dominantly inherited. The cardinal feature of these conditions is the endoneurial deposition of various amyloid proteins identified on nerve biopsy by positive staining (apple-green birefringence) with Congo red. The acquired forms occur with primary systemic amyloidosis and plasma cell dyscrasias. The protein deposited is immunoglobulin light chain. Identification of the specific proteins deposited in the familial amyloid neuropathies has facilitated classification. The first is transthyretin amyloidosis. Transthyretin, formerly called prealbumin, can be affected by several different amino acid substitutions, leading to phenotypic variations in this group. The second group is apolipoprotein A-I amyloidosis. The least common is gelsolin amyloidosis. The transthyretin and apolipoprotein A-I cases have painful distal sensory loss and autonomic dysfunction, and often carpal tunnel syndrome. Weakness can occur. The gelsolin cases have systemic amyloidosis with late-onset neuropathy.

TOXIC NEUROPATHY

Many therapeutic, environmental, and industrial agents can produce neuropathy. The major culprits are listed in [Table 446.6](#), and the most important are discussed in the following paragraphs. Most produce a distal axonopathy, often after prolonged exposure.

Pharmaceuticals	Industrial and Environmental Agents
Amiodarone	Acrylamide
Chloramphenicol	Allyl chloride
Chloroquine	Arsenic
Cisplatin	Buckthorn
Cocaine	Carbon disulfide
Dapsone	Diethylaminoisopropylamine
Doxifluridine	Ethylene oxide
Doxorubicin	Hexacarbons (e.g., n-hexane)
Ethambutol	Lead
Gold	Mercury
Hydralazine	Methyl bromide
Isoniazid	Organophosphates
Metronidazole	Polychlorinated biphenyls
Misonidazole	Thallium
Nitrofurantoin	Trichloroethylene
Nitrous oxide	Vaccor (pyriminone)
Nucleosides (ddC, ddI, ddT)	
Phenytoin	
Pyridoxine	
Suramin	
Taxol	
Thalidomide	
Vincristine	

TABLE 446.6. TOXIC NEUROPATHIES

PHARMACEUTICALS

Several antineoplastic agents commonly produce neuropathy. The best known of these, vincristine, causes neuropathy in most patients. Sensory symptoms occur first, followed by weakness, which is the most prominent feature on examination. Early cessation of treatment results in good recovery, but prolonged treatment leads to significant disability. Cisplatin produces a mainly sensory neuropathy at higher doses. Occasionally, the symptoms begin and progress after treatment is stopped. There is often gradual improvement. Taxol also causes a sensory neuropathy, often soon after the start of treatment when given in doses higher than 200 mg per square meter of body surface area. Suramin can cause a severe demyelinating neuropathy with bulbar and respiratory involvement in 10% of the patients.

Nitrofurantoin and isoniazid are the most frequent antibiotics to cause neuropathy. Nitrofurantoin neuropathy is more common after prolonged treatment and when there is coexistent renal failure. The symptoms may be rapid in onset, and weakness may be prominent. Recovery is good if the drug is stopped immediately. Isoniazid neuropathy happens most often in those who are slow acetylators and have high blood levels. Isoniazid interferes with the action of vitamin B₆. Peripheral neuropathy can be prevented in most cases with daily administration of 100 mg of pyridoxine.

Amiodarone, an antiarrhythmic drug, causes a mainly motor neuropathy after prolonged treatment at high doses. Recovery occurs with early drug stoppage. Gold, usually used to treat rheumatoid arthritis, rarely causes a subacute neuropathy. Numbness, often with hyperesthesia, is followed by weakness. Gradual recovery can occur. Pyridoxine (B₆), an essential vitamin, is safe in low doses but may cause a sensory neuropathy after prolonged use at high doses, often up to 1 g per day for a year. Gradual recovery occurs when the vitamin is stopped. Intravenous administration can result in the acute onset of an irreversible sensory neuropathy. Thalidomide causes dorsal root ganglion degeneration and selective involvement of large myelinated fibers. Distal painful paresthesias and numbness are common; patients develop palmar erythema and brittle fingernails.

TOXINS

Many environmental and industrial agents can produce neuropathy. Heavy metals have long been implicated but are now uncommon causes. Lead produces a mainly motor neuropathy after chronic low-level exposure, usually in smelters or battery manufacturing facilities. Oral ingestion of lead paint in children was once a common

cause. The onset is gradual, with the arms weaker than the legs. The pathologic process in humans is probably a distal axonopathy, although experimentally lead can cause demyelination. Arsenic also causes neuropathy after chronic low-level exposure or acute ingestion. The former is usually seen among miners and the latter as a result of attempted suicide or murder. Chronic exposure results in the gradual onset of a painful distal sensory neuropathy, whereas acute ingestion causes the subacute onset of a painful sensory–motor neuropathy. The pathologic process is distal axonal degeneration. Recovery after chelation may be satisfactory. Mercury is a rare cause of neuropathy; it more commonly causes CNS dysfunction.

Industrial agents have caused several neuropathy “epidemics”; organophosphates, the hexacarbons, and acrylamide are the best known. Many of these exposures occurred in factories, but accidental ingestion has occurred with some, such as triorthocresyl phosphate, an industrial lubricant that has been accidentally added to food or substituted for cooking oil. The hexacarbons are solvents and subject to intentional inhalation by “sniffers.” A chronic axonal neuropathy that is mainly motor develops. Acrylamide poisoning has usually come from inhalation or skin exposure in industry. A predominantly motor axonal neuropathy develops slowly and may resolve if caught early.

NEUROPATHY ASSOCIATED WITH METABOLIC DISORDERS AND NUTRITIONAL DEFICIENCY

Deficiency Disorders

Alcoholism is the major cause of neuropathy due to nutritional deficiency in the Western world. There remains some controversy over the role of alcohol as a neurotoxin, but most studies favor a primary role for multiple vitamin deficiency, thiamine in particular. Alcoholic polyneuropathy usually occurs in malnourished alcoholics, often after substantial weight loss. This is a distal axonopathy, as are other nutritional neuropathies. Sensory symptoms appear first, followed by distal weakness. About 25% of patients have distal pain and hypersensitivity (“burning feet” syndrome). There may be signs of alcoholic nutritional deficiency–related CNS disease such as cerebellar truncal ataxia or Wernicke’s disease. Treatment requires abstinence from alcohol, multiple vitamin supplements orally, intramuscular thiamine, and good caloric and protein nourishment. The neuropathy responds well to this regimen if treated early.

Dietary vitamin deficiency causing neuropathy occurs in the setting of severe nutritional deficiency. It is unusual for a single vitamin to be missing. The major vitamins involved are thiamine (B₁), riboflavin (B₂), niacin (B₃), and pyridoxine (B₆). The symptoms are similar to those of alcoholic neuropathy and reflect a distal axonopathy, often painful. Pure thiamine deficiency is classically associated with beriberi and niacin deficiency with pellagra, but these are seldom seen in pure form. Recovery depends on vitamin replacement at an early symptomatic stage. A similar neuropathy and sometimes signs of Wernicke’s encephalopathy can occur several months after gastroplasty for morbid obesity, especially if there is prolonged vomiting.

Vitamin B₁₂ deficiency has long been considered a cause of neuropathy. Myelopathy also occurs and is usually more prominent, often overshadowing the deficit caused by neuropathy. Distal sensory loss may result from myelopathy, but ankle areflexia likely reflects the neuropathy. There may be minor distal nerve conduction abnormalities. Malabsorption due to pernicious anemia or gastrectomy is the principal cause. Rarely, it can be seen in the setting of a purely vegetarian diet. Hematologic abnormalities are usually prominent. Treatment is parenteral vitamin B₁₂.

Vitamin E malabsorption also produces a neuropathy that may be obscured by CNS abnormalities. It occurs with chronic cholestasis and abetalipoproteinemia. It is a distal axonal neuropathy and responds to treatment only if caught early.

Metabolic Disorders

Uremia is the most common intrinsic metabolic cause of neuropathy, producing typical distal axonal changes and corresponding symptoms and signs. About 50% of chronic hemodialysis patients show signs, but it seldom produces major disability with modern treatment. The specific metabolite causing the neuropathic damage is unknown. The most effective treatment is renal transplantation.

Hypothyroidism is associated with a slowly progressive distal axonopathy. It presents with distal numbness and tingling and eventually includes weakness, which may become marked. This neuropathy responds well to early thyroid replacement therapy. Carpal tunnel syndrome is a common feature of hypothyroidism. The mechanism is different and is presumably related to myxedematous deposits in the carpal tunnel causing compression.

The porphyrias are well known but uncommon causes of neuropathy. They are caused by autosomal dominantly inherited defects in several different enzymes in the synthesis of heme, resulting in accumulation of intermediate products. Acute intermittent porphyria, the most common disorder, is characterized by acute attacks that usually begin after puberty. It remains latent in many carriers. Attacks are often provoked by drugs, including many sedatives, estrogens, various antibiotics, and ethanol. The first symptoms are usually crampy abdominal pain and mental disturbances, which may be severe, and, occasionally, seizures. The neuropathy then develops over days to weeks with weakness, either proximal or distal, limb pain, and paresthesias. The weakness may become severe and may include facial weakness and respiratory failure. Autonomic dysfunction is often present. A peak is usually reached in 6 to 10 weeks, followed by slow but often complete recovery. Death may occur in the acute phase. The neurologic features of variegate porphyria and hereditary coproporphyria are similar.

The differential diagnosis includes acute GBS and toxic neuropathies, such as those caused by organophosphates. A history of brown urine suggests porphyria. The key to diagnosis is the increased urine excretion of δ-aminolevulinic acid and porphobilinogen. The acute attacks often respond to high-dose intravenous glucose or intravenous hematin. Provocative drugs must be avoided. Identification of carriers and education about specific drug avoidance are essential.

Several defects in lipid metabolism cause neuropathy. Metachromatic leukodystrophy, usually caused by an autosomal recessively inherited deficiency of the enzyme arylsulfatase A, causes deposition of sulfatides in the central and peripheral nervous systems. It usually presents in late infancy with spastic weakness, dementia, and eventually blindness. Peripheral neuropathy is present and may produce hypotonia, weakness, and areflexia, but the CNS signs usually predominate. Both magnetic resonance imaging and autopsy demonstrate severe cerebral white matter damage. Nerve biopsies show segmental demyelination and metachromatic inclusions in Schwann cells. Nerve conduction velocities are severely slowed. Other lipid and lipoprotein disorders such as Krabbe’s globoid cell leukodystrophy, Tangier disease (high-density lipoprotein deficiency), and Bassen–Kornzweig disease (abetalipoproteinemia) also produce peripheral neuropathy.

CARCINOMATOUS NEUROPATHY

Sensory and motor neuropathy, sensory neuronopathy, and malignant infiltration of peripheral nerves all occur with carcinoma, lymphoma, and leukemia. The sensory and motor neuropathy is associated with many different tumors and seldom precedes tumor diagnosis. It is a distal axonopathy that progresses slowly. Its pathogenesis is unknown, but toxic, nutritional, and immunologic causes have been suggested.

The sensory neuronopathy syndrome is uncommon but is much more specific and better understood. Because it frequently presents months before the neoplasm is evident, a careful search for malignancy is necessary. It is most frequently associated with oat cell carcinoma of the lung and occasionally with other lung tumors and cancers of the breast, ovary, and gastrointestinal tract. The illness presents with distal tingling, numbness, and pain that spreads proximally and worsens over 2 to 3 months. Proprioceptive loss is marked, but all modalities are affected. The coordination and gait are impaired by sensory loss, and there may be pseudoathetosis. Weakness does not occur. The cerebrospinal fluid protein may be raised. Electrophysiologic studies show reduced or absent sensory nerve action potentials. Pathologic studies show degeneration of DRG cells with inflammation and secondary degeneration of sensory axons. In many cases associated with oat cell carcinoma, an IgG antibody specific for a tumor and neuronal antigen is found, which has been termed anti-Hu. Its role in the pathogenesis is not certain, but it might gain access to the DRG through its relatively deficient blood–nerve barrier to damage the DRG neurons.

Several other syndromes have been associated with malignancy. Both acute and chronic demyelinating neuropathies have been seen with cancers, most frequently Hodgkin’s disease. A curious transient motor neuropathy is sometimes seen with Hodgkin’s disease. Some loss of anterior horn motor neurons occurs, but the syndrome is self-limited. Neuropathies associated with myeloma were discussed earlier.

INFECTIOUS AND GRANULOMATOUS NEUROPATHIES

Infectious Neuropathy

Leprosy has been called the world’s most common neuropathy, but it occurs rarely in the West. It is caused by chronic infection with *Mycobacterium leprae*. Schwann

cells appear to be targets, especially those investing unmyelinated fibers. Small-fiber sensory loss is prominent, in cutaneous patches in both tuberculoid and lepromatous leprosy, and distally in the digits and other cool areas in the latter. Complete anesthesia of the extremities with ulceration and mutilation occurs in severe cases. Progression occurs over many years. Early treatment of the lepromatous variety with dapsone may result in stabilization.

Lyme disease, caused by the spirochete *Borrelia burgdorferi*, may cause a peripheral neuropathy. The organism is carried by ticks that infest mice and deer. The typical clinical course begins with the characteristic rash, erythema migrans, followed after a few weeks by systemic symptoms, including arthritis, carditis, meningitis, and sometimes radiculitis. In the chronic stage, there are persistent symptoms of skin, joint, and neurologic involvement. Cranial neuropathies are common, especially facial, usually during the meningitic phase. The peripheral nerves are affected in a variety of ways, reflecting what is thought to be a multifocal process. The lesions may involve the brachial or lumbosacral plexus or individual nerves or roots. A distal axonal sensory and motor neuropathy occurs in some cases. A form of GBS has been described. Cerebrospinal fluid pleocytosis distinguishes this from typical GBS. Antibiotic treatment is mandatory and is usually beneficial.

Neuropathy is common in HIV infection. Autopsy studies reveal nerve degeneration in almost all cases, and symptomatic neuropathy likely occurs in 30% to 50% of patients. Several distinct varieties of neuropathy occur and are related to the stage of the illness ([Table 446.7](#)). Both GBS and CIDP seem to occur with increased frequency in HIV infection. The clinical features are typical except that cerebrospinal fluid pleocytosis is common. Both neuropathies tend to occur early in the course of HIV infection, with GBS, in particular, often seen in relation to the initial HIV infection. Treatment is the same as for these neuropathies in non-HIV-infected patients.

Inflammatory demyelinating polyneuropathies
 Guillain-Barre syndrome
 Chronic inflammatory demyelinating polyneuropathy
 Multiple mononeuropathy (vasculitic)
 Distal sensory (+ autonomic) polyneuropathy
 Cytomegalovirus polyradiculoneuropathy
 Drug-induced polyneuropathy (ddl, ddC, d4T)

TABLE 446.7. HIV-RELATED NEUROPATHIES

Multiple mononeuropathies frequently occur later in the course of HIV infection. Major nerves may be affected, often with pain at onset. Nerve biopsies have often shown necrotizing vasculitis. The presumed mechanism is vascular deposition of immune complexes. Therapy is uncertain because there is often reluctance to use immunosuppression at that stage of the illness.

A distal, mainly sensory neuropathy is the most common neuropathy of AIDS, usually occurring late in the illness. It is a distal axonal neuropathy with nonspecific pathologic and physiologic features, and is of unknown cause. The legs are much more involved than the arms and pain may be a major feature, causing some disability. The neuropathy may be slowly progressive, and there is no specific treatment.

Cytomegalovirus infection is common in late-stage AIDS and may produce a recognizable and devastating neuropathy. Inflammatory lesions with axonal degeneration are found in the lumbar spinal roots. Cytomegalovirus may be cultured. The illness presents subacutely with a cauda equina syndrome with radiating lower back pain, asymmetrical weakness of the legs, sacral sensory loss, and, often, urinary incontinence. Occasionally, the arms are affected. The illness is progressive. Early recognition and treatment with ganciclovir may result in stabilization.

Iatrogenic dose-dependent neuropathy has been reported with anti-HIV treatment with the dideoxynucleotide analogs zalcitabine (ddC), didanosine (ddl), and stavudine (d4T). It appears to be a distal axonopathy.

Sarcoid Neuropathy

Sarcoidosis, a granulomatous disease of unknown etiology, causes peripheral neuropathy in 5% to 10% of cases. Granulomas are found within the endoneurium, presumably causing compression and possible ischemia of nerve fibers. Multiple mononeuropathy is the usual clinical presentation. Limb or trunk nerves can be affected, and patchy truncal sensory loss with pain is common. Cranial nerves may be involved, particularly the facial nerve, which is affected abruptly and often bilaterally. Rarely, a distal sensory and motor polyneuropathy occurs. Diagnosis is made by nerve muscle biopsies showing the typical granulomas and by the systemic involvement, usually pulmonary or cutaneous. Corticosteroids are often used, but there is no proof of effectiveness for the neuropathy. Individual nerve symptoms often improve spontaneously.

ISCHEMIC NEUROPATHY

Peripheral nerves are much more susceptible to occlusion of small vessels than large vessels. Atherosclerotic or embolic occlusion of major leg arteries often spares nerve function, but a mild sensory neuropathy is common in severe peripheral vascular disease, although it may be obscured by the ischemic features. Small-vessel disease caused by vasculitis commonly causes neuropathy, often with a distinctive pattern.

Multiple mononeuropathy is the classic clinical feature of vasculitic neuropathy. However, other conditions can produce this, as shown in [Table 446.3](#). Also, pathologic studies have shown that vasculitic neuropathy can present as a distal symmetrical sensory and motor polyneuropathy, perhaps in 25% of cases. Classically, individual nerves are affected acutely, with sudden loss of strength and sensation, often painful and dysesthetic. Gradual recovery may occur but can be very slow. At times, only cutaneous nerves are affected. Clinical and electrophysiologic examinations may reveal subclinical involvement of other nerves, which helps in diagnosis.

Several conditions ([Table 446.8](#)) can cause vasculitic neuropathy. Systemic vasculitis, notably polyarteritis nodosa, is an important cause, involving relatively larger vessels. Multiple organ involvement is usually easily found. Connective tissue diseases, rheumatoid arthritis, systemic lupus erythematosus, and Sjögren's syndrome can all cause vasculitic neuropathy. Another important cause is nonsystemic vasculitic neuropathy, with the vasculitis apparently confined to the PNS. Up to 30% of cases have this diagnosis, despite a search for systemic involvement.

Polyarteritis nodosa
 Allergic granulomatosis (Churg-Strauss syndrome)
 Rheumatoid arthritis
 Sjögren's syndrome
 Systemic lupus erythematosus
 Wegener's granulomatosis
 Hypersensitivity angiitis
 Systemic sclerosis
 Giant cell arteritis
 HIV infection
 Nonsystemic vasculitic neuropathy

TABLE 446.8. CAUSES OF VASCULITIC NEUROPATHY

Management involves first a specific diagnosis of nerve vasculitis. Whole-nerve biopsy is necessary to examine the epineurial vessels. Adjacent muscle should be sampled because it often yields a positive diagnosis whereas the segment of nerve sampled shows only nonspecific fiber loss. Fiber loss in sectors of nerve on cross section is suggestive of ischemic neuropathy. Evidence of systemic vasculitis must be sought to make a specific diagnosis. Treatment is difficult for two reasons. First, no trials have established proven therapies. Second, improvement from intervention is unlikely in the short term because recovery depends on axonal regeneration—a slow process. The best that can be expected is that no further lesions will develop. Prednisone and cyclophosphamide are the usual treatments and are required in polyarteritis nodosa and other systemic vasculitides. The prognosis in nonsystemic vasculitic neuropathy is better, and treatment must be judged accordingly.

IDIOPATHIC NEUROPATHIES

Idiopathic Distal Axonal Polyneuropathy

Chronic distal axonal polyneuropathy of uncertain cause is the diagnosis in 10% to 20% of patients who have undergone full evaluations in neuromuscular clinics. This group represents a diminishing proportion of patients as knowledge of disease and diagnostic methods improve. In general, these patients progress very slowly over many years and seldom have major disability. Reexamination on an annual basis is warranted.

Idiopathic Brachial Plexus Neuropathy

Idiopathic brachial plexus neuropathy, often called neuralgic amyotrophy, presents with shoulder pain and arm weakness, usually proximal. The upper brachial plexus is most involved, but occasionally individual nerves, such as the long thoracic nerve, may be affected. Wasting develops over several weeks. The pain subsides in 3 to 6 weeks but recovery of strength, which is usually incomplete, takes a year or more. Wasting persists. Electrophysiologic studies reveal axonal degeneration. The cause is unknown and there is no specific treatment. There is an autosomal dominantly inherited form of this disorder, known as hereditary neuralgic amyotrophy. It is characterized by recurrent episodes and may be bilateral.

CRITICAL-ILLNESS POLYNEUROPATHY

Critical-illness polyneuropathy develops in patients who are critically ill with multiple organ failure and sepsis, usually for more than 30 days. The first sign often is difficulty weaning from a respirator. Variable weakness and sensory loss are found. Physiologic and pathologic studies reveal axonal degeneration. No specific cause has been found, although nutritional factors, drugs, sepsis, and multiple organ failure may all play a role. Recovery is possible.

NERVE COMPRESSION AND ENTRAPMENT

Compression and entrapment of a nerve are not synonymous terms, but they may be difficult to differentiate. In general, entrapment is a slowly progressive chronic process, whereas compression is acute and may be repetitive. Both mechanisms can occur together. Compression and entrapment are the most common physical injuries affecting peripheral nerves. Other injuries, such as cold neuropathy, vibration neuropathy, radiation neuropathy, and electroshock neuropathy, are less common. The history can be helpful. For example, forestry workers who use chain saws are subject to so-called *vibration white finger* and commonly have a carpal tunnel syndrome, but they may be reluctant to disclose the source of the damage for economic reasons.

Entrapment produces a characteristic pathologic process. Internodal myelin is separated and prolapses into the adjacent internode. This is repeated over several segments. The same mechanism occurs in acute compressive neuropathy. Focal demyelination results in a variable degree of conduction block: if it is mild, electrophysiologic changes occur without clinical deficit; if it is severe, paresis or even paralysis results. Reversible myelin dysfunction also accounts for transient tingling, such as of the peroneal nerve when the legs are crossed. In these situations, myelin is not interrupted anatomically but it malfunctions because sodium channels fail to open. The extent of the conduction block is related directly to the force and duration of the compression. Herein lies the importance of prolonged tourniquet application, with its potential for paralysis. There also is a vascular element to most peripheral nerve injuries. However, the vascular component becomes important in several mononeuritis, especially diabetes, collagen vascular diseases, and carcinomas.

Those nerve fibers that have the largest diameters are involved earliest and most prominently with compression injuries. These include the alpha motor fibers, the type Ia muscle afferent fibers, and the type II cutaneous fibers.

The most common symptoms in carpal tunnel syndrome are nocturnal pain and dysesthesia in the absence of objective sensory or motor deficits. These findings are best explained by the involvement of small-diameter pain fibers and autonomic nerve fibers through a vascular mechanism. However, clumsiness may be an early and predominant complaint, and is in keeping with the compression of type Ia muscle afferent fibers.

Accurate localization usually is possible by clinical examination. Electromyography (EMG) can aid in localization; it often reveals the severity of the damage and suggests the prognosis. Computed tomography and magnetic resonance imaging are particularly useful for investigating entrapment of the spinal roots but also can be helpful for other nerves.

Systemic diseases that can underlie entrapment neuropathies are listed in [Table 447.1](#). Other symmetrical polyneuropathies can predispose to entrapment injury.

Myeloidosis
Blood dyscrasias
Cancer
Collagen vascular diseases
Diabetes
Guillain-Barré syndrome
Hunter's syndrome (mucopolysaccharidosis type II)
Hypothyroidism
Leprosy
Mumps
Pregnancy
Rheumatoid arthritis
Sarcoidosis
Tumaculous neuropathy

TABLE 447.1. SYSTEMIC CONDITIONS ASSOCIATED WITH ENTRAPMENT NEUROPATHY

The treatment of nerve entrapment usually is straightforward but can be difficult. Surgical decompression often is curative. Many cases remit spontaneously, especially if aggravating factors are removed. Autopsy studies in older patients have revealed asymptomatic ulnar and median nerve compression. A local hydrocortisone injection (25 mg) may be the only treatment necessary, as in carpal tunnel syndrome of pregnancy. Many cases of nerve entrapment associated with systemic diseases ([Table 447.1](#)) improve with treatment of the underlying disorder. A rare but distinctive cause of multiple compression neuropathies is hereditary neuropathy with liability to pressure palsies. This disorder is associated with excessively thick myelin sheaths and is a dominantly inherited disorder due to deletion of one copy of the gene for the myelin protein PMP22. These patients are prone to repeated compressive neuropathies and often have associated asymptomatic EMG abnormalities.

BENIGN BRACHIAL PLEXOPATHY

Benign brachial plexopathy usually presents as transient nocturnal numbness and paresis of the arm associated with a particular posture. It is seen more often in alcoholics and can occur as well in hereditary neuropathy with pressure palsies. Reversible brachial plexopathy can be confused with transient cerebral ischemic attacks.

THORACIC OUTLET SYNDROMES

The neurogenic thoracic outlet syndrome is rare. It predominantly affects young women and presents as painless thenar muscle wasting, which can be confused with carpal tunnel syndrome. The neck roentgenogram may reveal rudimentary cervical ribs, commonly on both sides. Compression usually results from a radiologically nonvisible fibrous band attached to a rudimentary rib. If ribs are seen, it is the smaller one that is important. EMG findings include a reduced compound muscle action potential from the thenar muscle as compared with a normal hypothenar muscle; a small or absent ulnar sensory nerve action potential; a small, prolonged, or absent ulnar F wave; and a small or undetectable ulnar sensory evoked potential compared with a normal median study. These findings suggest compression of the lower trunk of the brachial plexus, particularly the first thoracic nerve root. Decompression by removal of the offending fibrous band prevents further deterioration but seldom is curative.

The droopy-shoulder syndrome is a more common condition that also predominantly affects young women. It is characterized by pain or paresthesia in the shoulder, neck, arm, forearm, or hand that is exacerbated by palpation of the brachial plexus or downward traction on the arm. The patient usually has a long, graceful, swanlike neck and low-set shoulders with horizontal or downsloping clavicles. The second thoracic or lower vertebrae are visible above the shoulders on lateral cervical spine roentgenograms. Symptoms are relieved instantly by passive elevation of the shoulders. The physical examination and EMG are normal, and treatment involves

educational reposturing of the shoulders.

Physical injury to the brachial plexus also may be associated with cancer by tumor infiltration, compression, or radiation therapy. Radiation injury usually is painless, predominantly affects the upper trunk, and is associated with lymphedema. A painful lower trunk plexopathy associated with Horner's syndrome suggests direct compression from tumor infiltration.

Rucksack paralysis is an occupational hazard of hikers and military personnel. The lower trunk of the brachial plexus commonly is compressed, with weakness of the hand grip and numbness involving the ring and little fingers and extending to the medial aspect of the forearm. Any part of the brachial plexus may be involved. Most patients recover promptly after recognition, but axonal degeneration occasionally occurs.

MEDIAN NERVE LESIONS

CARPAL TUNNEL SYNDROME

Carpal tunnel syndrome is a common nerve entrapment syndrome that affects adults of all ages, women more than men. In women, it usually is idiopathic, but in men, house painting, carpentry, or the use of a power saw are associated activities. It is common in the later months of pregnancy and often remits after childbirth. It is important to recognize and treat diseases associated with carpal tunnel syndrome ([Table 447.1](#)).

Symptoms caused by the compression of large-diameter fibers produce median nerve motor weakness and sensory loss. Nocturnal pain and paresthesia probably result from small-fiber and autonomic nerve involvement on a vascular basis. The pain and discomfort can ascend as high as the shoulder. Tinel's sign and Phalen's maneuver are of limited diagnostic value.

The diagnosis can be confirmed by EMG in 85% of patients. Decompressive surgery should be considered on the basis of clinical rather than EMG criteria. Indications for surgery are persistent pain that does not resolve with nocturnal splinting and rapidly developing neurologic motor or sensory deficits. Chronic, painless carpal tunnel syndromes may not improve with surgery.

ANTERIOR INTEROSSEOUS NERVE ENTRAPMENT

The anterior interosseous nerve is a pure motor branch of the median nerve that supplies the flexor pollicis longus, the long flexors to the index and middle fingers, and the pronator quadratus. Entrapment occurs between the heads of the pronator teres under the tendinous arch of the flexor digitorum sublimis. The patient is unable to pinch the thumb and first finger together (the "OK" sign). Thenar muscles and sensation are normal.

EMG shows denervation in the flexor pollicis longus and pronator quadratus in the presence of normal terminal median nerve motor and sensory conduction and normal thenar muscle activity.

PRONATOR TERES SYNDROME

Occasionally, the median nerve is entrapped more proximally, producing weakness of all the muscles it innervates, except the pronator teres. Carpal tunnel symptoms are reported, along with weakness of the flexor pollicis longus and the finger flexors supplied by the median nerve. Pronation of the forearm is spared. If pronation is involved, a more proximal entrapment of the nerve has occurred. The most common cause is a ligament of Struthers (a fibrous extension of the supratrochlear spur at the distal humerus). EMG reveals abnormalities in the pronator teres muscle.

ULNAR NERVE ENTRAPMENT SYNDROMES

The ulnar nerve is entrapped commonly at the level of the elbow and rarely at the wrist (Guyon's canal).

CUBITAL TUNNEL SYNDROME

At the elbow, the ulnar nerve passes between the heads of the flexor carpi ulnaris under an aponeurosis (the cubital tunnel). The site of compression is not always discrete. EMG shows restricted slowing of conduction across the elbow. The pathologic signs of typical chronic nerve compression can be found in many asymptomatic patients. Repeated elbow flexion and minor trauma probably are responsible.

A sensory deficit is observed in an ulnar distribution, with little or no motor deficit. Pain in the elbow region may be a problem. Occasionally, there is wasting and weakness of the first dorsal interosseous muscle. Involvement of the hypothenar muscles usually is less pronounced. The more proximal flexor carpi ulnaris is involved only in about 25% of cases, even when motor symptoms are severe.

The results of surgical intervention are not clear. Improvement is considerably less than with surgery for carpal tunnel syndrome. Pain is relieved and further neurologic deficit is prevented. Surgical approaches are simple decompression, transposition of the nerve, and removal of the olecranon. Simple decompression is preferred.

Ulnar neuropathy can occur after surgery (particularly of the gallbladder or heart), coma, or severe burns. These situations produce an acute ulnar deficit with predominant sensory involvement. The mechanism appears to be acute infarction of the nerve at the elbow, and EMG suggests axonal degeneration. Surgery is contraindicated and may be harmful. Most patients recover spontaneously.

ULNAR NERVE ENTRAPMENT IN GUYON'S CANAL

The ulnar nerve enters the hand through an osseofibrous tunnel (Guyon's canal) formed by the pisiform and the hook of the hamate. In most cases, compression occurs at the distal end of the canal at the origin of the deep branch of the ulnar nerve, which is purely motor. Wasting and weakness of the interossei occur, but the hypothenar muscles, supplied by proximal branches, are spared. There are no sensory signs. Compression may occur slightly more proximally when the recurrent sensory branch is involved and may be difficult to distinguish from the cubital tunnel syndrome without EMG.

An easily reversible condition known as *bicycle rider's neuropathy* is caused by compression at the proximal end of Guyon's canal. In this condition, sensory and motor symptoms and signs develop.

RADIAL NERVE LESIONS

Lengthy pressure on the radial nerve in the spiral groove of the humerus in patients who are falling asleep or are drunk and have an arm hanging over the back of a chair produces so-called *Saturday night palsy*. The degree of deficit is related directly to the amount and duration of pressure.

Complete wristdrop develops. Examination reveals an inability to extend the fingers and wrist. The brachioradialis muscle is involved, but the triceps is spared. Sensory complaints are few and spontaneous recovery is the rule. If denervation is severe, recovery is protracted and a wrist support is required.

POSTERIOR INTEROSSEOUS SYNDROME

The posterior interosseous branch of the radial nerve is purely motor. Damage results in weakness of extension of the fingers and thumb. Wrist extensors are spared, apart from the extensor carpi ulnaris. Entrapment occurs where the branch passes through the supinator muscle or as a result of pressure from a lipoma or other benign tumor.

Characteristic initial drooping of the ring finger occurs, with subsequent weakness of other fingers. There is no sensory loss. EMG localization shows normal motor

unit activity in the extensor digitorum communis, extensor carpi radialis longus, extensor carpi radialis brevis, and brachioradialis, but abnormalities in the extensor carpi ulnaris, extensor digiti proprius, abductor pollicis longus, extensor pollicis brevis, and extensor pollicis longus. Surgical exploration usually is required.

TENNIS ELBOW

The condition known as *tennis elbow* is caused by entrapment of both the deep (posterior interosseous) and the recurrent epicondylar branches of the radial nerve. Pain usually is severe enough to force cessation of the offending activity, which prevents a motor deficit from occurring. Tennis elbow is common with the use of hammers or other tools, or with any activity that requires repeated forceful supination against resistance.

Symptoms usually resolve spontaneously, but a local intra-articular injection of hydrocortisone (25 mg) can help.

HANDCUFF PALSY

So-called *handcuff palsy* results from compression of the superficial radial nerve at the wrist. Handcuffs and tight watch bands or bracelets often are responsible. Numbness is experienced over the dorsum of the thumb and first finger and the web of skin between the two. If the neuropathy is severe, the radial nerve sensory action potential is lost.

PERONEAL NERVE PALSY

Common peroneal nerve palsy arises from compression at the fibular neck. It produces weakness of dorsiflexion and eversion along with sensory loss over the dorsum of the foot and the lateral aspect of the leg. It can be difficult to distinguish from a fifth lumbar root lesion. The resulting footdrop usually is acute and complete, and the ankle jerk is maintained. Pain or tenderness occurs at the fibular neck. In contrast, radiculopathy of the fifth lumbar nerve root commonly results in a partial, slowly developing footdrop along with a depressed or lost ankle jerk. Back pain and sciatica may be predominant. In addition, about 20% of patients with amyotrophic lateral sclerosis (motor neuron disease) have a footdrop.

Distal compression of the deep branch of the peroneal nerve produces weakness of dorsiflexion but normal eversion. Sensory loss is minimal. Compression of the superficial branch of the peroneal nerve results in weakness of eversion from paralysis of the peroneus longus and peroneus brevis, and from a sensory deficit over the dorsum of the foot extending proximally over the lateral aspect of the leg.

The only muscle supplied by the common peroneal nerve above the knee is the short head of the biceps femoris. If the results of needle EMG are normal, the lesion is at or below the fibular neck. This finding rules out a fifth lumbar–first sacral root lesion. In contrast, denervation of the tibialis posterior, which is innervated by a fifth lumbar nonperoneal nerve, points to a fifth lumbar radiculopathy.

Spontaneous recovery can take several weeks, and a foot splint may be required. In such a compressive lesion, there is no justification for surgical decompression. Repeated crossing of the legs should be discouraged.

LATERAL FEMORAL CUTANEOUS NERVE SYNDROME (MERALGIA PARESTHETICA)

The lateral femoral cutaneous nerve is derived predominantly from the second and third lumbar roots. It emerges from the lateral border of the psoas major muscle, runs laterally to cross the iliacus muscle, and passes through the inguinal ligament beneath the deep fascia of the upper thigh, supplying the skin over the lateral thigh. It may be entrapped as it passes under the inguinal ligament, producing chronic pain and paresthesia over the lateral thigh. This syndrome commonly is of sudden onset and probably results from vascular occlusion. It occurs in patients with diabetes accompanied by lumbar radiculoplexopathy, producing weakness of the quadriceps and loss of the knee jerk. It usually remits spontaneously and can be helped with carbamazepine (Tegretol, 200 to 300 mg per day). Rare chronic entrapment requires surgical decompression.

TARSAL TUNNEL SYNDROME

The posterior tibial nerve rarely is entrapped by the flexor retinaculum between the tibial malleolus and the posterior part of the calcaneus. Proximal entrapment involves the medial and lateral plantar nerves, causing painful paresthesia and sensory loss on the sole of the foot and weakness of the intrinsic foot muscles. Distal entrapment produces a medial or lateral plantar syndrome with a restricted sensory deficit. EMG shows a prolonged terminal latency to the abductor hallucis (medial plantar nerve) or the abductor digiti minimi pedis (lateral plantar nerve). Surgical decompression relieves the symptoms. Tarsal tunnel syndrome can be confused with reversible compression of the tibial nerve proximal to the ankle by tight-fitting ski or other boots.

FACIAL NERVE PALSY

Spontaneous and idiopathic Bell's palsy is the most common facial palsy. Accessory serratus anterior palsy and paralytic brachial palsy (neuralgic amyotrophy) probably have a similar pathogenesis.

Bell's palsy can occur at any age, may be unilateral or bilateral, and occasionally is recurrent. The deficit is variable, and 90% of patients recover spontaneously. Excessive tearing, hyperacusis, and loss of taste, which are clinical features indicating a proximal lesion of the facial nerve, are suggestive of a poor prognosis.

If the facial nerve can be stimulated after 4 to 5 days, a good recovery can be anticipated. Inability to stimulate the nerve accompanied by the development of fibrillation and positive sharp waves is suggestive of a poor prognosis. Aberrant reinnervation can occur and produces mass facial movements in the resultant interfascial synkinesis, accompanied by movement of the mouth. So-called *crocodile tears* may result from misdirection of the autonomic fibers subserving taste and lacrimation. Rarely, hemifacial spasm is a late feature.

In an attempt to prevent severe axonal degeneration, a short course (10 days) of corticosteroid therapy can be administered. The use of prednisone (50 to 100 mg per day) is recommended. Treatment must be started within 24 hours of presentation. Surgical decompression is controversial. An eye patch should be used to prevent corneal abrasions.

Mumps, mononucleosis, sarcoidosis, and Ramsay Hunt syndrome are associated diseases. In Ramsay Hunt syndrome, pain develops in and around the ear, with an associated vesicular eruption (herpes zoster). If the gasserian ganglion is involved, there may be sensory loss on the face. Cholesteatomas, acoustic neuromas, and sphenoid ridge meningiomas also may present as an acute or subacute facial palsy and require surgical exploration.

RADICULOPATHY

Cervical and lumbosacral nerve roots are subject to entrapment within the vertebral foramina by osteophyte formation or compression from a disk protrusion. Neck or back pain usually is the predominant symptom, with radiation down the arm or leg in an appropriate dermatomal distribution. Coughing or sneezing raises intraspinal pressure and increases the symptoms. Myotonic weakness and wasting can develop, along with loss of an appropriate deep tendon reflex.

Aradiculopathy should be investigated by EMG and magnetic resonance imaging or computed tomography before a contrast myelogram is considered.

The primary dorsal root ramus can be compressed, causing back pain. Paraspinal denervation can be detected on EMG, whereas the results of radiologic investigation usually are normal.

OTHER ENTRAPMENT NEUROPATHIES

ACCESSORY NERVE PALSY

Spontaneous accessory nerve palsy is rare. It may occur after an upper respiratory tract infection or an operation, or be associated with heavy exertion. Neck pain occurs initially, followed within several days by weakness of the trapezius muscle. There is drooping and inability to shrug the shoulders, with scapular winging. The winging is accentuated by lateral extension of the arm. This contrasts with the winging that occurs with serratus anterior palsy, which is brought out by forward extension of the arm. In addition, the inferior angle of the scapula moves upward and outward in accessory nerve palsy but downward and medially in serratus anterior palsy.

Accessory nerve palsy must be differentiated from the more common brachial plexopathy, suprascapular nerve palsy, and circumflex nerve injury. EMG shows slowed conduction along the distal part of the accessory nerve.

Spontaneous recovery over 6 to 9 months is the rule. During recovery, traction on the plexus may produce pain in the shoulder and arm.

SERRATUS ANTERIOR PALSY

Serratus anterior palsy is a common, painless mononeuritis that produces winging of the scapula accentuated by anterior extension of the arm. The tip of the scapula moves downward and medially. Most patients recover spontaneously. Persistence of the condition in young women can become a cosmetic problem.

SUPRASCAPULAR NERVE PALSY

Derived from the upper trunk of the brachial plexus (the fifth and sixth cervical nerve roots), the suprascapular nerve innervates the supraspinatus and infraspinatus muscles. Entrapment of this nerve within the suprascapular notch produces an inability to initiate elevation and extension of the arm. Rarely, the inferior branch is involved in isolation.

SAPHENOUS NERVE ENTRAPMENT

The saphenous nerve is a branch of the femoral nerve. It supplies the skin over the medial aspect of the leg below the knee. The saphenous nerve pierces the adductor canal just above the popliteal fossa, where it occasionally is entrapped. Pain is felt in the knee joint from compression of an articular branch. Paresthesia and sensory loss may be evident down the medial aspect of the leg. Surgical decompression usually is curative.

SURAL NERVE ENTRAPMENT

A purely sensory nerve, the sural nerve supplies the skin over the lateral aspect of the foot. It is derived mainly from the tibial nerve but also from the peroneal nerve (fifth lumbar–first sacral roots). It may be entrapped as it becomes superficial in the midcalf between the two heads of the gastrocnemius, where it pierces the fascia, causing pain over the lateral malleolus and outer aspect of the foot.

BENIGN MYOPATHIES OF CHILDREN

The benign myopathies of children often present as floppy-infant syndromes. They usually progress slowly or not at all, but occasionally lead to severe deficits and even death at an early age. Many of these conditions are transmitted genetically, although the patterns of inheritance can be unclear and variable. Most are characterized by specific biopsy findings from which their names are derived (e.g., central core disease, nemaline rod disease, centronuclear myopathy, congenital fiber-type disproportion).

MUSCULAR DYSTROPHIES

The muscular dystrophies are primary myopathies of genetic origin that usually have their onset in childhood and are progressive in nature. Although skeletal muscle bears the brunt of the genetic defect, other structures, including the heart and brain, may be involved.

The most common is Duchenne-type muscular dystrophy, a sex-linked recessive disorder that is transmitted by females and expressed only in males. The defective gene on the X chromosome (*Xp21*) is responsible for the gene product, dystrophin, which is localized to the inner surface of the muscle membrane. The absence or reduction of membrane dystrophin leads to the progressive muscle damage that produces the disease. As a result of progressive proximal weakness in the limbs and trunk, affected individuals usually are wheelchair-bound by their early teenage years and seldom live beyond 20 years of age. In a milder variant, Becker's muscular dystrophy, disability progresses more slowly and life expectancy is longer. Mental retardation and cardiomyopathy commonly coexist with muscular dystrophy, particularly the Duchenne type. Both Duchenne's and Becker's muscular dystrophy are characterized by pseudohypertrophy of the calves. Muscle biopsy reveals a myopathic pattern with random variation in fiber diameter, internally situated sarcolemmal nuclei, fiber splitting, "opaque" fibers, and a relatively marked increase in endomysial connective tissue.

Less common types of muscular dystrophy are named according to the primary distribution of muscle weakness. They include facioscapulohumeral muscular dystrophy, a dominant disease that produces facial and shoulder weakness with characteristic winging of the scapulae. The gene is on chromosome 4, but the abnormal gene product is not yet known. Limb-girdle muscular dystrophy is an autosomal recessive disorder that involves the pelvic girdle initially and the shoulder girdle later. There are several genetic disorders that are clinically diagnosed as limb-girdle dystrophy. The abnormal gene products have been defined for some and include an alteration in the ion-sensitive protease calpain. Oculopharyngeal muscular dystrophy is a rare and relatively benign dominantly inherited myopathy that produces bilateral ptosis, weakness of the extraocular muscles, dysphagia, and variable limb weakness.

MYOTONIC SYNDROMES

Myotonia is the persistent contraction of a muscle after the cessation of voluntary contraction or in response to a mechanical or electrical stimulus. Myotonia has a characteristic "dive bomber" sound on electromyography (EMG). It is a nonspecific finding and occurs in many different diseases.

MYOTONIC DYSTROPHY

Myotonic dystrophy is the most common myotonic syndrome. It is a dominantly inherited multisystem disorder attributable to a triplet repeat in a noncoding region of chromosome 17. It usually becomes evident between 15 and 30 years of age. Mild cases may be clinically inapparent. When the disease is fully developed, patients have bilateral ptosis, facial diplegia, frontal balding, and wasting of the temporalis and sternomastoid muscles. There is tapering of the arms and legs, with partial bilateral wristdrop and footdrop. By this stage, tendon reflexes usually are absent. Cataracts, infertility, cardiomyopathy, and mental retardation are part of the syndrome. Some patients, usually children of affected mothers, have a severe infantile form. Muscle biopsy may show a variety of nonspecific myopathic features. Classically, there is a marked increase in endomysial connective tissue, many internally situated sarcolemmal nuclei, ring fibers, and sarcoplasmic pads. There may be a predominance of type 1 muscle fibers.

MYOTONIA CONGENITA

Originally described by Thomsen, who had the disease himself, myotonia congenita has an autosomal dominant pattern of inheritance. It is a benign disorder associated with myotonia, which usually manifests as muscle stiffness at the beginning of or after exercise, and characteristically hypertrophied muscles. The importance of recognizing this syndrome lies in differentiating it from myotonic dystrophy.

PARAMYOTONIA CONGENITA

Paramyotonia congenita is one of the manifestations of hyperkalemic periodic paralysis. The myotonia may be apparent only after exercise or exposure to cold. Families have been described in which there has been overlap between the two manifestations of the disease. The pattern of inheritance is autosomal dominant.

INFLAMMATORY MYOPATHIES

POLYMYOSITIS

Polymyositis, the most common of the inflammatory myopathies, may begin acutely or in a subacute or chronic manner. It may occur in a pure form or be associated with a collagen vascular disease, such as systemic lupus erythematosus, rheumatoid arthritis, or scleroderma. Muscle weakness usually is diffuse and proximal, and involves the pectoral and pelvic girdles and the muscles of the neck. Muscle pain and tenderness also may be present. Systemic features include weight loss, dysphagia, and an elevated erythrocyte sedimentation rate. In addition, the serum creatine kinase level usually is elevated. The electromyogram is nonspecific, with fibrillation and positive sharp waves more evident than in most other myopathies. Muscle biopsy characteristically reveals necrotic and regenerating fibers and foci of autoaggressive inflammatory cells that invade otherwise normal-appearing muscle fiber.

Polymyositis is treated initially with corticosteroid therapy. A therapeutic response is evidenced by clinical improvement and a decreasing creatine kinase level. There is a role for cytotoxic immunosuppressive therapy in some patients. The role of intravenous immunoglobulin remains to be critically studied.

DERMATOMYOSITIS

Originally considered to be a variant of polymyositis with associated skin involvement, dermatomyositis should be regarded as a separate entity. The disease involves immune attack and destruction of small blood vessels in the muscle rather than the muscle fiber itself. For this reason, the muscle biopsy characteristically shows perifascicular atrophy of muscle fibers, as well as scattered muscle fiber neurosis and lymphocytic inflammation. The inflammatory infiltrate tends to be located more

in the interstitial connective tissue than in the muscle fiber itself. Malignancy may be associated with this disorder in older patients.

INCLUSION BODY MYOSITIS

Inclusion body myositis characteristically occurs in older individuals. In typical cases the clinical picture is distinctive. There is weakness of wrist flexors and finger flexors, as well as quadriceps. The disease is slowly progressive and often is associated with absent reflexes. Muscle biopsy reveals the changes of an inflammatory myopathy, with cytoplasmic vacuoles and ultrastructural findings of laminated membranous debris and filamentous inclusions measuring 10 to 20 nm. In contrast to polymyositis and dermatomyositis, inclusion body myositis does not improve with corticosteroid therapy.

SARCOIDOSIS

Sarcoidosis may involve muscle and rarely leads to symptomatic muscle disease, including weakness. Muscle biopsy shows sarcoid granulomas and, occasionally, myositis.

PARASITIC INFESTATIONS

Muscle infection results in weakness, tenderness, and pain. The most common parasitic infestations are trichinosis and cysticercosis. The diagnosis may be suggested by clinical findings or by the presence of calcification in the soft tissue on radiography. The diagnosis should be confirmed by muscle biopsy.

FOCAL NODULAR MYOSITIS

Focal nodular myositis is an unusual condition characterized by a progressively increasing lump in the muscle that on biopsy shows a histologic picture of myositis with necrosis, regeneration, and fibrosis. Because generalized polymyositis or some form of neurogenic disorder can develop, patients with focal myositis require careful follow-up.

METABOLIC MYOPATHIES

The metabolic myopathies are a large group of uncommon diseases with primarily autosomal recessive patterns of inheritance. They are characterized by fatigability and exercise intolerance, often associated with muscle cramps and pain, occasionally myoglobinuria, and eventually muscle weakness.

GLYCOGENOSES

Only a few of the more than ten recognized varieties of glycogenosis produce clinical myopathy.

MCARDLE'S DISEASE

McArdle's disease (glycogenosis type V, myophosphorylase deficiency) usually is inherited as a recessive trait, although a few autosomal dominant forms have been described. Patients classically complain of exercise intolerance with pain in the muscles on exercise. Myoglobinuria is common and may lead to renal impairment. The diagnosis may be supported by the presence of an abnormal ischemic exercise test in which the normal elevation in serum lactate levels after ischemic exercise fails to occur. Muscle biopsy may reveal abnormal glycogen storage in muscle fibers and the absence of phosphorylase staining.

ACID MALTASE DEFICIENCY

Type II glycogenosis in infants corresponds to Pompe's disease, but it also may occur in adults as an isolated skeletal muscle disorder. It is characterized by weakness, often of the respiratory muscles. Muscle biopsy shows multiple vacuoles containing glycogen in muscle fibers. Some of the glycogen is seen to be within lysosomes, which show striking acid phosphatase reactivity.

PHOSPHOFRUCTOKINASE DEFICIENCY

Type VII glycogenosis presents in a fashion similar to McArdle's disease and produces the same biochemical and electrophysiologic abnormalities. Muscle biopsy usually shows only minimal abnormalities, although a specific stain for phosphofructokinase demonstrates the absence of this enzyme activity. The diagnosis should be confirmed by muscle biochemical analysis.

LIPID STORAGE DISEASES

Carnitine deficiency can occur in a systemic form with widespread manifestations or can be localized to muscle. In the latter case, an autosomal recessive disorder, patients usually have slowly progressive weakness with occasional exacerbations. Muscle biopsy may show excessive lipid deposition, particularly in type I fibers.

Carnitine palmitoyltransferase deficiency usually affects young men, producing attacks of muscle pain and often myoglobinuria after periods of prolonged exercise. The results of muscle biopsy may be normal, and the diagnosis may require biochemical determination of carnitine palmitoyltransferase levels.

MYOADENYLATE DEAMINASE DEFICIENCY

The activity of myoadenylate deaminase can be demonstrated in muscle biopsy by histochemical and biochemical means. Myoadenylate deaminase deficiency may be seen in patients whose only complaints are excessive cramping and pain with exercise intolerance. However, patients with other recognized myopathic and neurogenic disorders have been described with this abnormality, and its significance remains in dispute.

MITOCHONDRIAL MYOPATHIES

The characteristic clinical finding in the mitochondrial myopathies is exercise intolerance, often with markedly elevated serum lactate levels after relatively little exertion. Some patients have fixed myopathic features, sometimes restricted to extraocular muscles. Other systems commonly are involved, particularly the central nervous system. In one group of mitochondrial myopathies, there is a morphologically demonstrable abnormality on muscle biopsy known as *ragged red fibers*, which appear ultrastructurally as abnormal mitochondria, commonly containing unusual crystalloid structures. One of these myopathies is the Kearns–Sayre syndrome, which is characterized by limb muscle weakness, retinitis pigmentosa, myocardial conduction abnormalities, and a positive family history. Others include the MELAS syndrome (mitochondrial encephalopathy, lactic acidosis, and strokes) and the MERRF syndrome (myoclonus epilepsy with ragged red fibers). Both myopathic and central nervous system abnormalities are present in these disorders.

The mitochondrial myopathies also can be characterized by muscle dysfunction without a definite histochemical mitochondrial abnormality. Various biochemical abnormalities of mitochondrial function have been demonstrated in some affected families.

ENDOCRINE DISEASES

Most endocrine disorders can affect muscle function, probably through failed calcium efflux or increased calcium influx into the T-tubular system of muscle. Hyperthyroidism and hypothyroidism, hyperadrenalism and hypoadrenalism, and hyperparathyroidism are associated with muscle weakness. Many of these conditions are reversible with treatment of the endocrinopathy.

MALIGNANT HYPERTHERMIA

Malignant hyperthermia is an unusual genetic disorder that occurs on exposure to certain inhalational anesthetics and results in the excessive release of calcium ions

from the sarcoplasmic reticulum. This produces hypercontraction of the muscle with associated severe rigidity and a marked increase in body temperature. Because this disease can be fatal, it is mandatory that a family history be obtained before any patient undergoes general anesthesia. Clinically, there may be no muscle complaints, although some patients with central core myopathy have been shown to have malignant hyperthermia. Diagnosis of the disease is difficult and may require the use of special techniques, including measurement of muscle contractility on exposure to solutions of caffeine and inhalational anesthetics. Patients with family histories of malignant hyperthermia should be considered affected unless proven otherwise, so that appropriate precautionary measures can be taken when general anesthesia is required.

DISEASES OF NEUROMUSCULAR TRANSMISSION

MYASTHENIA GRAVIS

In myasthenia gravis, antibodies against the acetylcholine receptor destroy the receptor site on the postsynaptic membrane. As a result, acetylcholine quantal release from the motor nerve terminals is ineffectual. Miniature end-plate potentials, the electrophysiologic measure of the response of the postsynaptic muscle membrane to quantal acetylcholine release, are reduced in size but not in number, reflecting the decreased availability of receptor sites.

The clinical result is exercise-induced muscle fatigability that resolves with a period of rest. Any skeletal muscle can be involved. Muscle end plates are dynamic structures with a turnover rate of 5 to 7 days, so that at any given moment, various end plates can be in different states of efficiency in response to acetylcholine.

Most patients with myasthenia gravis complain of double vision and ptosis. They also may have dysarthria, dysphagia, dysphonia, and difficulty with chewing and limb weakness. Only skeletal muscles are involved, and the sphincter muscles are spared. Sensory findings are absent and tendon reflexes are normal.

The presence of acetylcholine receptor antibodies in serum is specific for the diagnosis and is found in more than 90% of patients. Electromyograms, especially single-fiber studies, also are sensitive. About 5% of patients with myasthenia gravis have associated thymomas. These are treated by thymectomy, which is curative in about 75% of cases. Treatment otherwise involves the use of anticholinesterase drugs, often in combination with prednisone. Acute exacerbations may be treated by plasmapheresis. Disease that does not respond to conventional therapy can be treated with stronger methods of immunosuppression.

EATON–LAMBERT SYNDROME

Initially described in patients with oat cell carcinoma, Eaton–Lambert syndrome also has been shown to occur spontaneously or in association with conditions such as sarcoidosis, tuberculosis, blood dyscrasia, or penicillamine therapy. It is due to antibodies against a component of the calcium channel on motor axons, which produces failure of release of acetylcholine. As a consequence, miniature end-plate potentials are reduced in number but not in size.

Eaton–Lambert syndrome can mimic myasthenia gravis but also produces dry mouth, vague sensory findings, and sometimes absent reflexes, particularly when it is associated with cancer. Acetylcholine receptor antibodies are not present in the serum, and repetitive transmission studies show an exquisite increment in muscle potential amplitude with stimuli at 10 to 20 Hz. Plasmapheresis and immunosuppressive treatment can produce partial benefit.

BOTULISM

The toxin produced by *Clostridium botulinum* is one of the most potent biologic toxins. In adults, botulism usually results from improper sterilization of home-canned foods, resulting in ingestion of preformed toxin. Symptoms include blurred vision, obstipation, and dry mouth followed by variable degrees of asymmetrical weakness, including severe paralysis with respiratory failure. Midposition unreactive pupils and paresis of eye movements are usually seen. Treatment is with multivalent antitoxin, which must be given early, and patient and prolonged nursing care. Particular attention must be paid to respiratory care, occasionally including tracheostomy and assisted ventilation.

CLINICAL ASSESSMENT

Neuromuscular diseases often can be diagnosed on clinical grounds, but laboratory investigations may provide additional clues when doubt exists.

Features suggestive of primary muscle disease include proximal pelvic or pectoral girdle weakness with normal or only moderately depressed tendon reflexes, and the absence of sensory findings or fasciculation. There may be involvement of the facial musculature, producing a facial diplegia and weakness of the neck and trunk muscles. The weakness may be disproportionate to the minimal degree of muscle wasting that is present. Gowers' sign, in which the patient rises from the floor by "climbing up himself," is a nonspecific sign of pelvic girdle weakness. Muscle hypertrophy is characteristic of some muscle diseases in the early stages, particularly Duchenne-type muscular dystrophy. Muscle pain is not specific to muscle disease but also occurs in neurogenic conditions such as Guillain–Barré syndrome, motor neuron disease, and radiculopathy. However, muscle pain induced by exercise often indicates a metabolic myopathy.

Although many myopathies commonly are inherited, a negative family history may be deceptive. Family photographs can be revealing, uncovering such subtleties as facial diplegia, ptosis, or scapular winging in "normal" family members.

LABORATORY INVESTIGATION

BLOOD TESTS

The creatine kinase level often is elevated in primary myopathies and inflammatory myopathies. The presence of acetylcholine receptor antibodies in the blood is specific and sensitive for myasthenia gravis.

An ischemic exercise test may be helpful in elucidating some metabolic myopathies. The serum lactate dehydrogenase level normally rises after a period of ischemic exercise. This elevation fails to occur when there is a block in the metabolic glycolytic pathway, as in McArdle's disease and several rare glycogenoses.

ELECTROMYOGRAPHY

Needle EMG, although not disease-specific, usually makes it possible to differentiate between a primary myopathy and a neurogenic disease. The characteristic finding in myopathy is hyperrecruitment of motor units that are of reduced amplitude and duration because of the random fallout of muscle fibers within a motor unit.

MUSCLE BIOPSY

Muscle biopsy may be necessary to reach a diagnosis in difficult cases. The biopsy should be limited to mildly or moderately impaired muscle; end-stage muscle should not be sampled. Muscles that have been needed during EMG should be avoided. The variability of muscle involvement in some diseases can produce false-negative results, necessitating a second biopsy from another site.

Combined with clinical assessment and electrophysiologic results, routinely processed sections, frozen sections subjected to enzyme histochemistry, and, occasionally, specimens evaluated by electron microscopy provide useful diagnostic information. However, pathologic findings rarely are pathognomonic for any disease process.

CHAPTER 449: LUMBAR PUNCTURE AND CEREBROSPINAL FLUID ANALYSIS

GEORGE C. EBERS

Technique
 Normal Cerebrospinal Fluid
 Cerebrospinal Fluid in Disease: An Evaluation
 Complications

Lumbar puncture remains an essential study in the evaluation of meningeal and other diseases of the nervous system and for the instillation of radiographic contrast material and chemotherapy. The physician considering lumbar puncture should ask the following questions:

- Will the procedure yield useful information?
- Are there contraindications to the procedure?
- Do the benefits of the procedure outweigh the risks?
- Which tests maximize information and efficiency?

Lumbar puncture is contraindicated in patients with intracranial mass lesions; where it may introduce infection into the subarachnoid space; and before the correction of significant bleeding diathesis has been accomplished.

TECHNIQUE

The key to successful lumbar puncture is positioning. The patient is reassured and placed in a lateral decubitus position with knees flexed on the abdomen, neck flexed, and unrotated back perpendicular to the bed. After a local anesthetic is injected, a needle is inserted in the midline, perpendicular to the back, usually at the L4–L5 interspace (just below the iliac crest), and directed slightly rostrally. As the needle is advanced, the stylet is frequently removed to indicate whether the subarachnoid space has been reached in order to avoid entering the epidural venous plexus (denser ventrally). If the bevel is parallel to the longitudinal running fibers in the dura, it may lessen the chance of continued cerebrospinal fluid (CSF) leakage. Pressure measurement (usually 80 to 180 mm) is carried out before CSF removal and with the patient relaxed and the legs straightened. The fluid level should rise and fall with the pulse, and more so with deep respiration. The CSF pressure may be falsely elevated by straining (Valsalva's maneuver). Unexpectedly high CSF pressure from mass effect demands a contingency plan in case of deterioration. Lumbar puncture is safe in pseudotumor cerebri, in which CSF pressures may be high. It is more difficult when anatomical landmarks are obscured (e.g., in patients with obesity, spinal deformity), and puncture in the seated position or under fluoroscopic guidance may be necessary. Lateral cervical or cisternal puncture provides alternative routes under special circumstances.

NORMAL CEREBROSPINAL FLUID

Normal CSF (total volume 120 mL) is clear and colorless. It is routinely examined for differential cell count (first and last tube) and protein and glucose values. There are few cells in normal CSF (fewer than 4 mononuclear cells per microliter). A pleocytosis of more than 30 cells per microliter can be identified with the practiced eye by swirling the collecting tube (Tyndall's effect). CSF protein levels are normally in the range of 15 to 45 mg per deciliter for lumbar fluid. Elevation of these levels usually reflects alteration of the blood–CSF barrier. It is commonly seen in persons with diabetes. CSF protein levels above 80 mg per deciliter produce an increasingly yellow tinge (xanthochromia). The relative CSF/serum ratio of serum protein is inversely proportional to the protein's hydrodynamic radius, so that large proteins, such as IgM, are virtually absent from normal CSF. Below a subarachnoid block (e.g., by a lumbar epidural tumor), the CSF protein may exceed 1.5 g per deciliter and clot spontaneously (Froin's syndrome). In 95% of children age 3 months to 13 years, the CSF protein level is below 25 mg per deciliter. CSF glucose concentration is normally 0.6 times that of blood at equilibrium. Changes in the blood are reflected in CSF after a delay of 1 to 2 hours. Reduction of CSF glucose (hypoglycorrhachia) occurs in bacterial, fungal, and neoplastic meningitis and less often in subarachnoid hemorrhage, but also occasionally in viral, sarcoid, and rheumatic meningitis.

CEREBROSPINAL FLUID IN DISEASE: AN EVALUATION

The sensitivity and specificity of CSF studies in the conditions in which they are most valuable are outlined in [Table 449.1](#).

TABLE 449.1. SELECTIVE EVALUATION OF LUMBAR PUNCTURE

MENINGITIS

The removal of CSF itself can be diagnostic (improvement in normal-pressure hydrocephaly) or therapeutic in lowering pressure in cerebri pseudotumor.

In bacterial meningitis, CSF is important for a microbial diagnosis and *optima* antibiotic selection (see [Chapter 431](#), [Chapter 441](#), and [Chapter 442](#)). CSF pressure is often raised and the fluid may be turbid. Pleocytosis, which may exceed 1,000 cells per microliter, usually shows a predominance of polymorphonuclear leukocytes, although in 10% of cases (especially in neonates) it may be lymphocytic. Gram's staining is done on spun sediment, and the organism is seen in 60% to 90% of cases. Culture is diagnostic. Immunosuppressed patients and newborns may be atypical, showing little or no pleocytosis. A parameningeal infection (e.g., subdural empyema) may produce pleocytosis and slightly elevated protein with normal glucose and cultures. Tuberculous meningitis produces a high-protein, low-sugar, and lymphocytic pleocytosis. Acid-fast bacilli are seen with Ziehl–Nielsen staining in only 25% of cases. Viral meningitis is usually associated with mononuclear pleocytosis, but a polymorphonuclear leukocyte predominance may be present in up to 50% of early cases. Repeat puncture in 24 hours shows a mononuclear response predominating or developing. The protein level is often normal or modestly elevated. In sporadic meningoencephalitis (e.g., herpes simplex), an increase in red and white blood cell counts and protein is noted, with occasional reduction in the glucose. Polymerase chain reaction–based diagnosis is available for some organisms, but sensitivity and specificity have not been firmly established. The CSF in fungal meningitis shows mononuclear pleocytosis, low glucose, and elevated protein. In cryptococcal meningitis, the India ink wet mount demonstrates the clear capsule of the organism, and cryptococcal polysaccharide antigen is usually detectable by later agglutination. Multiple cultures of large CSF volumes may be needed to grow cryptococci and other fungi, but still may not grow *Coccidioides*. Serology is helpful in this instance.

NEUROSYPHILIS

Essentially all patients with neurosyphilis have a positive serum fluorescent treponemal antibody test. Confirmation of neurologic involvement is made by CSF examination. Although CSF serologic examination is of little value, active disease is characterized by mononuclear pleocytosis, normal or elevated protein levels, and local IgG antibody production with the presence of oligoclonal IgG bands.

NEOPLASTIC MENINGITIS

A mild pleocytosis, elevated protein level, and reduced glucose level are usual with meningeal infiltration by tumor. Malignant cells are seen in more than two-thirds of patients; detection of these cells is aided by taking large amounts of fluid directly into cytologic preservative. Tumor-specific monoclonal antibodies may also aid in the detection of malignant cells.

SUBARACHNOID HEMORRHAGE

Lumbar puncture almost invariably demonstrates bloody CSF. In true subarachnoid hemorrhage, the red blood cell count should stay the same in the first and last tube, and it should drop (often visibly) in traumatic puncture. The spun supernatant of a traumatic tap should be clear, but a spun supernatant may also be clear for 4 hours or more following subarachnoid hemorrhage before xanthochromia develops. Xanthochromic supernatant can also be seen occasionally in traumatic tap, which also raises the CSF protein level by 1 mg per deciliter for every 1,000 red blood cells per microliter and accounts for 1 white blood cell per microliter for every 7,000 red blood cells per microliter (assuming a normal hemogram). The CSF in subarachnoid hemorrhage can clear completely in 3 or 4 days in young people.

“AUTOIMMUNE” DISORDERS

CSF electrophoresis is used to demonstrate oligoclonal IgG bands. In several inflammatory/infective disorders, enough immunoglobulin product of single B-cell clones is present to show up as multiple single bands. Oligoclonal CSF bands are seen in multiple sclerosis, neurosyphilis, paraneoplastic cerebellar degeneration, and some other inflammatory disorders, and in a small percentage (less than 10%) of patients considered to be “normal” or to have noninflammatory disorders.

COMPLICATIONS

Complications of lumbar puncture include the following:

- Aggravation or precipitation of cerebral or cerebellar herniation in the presence of mass lesions may occur. A computed tomographic scan may be necessary before a lumbar puncture can be performed. Removal of CSF below a spinal block may also precipitate deterioration in cord function.
- Symptomatic epidural or subdural hemorrhage is rare unless coagulation is impaired.
- Postlumbar puncture headache affects 10% to 20% of patients and can be transiently incapacitating. Onset of the headache is often delayed by a few hours or longer. The headache is usually bilaterally occipital and frontotemporal, throbbing, and immediately relieved by lying down, only to return upon standing. It is caused by continued leakage of CSF through the dural puncture hole, with traction on pain-sensitive structures at the base of the brain resulting from low CSF pressure. Leaking may also be spontaneous or pressure-induced. (The removal of 10 mL of CSF is replaced in 30 minutes at the normal rate of CSF production of 0.3 mL per minute.) Risk is reduced by the use of small-gauge, “atraumatic” needles. The headache is managed by rest and analgesics and usually lasts for 1 to 2 days (occasionally several days).
- Back or root pain is transient but common.
- Introduction of infection rarely occurs.
- Spinal epidermoid cyst rarely occurs.
- Cranial neuropathies VI, IV, and VIII rarely occur.

CHAPTER 450: ELECTROENCEPHALOGRAPHY AND EVOKED POTENTIALS

DAVID B. MACDONALD

[Electroencephalography](#)
[Evoked Potentials](#)

ELECTROENCEPHALOGRAPHY

Clinical electroencephalography is based on the diffuse and regional synchronous postsynaptic potentials of radially oriented cortical pyramidal cell columns. These potentials generate spatiotemporally summated extracellular currents of sufficient voltage to detect at the scalp. Other electrically active cellular elements of the cerebrum with more random geometry contribute little to this summation. Thus, scalp recordings predominantly reflect electrical activity of the cortical pyramidal cells and indirectly their modulation by subcortical structures. Electroencephalography is the discipline of interpreting these recordings in a clinical context.

Electrical potential differences between selected pairs of 21 or more electrodes placed at standard scalp locations are amplified and displayed in anatomically organized multichannel graphs, similar to that done in electrocardiography. The electroencephalogram (EEG) in wakefulness and its appearance in different states (such as drowsiness, hyperventilation, sleep, and photic stimulation) is analyzed, and the findings are correlated with clinical information to form an interpretation. Standards for electroencephalographic training and practice and certifying board examinations exist; these generally require at least 6 months (preferably a year or more) of full-time training in order for an individual to qualify as an electroencephalographer.

Computer technology has replaced traditional analog techniques with digital recordings that augment diagnostic precision through mathematical manipulation. Advanced methods, including source localization, quantitative electroencephalographic brain mapping, and high-resolution electroencephalography are beginning to contribute to clinical medicine.

NORMAL ACTIVITY

Unlike electrocardiograms, EEGs contain rhythmic sinusoidal or sharply contoured patterns intermingled with more irregular waveforms. These patterns vary with age and state of arousal, and are characterized by their voltage, frequency, morphologic characteristics, distribution, symmetry, persistence, and reactivity. There are four clinically useful frequency bands: delta, below 4 Hz; theta, 4 to 7 Hz; alpha, 8 to 13 Hz; and beta, above 13 Hz. An ontogenic progression in the frequency content of the human EEG is seen from infancy, dominated by delta and theta activity, to adulthood, dominated by alpha and beta activity, and finally to senescence, when slower frequencies may reappear. A typical adult record contains the famous posterior “alpha rhythm” that reacts (attenuates or “desynchronizes”) to eye opening, a central “mu rhythm” that reacts to hand movements, and variable frontocentral beta activity. These features blend together over the scalp to create the “background.” Hyperventilation may induce diffuse paroxysmal slow waves; photic stimulation may induce time-locked occipital waveforms; drowsiness is accompanied by slower frequencies and sometimes paroxysmal events that are easily misinterpreted; sleep is defined and staged by the appearance of characteristic patterns. Many variations, some unusual or even rare, including benign epileptiform patterns, have been identified and shown to have no or uncertain clinical significance. Extreme amplification creates frequent artifacts from eye or tongue movement, scalp muscle, and other sources. Substantial training and experience are required to reliably identify these artifacts and shadings of normal before clinically meaningful interpretations can be expected.

ABNORMALITIES

There are four general categories of abnormality: asymmetry, dysrhythmia, persistent polymorphic delta activity (PPDA), and suppression. Asymmetry is an abnormal difference in background voltage between homologous regions. Nonspecific dysrhythmias are persistent, intermittent, or paroxysmal irregularities that demonstrate diffuse or focal cerebral dysfunction but do not imply any particular etiologic process. Excessive diffuse fast dysrhythmia is a common side effect of sedative medication. Other dysrhythmias are distinctive patterns with specific names (e.g., spike, burst suppression) and tend to have particular clinical correlations. PPDA—excessive delta activity present throughout the recording—signifies relatively continuous nonspecific brain dysfunction and may be generalized or focal. Focal PPDA is the hallmark of focal structural pathology but may also be seen in focal dysfunction without structural damage. Suppression refers to abnormal voltage depression, the most severe form of which is electrocerebral silence.

CLINICAL UTILITY

Electroencephalography is valuable in the investigation of intermittent or persistent brain dysfunction and remains essential in the evaluation of epilepsy. The recording of a clinical seizure may be diagnostic but occurs infrequently. Unequivocally abnormal interictal spike or sharp wave discharges uniquely reflect epileptic pathophysiologic processes and strongly support a diagnosis of epilepsy. However, caution is required because electroencephalographers vary in their ability to distinguish between epileptiform abnormalities and other apiculate or paroxysmal events, and because epileptiform discharges infrequently occur without a clinical history of epilepsy, especially in children. To detect these intermittent discharges, it may be necessary to repeat the study or to record a sleep EEG (which may activate epileptiform abnormalities). However, electroencephalography cannot exclude epilepsy because up to 10% of persons with epilepsy yield persistently negative interictal findings. Focal epileptiform abnormalities suggest a localization-related epilepsy syndrome, whereas diffuse epileptiform discharges generalized from onset suggest a generalized epilepsy syndrome, refining clinical diagnosis and aiding management.

Patients with impaired consciousness may benefit from electroencephalography. Evidence of nonconvulsive status epilepticus can lead to specific interventions; psychogenic unresponsiveness and the “locked-in syndrome” demonstrate essentially normal findings; encephalopathies produce nonspecific diffuse abnormalities; and marked focal temporal abnormalities in encephalitis may suggest herpesvirus. Some coma patterns have prognostic value, and electrocerebral silence characterizes brain death when hypothermia and suppressant drugs are excluded.

Electroencephalography can help to differentiate dementia from pseudodementia by providing objective evidence of cerebral dysfunction. Periodic sharp wave discharges may suggest Jakob–Creutzfeldt disease in the appropriate clinical setting.

Valuable specialized studies include prolonged video electroencephalographic monitoring with scalp or intracranial electrodes in difficult or surgical epilepsy cases, electrocorticography during epilepsy surgery, and monitoring in the operating room or intensive care unit.

EVOKED POTENTIALS

Evoked potentials are computer-averaged electrical responses of the nervous system elicited by specific stimuli. Random activity unrelated to the stimulus averages toward 0, while time-locked activity is revealed. The short latency sensory evoked potentials mentioned below are the most common in clinical use.

VISUAL EVOKED POTENTIALS

Usually, the occipital response to monocular stimulation with a reversing high-contrast black-and-white checkerboard pattern is recorded. In the absence of retinal or ocular disease, monocular absence or delay of the response suggests an ipsilateral prechiasmatic defect. Bilaterally symmetrical abnormality suggests bilateral but unlocalized visual pathway defects.

SOMATOSENSORY EVOKED POTENTIALS

Most commonly, responses to electrical stimulation of the median and tibial nerves are recorded from peripheral nerve, spinal cord, brain stem, and cortex (see [Chapter 451](#)). Delay or absence of expected responses may suggest and localize a somatosensory pathway defect. Visual and somatosensory evoked potentials are useful in the detection of subclinical abnormalities in multiple sclerosis and in other neurologic disorders.

BRAIN STEM AUDITORY EVOKED POTENTIALS

Responses to click stimuli from the distal auditory nerve through to the upper pons and midbrain are usually recorded. In neurology, brain stem auditory evoked potentials are useful in retrocochlear or brain stem dysfunction, such as suspected acoustic neuroma.

EVOKED POTENTIAL MONITORING

Brain stem auditory evoked potentials and somatosensory evoked potentials can be monitored intraoperatively or in the intensive care unit, and may help to prevent neurologic deficits. Motor evoked potential monitoring using transcranial electric stimulation and recordings from the spinal cord or distal muscles is emerging as a safe and reliable method to predict the integrity of the corticospinal system intraoperatively.

CHAPTER 451: NEUROPHYSIOLOGY: NERVE CONDUCTION AND ELECTROMYOGRAPHY

ANDREW A. EISEN

[Motor and Sensory Conduction Studies](#)
[Evaluation of Conduction Through the Proximal Peripheral Nervous System](#)
[Needle Electromyography](#)

The term *electromyography* (EMG) is generic and includes several electrophysiologic tests that are useful for examining the peripheral and central nervous systems. The different tests used are not mutually exclusive ([Table 451.1](#)). They complement each other, and often several are required to reach a logical conclusion. EMG is a sophisticated extension of the neurologic examination and should be designed specifically to evaluate further the clinical problem in each patient. There are no routines in EMG, making it challenging and exciting. Well-designed EMG enables a lesion to be localized, its severity determined, and the probable prognosis offered.

Test	Application
Motor conduction velocity	Focal neuropathies and polyneuropathies
Sensory conduction velocity	Focal neuropathies and polyneuropathies
F-wave response	Motor conduction through roots
H reflex	Sensory conduction through roots
Somatosensory evoked potentials	Sensory conduction through roots, sensory conduction through nerves that is not amenable to routine study, sensory potentials that are absent, and conduction through the spinal cord
Transcranial magnetic stimulation	Central motor conduction and conduction through proximal segments of peripheral nerve
Repetitive stimulation	Neuromuscular transmission failure
Needle electromyography	To document denervation, fasciculation, myotonia, reinnervation, myopathy, to differentiate upper vs. lower motor neuron weakness, and to differentiate true hysterical weakness
Single-fiber electromyography	Same as for needle electromyography, but gives additional information about the motor unit and is a sensitive indicator of neuromuscular failure

TABLE 451.1. APPLICATIONS OF ELECTROMYOGRAPHY

MOTOR AND SENSORY CONDUCTION STUDIES

Nerve conduction studies measure the velocity and the evoked amplitude of the largest, most rapidly conducting nerve fiber. Both motor and sensory studies are obtained. Seventy percent of the fibers in a peripheral nerve are of small diameter, including autonomic (sympathetic and parasympathetic) fibers, pain (C and A D fibers), and gamma efferent fibers supplying the intrafusal muscle fibers of muscle spindles. These fibers cannot be evaluated directly because the stimulating current required would be intolerable. The autonomic nervous system can be evaluated indirectly using several different techniques, but direct assessment of autonomic nerve fibers is still experimental. Therefore, normal results on conventional conduction studies do not rule out disease of the peripheral nerve but merely reflect normal conduction through the fastest conducting large-diameter nerve fibers. Further, routine conduction studies do not incorporate the proximal parts of the peripheral nervous system: the roots and plexus. Different techniques are required for their evaluation (see below).

Diseases of peripheral nerves may produce demyelination, degeneration of the axon, or both. Marked conduction slowing (velocities of 30 m per second or less) indicates demyelination of nerve. This may be focal [i.e., carpal tunnel syndrome, compressive ulnar neuropathy (cubital tunnel syndrome)] or diffuse and multisegmental (Guillain–Barré syndrome, hereditary neuropathies such as Charcot–Marie–Tooth disease). However, most toxins and deficiency states primarily involve the axon or cell body, with resulting degenerative nerve diseases, including most loss of the nerve fiber. Conduction velocity in these so-called axonal neuropathies may be normal; if slowing occurs, it usually is modest. However, the evoked potential amplitude is usually reduced, reflecting the loss of large nerve fibers.

No direct relation exists between the degree of conduction slowing and the severity of clinical disease. Marked conduction slowing can occur with minimal neurologic deficit, and vice versa. Similarly, improvement in conduction does not invariably follow, for example, decompressive surgery for carpal or cubital tunnel syndrome, even when there has been considerable clinical improvement. A nerve, once diseased, never returns to its normal structure, although it can transmit impulses in a sufficiently accurate manner to allow normal clinical function.

Other conduction characteristics require consideration. An important one is conduction block. The amplitude of the motor or sensory nerve action potential reflects the number of axons activated. The number can be reduced because of axonal destruction, as after trauma with resulting denervation. In addition to slowing of conduction described above in axonal neuropathies, demyelination can produce conduction block, which lowers the evoked amplitude in a fashion similar to functional loss of axons. The latter may be focal or multifocal. Functional conduction block may be seen early in carpal tunnel syndrome, cubital tunnel syndrome, radial nerve or Saturday night palsy, mild cases of Bell's palsy, and some cases of Guillain–Barré syndrome and chronic acquired demyelinating neuropathy, a disorder presumed to be immune-mediated ([Fig. 451.1](#)). This type of conduction block usually can be reversed in a short time unless axonal degeneration supersedes. Conduction block occurring in the absence of denervation heralds a good prognosis, but the recovery period can be protracted. Conduction slowing without conduction block is a useful means of distinguishing between acquired and hereditary demyelinating neuropathies; the latter usually do not demonstrate conduction block.

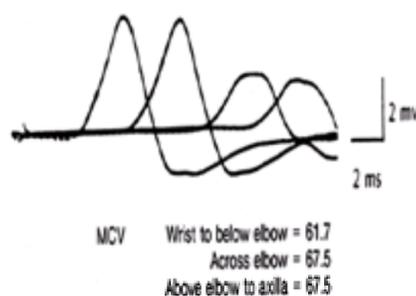

FIGURE 451.1. To localize a focal lesion of nerve, several sites along the nerve must be stimulated. In this example—a cubital tunnel syndrome—conduction velocity below the elbow is normal, as is the size of the distal two-compound motor action potentials, evoked by stimulation of the ulnar nerve below the elbow and at the wrist. Conduction from the axilla to above the elbow is also normal, but the two responses elicited by stimulation in the axilla and above the elbow are less than half the size of the distal responses. This indicates that there is a region of conduction block located at the elbow (cubital tunnel).

EVALUATION OF CONDUCTION THROUGH THE PROXIMAL PERIPHERAL NERVOUS SYSTEM

Conventional techniques for measuring motor and sensory conduction velocity cannot measure conduction through the proximal nerve segments, roots, or plexuses. Several techniques have been devised to measure conduction through these structures. They are F-wave measurement, H-reflex measurement, root stimulation, somatosensory evoked potential measurement, and cortical magnetic stimulation.

F-WAVE MEASUREMENT

When a motor nerve is stimulated, pulses travel in two directions: to the muscle supplied by the particular nerve stimulated, and antidromically toward the spinal cord. When they reach the spinal cord, the anterior horn cell is excited, setting up a second discharge that travels back down the nerve to reach and reexcite the same muscle (F wave). The F-wave action potential that can be recorded from muscle is small, but its latency is a measure of motor conduction through the nerve roots.

H-REFLEX MEASUREMENT

The H reflex is the electrical equivalent of the tendon jerk bypassing the muscle spindle. If the type Ia afferent fibers are stimulated selectively, which can be done using a small stimulus of long duration, a monosynaptic reflex is activated in which the anterior horn cells for a given muscle are excited. This can be used indirectly to measure sensory conduction through the nerve roots.

ROOT STIMULATION

By introducing a narrow-gauge needle so that its tip lies on the lamina or the vertebral body, the ventral roots of the spinal nerves can be stimulated. This technique makes it possible to measure motor conduction through the plexus and more distal nerve. The root stimulation technique is useful for evaluating brachial and lumbosacral plexopathies. The use of magnetic stimulation, which is relatively painless, has obviated the need for invasive needle stimulation.

SOMATOSENSORY EVOKED POTENTIAL

The somatosensory evoked potential is a cortically evoked response that is recorded from the scalp in a fashion similar to that of the electroencephalogram. The response is elicited via stimulation of a peripheral nerve. In patients with peripheral neuropathy, the somatosensory evoked potential can be used to measure sensory conduction velocity when this is not possible using conventional techniques. During recovery from nerve injury, the somatosensory evoked potential may be measurable many months before its peripheral counterpart, providing useful evidence of reestablished axonal continuity. The somatosensory evoked potential also may be used to measure conduction through a nerve from which it is difficult or impossible to record action potentials by conventional means because of anatomical inaccessibility.

These methods are better for evaluating plexopathies than radiculopathies because the shortness of the nerve root is diluted by the length of normally conducting nerve, which the F-wave, H-reflex, and somatosensory evoked potential techniques incorporate. Nevertheless, these tests have a place in the study of root lesions.

TRANSCRANIAL MAGNETIC STIMULATION

Transcranial magnetic stimulation enables in vivo painless stimulation of the awake human motor cortex, making it possible to evaluate the central motor pathways. This is particularly useful in amyotrophic lateral sclerosis, multiple sclerosis, and myelopathies resulting from lesions that are not visible on radiographs. Transcranial magnetic stimulation also can provide useful information regarding proximal parts of the peripheral nervous system.

NEEDLE ELECTROMYOGRAPHY

Needle examination of muscle often is the only means of determining the severity of disease and provides important information that cannot be obtained with conduction studies. The detection of myotonia, characterized clinically by delayed muscle relaxation after contraction, exemplifies this phenomenon ([Fig. 451.2](#)). There are three essential elements to needle EMG, each of which provides different information: analysis of spontaneous activity, the firing pattern of the motor units on voluntary effort, and the morphologic characteristics of the recruited motor units.

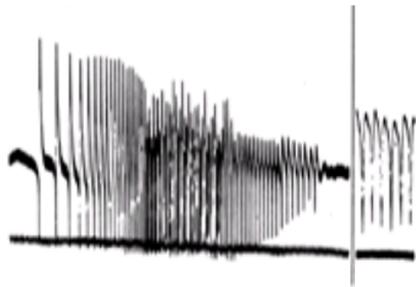

FIGURE 451.2. Myotonia is the clinical phenomenon of delayed muscle relaxation. It is most commonly seen in myotonic dystrophy but is symptomatic of several other hereditary and acquired diseases. Electrically there is a characteristic, high-frequency rhythmic discharge with a “dive bomber” sound. Electrical myotonia may be recorded without clinical counterpart.

SPONTANEOUS ACTIVITY

When the recording needle is inserted into a relaxed muscle, the muscle is electrically silent except for brief “insertional activity.” Loss of nerve–muscle continuity (denervation) results in fibrillation, which is the spontaneous firing of individual muscle fibers ([Fig. 451.3](#)). This cannot be seen clinically.

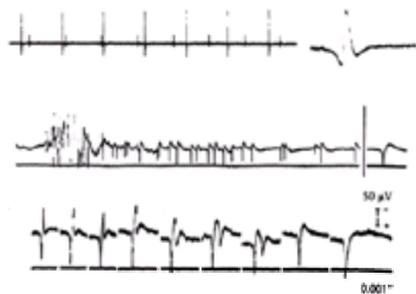

FIGURE 451.3. These fibrillation and positive sharp-wave potentials were recorded from the relaxed tibialis anterior muscle of a patient who had developed a peroneal palsy 2 weeks previously. Each spike and positive sharp wave reflects spontaneous, nonvisible contraction of a single, denervated muscle fiber. Fibrillation may also be seen in primary muscle disease if the end plate is separated from the nerve terminal.

The onset of fibrillation is related directly to the length of the nerve segment distal to the site of injury. In radiculopathy, for example, denervation appears first in the paraspinal muscles, then in the proximal limb muscles, and finally in the distal musculature. It may not be seen in the distal muscles of the arms or legs for up to 3 weeks after the injury. Therefore, in the early postinjury period, the absence of fibrillation does not rule out denervation. Once fibrillation has developed, it may persist

for many years. After disk surgery, fibrillation often can be recorded for at least a year. This finding makes it difficult to evaluate recurrent symptoms (“failed back surgery”) by needle EMG.

Fibrillation does not equate invariably with nerve disease. It also occurs in botulism, a disease of the neuromuscular junction, and in primary myopathies. In myopathies, it results from functional separation of a portion of the muscle fiber from its end plate.

Fasciculation is the spontaneous firing of part or all of a motor unit; all of the muscle fibers are innervated by a single motor neuron. Fasciculations can be clinically visible. When seen in isolation in the absence of clinical muscle wasting, weakness, or other EMG abnormalities, fasciculation usually is benign. Diseases associated with fasciculation invariably are neurogenic, with the most common being those that involve the anterior horn cell, such as motor neuron disease ([Fig. 451.4](#)). Myokymia (bursts of discharges) is less disease-specific but is not uncommonly associated with radiation neuropathy. Facial myokymia, usually resulting from multiple sclerosis, has a characteristic EMG pattern. Neuromyotonia, or Isaac's syndrome, also has a characteristic associated high-frequency spontaneous discharge. Occasionally, an early parkinsonian tremor that is not clinically apparent can be detected on needle EMG.

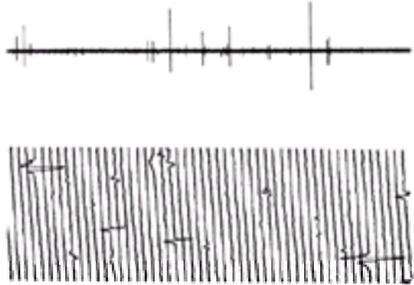

FIGURE 451.4. Fasciculation potentials. The top tracing was recorded at a slow sweep (1 minute). Given potentials occur only every few seconds and correspond to visible spontaneous muscle twitching. The lower tracing shows several (three or four) different fasciculation potentials recorded at a faster (10 millisecond) sweep. It is usually not possible to differentiate a “benign” from a “malignant” fasciculation, but one that is complex and is of increased fiber density is often associated with disease.

FIRING FREQUENCY

The earliest, and often the only, needle EMG abnormality is altered (rapid) firing of the motor units. This begins at the onset of the disease and lasts for as long as the disease is present. Normally, motor units seldom exceed firing frequencies of 8 per second; rates faster than 15 per second are abnormal. Increased firing frequency of motor units is compensatory for any lower motor neuron disease (myopathic or neurogenic disorders) but does not occur if effort is withheld voluntarily because of pain, malingering, or the presence of upper motor neuron disease.

MORPHOLOGY OF THE MOTOR UNITS

The motor units recorded on the needle examination usually are biphasic or triphasic. When the recording needle is positioned near the muscle fiber, the spike of the motor unit potential reflects activity in a single muscle fiber. However, activity also is picked up from other surrounding muscle fibers belonging to the same motor unit. It is not possible to record activity from all of the muscle fibers belonging to a given motor unit simultaneously because they are scattered diffusely throughout the muscle and many are outside the “pick-up range” of most of the electrodes used. This limitation means that any one needle site can sample only part of the motor unit. Therefore, it is customary to explore several different needle sites in a variety of muscles. The number sampled depends on the particular problem.

The motor unit changes dramatically in disease. As reinnervation proceeds through terminal or collateral spouting, it becomes larger because the same motor unit now innervates its own muscle fibers and several of those belonging to one or more “foreign” units. The motor unit potential becomes longer in duration and more complex in shape (polyphasic).

These changes in the motor unit potential are appreciated more readily using a single-fiber electrode. Single-fiber EMG makes it possible to measure several aspects of the motor unit. For example, because individual muscle fibers are easily recognized, they can be counted and assigned a fiber density. Fiber density increases as part of the reinnervation process.

FAILURE OF NEUROMUSCULAR TRANSMISSION

Several diseases are characterized by failure of neuromuscular transmission. The most common is myasthenia gravis, but others, such as botulism and Eaton–Lambert syndrome, are not rare. These conditions have specific clinical features but share the hallmark symptom of muscle fatigability on voluntary effort. However, not all muscle fatigue results from a neuromuscular transmission defect; other causes include multiple sclerosis, postviral fatigue syndromes, rare metabolic myopathies, and, most commonly, depression and other forms of psychogenic fatigue. EMG is helpful in identifying neuromuscular transmission as the cause of fatigue. A variety of electrophysiologic tests are used to detect neuromuscular transmission, but the most sensitive is jitter measurement using single-fiber EMG ([Fig. 451.5](#)). Jitter results from the variation of consecutive discharges of muscle fiber in relation to another fiber belonging to the same motor unit. Normally, jitter is small, about 50 μ s. In diseases of neuromuscular transmission, jitter can reach several hundred microseconds and eventually may fail completely. This is referred to as *blocking*. Treatment reduces jitter and abolishes blocking, so patients must be evaluated when they are not taking medication.

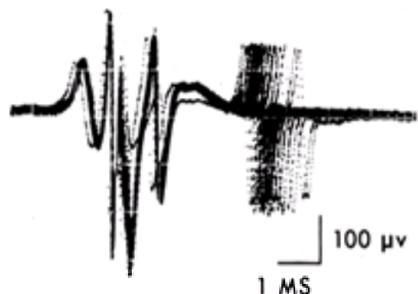

FIGURE 451.5. Electromyographic jitter. This recording, obtained from the extensor digitorum brevis muscle, was made using a single-fiber electrode. The patient, a 32-year-old woman, presented with intermittent, fatigable, bilateral ptosis. Myasthenia gravis was suspected. The complex motor unit potential (*left*) is followed by a single-muscle-fiber spike (*right*), which on consecutive discharges “jitters” excessively (about 1,000 microseconds, normal less than 50 microseconds). This is a sensitive measure of failed neuromuscular transmission. It is not specific for myasthenia gravis, however, because it is also seen in botulism and Eaton–Lambert syndrome.

SPINAL CORD CONDUCTION

The scope of EMG has been broadened to include the investigation of central nervous system diseases. One example is the measurement of spinal cord conduction,

which is useful in conditions that cannot be visualized by computed tomography or magnetic resonance imaging. In addition, many EMG methods are included under the general term *reflexology*. These are helpful in evaluating disorders of muscle tone (upper motor neuron spasticity, parkinsonian rigidity) and their responses to drug therapy.

CHAPTER 452: NEUROIMAGING

JACK O. GREENBERG

[Spectroscopy](#)
[Angiography](#)
[Diffusion/Perfusion Imaging in Acute Ischemic Stroke](#)
[Positron Emission Tomography](#)
[Ultrasonography](#)
[Clinical Applications](#)

The development of methods to image the brain has led to much of the progress in clinical neurology. Many earlier technologies are gone (e.g., pneumoencephalography, ventriculography, epidural venography), and plain skull films are being used less frequently. Spine plain films continue to have limited use in trauma, degenerative disease, and developmental abnormalities.

In the early 1970s, new imaging techniques revealed unprecedented information about structure and disease in living patients. In traditional shadow radiography, introduced in 1896, all shadow-producing structures appear superimposed, making delineation of tissue difficult. Tomography, developed between 1920 and 1940, created a series of slices representing only one plane through the tissue, which allowed the creation of a three-dimensional mental image of the structures.

In 1961, Oldendorf, using a deceptively simple apparatus, demonstrated that the distribution of radiodensities within a plane could be reconstructed. Hounsfield, beginning in 1967, used a computer to calculate an image of the body from x-ray readings taken from many different projections. Further refinement led to a great day in 1972 when a brain cyst was clearly seen in a woman with a suspected brain lesion using computed tomography (CT). CT continues to be an important technique in neuroimaging. It is more accurate than other techniques in defining acute brain hemorrhages (72 hours or less), especially in the subarachnoid space, but also within the brain when compared to magnetic resonance imaging (MRI). Bony abnormalities, including fractures and calcification, are also better defined by CT than MRI. CT historically has been faster than MRI and was more appropriate for the patient who could not cooperate or who had severe claustrophobia. Today, on newer scanners, MRI is as fast as CT. CT revolutionized the practice of neurology and neurosurgery, becoming as important to these specialties as bone roentgenology is to orthopedics. CT provided direct visualization of normal and abnormal soft tissues, unlike previous attempts at body imaging.

Despite its usefulness, however, CT is limited in its ability to characterize tissue. It shows tissues that have an electron density different from that of surrounding tissue. Iodinated contrast material can demonstrate lesions with an abnormal blood–brain barrier. Unlike MRI, it has no great analytical potential to define brain chemistry and function.

MRI is a form of tissue analysis in which radio waves applied in a magnetic field are used as a probe to measure and localize chemical characteristics. A radiofrequency pulse is introduced into tissue and the magnetic resonance is analyzed. Before imaging, the main magnetic field is uniform, strong, and constant. When actually imaging, gradient coils rapidly alter the magnetic field in all three planes to provide spatial localization. Because of the gradients, the protons spin at unique frequencies, allowing them to be encoded and localized in the field. CT can give gray–white contrast because the electron density (the source of detail in CT) of gray matter is 0.2% greater than that of white matter. Magnetic resonance proton imaging emphasizes free water and free fat protons. Even though the actual concentration of protons is similar in gray and white matter, gray matter contains about 15% more water than white (82% vs. 72%). Because the magnetic resonance system is designed to differentiate water protons from nonwater protons, there is considerably more contrast between gray and white matter in MRI than in CT when T2-weighted images are used. Lesions such as infarcts, tumors, and abscesses differ more profoundly in the quality and quantity of their water content than in their specific gravity, thus explaining the greater contrast in these lesions on MRI than on CT. Because cortical bone does not produce artifacts with MRI, the posterior fossa structures, sella, and spinal cord are easily seen. In CT, the x-ray must pass through a great deal of bone, resulting in artifacts (streaking and beam hardening). Medullary bone contains fatty and hematopoietic marrow, and these can be visualized in vivo for the first time and may open a whole new field of regional hematology.

The technologic advantage of MRI is that it can characterize and discriminate among tissues using their biochemical and physical properties. This includes water, fat, and blood and its breakdown products (hemosiderin and ferritin). The velocity of cerebrospinal fluid (CSF) and blood flow can be evaluated. Images can be obtained in three orthogonal planes, as well as obliquely, without moving the patient. Orthogonal imaging has been a boon to surgeons and radiation therapists and is also an excellent aid in learning and relearning neuroanatomy. Paramagnetic contrast agents allow for the safe demonstration of the breakdown of the blood–brain barrier. Unlike the agents used in CT, these are noniodinated and much less hazardous to the patient. Often, contrast is unnecessary in MRI; the use of these expensive agents should be tailored to each patient. MRI is safe, does not use ionizing radiation, requires little patient preparation, is noninvasive (unless contrast is used), and is accepted by all but the most claustrophobic or obese patients. It has become the diagnostic procedure of choice in almost all diseases of the brain and spine, and in many instances it is the only test necessary.

The disadvantages of MRI include the expense of purchasing, operating, and maintaining the equipment. The magnetic field will not allow the standard life-support equipment to be used. Patients with pacemakers and certain ferromagnetic and electronic devices cannot be imaged. Metal, such as clips from previous surgery, causes artifacts, which sometimes obscure the study. Previously, a relatively slow scan acquisition time resulted in motion artifact. Fast scanning, improved coils, chemical shift imaging, and other improvements used in concert have alleviated many of these problems.

SPECTROSCOPY

Particular nuclei, when exposed to an external magnetic field, resonate at a characteristic frequency. For example, a phosphorus 31 nucleus, when placed in an external magnetic field, precesses at a particular frequency, depending on where it is located on the phosphate chain of the ATP molecule. Thus, there is a frequency signature for different molecules containing the same atom. This allows for the study of the distribution and concentration of high-energy phosphate metabolites and phosphocreatine, the intracellular pH of tissue, and tissue temperature. How this will affect the clinical practice of neurology is uncertain, but it could lead to important biochemical information that will help our patients.

ANGIOGRAPHY

The development of MRI has diminished the use of angiography, especially as a screening tool for symptomatic neurology patients. Even more exciting is the development of magnetic resonance angiography (MRA), which in only a few years has become a clinically useful tool. In many instances it can replace routine angiography in the diagnosis of aneurysms, arteriovenous malformations (AVMs), carotid stenoses, dural sinus thrombosis, and other venous disorders ([Fig. 452.1](#)). Selective MRA provides information about the origin and direction of flow and circulation in collateral vessels. Flow effects can be seen in routine spin-echo imaging, including the ability to visualize aneurysms and AVMs, which will lead to further study with MRA. Carotid occlusions are often seen as a lack of flow void; this may be an indication for MRA in some stroke patients.

FIGURE 452.1. **A:** Three-dimensional time-of-flight magnetic resonance angiogram demonstrating an aneurysm at the top of the basilar artery (arrows). **B:**

Three-dimensional time-of-flight magnetic resonance angiogram demonstrating severe stenosis of the internal carotid artery (*arrow*).

DIFFUSION/PERFUSION IMAGING IN ACUTE ISCHEMIC STROKE

CT and standard T2-weighted MRI images are typically normal in the first few hours after the onset of ischemic stroke. Nonspecific changes, such as tissue swelling, arterial enhancement with contrast, or absent flow voids, may be present early. It takes 6 to 12 hours to detect the presence and extent of ischemic damage. In animal studies, diffusion weighted imaging (DWI) can visualize the ischemic changes within minutes of the stroke ([Fig. 452.2](#)). In standard MRI, the results depend on relaxation times, proton density, and flow. By adding short dephasing and rephasing current to the standard pulse sequences, the signal can be sensitized to the acquisition of molecular diffusion. In normal brains, there is an apparent diffusion coefficient (ADC) that is relatively uniform along the direction of axonal flow, but this coefficient declines rapidly in ischemic brains. The water protons have less brownian movement over time, leading to a reduction in ADC. In animal stroke models, DWI is highly predictive of ultimate infarction. When Λ -methyl-D-aspartate antagonists were given to rats 15 minutes after arterial occlusion, DWI studies performed at 30 and 180 minutes after stroke onset revealed hyperintense lesions that were 70% smaller in the treated group than in controls.

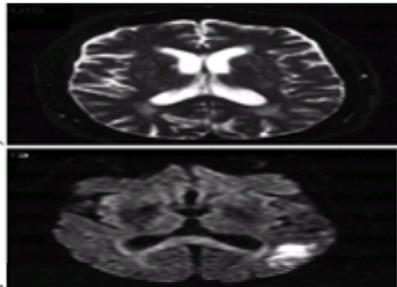

FIGURE 452.2. **A:** T2 Axial demonstrating some high signals posterior to posterior horns but no evidence of infarction in left parietal area. **B:** Diffusion-weighted study done at the same time (within 2 hours of ictus) demonstrates area of high signal in left parietal lobe, which is an area of ischemia.

Perfusion imaging is another new MRI technique that is promising in the evaluation of the acute stroke patient. The development of ultrafast scanning techniques, such as echo planar imaging and fast-gradient echo imaging, has led to the capability for scanning the entire brain in seconds, or less than a second per slice. This allows evaluation of brain microcirculation and provides quantitative information about localized changes in cerebral blood flow (CBF) and cerebral blood volume (CBV). Contrast agents, such as gadolinium, are injected intravenously. As the agent travels through the brain, it interferes with the acquisition of signal intensity in normally perfused brain tissue; ischemic brain tissue has less reduction of signal. Relative CBV can be calculated by evaluating signal intensity changes over time, and an index of CBF can be derived by dividing the relative CBF by vascular transit time. Perfusion imaging should provide easy and quick measurement of impaired CBF in stroke patients.

POSITRON EMISSION TOMOGRAPHY

Positron emission tomography (PET) is a complex, expensive method of brain imaging that depicts physiologic processes. It can supply information about oxygen and glucose metabolic rates, local CBF, blood volume, and oxygen extractions. The three-dimensional images provide real physiologic data regarding brain function. The combination of physical and chemical properties of positron-labeled compounds allows for quantifiable imaging.

Single photon emission computed tomography (SPECT) has recently been introduced. A flow tracer is tagged with a radionuclide and injected into the patient. A three-dimensional image of the distribution of the radionuclide is obtained using a gamma camera and CT techniques. SPECT may be able to predict the likelihood of an early stroke after a transient ischemic attack and can separate lacunar from cortical stroke. It also can differentiate ischemia from epilepsy as the cause of a neurologic symptom: ischemia causes an area of hypoperfusion on SPECT, but epileptic phenomena are often manifested by hyperperfusion.

ULTRASONOGRAPHY

The most important neurologic use of ultrasonography is in stroke. Eighty-five percent of strokes are ischemic, and it is here that ultrasonography plays an important role. At least half of ischemic strokes occur in large vessels, mostly the carotid artery. CT and MRI readily diagnose hemorrhagic strokes but often do not identify the blockage site in the large vessels. Ultrasonography is a noninvasive, accurate, quick, and relatively cost-effective way to visualize the vascular system and identify the cause of ischemic stroke. Recent studies confirm that tight carotid stenoses (greater than 70%) have better outcomes with carotid endarterectomy and medical therapy than with medical therapy alone. Ultrasonography is an effective way to identify these patients, who then may have angiography to identify these lesions further. In some centers, ultrasonography and MRA may suffice, although many surgeons are still reluctant to operate without contrast angiography. Ideally, this will not be the case as MRA becomes more widely accepted and improved.

Using duplex sonography, high-resolution B-mode gray-scale images of the vessels can be obtained and selective image-guided Doppler sampling performed. Blood flow velocities can be calculated. This technique should reach 90% to 95% sensitivity and more than 90% specificity for identifying significant carotid stenosis. Color flow imaging provides anatomical and hemodynamic information simultaneously. Transcranial Doppler sonography using low-frequency Doppler sonography can obtain flow velocity data from the basal cerebral arteries; this has opened a new window to the understanding of cerebral hemodynamics. Doppler techniques are allowing the detection of emboli for the first time.

CLINICAL APPLICATIONS

CEREBROVASCULAR DISEASE

The four basic goals in approaching the stroke patient are to identify the cause and mechanism of the stroke, to localize the lesion in the brain and particular blood vessel, to quantify the severity of brain damage to guide management decisions and prognosis, and to identify vascular lesions that may cause another stroke.

Often the clinical distinction among intracerebral hemorrhage, subarachnoid hemorrhage, and cerebral infarction is readily apparent, but sometimes the distinction is unclear. After a careful history and physical examination, an imaging procedure is usually necessary. In the acute bleed, CT is the best first test ([Fig. 452.3](#)). It readily demonstrates blood in any of the brain spaces, whereas the changes on MRI are subtle in the acute stage. MRI is especially weak in the diagnosis of subarachnoid hemorrhage, and CT is the imaging modality of choice. However, in the subacute and chronic stage of the hemorrhage, MRI is the test of choice and may demonstrate lesions (parenchymal and subdural) not seen on CT ([Fig. 452.4](#)). Sometimes the cause of the hemorrhage is readily seen on MRI (e.g., aneurysm, AVM, neoplasm); this guides the clinician to the next appropriate imaging study (e.g., angiography, MRA).

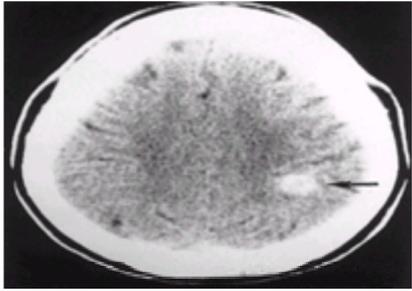

FIGURE 452.3. Computed tomographic scan demonstrating hemorrhagic contusion in the parietal lobe (*arrow*).

FIGURE 452.4. A: Acute intracerebral hemorrhage in left frontal area (TR 2128, TE 45) imaged in the first 24 hours. Hematoma (*long arrow*) is isointense to brain. The bright signal surrounding it (*short arrow*) is edema. Computed tomography (CT) showed a typical, high-density, easily diagnosed hematoma. **B:** Four weeks later, high-signal methemoglobin (*straight arrow*) is seen in the center surrounded by low-intensity hemosiderin (*curved arrow*), indicating the beginning of a more chronic phase (TR 2128, TE 90). CT at this time was isodense, and the hemorrhage was not as easily appreciated.

In the absence of hemorrhage, ischemia may be present. CT often demonstrates a hypodensity in a vascular pattern, but CT may be normal in the presence of a focal neurologic deficit; MRI may demonstrate a wedge-shaped hypointensity on the T1-weighted study and an increased signal in the same distribution on the T2-weighted study. The pattern of the lesion often identifies the offending branch, and the astute imager can often spot it. This is important because most lesions of the brain are of low intensity on T1-weighted studies and bright on T2-weighted studies. By using the clinical history and knowing the branch patterns of the major vessels, it is relatively easy to make a diagnosis or at least to establish a cogent differential.

Other features that can be identified in vascular and other lesions of the brain include surrounding edema, which may help the surgeon decide if the lesion is operable in the case of hematoma or help the neurologist determine the prognosis and medical treatment in the case of ischemic infarction. Hemorrhage may give rise to blockage of CSF pathways, leading to hydrocephalus. CT and MRI readily demonstrate this, allowing for ventricular drainage in the appropriate setting. The location of the lesion is helpful. A hemorrhage in the basal ganglia in a hypertensive patient does not require further studies. A lobar hemorrhage may be due to an AVM and requires angiography. A subarachnoid hemorrhage always requires angiography to identify aneurysms, the most likely source. MRI is superior to CT in the diagnosis of cavernous angiomas, AVMs, and tumors. The presence of other lesions, such as hemosiderin-lined cavities, suggests previous small bleeds, as in hypertensive patients, cocaine addicts, and patients with amyloid angiopathy. The latter would be particularly suspected in the presence of lobar hemorrhages in an elderly patient.

In most ischemic stroke patients, CT and, more often, MRI serve well as the first imaging study. Ultrasonography is often extremely helpful in illuminating the pathophysiology of the ischemic stroke. More complex studies, such as PET and diffusion/perfusion imaging, are not widely available but can be helpful. SPECT is more commonly available and, as mentioned previously, can be quite helpful in the stroke patient.

INTRACRANIAL NEOPLASMS

Of all the imaging modalities, MRI is the best single test in the diagnosis of brain tumor. Multiplanar techniques allow the exact location to be pinpointed. Features of common tumors on MRI have become widely recognized, as have the specific appearances of uncommon tumors. A safe contrast agent (gadolinium) makes possible the distinction between tumor and edema, which is so important to the surgeon in deciding where to biopsy the lesion. The T1-weighted sequence is exquisite for anatomy, and the T2-weighted image readily demonstrates the bright signal of increased water in the lesion. CT may be normal in a tumor and MRI abnormal ([Fig. 452.5](#)). Even with the use of contrast, there are differences: more metastases are seen with MRI than with CT, especially using a triple dose. If a patient has one metastasis on contrast-enhanced CT, contrast-enhanced MRI may demonstrate more than one lesion, thus completely changing the treatment and the prognosis. CT is a useful adjunct for identifying tumoral calcification.

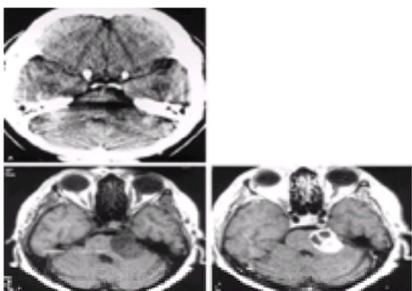

FIGURE 452.5. A: Computed tomographic scan originally read as normal in a patient with left-sided neurosensory hearing loss. In retrospect, low density is noted in the left cerebellopontine angle (*arrow*), along with much beam hardening artifact. **B:** T1-weighted axial magnetic resonance image in the same patient. Note the low-intensity large lesion in the left cerebellopontine angle compressing the fourth ventricle (*arrow*). This is much more obvious than on the scan, which also showed compression of the fourth ventricle. **C:** Enhanced T1-weighted magnetic resonance image demonstrating large enhancing lesion with two cysts. Enhancement of the eighth nerve complex confirms that this is a large acoustic neuroma.

Establishing whether a tumor is in the extra-axial or intra-axial space narrows the differential. A meningioma, the typical extra-axial lesion, has a sharp border, with a cleft of CSF between the tumor and brain. It may also cause inward displacement of the brain surface with compression of the white matter layers, the "buckled white matter sign." These findings may all be seen on the initial T1-weighted study. The suggestion of a meningioma should lead to contrast enhancement because small meningiomas may blend into the parenchyma, and many may not be bright on the T2-weighted study, as most other tumors are.

The signal intensity within the same tumor can vary, depending on cystic changes, hemorrhage, necrosis, calcification, fat, and vascularity. Several pulse sequences are necessary for qualitative analysis of signal intensity, including T1- and T2-weighted studies, proton density, and contrast-enhanced T1-weighted studies. Gradient

echo (T2*;) may identify calcium or hemosiderin not seen on routine spin-echo studies, especially in midfield magnets. It is often possible to infer the degree of malignancy in the contrast-enhanced scan because of more enhancement and other certain patterns. In CT, the iodine is made directly visible by attenuating the x-ray beam; paramagnetic contrast agents of MRI are made indirectly visible by diffusing to the extracellular space, where they enhance the relaxation rates of nearby water protons. In many cases, MRI with contrast is the only study necessary for the neurosurgeon to proceed with removal or biopsy ([Fig. 452.6](#)).

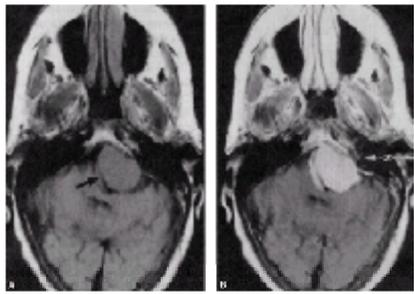

FIGURE 452.6. **A:** Axial T1-weighted magnetic resonance image in a patient with normal hearing demonstrating a large cerebellopontine angle lesion (*arrow*). **B:** Post-gadolinium T1 study on the same patient demonstrates that the eighth nerve complex (*arrow*) does not enhance, which confirms that this is a meningioma rather than an acoustic neuroma.

INTRACRANIAL INFECTION

CT and MRI demonstrate the gross neuropathologic process of infection of the brain and meninges, but neither is specific for any one disease. Multiple enhancing rings may be due to bacterial or nonbacterial infections or other pathologies, such as metastases, multiple sclerosis (MS), and contusions. As usual, the history and the associated symptoms direct the imager and the clinician to the correct diagnosis. The association of fever, travel in locations endemic to brain infections, and the location of the lesions is helpful. An example of the latter is a lesion in the temporal lobe with fever, headache, altered consciousness, and focal seizures, which should cause the clinician to consider herpes simplex encephalitis as the most likely diagnosis ([Fig. 452.7](#)). MRI is more sensitive than CT in revealing temporal and frontal lobe involvement. In the acute phase, MRI demonstrates swelling and edema, which is of low intensity on T1-weighted images and bright on T2-weighted images. When gadolinium is used, there is pial and cortical enhancement. If available, postcontrast T1-weighted images should be made with magnetization transfer, which improves contrast. In the late stages, tissue loss and brain necrosis are seen.

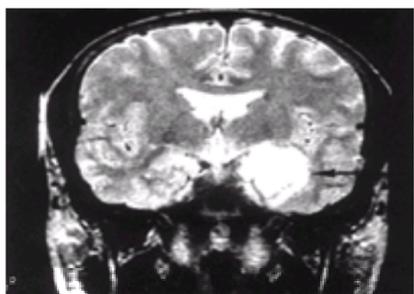

FIGURE 452.7. T2-weighted coronal magnetic resonance image demonstrating herpes simplex encephalitis in the left temporal lobe (*arrow*).

Neurologic involvement occurs in over 80% of patients with AIDS, and autopsy reveals an even higher frequency of CNS involvement in this disorder (90% or more). The illnesses may be the direct result of CNS involvement, such as AIDS dementia complex or HIV-associated myelopathy. They also may be related to immunosuppression, e.g., infections such as cerebral toxoplasmosis ([Fig. 452.8](#)) and cryptococcosis, or primary and metastatic neoplasm. Neuroimaging is essential in determining whether there is a focal mass lesion. The most common causes of intracranial mass lesions in HIV infection are toxoplasmosis and lymphoma, in that order of frequency. These patients may have subarachnoid or ventricular blockage. Cardiac-gated cine-flow MRI, which uses gradient-recalled images in various portions of the cardiac cycle, may yield important information about the location of the blockage and the direction of CSF flow. The most common cause of nonmass lesions in this setting is progressive multifocal leukoencephalopathy. This opportunistic infection is caused by the JC virus and is seen in 5% of AIDS patients. Nonenhancing lesions in the parieto-occipital and frontal white matter are present without mass effect. Serial CT or MRI shows a progressive increase in the size and number of lesions, with the focal lesions becoming diffuse and confluent. HIV encephalopathy shows nonspecific atrophy with widening of the fissures and cisterns. Periventricular white matter lesions are also seen. A young or middle-aged patient with a positive history of intravenous drug use or other dangerous behaviors with dementia and atrophy of the brain should be considered as a possible HIV suspect, and proper investigations should follow.

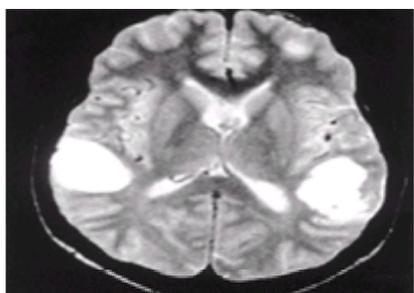

FIGURE 452.8. T2-weighted study in a young man with AIDS. The two high-signal lesions on either side represent toxoplasmosis.

MULTIPLE SCLEROSIS

There are about 300,000 to 500,000 MS patients in the United States, and about 200 new cases are diagnosed each week. CT occasionally demonstrates the typical distribution of lesions with dissemination in space, and enhancement patterns may indicate dissemination in time, but MRI has replaced CT in the diagnosis of MS. MRI has provided a quantum leap in the diagnosis of MS because of its exquisite sensitivity to the changes in water content of MS plaques. MRI may detect MS plaques at early stages, when the disease is often missed by other techniques. MRI has shown that MS is an evolving process in which lesions come and go; no other technique has been as successful in demonstrating this phenomenon. With the use of the latest equipment, MS plaques can be identified in 87% to 95% of cases; in the best hands, CT has been positive in 36% to 44% of cases.

The lesions are dark or isointense on T1-weighted images and bright on proton density and T2-weighted studies. Proton density can be especially helpful because

the CSF is gray and the plaques are bright, so there is less difficulty in differentiating one from the other. The lesions are either discrete or confluent. The former are focal, oval or round, and are located near the anterior or posterior horns of the ventricles; they may extend up to the subconvexity area. Confluent lesions are larger and cap the posterior horn of the ventricles with undulating borders. Unlike vascular lesions, MS often involves the corpus callosum and should be considered in all lesions of that structure, especially in the appropriate clinical setting. Lesions are often seen in the cerebellum, especially the peduncles and the brain stem. As with most diseases, the pathologic lesion is best demonstrated on the more T2-weighted studies. One common pattern is the ovoid lesion at right angle to the ventricles, which may be seen in up to 86% of MS patients ([Fig. 452.9](#)).

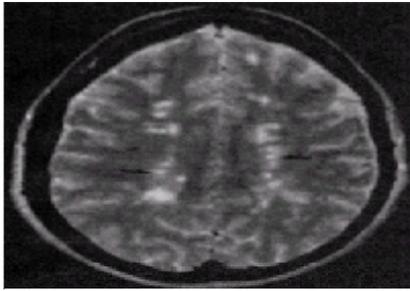

FIGURE 452.9. T2-weighted axial view in a young woman with multiple sclerosis. Note the high signals in a periventricular distribution horizontal to the ventricles (arrows).

The breakdown of the blood–brain barrier in the MS lesion allows for enhancement with contrast on both CT and MRI. It is usually unnecessary to enhance these lesions unless using a research protocol. In a young female patient whose lesions are clinically disseminated in time and space, and who has a positive MRI with typical horizontal lesions, there is rarely any need to proceed further with other studies (e.g., CSF, evoked potentials). However, these studies should be used when the evidence is not so clear.

What is the relation between an isolated attack of optic neuritis and possible future development of MS? In 31 studies involving optic neuritis followed for variable periods of time, 13% to 85% of patients developed clinical MS. One study found that 48% (23 of 48) of patients with optic neuritis had silent lesions of MS in the white matter. After 5 years, 19% had developed definite clinical MS. Two-thirds of the converting patients had abnormal MRIs, and one-third had normal studies. The authors concluded that an abnormal MRI did not necessarily predict future clinical MS. It is wise not to diagnose MS in the optic neuritis patient, even with an abnormal MRI, unless other clinical symptoms develop. Lesions may be seen in the optic nerve itself if thin T1-weighted sections are used with and without contrast. Lesions of the spinal cord are also seen occasionally. A young patient with a myelopathy and a bright intramedullary lesion of the cord on T2-weighted images (especially at C2) should have a brain MRI; if it is positive, no further studies are necessary.

DEVELOPMENTAL DISEASES OF THE NERVOUS SYSTEM

Because of its lack of ionizing radiation, its capacity to image in multiple planes, its capacity to demonstrate CSF dynamics, and its capacity to show myelination (allowing for the study of brain maturation), MRI is easily the procedure of choice in this area, which affects primarily infants and children. Sedation with close observation is mandatory; a nurse or anesthesiologist must monitor the patient before, during, and after the study when sedation is used.

The lack of myelination and the high water content of the brain in the infant and young child require different sequences in the performance of MRI. For unknown reasons, infarction in infants may be of lower signal intensity in the T2-weighted study, unlike that in older patients. Various insults to the brain, such as trauma, infection, ischemia, systemic disorders, chemotherapy, or radiation therapy, may cause delays in myelination. The latter is a dynamic process that begins before birth and is almost complete by age 24 months. MRI is unique in demonstrating these changes.

The T1-weighted sagittal view can make visible the entire nervous system of an infant or small child, and often demonstrates congenital anomalies in patients with developmental delays. Failure of neural tube closure (e.g., Chiari I and II malformations) is easily diagnosed. Sometimes patients with Chiari I malformations are referred to neurology clinics with the diagnosis of MS. In the past, myelography was necessary to identify this entity, but the use of myelography has dropped by as much as 80% in most neurology centers.

EPILEPSY

Epilepsy may be divided into idiopathic and symptomatic forms of the disease. In the latter, structural abnormalities are found and imaging is most helpful. Functional imaging is of academic interest in idiopathic epilepsy (e.g., CBF, receptor binding, and metabolism).

The common causes of symptomatic epilepsy include scars, atrophic lesions, tumors, vascular anomalies, cortical dysplasias, and stroke. In patients presenting with seizures due to a tumor, the symptoms are often indolent and the neurologic examination may be normal. MRI can detect tumors with a bright signal on a T2-weighted study when a contrast-enhanced CT is normal. Therefore, MRI should be done on all patients with symptomatic epilepsy. Performance of CT in addition is rarely needed, other than to make visible bone or calcifications (e.g., meningioma).

CT and, more recently, MRI are extremely useful in the surgical placement of intracranial electrodes and in stereotactic removal of the epileptogenic lesion. PET with ¹⁸F-fluorodeoxyglucose (FDG) is helpful in choosing patients for surgical removal of epileptogenic foci. Interictal unilateral temporal lobe hypometabolism may predict a good result after such surgery. During partial seizures, increased FDG uptake is present because of an increase in energy requirements. Neuroreceptor binding using PET can be useful in demonstrating neuronal loss in brain areas where there is diminished benzodiazepine binding.

In the presence of an equivocal electroencephalogram (EEG), SPECT perfusion scanning may be a less expensive method of determining whether a behavior is epileptic. SPECT and PET add important cognitive and behavioral information to the anatomical and structural information provided by MRI and CT. CT is often obscured by bony artifact in the middle fossa. Tumors presenting as a first seizure typically have no mass effect or edema. The use of contrast does not increase the detection of tumors in epilepsy because they usually are more benign lesions that do not precipitate a breakdown in the blood–brain barrier. Dysplasia, heterotopias, gyral malformations, abnormal clefts (schizencephaly), and migrational anomalies all may cause epilepsy and are readily made visible by MRI. Surgical removal of some of these abnormalities, including tumor, has been greatly enhanced by the use of MRI. Coronal MRI is very helpful in demonstrating focal atrophy in the hippocampus in 70% to 90% of patients with temporal lobe epilepsy.

AGING AND DEMENTIA

The new imaging techniques are useful in the study of brain development, maturation, and myelination, and these procedures are also of use in elderly patients. A primary difficulty is distinguishing a normal old person's scan from a demented person's scan. In both, atrophy is seen, and often it is impossible to make this distinction with routine CT or MRI. The most common—and therefore the most important—dementing illness is Alzheimer's disease. Using special angled cuts, the temporal horn and choroidal–hippocampal fissure can be imaged in a single slice and temporal lobe atrophy can be identified. The absence of temporal lobe atrophy differentiated normal from Alzheimer's patients with a specificity of up to 95% in one study. In another study, hippocampal lucency, probably related to widening of the choroidal fissures, correctly distinguished 80% of Alzheimer's and elderly control patients.

MRI allows the visualization of the temporal lobe with even greater clarity, especially in the coronal view. It has added a new phenomenon, the white matter hyperintensities (WMHs) or “unidentified bright objects” seen so often in normal persons, even in the early decades. WMHs have a definite association with increasing age, vascular risk factors (especially hypertension), and the presence of dementia, either degenerative or (especially) vascular. In one study of 101 normal controls age 31 to 84 years, WMHs were demonstrated in 48% and periventricular hyperintensities (PVHs) in 45%. The WMHs were small and discrete; the PVHs were caps at the ventricular apices or smooth, bright, thin lines around the ventricles. Subjects with risk factors (hypertension, diabetes, heart disease, or age greater

than 60 years) had more WMHs and PVHs. According to this study, the prevalence for WMHs and PVHs by decade is about 20% for the fourth decade, 30% for the fifth decade, 50% for the sixth decade, 60% for the seventh decade, and 70% for those older than 70 years. However, many persons with extensive WMHs have relatively subtle cognitive impairment and may have an otherwise completely normal neurologic examination.

The same researchers also studied the postmortem brain on six patients without clinically significant dementia or cerebrovascular disease who had WMHs incidentally on premortem MRI. They saw an abnormality in only one brain with visual observation. Histologic examination revealed areas of decreased myelination with thinned neuropil around fibrohyalinotic arteries. They speculated that this represented minor perivascular ischemia but not complete infarction as the most likely cause of WMHs.

PET studies suggest that regional metabolic interactions, especially between frontal and parietal association areas, become less tightly linked with normal aging. A decline in frontal metabolism is probably a feature of "usual" aging that corresponds with deterioration of frontal lobe executive functions with age.

Treatable disease (e.g., tumor, subdural hematoma, hydrocephalus, metabolic disease) can be found in only about 15% to 20% of demented patients. Once these diseases are excluded, one is left with either Alzheimer's or multi-infarct dementia in most of the rest. The following guidelines, proposed by Chawluk and associates, are clinically useful:

1. Mild to moderate PVHs on MRI may be seen in normal elderly persons as well as in patients with Alzheimer's or multi-infarct dementia; thus, this is usually not a helpful finding.
2. Scattered small subcortical hyperintensities may be seen in normal persons or demented patients, and are also generally not useful.
3. In patients 65 years or younger, the presence of medial temporal lobe atrophy, especially in the absence of prominent WMHs, strongly supports the diagnosis of Alzheimer's disease.
4. Extensive subcortical (white matter or deep gray nuclei, but no periventricular) high-signal abnormality, in conjunction with a positive Hachinski's ischemia score, suggests multi-infarct dementia.
5. The diagnosis of multi-infarct dementia is more likely if multiple cortical infarcts are seen or if CT demonstrates prominent subcortical lucencies.
6. In patients over age 65 years, the presence of medial temporal lobe atrophy does not necessarily indicate Alzheimer's, nor does the presence of moderate WMHs imply multi-infarct dementia.
7. The diagnosis of vascular dementia does not rule out coexistent Alzheimer's disease.

DISEASES OF THE SPINE

In most centers, the frequency of spine imaging has surpassed that of brain imaging, primarily because of the enormous numbers of persons with back pain. In Britain, every year 2 million adults consult their physicians for back pain, accounting for 6.5% of all visits to the general practitioner. In Britain, more than 19 million working days per year are lost due to back pain, with nearly 1 in 50 persons losing time from work.

One of the major challenges of any imaging modality is to ascertain whether the abnormality seen is causing the clinical symptoms. MRI, more than any other imaging modality to date, reveals "lesions" that are not producing symptoms. Astute clinical evaluation is necessary to decide whether a bright signal or an abnormal structure is of any clinical importance. More than ever, clinicians must be involved in this area to add important clinical input. There have been reports of asymptomatic lumbar disc herniations in patients who have had myelography for cervical problems; more recently, studies of large numbers of asymptomatic persons have revealed the incidence of disc herniations to be as high as 28%, with higher numbers of bulges and disc desiccation, all of which increase with age. Clinical judgment should be the major factor in determining whether or not surgery should be performed; a patient with an L2 radiculopathy should not have an L5–S1 disc removed "just because it is there" (Fig. 452.10).

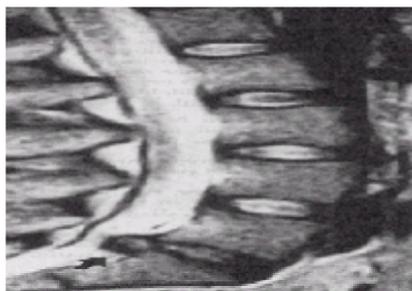

FIGURE 452.10. T2-weighted sagittal magnetic resonance image demonstrating a large disc herniation at L5–S1 (arrow).

Where high-resolution MRI of the spine is in daily use it is accepted as the diagnostic imaging modality of choice and has replaced other modalities, including myelography, CT, and plain-film radiography. The latter two are still useful in bony diseases and fractures and when the MRI is not diagnostic. In centers where the imagers have earned the trust of the surgeons, spine and cord lesions are removed without invasive myelography with all its discomfort and expense. When a patient with sciatica undergoes plain-film radiography, CT, MRI, electromyography, and, occasionally, evoked potentials followed by myelography, there is a lack of clinical astuteness or worse. Quality standards and practice guidelines should address and correct this.

The argument over field strength is fading as improved software makes low- and midfield imaging quite acceptable. Managed care does not allow every center to have the most expensive equipment when less expensive technology is adequate. The addition of surface coil imaging increases the signal-to-noise ratio by threefold to fivefold, and this one advance has conferred to spine MRI its current effectiveness. Fast scanning and phase-arrayed coils allow quick and excellent visualization of the entire spine, even in difficult patients. In some cases, tumor patients are being diagnosed and treated with radiation, without a costly hospital stay and all the attendant risks of intrathecal dye and excessive radiation.

MRI is superior to myelography and CT because of the following:

1. The ability to scan in the sagittal plane directly without reformatting
2. High sensitivity to pathologic lesions
3. Excellent tissue contrast, which allows separation of CSF, spinal cord, bone, discs, and other soft tissues
4. The potential for tissue characterization (e.g., blood, fat)
5. Significant additional information with the use of gadolinium

NERVOUS SYSTEM TRAUMA—HEAD INJURY

Before the advent of MRI, neuroradiologic evaluation sometimes failed to demonstrate pathologic processes in head trauma because conventional imaging techniques—based on interfaces and differences in tissue densities—could not provide adequate resolution and definition, particularly in small subdural hematomas and cerebral contusions. MRI has demonstrated the focal cortical lesions that provide the substrate for acute post-traumatic psychosis. The lack of association between these symptoms and the presumed subfrontal and temporal contusions is a known limitation of CT scanning.

CT and MRI both can detect hemorrhagic lesions. CT is best for acute hemorrhages; MRI is more sensitive in subacute or chronic hemorrhages, or nonhemorrhagic lesions such as cortical contusions and diffuse axonal injury. The latter two constitute 91.9% of all traumatic intra-axial lesions. MRI is also more sensitive in detecting brain stem injuries because of the lack of artifact in the posterior fossa that so often obscures the CT scan. As in other diseases, bony abnormalities, such as fractures, are better seen on CT. The advantage of CT in the rapid assessment of unstable patients who may need surgery is widely accepted.

SPINAL TRAUMA

Each year there are about 10,000 new cases of traumatic spinal cord injury. Plain films, tomography, CT, and myelography provide only indirect evidence of spinal cord injury (such as fractures with bony fragments), overall cord size and configuration, and patency of the subarachnoid space. MRI can directly image hemorrhage, edema, syrinx, and all other sequelae of spinal cord trauma. This information, along with observations from the neurologic examination, determines the initial management (medical or surgical) that will determine the ultimate outcome. The presence of cord edema and swelling correlates well with more severe deficits. As the severity of the deficit increases, the underlying cord contusion is likely to be larger and rendered more easily visible by MRI.

CHAPTER 453: SEROLOGIC AND MOLECULAR GENETIC DIAGNOSES

RUSSEL MARGOLIS AND CHRISTOPHER ROSS

The molecular genetic revolution is transforming our understanding of the classification and the pathogenesis of neurologic disorders. Disorders such as Alzheimer's disease (AD) and Parkinson's disease (PD), which were once thought to be almost entirely sporadic and hence nongenetic, are now known to have subtypes caused by distinct and readily detectable genetic mutations. Specific genetic diagnoses are now possible in a majority of familial spinocerebellar ataxias, ending a century of nosologic confusion. In concert with these advances in diagnosis, molecular genetics has provided numerous clues about the pathogenesis of various neurologic disorders. For instance, at least eight neurodegenerative diseases are caused by a mutation in which the number of CAG repeats in a gene becomes excessive. This repeat expansion is translated into a protein containing an excessively long stretch of consecutive glutamine residues, resulting in abnormal aggregates of the protein accumulating in the neurons of affected individuals. Other neurodegenerative diseases result from abnormalities in a group of proteins, including the amyloid precursor protein alpha synuclein and the microtubule-associated protein tau, which have provided a focus for studies of neuronal injury and death. The puzzling episodic nature of several disorders has become clarified by the discovery of causative mutations in genes encoding ion channels. Here we emphasize the unique issues that arise in genetic testing for neurologic disorders and some of the more widely available genetic tests for specific disorders. We also describe in brief the few serologic tests (excluding those for infectious agents) that may be of clinical value.

Despite the remarkable advances of the last decade, genetic tests provide a definitive diagnosis for a minority of patients with neurologic conditions. For the more common diseases, particularly AD and PD, the known genes account for a very small percentage of the total cases. In addition, genetic testing is expensive and can be misleading if used indiscriminately. Therefore, the major issue is determining the proper indications for obtaining a given genetic test. As a general rule, genetic testing tends to be most useful for patients with a known family history of a similar disorder or for patients with an usually early onset of a normally late-onset disease. On occasion, genetic testing may be helpful in a seemingly sporadic case of common disorder, particularly when the family history is not known or the presentation of the disease is unusual. As genetic variants that constitute risk factors for the late-onset disorders are uncovered, the indications for obtaining genetic tests will likely broaden.

A distinguishing feature of genetic testing is that the results have implications not just for the patient but for other family members as well. The determination that one family member has a genetic disease, particularly if it is a rare disease, implies that other family members with similar signs and symptoms also have that disease. This "diagnosis by proxy" is almost unavoidable, and the information may be viewed by symptomatic but untested family members in many ways. Some family members may regard knowing the "family diagnosis" with great relief; other may be indifferent; and for others, the news may be taken as a devastating invasion of their personal autonomy. Genetic counseling prior to genetic testing is essential in helping members of a family to resolve these issues.

The issues become more complex when a member of a family requests a presymptomatic genetic test (a test performed before the patient has developed any manifestations of the disease). The problem has been termed the "Tiresias complex" by Nancy Wexler in regard to HD (in which it has been most studied) in recognition of the Sophoclean aphorism that "it is but sorrow to be wise when wisdom profits not." The primary concern was that learning that one was destined to develop a progressive and fatal disease would lead to severe psychological reactions. In fact, worldwide experience with presymptomatic testing for HD has demonstrated that, with appropriate counseling, most individuals cope remarkably well. The incidence of serious adverse psychological reactions in these individuals has not been substantially different than would be expected had the same individuals not had the testing. More problematic concerns relate to possible discrimination in such matters as employment and insurance. Because of the complexities of consent and the uncertain implications for the future, it is not advisable to offer presymptomatic genetic testing to minors. At present, relatively few at-risk individuals are requesting presymptomatic testing for genetic disorders, such as HD, in which only symptomatic treatment is currently available. As treatments emerge that slow or even stop the fundamental disease process, the criteria for who should receive presymptomatic genetic testing and when they should receive it may change radically. In any case, referral to a genetic counselor or genetic specialist is essential prior to obtaining presymptomatic genetic tests.

Most genetic diagnosis involves methods such as the polymerase chain reaction, DNA sequencing, restriction digest, gel electrophoresis, and Southern blotting. New technologies, such as mass spectroscopy, for obtaining results faster, more accurately, and with less expense are on the horizon. While the technology for genetic diagnosis has become increasingly sophisticated and routine, test interpretation remains complex. For instance, in the triplet-repeat expansion disorders, such as HD and most of the SCAs, there are several different interpretations of test results depending on the length of the repeat (see below). In other situations, test results can only be interpreted in the context of results from other family members. Another issue involves the number of mutations that can cause a particular disease. For some diseases, such as HD, essentially all cases are caused by a single mutation. However, other disorders, such as early-onset AD, may arise from any of a number of different mutations, each requiring a separate genetic test. Furthermore, the interpretation of negative test results is complicated by the likelihood that other mutations causing a given phenotype will be discovered in the future.

For AD, genetic testing is indicated for patients with a family history suggestive of autosomal dominant transmission and early age of disease onset. About half of these cases will be caused by mutations in the *presenilin-1* gene. Rare families have mutations in the *presenilin-2* gene or the *amyloid precursor protein (APP)* gene. However, the great majority of AD patients have late-onset disease, usually without a family history of AD. Three different versions (alleles) of the *apolipoprotein E (ApoE)* gene have been discovered, termed 2, 3, and 4. The ApoE4 allele is a risk factor for AD and appears to predispose to an earlier onset. Individuals homozygous for ApoE4 (both the maternally and the paternally inherited copies of ApoE are of the ApoE4 allele) have a significantly increased risk for developing AD. However, because the ApoE4 allele is neither necessary nor sufficient for the development of AD and because testing for ApoE only marginally increases the sensitivity and specificity of an AD diagnosis, genetic testing for ApoE is not currently recommended. Mutations causing some cases of frontotemporal dementia, another relatively common cause of late-life cognitive impairment, have been identified in the *tau* gene on chromosome 17.

PD is rather like AD in that most cases appear sporadic, but a few families exist with clear Mendelian inheritance. Mutations in alpha synuclein are responsible for disease in a small number of families of Mediterranean origin. All of these have early-onset PD with typical neurologic and neuropathologic features. An early-onset recessive form of PD has also been described caused by mutations in a gene termed *parkin*. The clinical presentation tends to be atypical, and the pathology is remarkable for the loss of neurons in the substantia nigra without Lewy bodies. It is likely that in the future genetic risk factors for more typical cases of PD will be found.

HD illustrates the complexities of interpreting tests for triplet-repeat expansion. In most cases, the result will be relatively clear. Individuals with 27 or fewer CAG triplets in the *huntingtin* gene will not develop HD, whereas individuals with 41 or more CAG triplets will develop the disease. In the affected range, longer repeat lengths tend to lead to an earlier age of disease onset. However, individuals with 36 to 40 CAG triplets may or may not develop the disease, a phenomenon referred to as incomplete penetrance. Within this range, the longer the repeat, the greater the penetrance, such that only about half of the individuals with 36 triplets will develop HD before age 65 while most, but not all, individuals with 40 triplets will develop the disease. In addition, individuals with between 28 and 35 triplets have never been known to develop HD, but repeats of this length are unstable, and in paternal transmission may expand to a length sufficient to cause disease in the subsequent generation.

Dentatorubral-pallidolucylian atrophy (DRPLA) is a disease that resembles HD but is extremely rare outside of Japan. Like HD, DRPLA is caused by a CAG repeat expansion, though in a different gene (*atrophin-1*). The expansion mutation can be readily detected with a genetic test. The rarity of the disease in North America and Europe suggests that the test should only be obtained in families with an HD-like disorder after the HD mutation has been excluded.

The mutations that cause Wilson's disease, a disorder of copper metabolism manifested most prominently in the central nervous system and liver, can in principle be diagnosed by molecular genetic tests. However, there are many different mutations which can cause Wilson's disease, and therefore tests for ceruloplasmin levels and other metabolic indexes of copper metabolism are much more useful in initial efforts to establish the diagnosis.

The diagnosis of hereditary ataxia has been greatly improved by recent advances in molecular genetics. Friedreich's ataxia, a recessive disorder and the most common form of hereditary ataxia, results from the presence of long expansions of a GAA triplet repeat in both alleles of the *frataxin* gene, or, rarely, a GAA repeat expansion in one allele and a missense mutation on the other allele. Seemingly sporadic or autosomal dominant cases of ataxia not infrequently turn out to be cases of Friedreich's ataxia in which the recessive inheritance has been obscured.

The autosomal dominant ataxias are extremely difficult to separate on clinical grounds, and correct diagnosis is only possible with the assistance of genetic tests.

There are now at least eight of these disorders for which a specific genetic test is available, and it is likely that genetic testing for other subtypes will emerge over the next few years. On occasion, it is possible to predict which mutation is present in a given family (spinocerebellar ataxia type 7, for instance, typically involves visual impairment), but the extent of overlap in the clinical presentations makes such diagnoses the exception rather than the rule. Compounding the difficulty, most of the known mutations (including all for which routine genetic testing is available) are triplet-repeat expansions, in which the clinical presentation of a given disease will vary by repeat length. SCA2 and SCA3 are the most common of these disorders, but disease prevalence varies with patient ethnic origin. As with HD, there are complexities in interpreting the results of genetic tests, since the length of the repeat associated with each disease has both normal and abnormal ranges, occasionally with intermediate zones. For SCA8, penetrance appears to be incomplete, for reasons that are not yet clear. From a genetic testing standpoint, it is a reasonable strategy to test for these diseases as a group. It is also reasonable to consider genetic testing of selected ataxia patients with no known family history of a dominant ataxia, since occasionally the family history is obscured by lack of information, early parental death, or false paternity. However, the differential of sporadic cerebellar ataxia is complex (see [Chapter 435](#)).

Episodic ataxia type 1 (EA1, intermittent ataxia with persistent myokymia) and episodic ataxia type 2 (EA2, intermittent ataxia with persistent eye movement abnormalities) are caused by mutations in ion channels. Mutations in the potassium channel gene *KCNA1* result in EA1, while mutations in *CACNA1A*, a gene encoding a subunit of a calcium channel, result in EA2. Other mutations in *CACNA1A* cause familial hemiplegic migraine and SCA6.

In rare cases, sporadic ataxia may be the result of a paraneoplastic syndrome, in which an antibody against a tumor antigen cross-reacts with a neuronal antigen, triggering a destructive cytotoxic T-cell response. In addition to cerebellar damage, other paraneoplastic syndromes include encephalomyelitis, retinal degeneration, and dysfunction of the brain stem or limbic regions. The different antineuronal antibodies associated with paraneoplastic syndromes typically are associated with specific tumors. The presence of these antibodies therefore establishes a potentially treatable cause for the neurologic disease but may also help in the diagnosis and treatment of the underlying cancer. This is particularly important because the neurologic syndrome often presents before the cancer has been discovered or even suspected. Anti-Yo, found with gynecologic neoplasms, is associated with cerebellar degeneration, as is Anti-Ri, Anti-Tr, and Anti-Ma. The latter, as well as Anti-Hu (found with small-cell lung cancer and neuroblastomas) and Anti-Ta, can be associated with dysfunction of other brain regions.

Most cases of amyotrophic lateral sclerosis (ALS) are sporadic. However, about 10% have autosomal dominant transmission. About 10% of these cases are caused by a mutation in the *superoxide dismutase-1* gene (*SOD1*). Another rare motor neuron disease, spinal and bulbar muscular atrophy, is caused by CAG repeat expansions in the *androgen receptor* gene. Since this gene is located on the X chromosome, only males are affected, and the mode of inheritance is X-linked. A mutation in the gene *DYT1* has recently been shown to cause a form of familial dystonia.

The most well-known mitochondrial diseases are maternally inherited, a consequence of the maternal transmission of mitochondrial DNA. From the standpoint of genetic testing, it is important to recognize that the syndromes caused by mutations in mitochondrial DNA tend to overlap, with clinical features reflecting both the specific mutation and the percentage of mitochondrial DNAs that contain the mutation. Neurologic manifestations may include muscle weakness, ataxia, optic atrophy, seizures, dystonia, neurogenic hearing impairments, strokelike episodes, and mental retardation. Routine genetic testing is now commercially available for six of the mitochondrial syndromes ([Table 453.1](#)).

Disorder	Gene	Testing Availability
Spinocerebellar ataxia type 1 (SCA1)	<i>ATXN1</i>	Available
Spinocerebellar ataxia type 2 (SCA2)	<i>ATXN2</i>	Available

[The Physician as Health Care Coordinator](#)

Perhaps more than any other discipline in medicine, geriatric medicine (the diagnosis and management of diseases of elderly patients) combines the best aspects of the art and science of medicine. Elderly persons typically have several chronic diseases, have lost sensory function, and have lost considerable homeostatic reserve in a number of organ systems. The result of this constellation of events is a clinical conundrum in a patient whose evaluation is difficult and time consuming and who is very susceptible to environmental or iatrogenic perturbations. The physician, therefore, must have a comprehensive understanding of a vast array of disease processes, diagnostic avenues, and therapeutic possibilities and balance these with great care in developing an optimal and dynamic care plan for each older patient. Indeed, a physician caring for an older patient must be highly selective in applying the ever expanding diagnostic and therapeutic options available in current medical practice. Only by such careful and thoughtful selection can the physician avoid contributing to the initiation and promulgation of a cascade of adverse events. For all of these reasons, the diagnosis and management of disease in older patients is an enormous intellectual challenge, requiring integration of complicated multisystem care with a clear personal knowledge of the patient and his or her family, living situation, and support network. This challenge makes caring for the elderly most rewarding and satisfying on an emotional basis. Embodied in these concepts are several principles of geriatric medicine that are fundamental in the diagnosis and management of elderly patients, and it is the purpose of this chapter to delineate these.

PRESENCE OF MULTIPLE HEALTH PROBLEMS AND DISABILITIES

An ideal goal for health care in the United States can be stated very simply: for an individual to live an active and healthy life until death occurs at the upper limit of his or her potential life span. While life expectancy increased dramatically in the United States and other developed countries during the twentieth century, improvement in health and vitality has not shown equivalent advances. In fact, national surveys now indicate that most elders develop chronic diseases and typically experience several years of physical dependency before death. These dependencies are in part related to a clustering of chronic health problems, specifically affecting the eyes, ears, nervous system, heart, blood vessels, and joints. Fried and colleagues have proposed a modal pathway of physical frailty that begins with physical impairments, such as the onset of a chronic health problem (e.g., angina pectoris from progressive atherosclerosis) or age-related change in physiologic function (e.g., decrease in oxygen consumption with exercise) (Fig. 454.1). The impairment presents with clinical signs and symptoms (e.g. shortness of breath with exertion) that may at first result in a minimal loss of function, called *preclinical disability*. As the disease progresses or additional physical impairments develop, one becomes unable to perform a physical task such as climbing stairs, termed *disability*. Multisystem disease often associated with disabilities complicates to a great extent the approach to diagnosis and management of disease in older patients. Symptoms of one problem may be accentuated or blunted by the presence of chronic diseases and disabilities, and diagnostic and therapeutic interventions often are limited because of comorbidities. In addition, certain chronic conditions, particularly gait/balance disorders and depression, are associated with significant decline in functional status in community-dwelling older persons.

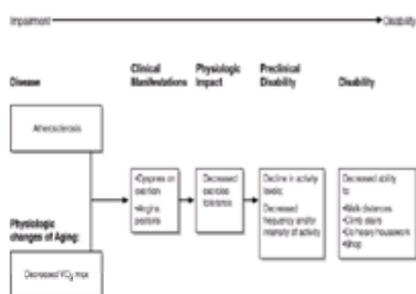

FIGURE 454.1. Model pathway of physical frailty. (From Fried LP, Kronmal RA, Newman AB, et al. Risk factors for 5-year mortality in older adults. The Cardiovascular Health Study. *JAMA* 1998;279:585–592, with permission.)

LOSS OF HOMEOSTATIC FUNCTION

Many physiologic functions deteriorate with aging alone. These physiologic losses result in the increased susceptibility of older individuals to perturbations created by disease, diagnostic undertakings, therapeutic interventions, or environmental stresses. Several examples illustrate this point. The decreases of body water and lean body mass that occur with normal aging result in a diminished volume of distribution of certain drugs, such as phenytoin, resulting in the greater likelihood of toxicity should that agent be prescribed. Drugs cleared by the liver or kidney, such as aminophylline or cimetidine, respectively, may result in higher blood levels should a standard dose be prescribed. Impaired thermoregulatory processes result in a greater risk of cold or heat injury. Impaired glucose metabolism with aging may result in hyperglycemia occurring in the setting of acute infection. These age-related homeostatic losses in organ function are an important cause of iatrogenic problems among the elderly, which are common. Also, because of these homeostatic losses, disease processes may present in complicated or atypical patterns. For example, even moderate salt and water losses such as might occur in higher environmental temperatures or as a result of acute diarrhea in the elderly often result in renal failure, delirium, stroke, or cardiac or gastrointestinal ischemia in an older person unable to withstand the perturbation because of impaired homeostasis in several organs. This results in a blurring of diagnostic pictures and requires that the physician be especially vigilant, broad thinking, and quick to recognize or anticipate impending catastrophes that could result from mild perturbation.

AGE-RELATED DISEASE: GENETIC AND ENVIRONMENTAL FACTORS

Many of the common diseases associated with aging, such as diabetes mellitus, certain cancers, and osteoarthritis have both genetic and environmental factors that contribute to their development. The genetic influences are thought to be polygenic, in contrast to the inherited diseases that manifest in childhood and young adulthood that result from single-gene defects, such as sickle cell anemia. For example, mutations in several genes coding for b-adrenergic receptors and proteins that regulate glucose metabolism are linked to the development of obesity and type II diabetes mellitus. Similarly, the environmental factors that contribute to the diseases of aging are also multifactorial and include both under- and overnutrition, sedentary lifestyle, tobacco use or exposure, alcohol consumption, radiation from the sun, or environmental pollution. Given the contributions of unhealthy behaviors to the development of the diseases of aging, the successful clinician's treatment plan must address the contributing behaviors and environmental factors.

ATYPICAL DISEASE

In the elderly, especially those who are frail, the loss of homeostatic function in the presence of multiple chronic diseases and disabilities modifies the presentation of an illness, which may appear quite atypically from that same illness in a younger individual. This complicates the approach to the diagnosis of disease in the elderly

and should sensitize and humble the clinician who is approaching the patient with a nonspecific change to the subtleties of this diagnostic challenge. For example, urosepsis may typically present as a deterioration of cognitive function without localizing signs and sometimes without even fever. Also, the pain response is typically blunted. The elderly patient with an acute myocardial infarction may manifest only breathlessness or a change in cognitive function without associated chest pain. Similarly, an acute abdominal crisis, such as appendicitis or diverticulitis, may present with a subtle observation by a relative or health professional of discomfort or change in mental status of the patient. Frequently, abdominal pain or typical gastrointestinal symptoms may be absent in such a patient. These warnings by observers, especially those who are intimately and regularly involved in the support of a frail elder, should be taken seriously by the clinician, just as a mother's observations regarding her child are always carefully considered by an astute pediatrician. A careful examination whenever there has been an indication of a change in status should focus on problems that are common and often "atypical" in presentation in the elderly, such as urinary tract infection, pneumonia, abdominal crisis, or drug toxicity.

Even when the clinician finds no clear diagnosis to account for a patient's symptoms, careful ongoing surveillance is mandatory. Serial observation is indeed the clinician's most valuable diagnostic tool. Waiting, watching, and worrying is a valuable diagnostic approach used by experienced geriatricians when an older person presents in a non-diagnostic manner. Often it is the frail homebound elder or nursing home patient who provides the most treacherous of diagnostic situations. Frequent telephone contact is especially important for such individuals. Information obtained in such subsequent contacts over time often provides the clue to the emerging problem or assurance that there is no serious underlying disorder. It is important for a physician to initiate such follow-up contacts. Most often patients or their caretakers after seeing a physician will assume that any serious illness has been ruled out and try not to be a burden by telephoning repeatedly. Further, the physician initiating the phone call demonstrates a great interest in the patient that leads to a better level of trust and communication between patient/caregiver and physician.

THE NARROW LIMIT OF THERAPEUTIC AND DIAGNOSTIC TOLERANCE

Part of the enormous challenge in providing health care to elders is the narrowing of diagnostic and therapeutic tolerance resulting from losses of homeostatic function and the presence of multiple diseases and disabilities. Quite simply, there is much less room for mistakes in judgment when caring for elderly patients than for younger individuals. In the elderly, a diagnostic test for one problem may adversely affect the overall function of a patient because of these losses. For example, dehydration and discomfort resulting from a bowel preparation initiated for colonoscopy may promptly result in reduced renal function, deterioration of mental function, and/or initiation of cardiac ischemia. Likewise a useful therapeutic agent for one problem may have a negative effect on another. For example, cimetidine administered appropriately for a duodenal ulcer may result in marked worsening of cognitive function in a minimally demented elder. A clinician who is caring for a frail elderly patient needs to be constantly vigilant for a variety of acute problems presenting in atypical fashion and alert to the confounding effect of chronic diseases, disabilities, and loss of homeostatic function. Failure to do this may result in misdiagnoses and, often, significant iatrogenic sequelae.

The diagnosis and management of disease in elderly patients typically is a much more time-consuming process than that in most younger patients. This is so because of the multiple problems characteristic of most frail elderly patients, including their loss of mobility and sensory function. Therefore, the clinician caring for elderly patients must make adjustments in practice to provide thorough and appropriate care. In the current reimbursement climate, this requires relative financial sacrifices because the payment by Medicare for the service provided is often comparatively low, given the relatively great amount of professional time required. Nevertheless, nonfinancial rewards may be greater in providing comprehensive, coordinated, compassionate care to the elderly, who are typically highly grateful. That to many physicians more than compensates for time expended. Finally, especially in geriatric medicine, physician extenders, such as physician's assistants, nurse practitioners, and nurse clinicians, effectively leverage the physician's effort to provide appropriate care to medically complex elders and allow increased time to provide patient and family education and counsel.

THE CONCEPT OF SMALL THERAPEUTIC GAINS

Because of the presence of chronic disease states and disabilities in elderly patients, cure is often not the goal; rather, the preservation or restoration of function is the aim. The physician who does not appreciate this fact will be frustrated by the establishment of unrealistic therapeutic goals. For a patient with a new and disabling problem, even the slightest improvement may be significant. For example, a patient who has had a stroke can improve his or her functional ability significantly if he or she can learn to transfer from a bed to a chair or from a chair to a toilet. Similarly, regaining the ability to self-feed or use a telephone permits the disabled person to function much more independently in a wider variety of environments, including the home. A patient impaired from propelling a wheel chair because of a minor episode of bursitis may become totally dependent from what otherwise might be considered a trivial problem. Also, an individual who is incapacitated socially because of urinary incontinence can achieve a very acceptable level of socialization by even partial control of the incontinent episodes. Similarly, the primary caregiver who is attentive to the adequate control of pain can improve the quality of life of elders with chronic disease or those who are facing the end of life.

Therefore, the physician must work with the patient and other health providers and caregivers to establish and achieve reasonable goals and, indeed, small therapeutic gains often are appreciated far more by elderly than by younger patients. In elderly patients small gains may yield major increases in self-worth and independence as they decrease the patient's personal and environmental support care requirements.

PREVENTION AND SAFETY

Preventive health care practices in medicine may be applied even to the oldest of the old and the younger elderly who may be frail. This includes attention to such vaccinations as influenza and *Streptococcus pneumoniae*, which have been shown to reduce mortality in the elderly. Also, there are now data to support the prescription of physical exercise to improve function, reverse age-related conditions such as diabetes and cardiovascular disease, and reduce pain in osteoarthritis even in the very old. Therefore, in the management of frail patients much can be done to diminish the risks of catastrophe, disease burden, and disability through timely and effective preventive strategies.

Preventive medicine for the elderly includes assessment of an individual's safety in the current living arrangement. Important safety risks are usually self-evident during a home assessment but are often difficult to elicit from a patient or caregiver during an office or hospital visit. Poor lighting, loose throw rugs, absence of handrails, and stairs in poor repair are typical examples of environmental factors that increase the risk of falling and injury. Solutions to some of these problems are simple, such as removing the throw rugs or using brighter light bulbs and night lights. The solution to others, such as installing handrails, may require a contractor. The physician or professionals working with the physician should be aware of the increasing number of home-repair services specifically focused on the health care needs of the elderly. A telephone call to the area agency on aging will help the physician identify such local resources. In the absence of such a service and where an elderly patient has no local family, the physician may want to provide the name of several reliable contractors.

An excellent communication system is vital for the security and safety of a fragile elder living at home. A workable, easily accessible telephone system, usually with extensions in several rooms, is advisable. There should be good lighting in the area of the telephone so that the patient can use the telephone effectively at night. Ideally the patient should have an automated instrument that will dial specified numbers with the press of a single button. Increasingly available in many communities are automated communication systems whereby a patient can contact a central monitoring service, which can respond by phone or send help if necessary. Such systems are offered by many hospitals, as well as government and community agencies that deal with the elderly.

Frequent visitors to an isolated elderly person are also important resources in the stabilization of and communication with a patient in his or her own home. Thus, the creation of an observer network should be part of the physician's plan to manage the homebound elderly patient. For the patient who requires skilled nursing care, a home health care agency may provide regular surveillance. Governmental programs may also be a resource for persons who qualify for state medical assistance. Many communities have a wide variety of well-developed resources that are available to help the elderly and their caregivers ([Table 454.1](#)). Examples are home-delivered meals, home repair and maintenance services, and domestic assistants supplied by agencies of the city, county, and state government as well as by many private voluntary and church organizations. The combination of resources available in each community is specific to that locale. The physician needs to be aware of these local resources; such knowledge can be gained by contacting the city, county, or state health department; a regional office on aging; or the department of social work at a local hospital. In addition, willing neighbors and friends may be crucial to provide support for the patient at home. Identification of these individuals by the physician is important when no local family is available or willing to provide surveillance.

TABLE 454.1. COMMUNITY RESOURCES FOR THE ELDERLY

ADVANCE DIRECTIVES (SEE CHAPTER 473)

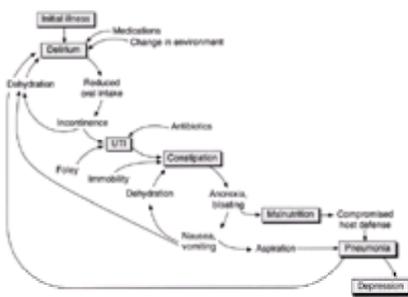

The physician caring for elderly patients should make a special effort to determine an individual's wishes should a crisis ever develop. While this principle applies to all adult patients, it is a more immediate and more universal concern among the elderly than among those who are younger. To avoid a precipitous, stressful, and inappropriate decision-making process, it is best to initiate discussions regarding cardiopulmonary resuscitation, prolonged artificial feeding, mechanical ventilation, or, in certain circumstances (e.g., a patient in a nursing home), indications for the appropriateness of hospitalization at a time when the patient and his or her family are able to consider the issues thoughtfully and thoroughly and are able to consult relatives and other counselors when making a decision. Most states have developed laws concerning durable power of attorney for health care or living wills. All patients should be encouraged to develop advance directives consistent with state laws. Of the several advance directives currently available, the naming of a health care agent is generally preferred. The advantages of appointing a health care agent are that (a) such a mechanism is universally applicable and (b) if there is a reliable agent who knows a patient's wishes well, the decisions of that patient in any situation are more likely to be followed. The living will, an advance directive that is often perceived as most important, is valid in most states only in restricted situations such as the presence of a terminal disease, persisting vegetative state, or end-stage medical condition from which there is no expectation of recovery. For example, the situation of a moderately demented patient usually would not meet the criteria for a living will to be applied.

Studies have shown that elderly individuals are not upset when their physicians initiate conversations about advance directives; in fact, they appreciate the opportunity to review these important concerns. Properly executed and honored advance directives may avoid therapy that is inconsistent with a patient's wishes. For the many patients who fear prolonged suffering and disability more than they fear death, care can be properly focused and maximum comfort and dignity provided. Important as it is to help a patient develop advance directives, it is of equal importance to ensure that developed advance directives are widely noted and prominently displayed in a patient's record, so that all involved health care providers can be aware of them and honor them strictly.

CONTINUUM OF HEALTH CARE FOR THE ELDERLY

The physician who cares for the elderly patient is called on to render care in a variety of settings, including the traditional medical office, the patient's home, a senior citizens complex, the hospital, and the nursing home. The most effective medical care of the elderly is provided in the least restrictive environment. A significant number of noninstitutionalized elderly persons are homebound and cannot be transported to a medical office without a specially equipped bus or van, or an ambulance. In spite of this, only a very small number of patient-physician encounters occur in the home. Yet a house call allows first-hand evaluation of the patient's environmental circumstances and interactions with family and other caregivers. The physician can better assess the patient's physical function and need for home services, such as physical therapy and durable medical equipment, which require a physician's order. House calls result in a rapport between physician, patient, and family that can be immensely gratifying.

Whenever possible, an elderly person recovers from an acute illness most comfortably at home, as hospitals are necessary but dangerous environments for elderly patients. This is especially so for elderly patients who are critically ill. Such patients commonly sustain nosocomial complications, which initiate an accelerated cascade of events resulting in death or permanent loss of function, and often long-term institutionalization. The attending physician plays a critical role in minimizing the chance of such a scenario taking place. The attending physician is the "captain" of the health care "team" or the "conductor" of the health care "orchestra," to use two common metaphors. This role is of paramount importance and requires a broad knowledge base, an enormous amount of tact, and a major commitment of time. Figure 454.2 depicts a typical scenario of a seriously ill elderly patient hospitalized for an acute illness. To prevent or minimize the chances of such a sequence requires sustained vigilance and coordination with nurses, therapists, consultants, and all other hospital personnel to preserve a patient's function, to prevent iatrogenic injury, and to provide maximum comfort and human dignity.

hours of rehabilitation therapy daily), required for CARF level rehabilitation. The physical therapist addresses mobilization and endurance, while the occupational therapist teaches adaptive approaches to personal care. Nurses implement scheduled toileting to correct hospital-acquired incontinence, a commonly seen new problem. The nutritionist assesses dietary preferences and nutritional needs to promote adequate oral intake, enhance wound healing, and improve constipation that occurs during the hospitalization as a result of medications and lack of physical activity. A psychologist assists the patient and family in coping with a new physical or mental disability. The physician's role is to coordinate the services provided by the rehabilitation team and to reassess the medical plan implemented in the hospital setting. For example, as an older man is recovering from a stroke and begins to stand and ambulate with the use of a walker, orthostatic hypotension may become evident, thus necessitating an adjustment in antihypertensive medications.

With increasing physical and cognitive decline, the ability of a frail elder to live safely in his or her own home may be lost, particularly if there is a lack of family to provide 24-hour supervision. Alternatives to institutionalization include senior assisted-living apartments or assisted-living facilities where more functional seniors can receive minimal nursing services. Continuing care (life care) communities provide a range of services but are often not an option for seniors with ordinary incomes and assets. For elders who prefer to remain at home, in-home services can be purchased as needed, such as home maintenance, meal preparation, and personal care. Physicians must be aware that such services are not provided for the long term by Medicare or most other health insurance programs. While often these services must be purchased individually, there is growing interest in comprehensive, community-based "life care" services provided by a single vendor for a monthly fee. Medical day centers, under physician's order, may provide needed daytime supervision for seniors with dementia or physical disability while family caregivers are employed.

Nursing home placement often is the only option for seniors who are functionally dependent in basic activities of daily living and who lack a social support system to provide such care. There are state and federal regulations that govern the medical care provided to nursing home residents. The Omnibus Budget Reconciliation Act of 1987 set exacting operational standards for nursing homes that participate in the Medicare and Medicaid programs. These regulations, which became effective in 1995, require a safe environment with minimal use of physical and chemical restraints and that provides residents with physical comfort, adequate nutrition, timely medical care, and recreation. Often, family members seek advice from the physician before selecting a nursing home.

THE PHYSICIAN AS HEALTH CARE COORDINATOR

Because an elderly patient typically has a constellation of chronic health problems, lost functional ability, and developed dependencies, health care for such an individual must be multifaceted and usually requires support from many individuals. In fact, multidisciplinary health care is the norm in geriatric medicine. Whether the patient is at home, in the acute hospital, in the nursing home, or in a life care community, often several allied health professionals or laypersons will be providing care. The physician will need to be acquainted with these individuals and their capabilities because they are much more likely to be involved closely and on a day-to-day basis with the patient than is the physician. Such individuals are at once the first to make observations regarding change in a patient and the first to provide the care prescribed by the physician. Critical communication to and from the patient and the physician will be accomplished by such individuals. Accordingly, the physician must take the lead in establishing avenues of communication and rapport with these helping persons. Respect for and understanding of the various disciplines represented in an individual care program are critical for effective communication. This requires the physician to be familiar with the capabilities and contributions of nurses; physician's assistants; nurse practitioners; social workers; physical, occupational, and recreational therapists; home health aides; and case managers. While the coordinating role of physician in a multidisciplinary team is time consuming, it is absolutely crucial. Confounding the problem is that a health care network supporting an elder individual is often quite unconnected and may involve a variety of different organizations that are community-, government-, or hospital-based. In spite of such a maze, it remains the physician's responsibility to work with this diverse group as the physician is responsible for orchestrating, from among the available resources, the best possible care for the patient.

The coordinating role of the physician is never more critical or complex than it is in geriatric medicine. This is so because (a) older individuals have multiple health problems, (b) there is an ever increasing complexity in the health care system, (c) the scientific basis of medical practice is expanding continuously, and (d) there is a wide reliance on subspecialists in current practice patterns. Therefore, initiating and coordinating consultations to specialists and reviewing previous evaluations and records that are often widely scattered are important tasks that are both labor-intense and undercompensated. However, should this coordinating role for physicians not be performed well, the patient may suffer discomfort, disability, and the lack of appropriate resource utilization.

[Differential Diagnosis](#)
[Strategies for Optimal Care Management](#)

PRESENTATION

Unless previously diagnosed, high blood pressure is usually detected in an asymptomatic older person at a routine office visit or through various programs that offer blood pressure screening examination to older people. However, in about 10% of older people, high blood pressure is first diagnosed when the older person presents with a clinical event that was probably triggered by longstanding high blood pressure, such as stroke, congestive heart failure, or myocardial infarction. On the other hand, at times older patients complain of dizziness or headaches that they believe might be associated with elevations of blood pressure; however, studies have consistently shown that, unless the blood pressure is either extremely high or extremely low, symptoms are usually absent unless the patient presents with a cardiovascular clinical event. However, as blood pressure increases with age, the baroreceptor reflex is diminished, and patients may also present with either postural hypotension or postprandial hypotension.

Elevation of either systolic blood pressure (SBP) or diastolic blood pressure (DBP) is a prevalent problem with major health implications in older patients. In all industrialized countries, average SBP rises throughout the life span, whereas average DBP rises until age 55 to 60 years and then levels off or even declines. Therefore, most of the increase in prevalence of high blood pressure in older persons results from an increase in isolated systolic hypertension (SBP higher than 140 mm Hg, DBP lower than 90 mm Hg).

Although the clinical treatment of hypertension has classically focused more on DBP levels, epidemiologic data indicate that for middle-aged and elderly adults, SBP is more predictive of future cardiovascular disease than DBP.

Estimates of the prevalence of hypertension [both systolic/diastolic hypertension (SDH) and isolated systolic hypertension (ISH)] in persons older than 65 years vary greatly, depending on the age and race of the group studied, the blood pressure cutoff point used for the definition of hypertension, and the number of measurements made. Because levels of DBP tend to stabilize at about 55 years of age, the prevalence of SDH tends to be constant at age 55 and older. Based on estimates from the Hypertension Detection and Follow-up Program, the prevalence of SDH in persons older than 65 years is about 15% in whites and 25% in blacks. In screening for the pilot study of the Systolic Hypertension in the Elderly Program (SHEP), ISH was found in about 10% of persons aged 70 years and 20% of persons older than 80 years (both black and white).

PATHOPHYSIOLOGIC FACTORS

The exact causal mechanisms for development of hypertension in the elderly, as compared with younger persons, remain to be fully determined. Because most cases of SDH occur by age 55 years, it is unlikely that the pathophysiology of SDH is much different in the elderly than it is in the middle-aged. Older persons with hypertension usually have lower renin levels and are more sensitive to sodium repletion or depletion than are younger hypertensive individuals. Structural changes in the large vessels may play a predominant role in the rise of SBP levels with age. Both a decrease in connective tissue elasticity and an increase in the prevalence of atherosclerosis result in an increase in peripheral vascular resistance and aortic impedance with age. There is a strong negative correlation between large-vessel compliance and systolic pressure in older patients. A decrease in aortic compliance results in greater resistance to systolic ejection and disproportionate elevations of SBP. However, the hemodynamic characteristics of ISH are different in patients younger than 40 years compared with patients older than 65 years. Younger patients with ISH usually demonstrate a hyperkinetic circulation manifested by a significantly increased heart rate, elevated left ventricular ejection rate and cardiac indexes, and normal vascular resistance. On the other hand, older patients with ISH tend to have a normal heart rate, significantly reduced cardiac and left ventricular ejection rate indexes, and increased vascular resistance. Also, plasma volume is reduced in older patients with ISH.

Because renin levels usually are lower in older patients, it is unlikely that the renin–angiotensin system plays a major role in the pathogenesis of ISH. However, functional changes in vascular smooth muscle may have some impact on the increased peripheral resistance seen in elderly patients with ISH. Studies in animals indicate that α -adrenergic responsiveness of vascular smooth muscle is not greatly changed with age. However, β -adrenergic responsiveness of vascular smooth muscle declines with age, with a consequent decrease in the relaxation of vascular smooth muscle. Therefore, it has been postulated that the increase in peripheral resistance in elderly hypertensives with ISH may be caused in part by diminished β -adrenergic-mediated vasodilatation, whereas α -adrenergic-mediated vasoconstriction continues unabated.

HISTORY AND PHYSICAL EXAMINATION

Although most older individuals who present with high blood pressure are asymptomatic, it is important to question patients about potential symptoms related to acute rises in blood pressure as well as symptoms related to the vascular complications of high blood pressure ([Table 455.1](#)). For instance, questions regarding syncope, tachycardia, flushing, headaches, chest pain, nocturnal dyspnea, and numbness or localized paralysis of a part of the body are all appropriate. Of course, it is important to question the patient about previous times when blood pressure may have been measured and, if possible, it is important to document the duration for which the blood pressure has been elevated. Often older persons who present with elevations of blood pressure report having been treated previously with antihypertensive agents. It is important to document the type of antihypertensive agent used, its effectiveness, and any reason for its discontinuation. Finally, older patients frequently take multiple prescription or over-the-counter medicines, some of which can cause an elevation of blood pressure. These include sympathomimetics, nonsteroidal anti-inflammatory drugs, alcohol, caffeine (acutely only), postmenopausal hormone replacement therapy (rarely), and corticosteroids (including heavy topical use).

Symptoms Related to Pressure Rise
Headache (only with very high pressure)
Clouded sensorium
Syncope
Seizures
Tachycardia
Dyspnea
Symptoms Related to Chronic Effects of High Blood Pressure
Postprandial syncope
Postural syncope
Edema
Dyspnea
Symptoms/Conditions Related To Cardiovascular Morbidity
Low energy (low cardiac output)
Symptoms of multi-infarct dementia
Stroke
Myocardial infarction
Congestive heart failure
Renal failure

TABLE 455.1. SYMPTOMS RELATED TO HIGH BLOOD PRESSURE

The physical examination should focus on examining the patient for potential signs of organ damage from high blood pressure and for any potential underlying physical abnormalities that may contribute to the rise in blood pressure. Examination of the retina for signs of arteriolar damage and other fundoscopic changes, the heart (particularly heart size), and the peripheral blood vessels is critical. Many older people with longstanding untreated high blood pressure present with a combination of high blood pressure–related fundoscopic changes, a diffuse lateral cardiac point of maximum impulse, and diminished peripheral pulses. Auscultation

of the major vessels for bruits is important to help assess the degree of atherosclerosis. Of particular importance are the carotid arteries and abdominal aorta. In addition, auscultation should be done over the kidneys because renal artery stenosis is the most common secondary cause of hypertension in older adults. Checking the patient for Osler's sign (a palpable radial or brachial artery after the blood pressure cuff has been inflated above peak SBP) is not advised because it has low sensitivity and specificity for pseudohypertension (discussed in more detail later).

Meticulous and accurate measurement of the blood pressure itself is the most critical component of the physical examination in an elderly person with high blood pressure. This is also the part of the physical examination that may be the most poorly performed in terms of reliability and accuracy. First, blood pressure should only be measured in an older person who is seated, with his or her back supported, and after 5 minutes of rest. The blood pressure cuff should be placed just above the elbow, and the arm should be resting so that the cuff is at the same level as the heart in the chest cavity. Blood pressure should never be taken over clothing, and use of an appropriate cuff size is critical. The width of the cuff should be about 40% of the circumference of the patient's arm. If the clinician is in doubt about the size of cuff to use, use of an oversized cuff introduces very little measurement error, whereas use of an undersized cuff can induce a great deal of measurement error. While the sphygmomanometer cuff is being inflated, the clinician should palpate the radial artery and continue to inflate the cuff until the pulse at the radius is obliterated (this avoids mismeasurement due to an auscultatory gap). A standard mercury sphygmomanometer is the instrument of choice, although aneroid sphygmomanometers are reasonably accurate if standardized every few months against a mercury sphygmomanometer. A common source of measurement error is overly rapid deflation of the cuff. The cuff should be deflated at the rate of 2 mm per second.

The diagnosis of high blood pressure should be based on the average of three measures taken over two or three visits. By doing this, the natural variation in blood pressure is somewhat diminished and a more reliable estimate of the true intra-arterial pressure can be obtained. Once the average of six to nine measures is obtained, the patient can be classified according to the potential severity of high blood pressure. The most recent classification system is shown in [Table 455.2](#). It is important to note that ISH *is covered* by this classification system because the stage for a given patient is determined by the component of blood pressure (SBP or DBP) that is highest. Recent studies of the utility of ambulatory blood pressure monitoring (ABPM) indicate that persons who have stage 1 hypertension can be controlled with less medication or even no medication (e.g., erroneous diagnosis based on office blood pressure) if ABPM is used. Some studies indicate that 24 ABPM measures are more highly correlated with end-organ damage than office blood pressures. Most older people with stage 2 or higher hypertension after an average of six to nine office measurements have true high blood pressure. There may be some room for a routine use of ABPM in persons with stage 1 hypertension where diagnosis is in doubt because the blood pressure varies a great deal from visit to visit, or in special instances when circumstances may dictate the relevance of blood pressure to symptoms (e.g., postprandial syncope).

Blood Pressure Stages (mm Hg)	Risk Group A (No Risk Factors; No T0DCC2)	Risk Group B (At Least One Risk Factor; Not Including Diabetes; No T0DCC2)	Risk Group C (T0DCC2 and/or Diabetes, With or Without Other Risk Factors)
High-normal (130-139/85-89)	Lifestyle modification	Lifestyle modification	Drug therapy*
Stage 1 (140-159/90-99)	Lifestyle modification (up to 12 mo)	Lifestyle modification† (up to 6 mo)	Drug therapy
Stage 2 and 3 (≥160/100)	Drug therapy	Drug therapy	Drug therapy

*Lifestyle modification should be adjunctive therapy for all patients recommended for pharmacologic therapy.
†T0DCC2 refers to target organ disease/clinical cardiovascular disease (see Table 4).
‡For patients with multiple risk factors, clinicians should consider drug as initial therapy plus lifestyle modifications.
§For those with heart failure, renal insufficiency, or diabetes.
¶For example, a patient with diabetes and a blood pressure of 140/90 mm Hg plus left ventricular hypertrophy should be classified as having stage 1 hypertension with target organ disease (left ventricular hypertrophy) and with another major risk factor (diabetes). The patient would be categorized as stage 1, risk group C, and recommended to immediate initiation of pharmacologic treatment.

TABLE 455.2. RISK STRATIFICATION AND TREATMENT^a

The other concern with regard to accuracy of office blood pressure measurements has to do with “white-coat hypertension.” Actually, part of the problem of white-coat hypertension is related to poor measurement technique in the physician's office, including not allowing the patient to rest for 5 minutes before the measurement and not having the patient comfortably seated with the back supported. If the nature of the practice is such that it is too inefficient or cumbersome to follow carefully standard blood pressure measurement techniques, then ABPM probably can be a valuable adjunct to confirming a suspected diagnosis of high blood pressure in an older person.

Because the prevalence of postural hypotension increases as the blood pressure increases, older persons with elevations of blood pressure also should regularly have the blood pressure measured both supine and standing. As much as 10% to 15% of untreated elderly persons with high blood pressure have a decrease in standing SBP of 20 mm Hg or more.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

Current national guidelines for laboratory tests include a urinalysis, complete blood count, fasting serum glucose, and cholesterol with high-density lipoprotein and triglyceride (for estimations of low-density lipoprotein), serum potassium, creatinine, uric acid, and a 12-lead electrocardiogram. Although older persons with high blood pressure have a higher prevalence of cardiac enlargement than younger people, routine echocardiographic screening is not recommended.

DIFFERENTIAL DIAGNOSIS

The diagnosis of high blood pressure is relatively straightforward except for the issues of measurement, misclassification, and stress responses. Measurement has been discussed earlier. There is one major type of misclassification, pseudohypertension, and one major type of stress response, white coat hypertension. Pseudohypertension is thought to occur in elderly people who have very rigid arteries. It is known that the rigidity of arteries on average goes up with age. The indirect sphygmomanometer can overestimate the true intraarterial pressure because increased pressure is required for the blood pressure cuff to compress a stiff artery. Unfortunately, studies of this phenomenon do not contain representative samples of older people, so it is difficult to assess the potential prevalence of this condition in the general population. In addition, the articles on this subject indicate that although there may be some increased estimate of blood pressure by indirect sphygmomanometry in older people, the actual magnitude of misclassification in most patients is not that high and often does not alter whether an older person would be classified as having hypertension. Ancillary studies associated with SHEP indicate that the prevalence of pseudohypertension is low in an aging cohort. A diagnosis of pseudohypertension should be suspected in older persons who have relatively high blood pressures but have no evidence of end-organ damage, or in older persons who have symptoms of excessive low blood pressure on antihypertensive therapy even though their blood pressures appear to be in the normal range. In other words, pseudohypertension is really only diagnosed based on clinical presentation and is not a common phenomenon.

White-coat hypertension is thought to be a stress response whereby a person in a doctor's office, particularly when confronted with the doctor and/or the impending examination, has a stress response and an increase in blood pressure. Some researchers have indicated that the proportion of patients diagnosed as having high blood pressure in an office practice who actually have normal blood pressure but are classified as hypertensive because they have white-coat hypertension may be as high as 20% to 25%. However, studies of this phenomenon give few details with regard to indirect blood pressure measurement methodology and provide insufficient data to estimate the true prevalence of white-coat hypertension. For years, many physicians have obtained home blood pressure readings to verify their office readings. Having a visiting nurse visit the home once or twice, or having the patient's spouse take the blood pressure with a calibrated device, is cheaper than ABPM and can alert the physician to the possibility that the patient is exhibiting a stress response.

The other aspect of differential diagnosis of primary (essential) systolic or diastolic hypertension in older persons is whether there may be underlying secondary causes that could be treated so that the blood pressure can return to normal. However, probably less than 1% of older persons have a secondary cause of hypertension amenable to targeted therapy. The most common cause of secondary hypertension in older persons is renal vascular hypertension, but this diagnosis is difficult to make, and surgical treatment is often less than curative. Criteria for considering an evaluation for an underlying secondary cause of hypertension are listed in [Table 455.3](#).

New onset of stage 3 or 4 hypertension in person older than 60 years
 Hypertension refractory to three-drug regimen
 Clinical or laboratory findings suggesting identifiable causes of hypertension
 Spontaneous and refractory hypokalemia while on thiazides
 Symptoms suggestive of pheochromocytoma
 Continued creatinine rise while on appropriate antihypertensive therapy

TABLE 455.3. INDICATIONS FOR FURTHER EVALUATION FOR SECONDARY HYPERTENSION

STRATEGIES FOR OPTIMAL CARE MANAGEMENT

MANAGEMENT

Once the diagnosis of high blood pressure has been firmly established in an older person, the first step in managing the patient is to assess his or her nutritional habits and lifestyle. Excessive ethanol abuse, high sodium intake, increased body weight, inactivity, and use of certain drugs, such as oral sympathomimetics or nonsteroidal anti-inflammatory drugs, alone or in combination, may actually be the culprit in raising the blood pressure. At present, it would be prudent to advise weight loss, decreased sodium intake, increased physical activity, and a review of over-the-counter and prescription medications for all older persons before prescribing drug treatment for high blood pressure.

Most older individuals who have been diagnosed with high blood pressure ultimately go on to antihypertensive therapy. The goals for blood pressure lowering are shown in [Table 455.2](#). The choice of drugs and their proper usage have been well detailed in the Joint National Committee–6 (JNC-6) recommendations from the National Heart, Lung and Blood Institute. A recommended approach to the management of an elderly person with high blood pressure is as follows:

1. The stage of hypertension ([Table 455.2](#)) should be established; this can be based on the SBP alone.
2. Stages 1 and 2 should first be verified by averaging the blood pressure measurements from three visits (three measurements per visit). If confirmed, the patient should first be treated conservatively with nonpharmacologic interventions. If the blood pressure does not drop into the high-normal range in 3 to 6 months, institute pharmacologic therapy. With drug dosage, “start low and go slow.”
3. A diuretic is the drug of first choice for the treatment of hypertension in older patients. Diuretic dosages equivalent to 12.5 to 25 mg per day of chlorthalidone (or hydrochlorothiazide) appear to be most effective. The risks associated with toxicity outweigh efficacy once the dosage increases above the equivalent of 25 mg per day. Use of a potassium-sparing agent is indicated if the serum potassium falls in the first 6 months.
4. Mitigating factors such as comorbid disease or persistent lipoprotein disorders may mandate another first choice for monotherapy ([Table 455.4](#)).

Condition	Preferred	Not Preferred
Coronary artery disease	B	—
Congestive heart failure	D, ACE	B, Ca
Systolic	Ca, ACE	—
Diastolic	—	—
Arrhythmias	B, CA	—
Peripheral arterial disease	Ca	B
Obstructive pulmonary disease	Ca	B
Diabetes	ACE, CA	—
Hyperlipidemia	ACE, Ca	—
Gout	—	D

D, diuretic; B, β-blocker; Ca, calcium channel blocker; ACE, angiotensin-converting enzyme inhibitor.

TABLE 455.4. CONCOMITANT CONDITIONS AFFECTING CHOICE OF ANTHYPERTENSIVE AGENT

5. Pharmacologic therapy should not be continued for elderly patients with stage 1 hypertension in whom significant side effects persist despite attempts with a variety of pharmacologic agents.
6. After blood pressure has been controlled for 6 months, the dosage of the drug should be lowered if possible.

Once a plan for management with nondrug and drug therapy is devised for an older patient with high blood pressure, the issue of adherence becomes critical. Unfortunately, self-report of adherence and pill counts have been proved to be less than totally accurate in assessing overall adherence. Research findings indicate that it is important to assess adherence as best the physician can (self-report, pill count, talking with the spouse or significant other), and that if the physician does this on a routine basis, compliance will probably increase or be maintained even though the physician will never have a precise estimate of the actual level of patient adherence.

COMPLICATIONS AND PITFALLS

Complications or problems in the management of high blood pressure in older people range from the subtle to the fatal. More subtle complications of antihypertensive medications include postural hypotension, notably after meals, falls, depression, and mild to moderate clouding of the sensorium.

On every visit, the clinician should include a formal evaluation of mental status and mood, and directly measure postural changes in blood pressure as well as question the patient about symptoms of dizziness. It is also crucial to obtain a history from family members with regard to the patient’s relative vitality, cognition, and overall state of health.

Studies indicate that less than half of all persons diagnosed with high blood pressure and on therapy are under good control. These problems are related to nonadherence to therapeutic regimens, use of therapeutic regimens with multiple side effects, cost of therapeutic regimens, and inadequate attention to adherence by physicians. Elderly patients should be given various compliance aids, particularly pill boxes, which give immediate feedback with regard to noncompliance. Families and relatives of older patients should be enlisted in the effort to maintain adherence to the therapeutic regimen. On the other hand, if older individuals adhere rigidly to an antihypertensive regimen, they may encounter problems from side effects of medications. Frequently, older people who experience side effects from prescription medications are more likely to attribute the cause of the side effect to the aging process than the drug itself.

Indications for HOSPITALIZATION

Simply putting an older person in a hospital can have disastrous complications in terms of loss of function and iatrogenic disorders. Therefore, indications for hospitalization must be carefully weighed. In general, older persons with problems related to high blood pressure should be hospitalized only in the most extreme circumstances. Specifically, any older person who presents with a SBP greater than 240 mm Hg or a DBP greater than 125 mm Hg should be hospitalized if the pressure cannot be brought down in the physician's office. If the pressure can be reduced in the physician's office, careful home monitoring on a daily basis can be a substitute for hospitalization. Any older person who has this level of elevation of blood pressure and who has either an altered sensorium, papillary edema, or other signs of central nervous system dysfunction should be hospitalized immediately. In addition, any older person with a dramatically elevated blood pressure who has focal neurologic deficits, signs or symptoms of congestive heart failure, or other ischemic disorders should also be hospitalized.

Indications for REFERRAL

Indications for referral of older persons with high blood pressure are straightforward:

1. An older person who maintains systolic pressures above 179 mm Hg or diastolic pressures above 109 mm Hg despite two-drug therapy should be referred to an expert consultant.
2. An older person with new onset of very high elevations of systolic or DBP should be referred to a consultant.
3. An older person with symptoms suggestive of pheochromocytoma or other secondary causes of hypertension should be referred to a consultant.
4. An older person with repeated episodes of blood pressure escaping from control, possibly with cardiovascular events or side effects, should be referred to a consultant.

COST-EFFECTIVENESS

For persons of any age, drug management of uncomplicated high blood pressure does not clearly result in net cost savings. In other words, it is difficult to predict for any level of SBP or DBP which patients will have a cardiovascular event at a given point in their lives. Treatment of mild to moderate high blood pressure does prevent some suffering and the cost of some future hospitalizations. However, according to one study, these savings are more than offset by the cost of long-term therapy. It appears that only 22% of the cost of treating moderate diastolic hypertension (DBP greater than 105 mm Hg) and only 15% of the costs of treating mild hypertension (DBP 90 to 104 mm Hg) is recovered. In 1984 U.S. dollars, costs per quality-adjusted life-year saved by treatment for a DBP of 90 to 94, 95 to 104, and 105 or more mm Hg are \$45,000, \$22,000, and \$9,000, respectively. The cost of the medication used has substantial impact on the cost per year of life saved. However, as in all medical therapy, preventive interventions that result in net cost savings are very rare.

If a physician uses an inexpensive generic drug, then the cost per cardiovascular event or cost per year of life saved compares relatively favorably with that for other preventive measurements (e.g., smoking cessation). If physicians choose antihypertensive agents based on concepts of potential drug class benefits (e.g., calcium channel blockers and angiotensin-converting enzyme inhibitors) without a prior trial of a less expensive agent, there is no scenario under which the treatment of hypertension is cost-effective relative to that of other preventive services.

No one would argue against managing high blood pressure in patients who have a variety of concomitant conditions (e.g., angina pectoris, congestive heart failure) with drugs that will both lower the blood pressure and control the concomitant condition. However, more than 60% of older persons with high blood pressure do not have overt end-organ disease. To treat these patients with nongeneric medications increases the cost dramatically and lowers the cost-effectiveness exponentially.

This does not mean that it can never be cost-effective to treat high blood pressure in older patients. In fact, because high blood pressure-related complications are still as preventable in older as in younger persons, and because older persons have a higher absolute number of events, treating high blood pressure in older individuals is actually relatively more cost-effective at the start. Therefore, the issue of whether treatment is cost-effective is driven not by the age of the patient but by the cost of the drug.

[Laboratory Studies and Diagnostic Tests](#)
[Differential Diagnosis](#)
[Strategies for Optimal Care](#)

PRESENTATION

Diabetes mellitus is a common health problem affecting elderly people, with a prevalence rate of 15% to 20% in persons over the age of 65 years in the United States. Diabetes mellitus is not a benign condition in older people, as it is associated with substantially increased risk for long-term diabetes complications and associated mortality. Older adults can present with any of the full spectrum of the heterogeneous manifestations of diabetes mellitus. At one end of this spectrum is asymptomatic hyperglycemia of type 2 diabetes mellitus. Indeed, it is estimated that approximately one-third of older adults who meet current American Diabetes Association (ADA) criteria for diabetes mellitus (see [Chapter 411](#)) are unaware of the diagnosis.

While type 2 diabetes is by far the most common form in an older adult population, increasing numbers of individuals with type 1 diabetes mellitus are living to old age. Such individuals have the usual metabolic characteristics of type 1 diabetes, with labile hyperglycemia and risk for development of diabetic ketoacidosis. Those with a long history of diabetes may exhibit any of the full range of diabetes complications. Much more rarely, an older individual may present with a new onset of symptomatic hyperglycemia and ketoacidosis.

The usual lag time between diagnosis of diabetes and the development of diabetes-related complications is not well defined in an older adult population. This may reflect some interaction between aging and the mechanisms by which hyperglycemia leads to diabetes complications. In addition, as suggested by the high rate of undiagnosed diabetes in the older adult population, it is possible that some older patients with type 2 diabetes may have had asymptomatic hyperglycemia for a substantial period of time prior to their diagnosis. For this reason, a careful search for evidence of diabetes complications should be carried out in older patients, even when the diagnosis of diabetes is recent. Diabetes mellitus with poor control of hyperglycemia is one cause of an insidious decline in an older patient, with weight loss, muscle weakness, and deterioration of functional status. As control of hyperglycemia can reverse the deterioration in such a patient, appropriate diagnosis and treatment is particularly important.

An extreme form of metabolic decompensation that is of particular concern in older adults is the hyperosmolar coma syndrome, characterized by marked hyperglycemia, hyperosmolality, and severe volume depletion. The associated mortality rate is high, in part because there is often a severe underlying illness, such as pneumonia or cerebrovascular accident. Associated renal insufficiency limits renal excretion of glucose, thereby accelerating the degree of hyperglycemia. Metabolic acidosis may be present but is due to accumulation of lactic acid rather than ketoacids. This condition may occur in an older individual with no prior diagnosis of diabetes or a history of type 2 diabetes not considered severe enough to warrant pharmacologic therapy. Hyperosmolar coma is associated with marked elevations of stress hormones and insulin deficiency. The explanation for lack of mobilization of fatty acids and production of ketoacids under these circumstances remains unclear.

PATHOPHYSIOLOGIC FACTORS

The reasons for the high rates of type 2 diabetes in older populations are not known, but there appears to be a complex interaction among genetic, lifestyle, and aging influences, as illustrated in [Fig. 456.1](#). The heterogeneity of type 2 diabetes likely reflects the varying contributions of each of multiple factors to the development of hyperglycemia in a given individual or family. Many studies have demonstrated age-related glucose intolerance in normal people who do not meet the criteria for diabetes mellitus. One cause of this glucose intolerance is an age-related decline of pancreatic b-cell function. Another factor contributing to age-related glucose intolerance is a decline in sensitivity to the metabolic effects of insulin with age. This age-related impairment of insulin action is due to effects on the insulin-signaling mechanism that limit the mobilization of glucose transporters needed for insulin-mediated glucose uptake and metabolism in insulin-dependent tissues, such as muscle and fat. There is currently little evidence for an age-related impairment of insulin effects on protein or fat metabolism. The age-related decline in insulin action is due in part to age-related changes in body composition (increased adiposity, particularly centrally, and decreased muscle mass) and decreased physical activity.

FIGURE 456.1. Summary of factors that may contribute to the high rate of diabetes mellitus and impaired glucose tolerance among elderly persons. (From Halter JB. In Masoro EJ, ed. *Handbook of physiology. Section 11: aging*. New York: Oxford University Press, 1995, with permission.)

Coexisting illness can be another confounding factor affecting insulin sensitivity in an older person. Both hypertension and hyperlipidemia are common in older people and have been associated with diminished insulin sensitivity. An acute illness can precipitate hyperglycemia because of effects of stress hormones to cause insulin resistance and to inhibit insulin secretion. Finally, drugs that may be used by older people may also contribute to hyperglycemia by causing insulin resistance ([Table 456.1](#)). Impaired pancreatic b-cell adaptation to insulin resistance further contributes to age-related glucose intolerance and risk for diabetes mellitus.

Adrenergic agonists	Nicotine
? β -Adrenergic blockers	Alcohol
?Calcium channel blockers	Nicotinic acid
Glucocorticoids	Oral contraceptives
Growth hormone	(estrogen/progesterone)
Nonsteroidal anti-inflammatory drugs	Phenytoin
	Pentamidine

TABLE 456.1. DRUGS THAT MAY INCREASE GLUCOSE LEVELS

The pathophysiology of diabetes complications appears to be similar in older and younger patients. Chronic exposure to hyperglycemia leads to protein glycosylation and subsequent formation of advanced glycosylation end products. The advanced glycosylation end products can accumulate in slow-turnover proteins, such as collagen, potentially leading to tissue damage and injury. Tissue exposure to high concentrations of glucose can also lead to accumulation of metabolic products of the aldose reductase system, including non-metabolized molecules such as sorbitol. Such accumulation can affect cellular energy metabolism and contribute to cell injury and death. The possibility also exists that the genetic complexity of type 2 diabetes may contribute to the risk for one or more long-term complications of diabetes independent from the effects of hyperglycemia.

HISTORY AND PHYSICAL EXAMINATION

An older patient with diabetes should have a thorough history and physical examination at periodic intervals. This medical evaluation should address diabetes self-management activities and skills, diabetes knowledge, medication use, cardiovascular risk factors, health maintenance activities, and microvascular and macrovascular complications of diabetes. Given the uncertainty about the duration of diabetes mellitus for many older patients, the search for evidence of diabetes complications should not be postponed. Thus, the medical evaluation should be complemented by a detailed eye examination by an ophthalmologist, as early signs of diabetic retinopathy can be easily missed. Given the high rate of vascular disease in older people with diabetes mellitus, a careful assessment for evidence of cerebrovascular disease, coronary heart disease, and peripheral vascular disease should be carried out. In addition to a thorough neurologic exam for evidence of neuropathy, a careful foot examination is needed to identify possible structural abnormalities that might contribute to risk for skin breakdown and damage. The genitourinary system should be a focus for attention, as many older patients may have other factors contributing to bladder or sexual dysfunction that may be exacerbated by the coexistence of diabetes. Because of the high frequency of coexisting health problems in older patients, a thorough review of drug utilization is important. The drug history will help to identify drug therapy that may be contributing to the patient's hyperglycemia ([Table 456.1](#)) as well as drug interactions that may affect diabetes management.

The search for and documentation of coexisting illnesses may have a substantial influence on the decision about the intervention chosen for management of diabetes in an older patient. In particular, a coexisting illness that substantially limits remaining life expectancy will affect any decision regarding the goal for control of hyperglycemia. The diet history should address the patient's cultural and historical background, which may have a substantial impact on the efficacy of various types of dietary interventions. Oral health should be assessed, given the frequency of oral health problems in older adults and the importance of oral health to dietary intervention.

Several aspects of the history and physical examination are particularly important for an older patient with diabetes. These include an assessment of the patient's functional status for activities of daily living. Functional status may influence decisions about the choice of therapeutic regimen for the patient in terms of goal setting as well as the patient's ability to adhere to a diabetes treatment program. The patient's cognitive and psychosocial status should also be carefully assessed. Cognitive function may be critical, given the complexity of many diabetes management programs. Cognition is key to recognition and treatment of hypoglycemia and in turn may be worsened by recurrent hypoglycemia. The presence of a psychiatric disorder, such as depression, could have a major impact on diabetes treatment and require a separate intervention. The patient's socioeconomic status can also have an important impact on the diabetes treatment plan and should be assessed. The degree of support available from caregivers can affect treatment plans, as caregivers can compensate for some of the patient's own limitations in self-care capabilities and can play a key role in promoting the effectiveness of lifestyle interventions. The patient's economic status may affect the ability to adhere to a costly medical regimen, and cultural influences may have to be considered as a treatment plan is developed.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

The current criteria for diagnosis of diabetes mellitus (see [Chapter 411](#)) are not adjusted by age. Thus, the same diagnostic criteria apply to older persons. The ADA's recommendations focus on the fasting glucose level for clinical purposes. However, it should be recognized that a substantial number of older persons meet the post-glucose challenge criteria for a diagnosis of diabetes mellitus but do not meet criteria based only on the fasting glucose level. Thus follow-up testing and possible use of an oral glucose tolerance test should be considered in some older people with borderline fasting glucose levels. Diagnostic tests for diabetes-related complications should be carried out as in a younger population, based on the findings from a thorough history and physical examination. Given the high rate of asymptomatic or mildly symptomatic cardiovascular disease in this population, a low threshold should be set for a Doppler evaluation for carotid artery stenosis or reduced extremity blood flow and for cardiovascular stress testing. Blood and urine screening for kidney disease should be carried out as in younger patients, but the interpretation may be more difficult in an older patient with other potential causes for kidney disease. Screening for a lipid disorder should also be carried out, as there is growing evidence that both older persons and persons with diabetes can benefit from lipid-lowering therapy to reduced risk for cardiovascular disease.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of hyperglycemia in an older adult should consider the potential contribution of drug therapy or a coexisting illness to the hyperglycemia and identify individuals in whom hyperglycemia is secondary to an underlying illness. Ideally, it is best to reevaluate glucose levels after discontinuing any of the drugs listed in [Table 456.1](#) to determine if the criteria for diabetes are still being met. Similarly, glucose levels should be reevaluated after resolution of an acute concomitant stressful illness. As in a younger patient, endocrine syndromes with overproduction of stress hormones or conditions resulting in severe damage to the pancreas can lead to significant hyperglycemia and should be considered in the diagnosis.

STRATEGIES FOR OPTIMAL CARE

MANAGEMENT

Hyperglycemia

The first key step in developing a diabetes management program for an elderly patient is to establish the treatment goal. The ADA recommends a goal of a fasting glucose less than 120 mg per deciliter and a hemoglobin A_{1c} within 1 g % of the upper limit of normal to markedly reduce the risk for diabetes complications. The ADA's recommendation is broad and not limited to a specific type of diabetes or to any age group. However, it may be neither feasible nor appropriate to attempt to establish such a goal for some elderly patients. [Table 456.2](#) lists some of the factors to consider in deciding on a treatment goal designed to minimize risk for diabetes complications in an older patient.

Patient's estimated remaining life expectancy
Patient's preference and commitment
Opinion of the primary care provider: control vs. complications
Availability of support services
Economic issues
Coexisting health problems
 Major psychiatric disorder
 Major cognitive disorder
 Diabetes complications
 Major limitation of diabetes functional status
Complexity of medical regimen

TABLE 456.2. FACTORS TO CONSIDER IN SETTING A DIABETES TREATMENT GOAL FOR ELDERLY PATIENTS

A limited remaining life expectancy shortens the time in which long-term complications can develop and progress. However, the life expectancy of older adults is increasing. Thus, for example, it would be hard to justify abandoning the ADA's goal in an otherwise healthy 75-year-old woman with a recent diagnosis of diabetes mellitus, since such a person's remaining life expectancy may be 15 years or more. The commitment on the part of an adequately informed patient is clearly critical to

achieve tight diabetes control. Availability of a supportive environment, including a strong, committed diabetes treatment team and adequate economic support for an intensive treatment program, are also important issues. Any decision about an intensive treatment program must take into account coexisting conditions and the overall complexity of the patient's medical regimen. The existence of advanced diabetes complications in a patient may provide a rationale for less strict control of hyperglycemia. A significant psychiatric or cognitive disorder may also preclude implementation of an intensive management program. However, many older adults are able to devote a substantial amount of time to their own health care and are able to manage complex multidrug interventions for multiple health problems. The ADA's recommended intensive treatment goal may be appropriate for such individuals.

Regardless of whether a decision is made to try to prevent diabetes complications with intensive diabetes management, the treatment plan for virtually all older patients with diabetes should prevent metabolic decompensation and control other risk factors that may contribute to diabetes complications. Metabolic decompensation with weight loss, muscle wasting, and a catabolic state is unlikely to occur if the average circulating glucose level is in the range of 200 mg per deciliter and the glycosylated hemoglobin value is within 3% to 4% of the upper limit of normal. Thus, this seems a reasonable target goal for basic diabetes care. Coexisting hypertension, hyperlipidemia, and cigarette smoking should be identified and treated, and all elderly patients with diabetes should receive a basic diabetes education, including recognition and treatment of hypoglycemia. Basic diabetes care should include yearly follow-up and reevaluation for the development of diabetes complications, and intervention for those complications as appropriate.

Elderly individuals who are selected for an aggressive treatment program meeting ADA guidelines should receive all aspects of basic diabetes care, including aggressive detection and treatment of hypertension, hyperlipidemia, and cigarette smoking; monitoring for diabetes complications; and institution of complication-specific interventions. Elderly patients participating in an aggressive treatment program should be trained to carry out home blood glucose monitoring on a regular basis and should participate in a formal diabetes education program that covers various treatment approaches for hyperglycemia, including diet, exercise, and medications. Access to a multidisciplinary diabetes care team should be part of an aggressive treatment program.

The full range of therapeutic options for diabetes management, including diet, exercise, oral agents, and insulin, is available for use in elderly patients (see [Chapter 411](#)). There is no absolute contraindication to any of these agents in relation to age. All of the newer oral agents have been tested in older patients, at least in short-term trials, and there is a growing body of information regarding the response of older patients to all diabetes treatment interventions. At this point there is no clear, preferred algorithm to utilize for an older patient with diabetes. Factors to consider include whether the treatment target is for basic care or an aggressive program, the side-effect profile of the various agents that are available (discussed below), the costs of the various agents, and the overall complexity of the medical regimen. For example, combination therapy with different categories of oral agents and/or insulin may be attractive in a patient with few other health problems. However, single-agent therapy may be more attractive for an elderly patient who is already on multiple medications for several coexisting health problems. There is also growing recognition that achievement and maintenance of the ADA's target for hyperglycemia control is difficult for many patients with type 2 diabetes, even on combination drug therapy. Thus, more ongoing, intensive effort may be needed than is the usual standard practice.

Diabetes Complications

As in younger patients with diabetes, identification and management of hypertension and lipid abnormalities should be part of optimal diabetes care. Smoking cessation should also be emphasized. Use of aspirin to reduce cardiovascular risk, angiotensin-converting enzyme inhibitors for diabetic renal disease, and aggressive intervention for diabetic retinopathy should also be provided to elderly people. Since older patients with diabetes are at high risk for amputation, careful attention to peripheral vascular disease, neuropathy, and foot care is also critical.

COMPLICATIONS AND PITFALLS

Hypoglycemia is the primary short-term risk of a diabetes treatment program, particularly one that is targeted at achieving near-normal control of glucose levels. [Table 456.3](#) summarizes a number of risk factors for hypoglycemia in an older patient with diabetes. As counterregulatory hormone responses are important for both symptom recognition and hypoglycemia counterregulation, impairment of autonomic nervous system reflexes can contribute to the risk for hypoglycemia. As in younger patients, this can occur in the setting of previous bouts of hypoglycemia, leading to the hypoglycemia unawareness syndrome. Some older patients may have autonomic neuropathy due to longstanding diabetes or other causes. Other older patients are treated with b-adrenergic blocking drugs or other antiadrenergic agents for cardiovascular diseases.

Impaired autonomic nervous system function
Diminished glucagon secretion
Poor or irregular nutrition
Cognitive disorder
Use of alcohol or other sedating agent
Polypharmacy
Kidney or liver failure

TABLE 456.3. RISK FACTORS FOR HYPOGLYCEMIA IN OLDER DIABETIC PATIENTS

Some patients with longstanding type 1 diabetes or those with diabetes due to inflammatory disease of the exocrine pancreas may have impaired glucagon secretion as well. Patients who have relatively poor nutrition and an irregular meal pattern can be at increased risk of hypoglycemia, in part because of inadequate maintenance of muscle and liver glycogen stores. Use of alcohol or a sedating agent should be avoided in patients receiving hypoglycemic agents, particularly if an aggressive treatment program is being pursued. A coexisting cognitive disorder will interfere with recognition of hypoglycemia and possibly affect decisions about responding to hypoglycemia. Patients with underlying renal or hepatic insufficiency may have problems related to the elimination of hypoglycemic agents—particularly an issue for sulfonyleurea drugs. A patient with severe hepatic insufficiency may have difficulty mobilizing a counterregulatory increase of glucose production. Finally, any complex drug regimen may include agents that influence the pharmacokinetics of hypoglycemic agents, or counterregulatory or behavioral responses to hypoglycemia, and therefore should be an issue when considering risk for hypoglycemia.

Despite all of these issues and concerns, many older patients with diabetes can be treated aggressively with minimal risk for hypoglycemia. By providing a strong educational program focused on hypoglycemia recognition and treatment, and considering the risk factors outlined in [Table 456.3](#), problems with severe hypoglycemia can generally be avoided. Studies of hypoglycemia counterregulatory mechanisms have identified only subtle alterations in healthy older adults, and patients who are hyperglycemic actually have elevated thresholds for counterregulation. Furthermore, patients with type 2 diabetes generally are at less risk for severe hypoglycemia than intensively treated patients with type 1 diabetes. Thus, the rate of severe hypoglycemia in older, type 2 diabetes patients appears to be substantially lower than in patients participating in the Diabetes Control and Complications Trial, for example.

Dietary issues may affect management of older adults with diabetes. Older adults with a significant mobility limitation may be relatively inactive and have low caloric utilization. Thus, caloric intake may have to be limited to rather low levels to achieve significant weight reduction. The potential benefit of caloric restriction and weight reduction under such circumstances has to be balanced against the potential risk for complications related to undernutrition. Elderly patients may have difficulty with access to food in terms of both food preparation and shopping for food. Furthermore, dietary habits established over a lifetime, and often with a cultural background, may be particularly difficult to modify. Older men living alone may have limited food preparation skills. Following a dietary prescription may be particularly difficult for a patient with impaired cognitive function. Any of these issues can be modified if there is sufficient caregiver and/or social service support that can assist with providing meals in the home setting. Problems with taste and oral health, which are common in older people, may further limit adaptation to a prescribed diet. Oral health problems can be exacerbated by diabetes, which may increase the rate of periodontal disease. This may be a growing issue as increasing numbers of older adults are keeping their teeth for longer periods. Xerostomia is also more common in older people owing to decreased salivary gland flow, sometimes exacerbated by coexisting medication use.

Exercise training may be a useful adjunct to drug therapy and may contribute to the enhanced effectiveness of glucose-lowering agents. Given the high prevalence of coronary artery disease in older patients with diabetes mellitus, which may often be asymptomatic or atypical in its symptoms, it is important for such patients to have medically supervised stress testing prior to entering any challenging exercise training program. An additional issue to consider in an older person is the potential for foot and joint injury with upright exercise such as jogging. Thus, particular attention should be given to the foot examination in an older person prior to and during the course of exercise training. Because it may enhance glucose uptake by muscle, exercise training may contribute to the risk for hypoglycemia in patients who are taking hypoglycemic agents.

Sulfonylurea drugs have an established, long record of safety, with hypoglycemia being the main side effect of significance. These agents should not be used in patients with renal insufficiency or with significant liver disease, as they are dependent on the liver for metabolism and on the kidney for excretion. Hyponatremia has also been observed as a complication of sulfonylurea use in some patients. Because of similar risk with the use of thiazide diuretics, the combination of thiazide and sulfonylurea drugs should be avoided.

α-Glucosidase inhibitors work by inhibiting the key gastrointestinal enzyme responsible for breakdown of carbohydrates prior to absorption. The major side effect is local to the gastrointestinal tract, as these drugs are not absorbed to any significant degree. However, 20% to 30% of patients may develop diarrhea. To some degree this may be a welcome side effect in some elderly people with chronic constipation, and other patients may tolerate it without much discomfort.

The most common side effect of *metformin* is gastrointestinal discomfort, which in some patients can be associated with decreased appetite and modest weight loss. While some have viewed this as a potential benefit for a patient on a weight reduction program, this effect must be balanced against the degree of symptoms and the appropriateness of decreased caloric intake and weight loss in a specific individual. The biguanide class of drugs can be associated with development of life-threatening lactic acidosis under some circumstances. While this complication appears to be rare in patients with metformin, the drug should not be used in patients with chronic congestive heart failure and should be withheld during acute hospitalization for any major illness that could result in decreased tissue perfusion as a precipitating factor for lactic acidosis. Metformin should also be avoided in patients with significant liver disease or renal insufficiency (a creatinine level greater than 1.5 mg per deciliter).

Thiazolidinediones have largely been well tolerated in initial clinical trials that have included older adults. One disadvantage is their high cost. Because of reports of severe idiosyncratic hepatic toxicity with troglitazone, liver enzymes should be monitored during treatment with one of these drugs, and significant elevation should result in prompt discontinuation.

Insulin can be used for an older patient with type 2 diabetes, either as a primary hyperglycemic agent or to maintain glucose control in the hospital setting during acute stressful illness or when oral agents cannot be ingested. There are virtually no absolute contraindications to the use of insulin. Insulin can effectively lower glucose levels in virtually any patient and in sufficient dosage has at least the potential to normalize circulating glucose levels if the regimen intensity is sufficient. However, the requirement for injection may represent an insurmountable psychological barrier for some patients, and for others insulin injections may not be feasible due to functional limitations or insufficient caregiver support. Hypoglycemia is the major risk associated with the taking of insulin, as discussed previously. It should be kept in mind that achievement of a basic goal for hyperglycemia management can often be accomplished with a fairly simple regimen of one or two injections of intermediate-acting insulin in a patient with type 2 diabetes. Another concern regarding use of a high dose of insulin is the potential for weight gain. However, the largest weight gain often occurs in individuals who have lost a substantial amount of weight prior to insulin therapy due to decompensated diabetes. For other patients, it may be necessary to balance the potential risk of weight gain against the benefit of lowering the circulating glucose level.

INDICATIONS FOR HOSPITALIZATION OR REFERRAL

Diabetes mellitus is one of the most common diagnoses of patients who are hospitalized. However, hospitalization is usually for a diabetes-related complication rather than the metabolic disturbance itself. Hyperglycemia can be managed on an outpatient basis unless there is associated significant metabolic acidosis or the hyperglycemia has been severe enough to lead to volume depletion requiring intravenous fluid therapy. Particular attention should be paid to areas of skin breakdown or apparent infection in the lower extremity of an older patient with diabetes. These lesions may appear indolent due to poor vascular supply that does not support an inflammatory response. Hospital admission may be appropriate for individuals with such lesions if very close outpatient follow-up is not possible and self-care ability is questionable. In an analogous fashion, there should be a low threshold for hospital admission for an older patient with chest pain, as clinical manifestations of coronary artery disease may be atypical or silent in such individuals.

COST-EFFECTIVENESS

There is great potential for cost savings due to the high morbidity associated with diabetes and its complications in older adults, and the associated high rates of utilization of acute hospital and long-term care services. Interventions for hypertension and lipid lowering are likely to be cost-effective, even a primary prevention approach for lipid lowering. There is also strong evidence for support of interventions for diabetic neuropathy and nephropathy in older adults. However, the cost-effectiveness of glucose level lowering in this population has been questioned, given the limited information about the rate of development of microvascular complications in relation to hyperglycemia in older adults and the overall lack of clear evidence of benefit for glucose lowering to reduce the rate of macrovascular disease in any population. Clearly, further study is needed.

CHAPTER 457: APPROACH TO THE ELDERLY PATIENT WITH DYSLIPIDEMIA

WALTER H. ETTINGER, JR. AND WILLIAM R. HAZZARD

[Aging and Lipoprotein Metabolism](#)
[Association of Lipoprotein Lipids with Coronary Heart Disease in Older People](#)
[Treatment of Dyslipidemia in the Elderly Patient](#)
[Summary](#)

Coronary heart disease (CHD) is the leading cause of death and disability in the elderly, and most CHD deaths occur in older persons. Although CHD mortality is declining, even among the very old, the prevalence, yearly incidence rates, and costs of CHD in the elderly will increase dramatically through the first decade of the twenty-first century because of the aging of the population. Therefore, efforts to reduce the premature mortality, disability, and costs associated with CHD in older persons are an important public health priority.

Dyslipoproteinemia is a modifiable risk factor for CHD in young and middle-aged adults. This is dealt with extensively in [Chapter 12](#) and [Chapter 13](#). However, the role of lipoprotein lipids as risk factors for CHD in older adults is controversial, as are recommendations for treatment. This chapter addresses this controversy by describing changes in lipoprotein metabolism and blood lipid levels that occur with age, reviewing the evidence linking blood lipid levels with CHD in older persons, and discussing special considerations for treatment of dyslipoproteinemia in older persons.

AGING AND LIPOPROTEIN METABOLISM

Between childhood and midlife (around 50 years of age), increasing age is associated with alterations in average plasma lipid levels principally attributable to age-associated physiologic or normative processes: puberty and subsequent sex steroid secretion patterns and increasing adiposity in both genders. Between infancy and adolescence, average total plasma, low-density lipoprotein (LDL) and high-density lipoprotein (HDL) levels, and LDL/HDL ratios are equivalent between the genders ([Fig. 457.1](#)). However, between puberty and age 50 years (around the menopausal age for women), average LDL and hence total plasma cholesterol levels rise in both genders, presumably because of increasing adiposity. However, the rate and amount of increase are lower in women than men, a circumstance that is reversed after the age of menopause. Hence, the difference in lipid levels between men and women is presumably attributable to the effects of endogenous sex hormones, with estrogens in women reducing LDL cholesterol concentrations, an effect lost with cessation of ovarian estrogen secretion in postmenopausal women. Average LDL levels in postmenopausal women exceed those in men of comparable age. Although the cause of this phenomenon remains uncertain, it may be attributable to the conversion of testosterone to estrogens in men. Thus, testosterone, unlike exogenous androgens such as anabolic steroids, which are not metabolized to estrogen, does not raise LDL cholesterol concentrations; however, lack of estrogen clearly does.

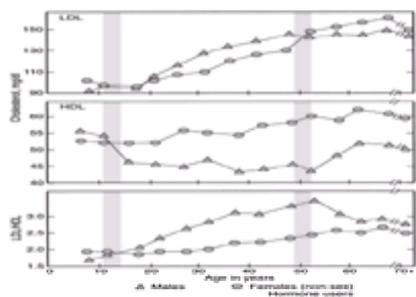

FIGURE 457.1. Median North American population high-density lipoprotein (HDL) cholesterol, low-density lipoprotein (LDL) cholesterol, and the ratio between the two versus age in white subjects. (Data from Lipid Research Clinic Prevalence Survey.)

Regarding HDL, whereas average concentrations in women do not decline between puberty and menopause (and even beyond menopause), levels decrease in boys across puberty (in parallel with the Tanner adolescent development scale) and, presumably because of continuing testosterone secretion, remain lower in men than women throughout the remainder of life. Because the effects of androgens on HDL appear to be greater than those of the deficiency of estrogen in postmenopausal women on LDL levels, the LDL/HDL ratio (a single index of lipid-related atherogenic risk preferred by many practitioners) remains higher in men than women throughout adult life, although the gender differential declines in the postmenopausal era (even as the gender differential in cardiovascular risk narrows, principally attributable to a slower age-related rise in cardiovascular disease deaths in men beyond age 50 than in postmenopausal women). It is of practical significance that because average LDL levels in postmenopausal women exceed those in men of comparable age even as their HDL levels remain higher, the mean total plasma cholesterol levels in postmenopausal women exceed those in men of comparable age (even as their cardiovascular risk remains lower, principally attributable to a lower LDL/HDL ratio). Thus, screening of older adults using total plasma cholesterol levels identifies more hypercholesterolemic women than men. This underscores the National Cholesterol Education Program Adult Treatment Panel II (NCEP-ATP II) recommendation that screening include HDL cholesterol levels so as not only to avoid missing the patient at increased risk by virtue of a low HDL but to be able to reassure those with average or even high HDL cholesterol levels that they may be at acceptable CHD risk because of the probable protective effect of HDL in offsetting the adverse risk associated with an elevated LDL.

The mechanism of the increase in average LDL cholesterol levels between puberty and midlife remains controversial. Certain investigators have suggested time-related saturation of hepatic and extrahepatic tissue cholesterol levels, down-regulating the LDL receptor. However, increasing average adiposity, especially that in central or upper body distribution, is a more likely explanation because those who remain slender with advancing age have LDL and total cholesterol levels at the lower end of the distribution, and changes in population average cholesterol concentrations are correlated with changes in weight throughout adult life. Although the upper body pattern of that adiposity (reflecting intra-abdominal stores) is more characteristic of men (the “android” pattern), women who do gain weight in the male pattern (as well as those with hyperandrogenism, notably the polycystic ovary syndrome) appear to be at special risk for dyslipoproteinemia, diabetes, hypertension, and coronary heart disease as well (“syndrome X”). However, these age-associated average plasma lipid changes are complete in most people by midlife (men by their sixth and women by their seventh decade), and average cholesterol and triglyceride levels stabilize beyond that point, ultimately declining in advanced old age. Thus, new-onset dyslipidemia is highly uncommon in the elderly, and the prevalence of hyperlipidemia declines in old age.

For this reason, identification of new-onset or exaggerated hyperlipidemia in an elderly patient demands an especially careful search for secondary causes. These include those diseases of increasing incidence with advancing age, notably diabetes mellitus and hypothyroidism, and drug-related causes (see [Chapter 31](#)), especially corticosteroids, b-blockers, and thiazides (the latter in combination being a cause of both a low HDL and an increased triglyceride in hypertensive individuals). The decision to discontinue or change these medications must be weighed against the benefits, especially in lowering blood pressure or, in the case of b-blockers, the protective effects conferred when given after a myocardial infarction.

Evidence suggests that, just as in younger people, population average cholesterol levels are decreasing in older people, and their total lipid profiles may be improving. These changes presumably result from secular changes in diet, as well as recognition and treatment of dyslipidemia. Nevertheless, the number of older persons eligible for referral and treatment of dyslipoproteinemia using the NCEP guidelines is substantial. For example, data from the third National Health and Nutrition Examination Study, a population-based study of U.S. adults, indicate that approximately 50% of men and women older than 65 years would require at least dietary therapy for dyslipoproteinemia using the NCEP-ATP II guidelines. Furthermore, even if a 10% reduction in LDL cholesterol were to be achieved from dietary therapy, between 15% to 20% of persons older than 65 years would require pharmacologic therapy for hyperlipidemia, including a substantial number of individuals older than 80 years. The annual cost of such therapy would be in the billions of dollars.

ASSOCIATION OF LIPOPROTEIN LIPIDS WITH CORONARY HEART DISEASE IN OLDER PEOPLE

Given the importance of CHD as a cause of death and disability in the older population and the high prevalence of dyslipoproteinemia in that population, the potential exists to reduce the incidence of CHD by treating dyslipoproteinemia. However, any recommendation to treat dyslipidemia in older people is based on extrapolation of results from clinical trials in middle-aged people. There are no published clinical trials that have examined the effect of therapy for dyslipidemia on incident CHD in the elderly in either primary- or secondary-prevention studies. Moreover, the epidemiologic data linking blood lipid levels to incident CHD in older people are conflicting and controversial.

The strength of the association between lipoprotein lipids and CHD depends on the person's age, gender, and health status. The weight of the evidence suggests that a positive association of LDL cholesterol with incident CHD most clearly exists in the "young-old" (age 55 to 75 years), and the strength of this relation is stronger in men than in women. The inverse relation between HDL cholesterol and CHD also appears to be present among the young-old. However, relative risk of dyslipidemia-related CHD is smaller for an older person than for one of middle age. However, the population-attributable risk of dyslipidemia is larger in the elderly because of the exponential rise in the number of cases of CHD occurring in older people. The implications of the larger population-attributable risk is that treatment of dyslipidemia, if proven useful, would prevent more cases of incident CHD in older people than middle-aged and younger people.

Beyond the age of 75 years, most data suggest that the association of lipid levels with CHD largely disappears. Indeed, several studies have shown that the relation between lipid levels and incident CHD, as well as total mortality, reverses among the "old-old!" That is, persons with higher levels of total and LDL cholesterol have longer survival and less CHD than those with lower levels.

There are several explanations for these seemingly contradictory findings, and above all the data should not be interpreted to suggest a causal relationship between high cholesterol and survival. First, the weakening relationship between lipid levels and incident CHD may reflect what has been called the "harvest effect." That is, persons who are most susceptible to the adverse effects of dyslipidemia contract disease and die prematurely. This results in fewer hypercholesterolemic survivors among older persons and accounts in part for the decline in average cholesterol levels among the elderly in cross-sectional population studies. It also means that elderly populations are enriched with those who have had no ill effects from high cholesterol levels (notably those with high HDL levels).

Second, health status affects the lipid-CHD-survival relation. Poor health status or illness, especially when of an inflammatory nature, often results in a lowering of total serum cholesterol and lipid subfractions. The incidence of chronic and acute diseases increases with age; thus, lipid levels measured in older people may be lower because of such diseases and not reflect usual lifetime levels. Moreover, given emerging evidence that inflammatory diseases (e.g., *Chlymadia pneumoniae*) may contribute to CHD, the circumstance may arise whereby cholesterol levels are falling just as the risk of CHD is rising. A person with low cholesterol due to poor health may develop clinical CHD related to his or her previously high cholesterol level, and the lifetime risk of the association between cholesterol and CHD will be underestimated at the time of its clinical manifestation. Thus, the Framingham study suggested that cholesterol levels measured in middle age were more predictive of CHD in old age than the levels measured nearer the advent of such CHD. Health status may thereby partly explain in turn the inverse relation between high cholesterol and survival. High cholesterol levels in persons who are relatively resistant to the effects of dyslipidemia on the development of heart disease also may reflect the absence of active inflammation and other potentially fatal diseases.

In addition to influencing cholesterol levels, health status appears to affect the direction of the association of cholesterol with CHD, as is most clearly demonstrated in studies by Harris and colleagues. When subjects were stratified either by activity level (a surrogate index of overall health) or prior weight loss, different patterns of the lipid-heart disease association were seen. Among older persons who had not lost weight or who reported a high physical activity level, there was a graded positive response between total cholesterol and CHD. In contrast, among persons who had lost weight or were inactive, the relation between cholesterol and CHD was negative. When these data were combined, no overall association was found between cholesterol and incident CHD. Therefore, the positive association between lipoprotein lipids and heart disease risk may be maintained in elderly persons who are vigorous and otherwise healthy but lost or even inversely related to CHD among the frail and failing. Finally, a distinction should be drawn between CHD (proceeding from coronary atherosclerosis) and cardiovascular disease (CVD) morbidity and mortality in the elderly. Whereas CVD mortality rises exponentially with age, the portion that CHD may contribute as a direct cause of such mortality may actually decline. Thus, congestive heart failure (CHF) as a final common pathway proceeding from the convergence of CHD hypertensive heart disease and age-related decline in left ventricular compliance has already emerged as the commonest reason for hospitalization of Medicare beneficiaries in the United States.

In summary, abnormal lipoprotein lipid levels appear to remain risk factors for coronary heart disease in young-old persons, especially those who are healthy and active. The potential for preventing premature CHD in this group is high because of the greater attributable risk of dyslipidemia in older persons. However, most studies suggest that the relation between lipid levels and incident CHD as well as total mortality does not hold up in advanced old age because of confounding influences of the diseases that are so prevalent in this group, including other, non-CHD causes of CVD morbidity and mortality.

TREATMENT OF DYSLIPIDEMIA IN THE ELDERLY PATIENT

The decision to treat dyslipidemia in older people is still based largely on results from middle-aged people. However, several recent studies of lipid-lowering agents in men and women with existing vascular disease (so-called secondary-prevention trials) have found that persons 65 to 75 years of age benefited from treatment. Clinical trials in otherwise healthy older persons with dyslipidemia are ongoing. There is no a priori reason to believe that the young-old would not benefit from treatment, as have middle-aged individuals. The difficulty comes in the old-old, especially those over age 80.

If treatment for dyslipidemia is to be initiated in an older person, what modalities should be used? Here the advice to clinicians is relatively straightforward. All modalities of therapy for dyslipidemia, both dietary and pharmacologic, that are effective in younger persons have been demonstrated to be equally safe and effective among the elderly.

Nonetheless, there are several factors to consider when treating the elderly patient for dyslipidemia (see [Chapter 12](#) and [Chapter 31](#)). When instituting dietary therapy, care must be taken not to cause iatrogenic malnutrition, defined as excessive weight loss or inadequate intake of micronutrients. The latter may lead to increased risk for nutrition-related conditions, such as osteoporosis, because weight loss and inadequate calcium intake accelerate bone loss or lead to muscular weakness, both of which contribute to fall-related fractures (see [Chapter 462](#)). When considering pharmacologic therapy ([Table 457.1](#)), estrogen deserves special consideration for treatment of dyslipidemia in older women not only because of its proven efficacy in both lowering LDL and raising HDL but because CHD incidence is reduced by approximately 50% in women taking estrogen, and other beneficial effects such as decreased fracture risk may accrue. Evidence from the Prospective Estrogen-Progestin Intervention Trial in middle-aged women indicates that both estrogen alone and estrogen combined with progestin are effective agents in reducing LDL cholesterol and raising HDL cholesterol (although combination therapy has less effect on HDL because of the HDL-lowering effects of androgenic progestins) in postmenopausal women. However, both regimens significantly raise triglyceride levels (suggesting caution in prescription of estrogen in those with preexisting hypertriglyceridemia). Moreover, the sobering adverse early results of estrogen treatment of women with established CHD in the recent Heart Estrogen Replacement Study (HERS) trial have reduced enthusiasm for such therapy and underscored the importance of the Women's Health Initiative Primary Prevention Trial to resolve this issue.

Agent	Effectiveness	Comments
Estrogen	↓ LDL, ↑ HDL, ↓ TG	Has benefits on coronary heart disease risk beyond lipid effects; also positive effects on bone density
Human menopausal gonadotropin-releasing hormone agonist A reductase inhibitor	↓ LDL, ↓ HDL, ↓ TG	Potent, safe, well tolerated but expensive
Niacin	↓ LDL, ↑ HDL, ↓ TG	Inexpensive but high incidence of side effects in clinical practice
Binding resins	↓ LDL, ↓ HDL, ↓ TG	May be used in low doses in combination with other drugs to enhance effects; side effects often limiting
Fibric acid derivatives	↓ LDL, ↓ HDL, ↓ TG	Most effective for people with high TG and low HDL

LDL, low-density lipoprotein; HDL, high-density lipoprotein; TG, triglyceride.

TABLE 457.1. PHARMACOLOGIC THERAPY FOR DYSLIPIDEMIA IN THE ELDERLY

Among the other agents for dyslipidemia, the 3-hydroxy-3-methylglutaryl reductase coenzyme A (HMG-CoA) reductase inhibitors ("statins") have several advantages in older people. They are the most potent LDL-lowering agents of any of the hypolipidemic drugs, and low doses of these agents are effective and safe in older people. In addition, HMG-CoA reductase inhibitors have the lowest discontinuation rate of any of the dyslipidemic agents because of the low burden of side effects. The disadvantage of these medications is their high cost (which will become less onerous as competing congeners enter the market). Niacin and bile acid-binding resins also are effective lipid-lowering agents in older persons. Niacin is the most potent agent for raising HDL cholesterol concentrations. However, these medications often are not well tolerated by older patients and are frequently discontinued because of side effects (notably flushing and dyspepsia with niacin and abdominal discomfort and constipation with the binding resins). Fibric acid derivatives are most useful for persons with elevated triglycerides and low HDL.

When more aggressive therapy is needed, combinations of hypolipidemic agents can be used. Low-dose bile acid-binding resin combined with a fibrate or HMG-CoA reductase inhibitor is a potent combination for lowering LDL levels. However, caution is indicated in aggressive combination lipid-lowering therapy in older people (especially HMG-CoA reductase inhibitors and niacin or a fibrate in the presence of renal insufficiency or therapy with immunosuppressives.) The NCEP-ATP II recommendations are to lower LDL cholesterol below 100 mg per deciliter for persons with existing CHD. Given the lack of efficacy data in older persons and the possible need to be aggressive with therapy to achieve this level of LDL cholesterol, special caution should be exerted in pursuing this goal in an elderly patient.

SUMMARY

Although the data suggest that treatment of dyslipidemia can prevent CHD in younger and middle-aged people, the data that address this issue in older people are incomplete and mixed. There are no published clinical trials that have shown benefit from treating dyslipidemia in older people. The epidemiologic data suggest that lipid levels predict CHD in the young-old but that these relationships do not hold up among persons older than 75 years. Thus, as a general recommendation, hypolipidemic therapy should be reserved for persons younger than 75 years who are in good health. Very aggressive therapy should be avoided because of the cost, side effects, and lack of efficacy data, especially in the old-old (more than 75 years).

the geriatric population, a wide variety of medications can play a role in the development of incontinence ([Table 458.1](#)). Whenever feasible, stopping the medication, switching to an alternative, or modifying the dosage schedule can be an important component of the treatment for incontinence (and possibly the only one necessary).

BASIC TYPES OF URINARY INCONTINENCE

There are four basic clinical types of urinary incontinence ([Table 458.2](#)). These types of incontinence are not mutually exclusive, and many older patients have more than one type. The most common type of incontinence in women younger than 75 years of age is stress incontinence. The most common type of incontinence among men and patients of both sexes older than 75 years is urge with involuntary bladder contractions (detrusor instability, or detrusor hyperreflexia when associated with a neurologic disorder). Older women commonly present with “mixed” incontinence and have symptoms of both stress and urge types. Although involuntary bladder contractions are most often associated with urge incontinence and neurologic disorders such as stroke and dementia, they also occur in about one-third of women with stress incontinence and 50% to 60% of men with prostatic obstruction. Overflow incontinence is less common, but it important to recognize because of the potential for chronic large postvoid residual urine volumes to cause recurrent infections or upper urinary tract damage.

Type	Symptoms	Common Causes
Stress	Involuntary loss of urine (usually small amounts) that increases in size abdominal pressure, such as that caused by coughing, laughing, and changing position. Stress incontinence may be worsened by constant wetting.	Weakness and laxity of pelvic floor musculature resulting in hypermobility of the bladder base and proximal ureters. Bladder outlet or urethral sphincter weakness/dilation often is difficult to relate to prior surgery or trauma.
Urge	Leakage of urine usually large, but often variable volume because of inability to delay voiding after sensation of bladder fullness is perceived.	Bladder hyperactivity isolated or associated with one or more of the following: Local prostatic conditions, such as cystitis, urethritis, typhoid fever, gonorrhea, bacterial prostatitis, repeated bladder infections. Central nervous system disorders, such as stroke, dementia, parkinsonism, spinal cord injury or disease. Anatomical obstruction by prostate, large uterine fibroids, or the ureters. A contractile bladder associated with diabetes mellitus or low spinal cord injury.
Overflow	Leakage of urine (usually small amounts) resulting from mechanical forces on an overdistended bladder. May respond better to stress and urge.	Obstruction of the bladder outlet by prostate, large uterine fibroids, or the ureters. A contractile bladder associated with diabetes mellitus or low spinal cord injury.
Functional*	Urinary leakage associated with inability to fully relax or impairment of cognitive or physical function by psychological, anatomical, or environmental factors.	Severe dementia Anxiety Physical debility Incontinence pills Inability of caregiver to manage incontinence Depression

*Functional incontinence should be a diagnosis of exclusion. Many frail geriatric patients have functional factors that may contribute to incontinence but may also have identifiable and specifically treatable conditions underlying the incontinence.

TABLE 458.2. BASIC TYPES AND CAUSES OF URINARY INCONTINENCE

DIAGNOSTIC EVALUATION

GENERAL APPROACH

Components of the diagnostic evaluation of an incontinent patient are shown in [Table 458.3](#). The appropriate extent of the diagnostic evaluation, especially with respect to the need for cystourethroscopy and urodynamic tests, is controversial. These procedures are relatively invasive and expensive, requiring specialized equipment and personnel trained in their use and the interpretation of results. These procedures also are time consuming, are frequently uncomfortable, and put patients at risk of infection. On the other hand, in carefully selected patients, such procedures can be essential for determining an appropriate treatment plan. A general approach to the diagnostic evaluation is illustrated in [Fig. 458.1](#).

Component	Details
History	Duration, frequency, timing, precipitating factors, associated symptoms, impact on quality of life, previous treatments, medication review, cognitive and functional status.
Physical Examination	General appearance, vital signs, cardiovascular, respiratory, abdominal, pelvic/rectal examination, neurological examination, cognitive and functional assessment.
Urinalysis	Urinalysis, urine culture, postvoid residual (PVR) measurement.
Imaging	Renal ultrasound, cystourethroscopy, urodynamic studies.
Management	Behavioral modification, pharmacologic therapy, surgical options, referral to specialists.

TABLE 458.3. COMPONENTS OF THE DIAGNOSTIC EVALUATION OF GERIATRIC URINARY INCONTINENCE

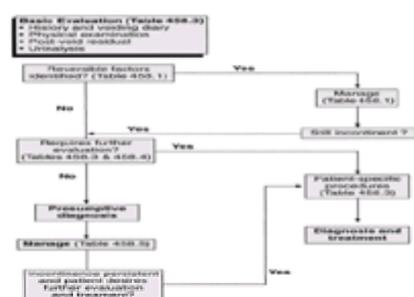

FIGURE 458.1. Basic approach for evaluation of geriatric urinary incontinence.

BASIC EVALUATION

All incontinent patients should have a focused history and physical examination, postvoid residual determination, and urinalysis ([Table 458.3](#)). The history should focus on a review of active medical problems and all medications; the onset of the incontinence and any precipitating factors; the timing, frequency, and amount of urine loss (voiding diaries, which record the timing and amount of continent and incontinent voids and precipitants of the incontinent episodes, can be helpful if the patient or a caregiver can complete them); and the irritative, stress, obstructive, or other symptoms associated with the incontinence.

The physical examination should include a basic assessment of cognitive function (such as questions about memory and orientation) and mobility (such as watching the patient rise from a chair and ambulate down a hallway). The exam should include a cardiovascular examination to detect signs of volume overload, especially in patients with nighttime symptoms; a neurologic examination focusing on the lumbosacral innervation and the exclusion of an occult neurologic disorder, such as parkinsonism or spinal cord lesion; suprapubic palpation after voiding; and pelvic and rectal examinations. The pelvic examination in women should include observation of the timing and amount of any urine loss with stress maneuvers (e.g., forceful coughing). This should be done, whenever possible, while the patient's bladder is comfortably full in the supine and standing positions. Many older women have small cystoceles, which may or may not be related to the pathogenesis of their incontinence. Thus, the presence of a small cystocele should not automatically lead to consideration of surgical repair. Most older women who are not taking estrogen have vaginal mucosal atrophy (pale, thin vaginal mucosa with loss of folds); this finding should be differentiated from atrophic vaginitis, in which the preceding findings are present, along with inflammation and friability of the vaginal mucosa.

A postvoid residual should be done within a few minutes after the patient voids by catheterization or ultrasonography. If catheterization is performed, the urine

obtained should be sent for urinalysis. If not, a clean voided specimen should be collected for urinalysis.

FURTHER EVALUATION

Selected patients should have additional tests or be referred for further gynecologic, urologic, or urodynamic evaluation ([Table 458.3](#) and [Table 458.4](#)). Women who do not meet any of the criteria for referral can be treated initially for either stress or urge incontinence based on their predominant symptom. Women in whom both types of symptoms are common and bothersome can be treated with a combination of therapies (see next section). Men who do not meet criteria for referral and who have symptoms of urge incontinence can be given a therapeutic trial of behavioral or pharmacologic treatment. Patients who fail to respond adequately to behavioral and pharmacologic interventions or whose symptoms do not clearly fit with either stress, urge, or combined types of incontinence should also be referred for further gynecologic or urologic evaluation.

TABLE 458.4. EXAMPLES OF CRITERIA FOR FURTHER UROLOGIC, GYNECOLOGIC, OR URODYNAMIC EVALUATION OF INCONTINENT GERIATRIC PATIENTS

TREATMENT

[Table 458.5](#) outlines the primary treatments for the four basic types of urinary incontinence. Other therapeutic approaches, such as electrical stimulation and the use of artificial sphincters, are also employed to treat urinary incontinence but are rarely used in older patients at present.

Type of Incontinence	Primary Treatments
Stress	Behavioral therapy (pelvic muscle exercises, biofeedback) α-Adrenergic agonists Estrogen (added to α-agonist; topical preferred route of administration) Surgical bladder neck suspension Periurethral collagen injections
Urge	Behavioral therapy (bladder training, pelvic muscle exercises, biofeedback) Bladder relaxants Estrogen (if atrophic vaginitis present) Surgical removal of obstructing or other irritating pathologic lesions
Overflow	Surgical removal of obstruction Intermittent catheterization (if practical) Indwelling catheterization
Functional	Prompted voiding Environmental manipulations (accessible toilets) Incontinence undergarments and pads External collection devices Bladder relaxants (selected patients with concomitant urge incontinence) Indwelling catheters (selected patients)

TABLE 458.5. PRIMARY TREATMENTS FOR DIFFERENT TYPES OF GERIATRIC URINARY INCONTINENCE

STRESS INCONTINENCE

Women whose initial evaluation suggests that stress incontinence is the predominant type should be instructed to perform pelvic muscle (Kegel) exercises and to void regularly to avoid a full bladder. To be effective, pelvic muscle exercises must be taught properly, practiced regularly by the patient, and used in the patient's everyday life to help prevent incontinent episodes. For this approach to be effective, patients must be motivated and capable of performing pelvic muscle exercises and practice them numerous times (e.g., up to 50 times) daily. Biofeedback using rectal or vaginal recordings of pressure or muscle activity may be a helpful adjunct in some patients if it is available. Factors such as obesity and chronic coughing should be addressed if possible. If these techniques are not successful and no contraindications exist, an α-agonist (pseudoephedrine 30 to 60 mg three times a day, phenylpropanolamine 75 mg twice a day, imipramine 10 to 25 mg three times a day) and estrogen (orally or vaginally) can be added. If the patient still has bothersome symptoms after an adequate trial of these treatments, or if she cannot (or is unwilling to) be treated with these approaches, she should be referred for further evaluation and consideration for surgery. Surgical bladder neck suspension procedures are highly effective and usually well tolerated when performed by an experienced surgeon in carefully selected older women with stress incontinence. For both female and male patients with stress incontinence that is primarily related to urethral sphincter weakness (as opposed to hypermobility of the bladder neck in women), periurethral injections of collagen may be effective.

URGE INCONTINENCE

Patients with urge incontinence can be treated with behavioral therapy. Pelvic muscle exercises work because voluntary contraction of pelvic floor muscles inhibits bladder spasticity and contraction. Other behavioral therapies include bladder training for functional and motivated patients, and scheduled toileting or prompted voiding for patients with impaired cognitive or physical functioning. Bladder relaxant drug therapy with an anticholinergic or antispasmodic agent can be added as necessary. All bladder relaxant drugs, including dicyclomine, imipramine, oxybutynin, and propantheline, have some systemic anticholinergic effects, and their use may be limited by bothersome side effects, especially dry mouth. Newer agents, such as tolterodine and extended-release oxybutynin, have fewer side effects, which may result in fewer patients discontinuing the medication. The development of urinary retention is of particular concern, and patients treated with these drugs should be carefully followed for symptoms of retention (and in some cases have periodic postvoid residual determinations). Men with irritative symptoms (urgency, urge incontinence, nocturia) associated with benign prostatic enlargement may benefit from a careful trial of an α-antagonist (e.g., terazosin, tamsulosin) if surgery is neither indicated nor desired for obstruction.

OVERFLOW INCONTINENCE

Patients with overflow incontinence due to anatomical obstruction require surgical intervention unless contraindicated. Patients with overflow incontinence due to an acontractile bladder should be treated with catheter drainage because pharmacologic treatment with a cholinergic agonist or α-adrenergic antagonist usually is not effective on a long-term basis. Although clean (nonsterile) intermittent catheterization may be the treatment of choice for younger patients with urinary retention due to neurologic disorders, this technique may be impractical for older patients who cannot perform it themselves and who do not have a caregiver available. Intermittent catheterization may also be uncomfortable and lead to complications in older men, and it may be unsafe in nursing homes where infection control practices and nosocomial infections are a concern. In these situations, a well-managed chronic indwelling catheter should be considered to relieve the urinary retention, control the incontinence, and prevent upper urinary tract damage and symptomatic infections.

FUNCTIONAL INCONTINENCE

The primary treatment for functional incontinence is a behaviorally oriented approach. The success of behavioral therapies for functionally impaired incontinent patients, such as prompted voiding, is critically dependent on the availability and motivation of caregivers in home and institutional settings. The appropriate use of

environmental manipulations and toilet substitutes (e.g., portable commodes) can be helpful to these patients. For patients with functional incontinence who are suspected of also having urge incontinence, based on history and caregiver observations, a trial of a bladder relaxant may help if the patient is attempting to toilet regularly but is still having incontinence episodes. Because many of these patients have substantial impairment of cognitive function, they should be monitored carefully for the development of drug side effects. Nonspecific supportive management techniques, such as incontinence undergarments and pads and external catheters, can be helpful for patient comfort but should not be used as a convenience or in a manner that fosters further dependence. For severely impaired women who are agitated or uncomfortable from pain whenever they are toileted or changed, or who have skin lesions being contaminated by urine, use of an indwelling catheter is a reasonable approach. Chronic indwelling catheters should not, however, be used for functional incontinence unless a specific indication exists because of the risk of recurrent systematic urinary tract infections. When chronic catheters are indicated, careful catheter management may help prevent complications.

CHAPTER 459: APPROACH TO THE ELDERLY PATIENT WITH ALTERED MENTAL STATUS

SHARON K. INOUE

[Definition of Delirium](#)
[Incidence and Epidemiology](#)
[Etiologic Factors](#)
[Pathogenesis](#)
[Clinical Findings](#)
[Clinical Assessment and Laboratory Findings](#)
[Strategies for Optimal Management](#)

Acute alteration in mental status represents a leading presenting symptom for acutely ill older persons, accounting for at least 30% of emergency evaluations of older persons. In fact, alterations in mental status serve as a barometer for the underlying health status of elderly persons and are often the only manifestation of serious underlying disease.

Figure 459.1 presents a systematic approach to the evaluation of altered mental status in the older patient. The first step in evaluating altered mental status is to establish the patient's baseline cognitive functioning and the time-course of any cognitive changes. Chronic impairments developing or progressing over months to years are most likely attributable to a dementia, which should be evaluated accordingly (see Chapter 466). Acute alterations occurring over hours to weeks that may be superimposed on an underlying dementia should be further evaluated with cognitive assessment to determine whether delirium is present. If delirium features are not present (see below), then further evaluation for major depression, acute psychotic disorder, or other psychiatric disorders (see Chapter 39 and Chapter 460) is indicated. The focus of this chapter is delirium, or acute confusional state, which is the most common and serious cause of acutely altered mental status in older persons.

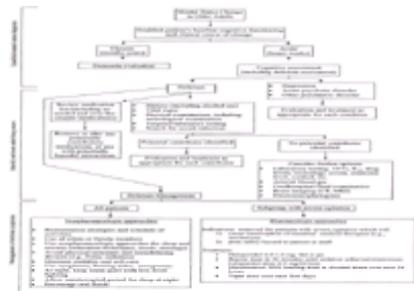

FIGURE 459.1. A systematic approach to the evaluation of mental status change in the older adult. TFT, thyroid function tests; B₁₂, vitamin B₁₂ assay; CT, computed tomography; MRI, magnetic resonance imaging; IM, intramuscular injection; PO, oral administration.

EVIDENCE LEVEL: A: Inouye SK, Van Dyck CH, Alessi CA, et al. Clarifying confusion: the confusion assessment method. A new method for detection of delirium. *Ann Intern Med* 1990;113:941-948.

DEFINITION OF DELIRIUM

The definition of and diagnostic criteria for delirium continue to evolve (Table 459.1). The standardized criteria for delirium appearing in the *Diagnostic and Statistical Manual Version IV (DSM-IV)* of the American Psychiatric Association are being used as the current diagnostic standard. However, these criteria were based on expert opinion, and their diagnostic sensitivity and specificity have not been tested. The Confusion Assessment Method (CAM) provides a simple, validated tool that is currently in widespread use for identification of delirium. The CAM algorithm, which is based on the presence of the features of acute onset and fluctuating course, inattentiveness, and either disorganized speech or altered level of consciousness, has a sensitivity of 94% to 100%, specificity of 90% to 95%, and negative predictive value of 90% to 100% for delirium.

TABLE 459.1. DIAGNOSTIC CRITERIA FOR DELIRIUM

INCIDENCE AND EPIDEMIOLOGY

The prevalence of delirium—that is, cases present at the time of hospital admission—ranges from 14% to 24%, and the incidence of delirium—that is, new cases arising during hospitalization—ranges from 6% to 56%. The rates of postoperative delirium are estimated at 10% to 52%. Higher delirium rates are found when more frequent and sensitive surveillance methods are used in populations that include older, surgical, and intensive care patients. Hospital mortality rates associated with delirium range from 25% to 33%, analogous to rates associated with acute myocardial infarction or sepsis. Based on extrapolations from U.S. vital health statistics, each year delirium complicates hospital stays for over 2.3 million older persons, involving in excess of 17.5 million inpatient days and accounting for more than \$4 billion (1994 U.S. dollars) of Medicare expenditures. Moreover, substantial additional costs associated with delirium accrue after hospital discharge because of the increased need for institutionalization, rehabilitation services, home health care, and other health care services.

ETIOLOGIC FACTORS

MULTIFACTORIAL MODEL

Similar to other common geriatric syndromes (e.g., falls, incontinence, and pressure sores), delirium represents an intrinsically multifactorial syndrome. Thus, the development of delirium usually involves a complex interrelationship between a vulnerable patient with pertinent predisposing factors and noxious insults or precipitating factors. For example, patients who are highly vulnerable to delirium at baseline (e.g., such as cognitively impaired or severely ill patients) may develop delirium with even relatively benign insults, such as a single dose of a sedative medication (e.g., diphenhydramine). Conversely, patients who are not vulnerable would be relatively resistant, with delirium resulting only after exposure to multiple noxious insults. The effects of multiple risk factors appears to be cumulative. To the

clinician, the importance of this multifactorial etiologic process is that removal or treatment of one factor alone is usually insufficient to resolve the delirium. Instead, the full spectrum of predisposing and precipitating factors must be addressed.

PREDISPOSING FACTORS

Predisposing factors for delirium include preexisting cognitive impairment or dementia, severe underlying illness and comorbidity, functional impairment, advanced age, chronic renal insufficiency, dehydration, malnutrition, and vision or hearing impairment. Dementia is an important and consistent risk factor for delirium, and patients with dementia have a twofold to fivefold increased risk for delirium. Moreover, one-third to one-half of delirious patients have an underlying dementia. Nearly any chronic medical illness can predispose to delirium, including diseases involving the central nervous system (e.g., Parkinson's disease, cerebrovascular disease, mass lesions, trauma, infection, collagen vascular disease), as well as diseases outside the central nervous system, such as infectious, metabolic, cardiac, pulmonary, endocrine, and neoplastic diseases. A validated predictive model, developed to determine delirium risk at the time of hospital admission, identified the following independent predisposing factors: severe underlying illness, vision impairment, baseline cognitive impairment, and high blood urea nitrogen/creatinine ratio (used as an index of dehydration).

PRECIPITATING FACTORS

Leading precipitating factors identified in previous studies have included medications (see below), immobilization, use of indwelling bladder catheters, use of physical restraints, dehydration, malnutrition, iatrogenic events, medical illnesses, infections, metabolic derangement, alcohol or drug intoxication or withdrawal, environmental influences, and psychosocial factors. Immobilization can lead to delirium and functional decline within a few days, yet physicians routinely order bed rest or minimal activity in 57% of patient-days of hospitalization, often without medical justification. Moreover, medical devices (e.g., indwelling bladder catheters and physical restraints) can further contribute to immobilization. Iatrogenic events, occurring in 29% to 38% of older patients, include complications of diagnostic or therapeutic procedures, transfusion reactions, bleeding due to over-anticoagulation, and the like. Insufficiency of any major organ system can precipitate delirium, particularly renal or hepatic failure. Occult respiratory failure has emerged as an increasing problem in elderly patients, often lacking the typical signs and symptoms of dyspnea and tachypnea, and easily overlooked by measuring oxygen saturation alone. Acute myocardial infarction or congestive heart failure commonly presents as delirium or "failure to thrive" in an elderly patient, without the usual symptoms of chest pain or dyspnea. Occult infection is a particularly noteworthy cause of delirium, since older patients frequently fail to mount the expected febrile or leukocytic response to infections, such as pneumonia, urinary tract infection, endocarditis, abdominal abscess, or infected joint. Metabolic disorders may contribute to delirium, such as hyper- or hyponatremia, hypercalcemia, acid-base disorder, hypo- and hyperglycemia, thyroid or adrenal disorders. A validated predictive model, developed to determine delirium risk based on exposure to precipitating factors during the course of hospitalization, identified the following independent precipitating factors: use of physical restraints, malnutrition, more than three medications added during the previous day, indwelling bladder catheter, and any iatrogenic event.

DRUG USE AND DELIRIUM

Medications, the most common remediable cause of delirium, contribute to at least 40% of delirium cases. Many medications can cause delirium; the most common are those with known psychoactive effects, such as sedative-hypnotics, narcotics, H₂-blockers, and medicines with anticholinergic effects. In previous studies, use of any psychoactive medication was associated with a 4-fold increased risk of delirium, whereas use of two or more psychoactive medications was associated with a 5-fold risk. Sedative-hypnotic drugs have been associated with a 3- to 12-fold increased risk of delirium; narcotics with a 3-fold risk; and anticholinergic drugs with a 5- to 12-fold risk. Delirium increases in direct proportion to the number of medications prescribed due to adverse effects of the medications themselves, as well as the increased risk of drug-drug and drug-disease interactions. Recent studies provide strong evidence that inappropriate use and overuse of psychoactive medications are common in older patients, and that many cases of delirium and related adverse drug events may be preventable.

PATHOGENESIS

The pathogenetic mechanisms of delirium remain obscure. Delirium appears to be a functional rather than a structural lesion, with electroencephalographic studies demonstrating global functional derangements and generalized slowing of cortical background (alpha) activity. The leading hypothesis considers delirium to be the final common pathway of many different pathogenetic mechanisms, culminating in widespread reduction of cerebral oxidative metabolism with resultant impairment of cholinergic transmission. Proposed mediators examined have included b-endorphin, somatostatin, lymphokines, tryptophan, phenylalanine metabolites, and cortisol. Although delirium has been considered a transient syndrome, several of these basic mechanisms may not be reversible, particularly those resulting in hypoxic tissue injury. Moreover, the dose and duration of the insult may impact greatly on the reversibility of the delirium.

CLINICAL FINDINGS

KEY FEATURES

The cardinal features of delirium are acute onset and inattentiveness. Determining the acuity of onset requires accurate knowledge of the patients' baseline cognitive functioning. Extra effort may be required to ascertain this information, such as pursuing a reliable informant (e.g., family member, caregiver, or nurse). Another key feature is the fluctuating course of delirium, with symptoms tending to come and go or increase and decrease in severity over a 24 hour period. Lucid intervals are characteristic, which can sometimes be misleading. Inattentiveness is recognized as difficulty with focusing, maintaining, and shifting attention. Delirious patients appear easily distracted, have difficulty following commands, and often perseverate with an answer to a previous question. On cognitive testing, patients may manifest difficulty with simple repetition tasks, digit spans, or backward recitation of months. Other key features include a disorganization of thought, a manifestation of underlying cognitive or perceptual disturbances, and altered level of consciousness (typically lethargy, with reduced awareness of the environment). Although not cardinal elements, features commonly associated with delirium include disorientation, cognitive deficits (e.g., memory impairment, aphasia), psychomotor agitation or retardation, perceptual disturbances (e.g., hallucinations, illusions), paranoid delusions, emotional lability, and sleep-wake cycle disruption.

FORMS OF DELIRIUM

Delirium can present in either hypoactive or hyperactive forms. The hypoactive form of delirium—characterized by lethargy and reduced psychomotor activity—is the most common form in older patients. This form of delirium is often unrecognized and is associated with a poorer overall prognosis. The hyperactive form of delirium, in which the patient is agitated, vigilant, and often hallucinating, is rarely missed. Importantly, patients can fluctuate between the hypoactive and hyperactive forms. Moreover, partial or incomplete forms of delirium have been recognized to be common, particularly during the resolution stages of delirium.

DIFFERENTIAL DIAGNOSIS

The leading differential diagnoses for delirium ([Fig. 459.1](#)) are dementia, depression, and nonorganic psychotic disorders. The most difficult challenge in differential diagnosis is distinguishing dementia, a longstanding confusional state, from delirium alone or delirium superimposed on dementia. The differential diagnosis is crucial, however, because delirium often represents a medical emergency; obtaining the history is critical to making this distinction. These two conditions are differentiated both by the acuity of symptom onset in delirium (dementia is much more insidious), and the impaired attention and altered level of consciousness associated with delirium. It is important to note that disorientation and memory impairment are not useful in differential diagnosis because these features may be present with both conditions and may be absent in delirium. Other conditions for differential diagnoses include depression and nonorganic psychotic disorders. Although paranoia, hallucinations, and affective changes can occur with delirium, the key delirium features of acute onset, inattentiveness, altered level of consciousness, and global cognitive impairment will assist with the recognition of delirium. In cases involving an uncooperative patient or where an accurate history is unavailable, it may not be possible to establish the diagnosis with certainty. In these cases, because of the potentially life-threatening nature of delirium and its high occurrence rate in the older hospitalized population, it is prudent to manage the symptoms as a delirium and search for reversible insults (e.g., intercurrent illness, metabolic derangements, drug toxicity) until further information can be obtained.

CLINICAL ASSESSMENT AND LABORATORY FINDINGS

Delirium is a clinical diagnosis, relying on careful observation and history taking from reliable informants. Identification of the multifactorial contributors to the delirium is of critical importance because many of these factors are treatable; if left untreated, they may result in substantial morbidity and mortality. Because the potential contributors are innumerable, the search requires astute clinical judgment combined with a thorough medical evaluation. The challenge is enhanced by the frequently

nonspecific, atypical, or muted presentation of the underlying illness in older persons. In fact, delirium may be the *only* sign of underlying life-threatening illness, such as pneumonia, urosepsis, or myocardial infarction, in the geriatric population.

The first step in evaluation should include cognitive assessment and determining any acute change from the patient's baseline level of cognitive functioning. Because cognitive impairment can be easily missed during routine conversation, a brief cognitive screening test, such as the Mini-Mental Status Examination, is recommended. Attention should be assessed with simple tests, such as a forward digit span (inattentiveness indicated by inability to repeat five digits forward) or a backward recitation of the months. The comprehensive history and physical examination remains the cornerstone of the evaluation of delirium. The history should be targeted to establishing the patient's baseline cognitive functioning and the course of any mental status changes, as well as obtaining clues about potential precipitating factors, such as recent medication changes, intercurrent infections, or medical illnesses. The physical examination should include a detailed neurologic examination for focal deficits and a careful search for signs of head trauma, infection, or other acute medical process.

Review of the medication list, including over-the-counter medications, should be carried out for every patient. Medications with psychoactive effects should be removed or minimized whenever possible. In older patients, psychoactive medications may cause adverse effects even at dosages and measured drug levels that are within the "therapeutic range". When these medications cannot be removed, dosage reduction or substitution of less toxic alternatives is recommended. The side effects and potential interactions of all current drugs should be reviewed. Finally, chronic medication and alcohol use should be carefully reviewed to evaluate for any potential withdrawal effects; often high-risk substance use is unrecognized or overlooked during the initial phase of the acute illness and hospitalization.

For the laboratory assessment, the evaluation must be tailored to the individual situation, requiring substantial clinical judgment. An astute history and physical examination, review of medications, targeted laboratory testing, and search for occult infection should be adequate to identify the majority of potential contributors to the delirium. Further testing should be tailored to the clinical picture (e.g., further laboratory testing might include thyroid function tests, vitamin B₁₂ level, drug levels or toxicology screen, ammonia level). In patients with cardiac or respiratory diseases, or with related symptoms, an electrocardiogram and/or arterial blood gas determination may be indicated. The indications for cerebrospinal fluid examination, brain imaging, or electroencephalography remains controversial. Overall, these tests are probably indicated in less than 10% of delirium cases, and the diagnostic yield for these procedures is low. Clearly, cerebrospinal fluid examination is indicated for febrile delirious patients where meningitis or encephalitis is suspected. Brain imaging (computed tomography and magnetic resonance imaging) should be reserved for patients with new focal neurologic signs, with history or signs of head trauma, or without another identifiable cause of delirium. Electroencephalography, with a false-negative rate of 17% and a false-positive rate of 22% for distinguishing delirious and nondelirious patients, has a limited role. It is most useful in the detection of occult seizure disorders and in the differentiation of delirium from nonorganic psychiatric disorders.

STRATEGIES FOR OPTIMAL MANAGEMENT

PREVENTION OF DELIRIUM

Preventing delirium before it occurs, or primary prevention, is the most effective strategy to reduce delirium and its attendant complications. Preventive strategies addressing delirium risk factors have been shown to be effective in a controlled clinical trial. Ideally, preventive strategies should address both predisposing and precipitating factors for delirium. [Table 459.2](#) indicates well-documented delirium risk factors and tested preventive interventions for each risk factor. These risk factors were selected since current evidence supports both the clinical relevance and the remediable nature of each risk factor with practical interventions. Implementation of these preventive interventions resulted in a 40% risk reduction for delirium in hospitalized older patients.

TABLE 459.2. DELIRIUM RISK FACTORS AND RECOMMENDED INTERVENTIONS

NONPHARMACOLOGIC MANAGEMENT

For management of delirium symptoms, nonpharmacologic approaches should be used for every delirious patient and are beneficial in most patients. These approaches include presence of family members, orienting influences, use of sitters, transferring a disruptive patient to a private room or closer to the nurse's station (for increased supervision). Personal contact and communication are of vital importance, using reorientation strategies, simple instructions, and frequent eye contact. Patients should be allowed to participate in decision making about their care as much as possible. Eyeglasses and hearing aids should be worn to reduce sensory deficits. Mobility, self-care, and independence should be encouraged; physical restraints should be avoided because of their adverse effects on mobility and emotional state, their questionable efficacy, and their potential to increase patient agitation and cause injury. Clocks, calendars, and the day's schedule should be provided to assist with orientation. Room and staff changes should be kept to a minimum. A quiet environment with low-level lighting is optimal for the delirious patient. Provision of an uninterrupted period for sleep at night is of critical importance in the management of the delirious patient. This requires coordination of nursing and medical procedures, such as medications, vital signs, intravenous fluids, and treatments. System-wide changes may be needed to ensure a low level of noise at night, including hallway noise and conversations. Nonpharmacologic approaches for relaxation, including music, relaxation tapes, and massage, can be highly effective in the management of agitation in patients with delirium.

DRUG THERAPY

Pharmacologic approaches should be reserved for patients with severe agitation, which may result in the interruption of essential medical therapies (e.g., intubation, intra-aortic balloon pumps, dialysis catheters) or may endanger the safety of the patient or staff. However, any drug used for the treatment of delirium will have psychoactive effects, which may further cloud the patient's mental status and obscure efforts to follow his or her mental status. Thus, the drug should be given in the lowest dose for the shortest time possible. Neuroleptics are the preferred agents of treatment, with haloperidol representing the most widely used treatment for delirium. If parenteral administration is required, intravenous use results in rapid onset of action with short duration of effect, whereas intramuscular use has a more optimal duration of action. The recommended starting dose of haloperidol is 0.5 to 1.0 mg orally or parenterally, followed by a repeated dose every 20 to 30 minutes after vital signs have been checked until sedation has been achieved. The end point should be an awake but manageable patient. The average elderly patient who has not previously been treated with neuroleptics should require a total loading dose of no more than 3 to 5 mg of haloperidol. Subsequently, a maintenance dose of one-half of the loading dose should be administered in divided doses over the next 24 hours, with tapering doses over the next few days. The leading side effects of haloperidol include sedation, hypotension, acute dystonias and extrapyramidal side effects, and anticholinergic effects (e.g., dry mouth, constipation, urinary retention).

Benzodiazepines are not recommended for treatment of delirium because of their tendency to cause oversedation and exacerbation of the confusional state. However, they remain the drugs of choice for treatment of withdrawal syndromes from alcohol and sedative drugs. For geriatric patients, lorazepam is the recommended agent of this class because of its favorable half-life (10 to 15 hours), lack of active metabolites, and availability of a parenteral form.

HOSPITAL-WIDE CHANGES

The optimal management of delirium requires system-wide changes to improve the quality of hospital care for older patients. Interventions needed to reduce delirium rates include education of physicians and nurses to improve recognition and heighten awareness of the clinical implications of delirium; encouragement of cognitive

assessment of all elderly hospitalized patients; provision of incentives to change practice patterns that lead to delirium (e.g., immobilization, overuse of psychoactive medications, bladder catheters, and physical restraint); and creation of systems that enhance high-quality geriatric care (e.g., geriatric expertise, case management, clinical pathways, and quality monitoring for delirium). With its common occurrence, its frequently iatrogenic nature, and its close linkage to the processes of care, incident delirium serves as an invaluable marker for the quality of hospital care and provides an opportunity for overall improvement.

CHAPTER 460: APPROACH TO THE ELDERLY PATIENT WITH DEPRESSION

DAN G. BLAZER

[Pathophysiologic Factors](#)
[Laboratory Studies and Diagnostic Tests](#)
[Differential Diagnosis](#)
[Strategies for Optimal Care Management](#)
[Prognosis](#)

Depression is a common syndrome among elderly patients that is caused by a number of different diseases and psychosocial stressors that can afflict older adults. The causes of depression range from carcinoma of the pancreas to bereavement. Although most elderly people are satisfied with their lives and experience only episodic or mild symptoms of depression, persistent and severe depression must not be overlooked in diagnostic workups and therapeutic interventions prescribed by physicians caring for older adults.

The symptomatic presentations of depression in late life are by and large similar to the presentations throughout adulthood. The differences in symptom presentation that often are attributed to increased age, such as pseudodementia and depression masked as physical illness, are usually secondary to comorbidity (i.e., depression associated with dementia or physical illness and therefore not related to age). However, depressed older adults may differ from the depressed in middle age in that they more often experience weight loss and less often report feelings of worthlessness and guilt. Although elderly people suffering from major depression perform less well on objective tests of cognitive functioning, they are no more likely to complain of memory problems and concentration than middle-aged depressives.

PATHOPHYSIOLOGIC FACTORS

Biologic, psychological, and social factors contribute to the etiologic process of depression. Even in the so-called biologic depressions, psychological and social factors contribute to the onset and progression of the depressive syndrome. The relative contribution of the various factors to depression may vary with age. Among the biologic factors, structural changes (subcortical white matter lesions now designated as vascular depression) are found more frequently in the brains of older adults suffering from major depression when studied with magnetic resonance imaging. These changes are more prevalent in the depressed elderly than in age-matched older adults diagnosed with dementia of the Alzheimer's disease type, as well as in age-matched controls. Recent studies suggest that persons with vascular depression present with a different symptom profile, such as more frequent anhedonia and with fewer psychological symptoms.

Dysregulation of the neurotransmitter system has been the most frequently implicated biologic factor contributing to depression at all ages. Studies have documented differences in neuronal transmission in depression. For example, platelets, a derivative of tissue of neural origin, contain natural binding sites for the antidepressant imipramine. When imipramine is radioactively labeled, persons diagnosed with major depression exhibit a decrease in binding sites compared with control subjects. By this technique, depressed elderly individuals exhibit a decreased number of binding sites (they are down-regulated) compared with persons of similar age who are not depressed.

Dysregulation of the hypothalamic–pituitary–adrenal axis has also been implicated as a biologic cause of depression. Depressed patients usually exhibit elevated cortisol levels and are less likely to suppress cortisol secretion when given dexamethasone (the dexamethasone suppression test). Older adults less than 75 years of age usually exhibit hypothalamic–pituitary–adrenal function similar to that of middle-aged adults. However, in persons older than 75 years, elevated dexamethasone cortisol levels are commonly seen. Older adults may therefore also be more biologically predisposed to depression secondary to a breakdown of hypothalamic–pituitary–adrenal regulation.

Some investigators have suggested that the elderly are psychologically predisposed to depression because they experience losses of family and friends more often than younger people. In most cases, however, the elderly appear to tolerate loss of significant others better than those who are younger. One reason for this increased adaptation to loss is that loss in late life is an “on-time” event; that is, older adults anticipate that they will lose spouses, siblings, and lifelong companions. They often mentally rehearse their adjustment to the loss, even though they may not discuss an anticipated loss openly. Older adults also appear somewhat more protected from the adverse consequences of a breakdown in their social support system. Therefore, even though the elderly may be more biologically vulnerable to the onset and progression of depression than middle-aged people, they also may be more psychologically protected.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

The evaluation of the symptoms and history of the depressive syndrome remains the cornerstone of the diagnostic workup of the depressed older adult. The history and physical examination should be accompanied by a review of all current medications, both those prescribed and those bought over the counter. Many drugs, such as sedative-hypnotic and antihypertensive agents, can precipitate a depressive episode. Laboratory tests inform the clinician of systemic illnesses that cause depressive symptoms ([Table 460.1](#)). Measurement of vitamin B₁₂ levels can uncover pernicious anemia, and thyroid function studies can disclose hypothyroidism. Thyroid dysfunction during an episode of late-life depression is usually minimal, however, and returns to normal with recovery from the depressive episode.

Abnormality	Incidence (%)
Hyperintensities in subcortical regions of the brain on magnetic resonance imaging	30–50
Nonsuppression of cortisol after dexamethasone administration	50–70
Decreased RFM latency and decreased stage 4 sleep on polysomnography	70
Mild lowering of thyroxine and elevation of thyroid-stimulating hormone on thyroid function studies	>50

TABLE 460.1. ABNORMALITIES ON LABORATORY TESTS ASSOCIATED WITH SEVERE MAJOR DEPRESSION IN THE ELDERLY

Given the increased evidence of vascular lesions among the depressed elderly, there is reason to order magnetic resonance imaging to further refine the diagnosis of late-life depression and predict the prognosis. Nevertheless, the test is expensive and it does not inform the clinician regarding therapy. Sleep abnormalities in people suffering from depression in late life and in normal elderly people are similar and include decreased rapid-eye-movement latency, increased awakenings during the night, and early morning awakening; however, depressed elderly patients exhibit these changes more than age-matched controls. Polysomnography is not of value in the routine workup of major depression.

DIFFERENTIAL DIAGNOSIS

Most older adults who complain of depression to a primary care physician suffer from minor or subsyndromal depression (a depression that does not meet criteria for either major depression or dysthymic disorder). Many of these depressed elders may suffer from adjustment disorder with depressed mood or adjustment disorder with mixed depressed and anxious mood. Others, however, suffer intermittent mood swings that are not associated with environmental stressors. Still others are either entering a major depressive episode or are recovering from an episode. Some investigators have suggested that subsyndromal depression can be effectively treated with low doses of antidepressant medication. However, no studies to date have conclusively demonstrated the efficacy of pharmacologic therapy for minor,

intermittent depressive symptoms in late life.

Although less common, major depression is the most severe of the depressive syndromes in late life. The disorder is diagnosed when the elderly person reports a 2-week history of a depressed mood or loss of interest or pleasure in usual activities, plus four of the following symptoms: poor appetite or weight loss; insomnia; psychomotor agitation or retardation; lethargy; feelings of worthlessness or self-reproach; difficulty concentrating; and suicidal thoughts. The clinician can usefully disaggregate the symptoms into biologic (such as sleep disturbance, decreased appetite, psychomotor agitation or retardation, diurnal variation in severity of symptoms, and previous response to a biologic therapy) versus psychological symptoms (such as guilt and worry). When major depression is severe, a psychotic episode (presence of mood-congruent delusions and auditory hallucinations) must be distinguished from a nonpsychotic depression. Between 10% and 20% of elderly persons suffering from major depression report a history of manic episodes. Other elderly persons suffer episodes of mania but never experience an episode of major depression. In both cases, the elderly patients are diagnosed with bipolar disorder.

Dysthymic disorder is a less severe but more chronic depressive syndrome. The elderly person must have suffered persistent depression for all or most of 2 years to meet diagnostic criteria for this disorder. Dysthymic disorder rarely begins in late life and is usually a residual disorder from middle age. Nevertheless, this chronic disorder can be exacerbated by psychosocial stressors of physical disability. Dysthymic disorder and major depression often coexist (an elder with dysthymic disorder falling into a more severe depressive episode), but many elders experience dysthymic disorder without ever experiencing an episode of major depression.

Major depression accompanies dementia of the Alzheimer's disease type and vascular dementia in about 20% of cases. Therefore, a most important diagnostic task is not the differentiation of depression from dementia per se but rather the recognition of a treatable depression in the midst of dementia. Other age-related disorders can mimic depressive disorders. Idiopathic insomnia is a common and disturbing disorder for many elderly people. The combination of significant sleep problems and mood changes that accompany loss of sleep must be differentiated from a major depression that presents with significant sleep abnormalities. Idiopathic insomnia is more likely to be insidious in onset, whereas the sleep problems that accompany major depression are more acute in onset. Physical illnesses, such as chronic congestive heart failure, cause the older adult to lose energy and report less pleasure from life. A depressed mood may be a reaction to the physical disability.

STRATEGIES FOR OPTIMAL CARE MANAGEMENT

The treatment of late-life depression includes four essential components: removal of causative factors, such as medications; pharmacotherapy; psychotherapy; and electroconvulsive therapy (ECT). Each of these interventions requires close coordination with the family of the depressed elderly patient. Families often are the first to insist that the depressed person seek professional consultation, and families are essential allies in the process of implementing a therapeutic plan.

Once potentially harmful medications have been discontinued, the clinician should prescribe antidepressant medications to those who suffer from major depression, especially with melancholia or psychotic features. The selective serotonin reuptake inhibitors are the drugs of choice because they have fewer side effects; however, tricyclic antidepressants are just as effective. Nortriptyline and desipramine are the preferred tricyclics because they have relatively mild anticholinergic effects and a low frequency of cardiotoxicity. Fluoxetine, sertraline, and paroxetine and nefazodone have all been useful as selective serotonin reuptake inhibitors. Dosage and side effects are presented in [Table 460.2](#).

Class and Agent	Recommended Starting Dose	Side Effects of Class
Tricyclic antidepressants		
Nortriptyline	50 mg qd	Anticholinergic effects
Desipramine	50 mg qd	Postural hypotension, potential for fatal overdose
Selective serotonin reuptake inhibitors		
Fluoxetine	10 mg in the a.m.	Agitation, insomnia, weight loss
Sertraline	50 mg in the a.m.	Persistence of side effects because of long half-life
Paroxetine	20 mg in the a.m.	
Nefazodone	100 mg b.i.d.	

TABLE 460.2. ANTIDEPRESSANT THERAPY FOR MAJOR DEPRESSION IN OLDER ADULTS

If an elderly patient suffers from a severe depression with many biologic symptoms that do not respond to a traditional antidepressant or exhibit a propensity to rapidly relapse, antidepressant therapy can be augmented with drugs such as lithium carbonate or carbamazepine. Doses of lithium can be much lower than at earlier stages of life, and therapeutic blood levels of 0.3 to 0.6 mEq per deciliter are usually adequate. Psychostimulants, such as methylphenidate, 5 to 10 mg in the morning, are widely prescribed to lethargic elders but have not been proved effective in the treatment of more severe depressive disorders.

Drug therapy alone is not sufficient treatment for depressed older adults, even when the depression appears to be predominantly of biologic origin. Psychotherapy, especially the cognitive and behavioral therapies, augments drugs in treating melancholic depressions. Perhaps the most beneficial result of psychotherapy is that it may reduce the likelihood of a recurrence of the depressive episode and enable the depressed elder to reintegrate into his or her social network.

The elderly are less likely than younger persons to respond to antidepressant medications during a severe depressive episode. However, late-life depressive episodes respond exceptionally well to ECT. Refined techniques in the administration of ECT have improved the tolerance of it; pulse-unilateral stimuli to the nondominant hemisphere and the advent of multiple methods of physiologic monitoring during treatment (electroencephalography, electrocardiography, and strain gauge monitoring of respirations) have reduced morbidity during treatment. Even with the use of nondominant ECT, however, memory impairment is a common side effect.

PROGNOSIS

The depressive disorders, especially major depression and dysthymic disorder, are chronic disorders characterized by relapse and presence of residual symptoms. Among those elderly who recover from an episode of depression within a year of onset, about one-third suffer a relapse during the year after recovery. Older persons are just as likely to recover from an episode of major depression and no more likely to suffer a relapse than younger persons. However, the elderly may be more vulnerable to residual symptoms of depression for months and even years following an acute depressive episode.

CHAPTER 461: APPROACH TO THE ELDERLY PATIENT WITH DISORDERS OF FLUID AND OSMOLALITY REGULATION

JO WIGGINS

[Normal Aging Changes in the Kidney](#)
[Physiologic Changes with Aging](#)

The kidney is responsible for the maintenance of fluid and electrolyte homeostasis. One-fifth of the body's circulating volume passes through the kidney every minute. This is such an important function that nature has endowed the kidney with a huge reserve capacity. Data are now becoming available from individuals who donated a kidney earlier in life. To date, no long-term decline in fluid or electrolyte homeostasis has been demonstrated. There are, however, aging-related changes in the kidney, which over time do compromise the kidney's ability to cope with large and rapid changes in fluid or electrolyte load. These changes are not manifest under normal conditions, but the challenges presented by disease, medications, or iatrogenic interventions can overwhelm the aging kidney's ability to maintain the normal volume and osmolality of the extracellular fluid compartment.

NORMAL AGING CHANGES IN THE KIDNEY

The basic functional unit of the kidney is the nephron. Nephrons differentiate during fetal development and finish their maturation during the first year of life. After this time no new nephrons are made. Renal mass declines with age due primarily to cortical atrophy. Starting in the fourth decade of life, nephrons are lost in a process known as glomerular sclerosis. There is roughly a 10% decline in nephron number per decade. This has been shown both in cross-sectional studies and in an ongoing longitudinal study that is part of the Baltimore Longitudinal Study of Aging. There is also progressive sclerosis of the afferent arteriole, which does not then filter its load through the glomerular tuft, but in effect "shunts" unfiltered blood from afferent to efferent arteriole. This sclerosis happens independent of systemic vascular disease, and the changes of hypertension and atherosclerosis are superimposed on this aging process. There is a parallel loss of tubules, resulting in the development of interstitial fibrosis. There is also significant increase in mesangial matrix and thickening of the basement membrane. Although these changes represent "normal aging" in the population as a whole, there are huge individual variations, with some otherwise healthy people showing declines in nephron mass at twice the predicted rate, and others showing no demonstrable decline at all. At the present time, we do not understand the reasons behind these aging-related changes and have no insight into why some aging persons do not appear to experience any decline in renal function over time.

PHYSIOLOGIC CHANGES WITH AGING

RENAL BLOOD FLOW

Average renal blood flow decreases about 10% per decade, dropping from 600 mL per minute per 1.73 m² to 300 mL per minute to 1.73 m² by the ninth decade. This is accompanied by increasing resistance in both afferent and efferent arterioles. These changes occur independent of cardiac output and reductions in renal mass. This decline in renal blood flow is thought to contribute to the decline in efficiency with which the aging kidney responds to fluid and electrolyte load and loss.

GLOMERULAR FILTRATION RATE

In concert with the decline in nephron numbers, glomerular filtration rate (GFR) falls with aging. Starting in the fourth decade, GFR declines at about 10% per decade. Serum creatinine, however, tends to remain stable. This is because muscle mass, the source of creatinine, also declines as lean body mass is replaced by fat. This maintenance of serum creatinine can be very misleading in older persons, who can lose significant filtration capacity without demonstrating a marked rise in creatinine. GFR can be estimated using the Cockcroft Gault equation:

$$\text{Creatinine clearance} = (140 - \text{age, years})(\text{weight, kg}) 72 \times (\text{serum creatinine concentration, mg/dL})$$

For women, multiply by 0.85.

Use of this equation to estimate GFR for a 230-lb, 25-year-old football player with a serum creatinine of 1.8 mg per deciliter gives an estimated creatinine clearance of 93 mL per minute. Use of the same calculation for an 85-year-old woman weighing 110 lb with the same serum creatinine gives an estimated GFR of 18 mL per minute. Thus, high-normal or minimally elevated serum creatinines in frail elderly patients reflects a large drop in their GFR. The physiologic consequences of this are seen frequently in medical practice, where older patients have a compromised ability to excrete a salt and water load, and develop extracellular fluid overload when given intravenous fluids. Careful use of fluids and renal dosing can thus prevent many of the complications that the frail elderly experience in hospital.

TUBULAR FUNCTION

Homeostasis of electrolytes and water is maintained by the transport systems of the tubule. The decline in the number of nephrons with aging results in a decrease in the ability of the tubule to respond to challenges. The decline in filtration volume as a result of sclerosis in the glomerulus and afferent arteriole results in a diminished volume of filtrate to the tubule. This reduces the kidney's ability to regulate sodium and potassium concentrations, decreases the ability to excrete an electrolyte or acid load, and diminishes the urinary concentrating ability. There are also changes in hormonal responses to salt load and salt deprivation. Older individuals have a much lower renin response to reductions in circulating volume, salt deprivation, or upright position. This results in diminished aldosterone release, with a failure to conserve sodium. Studies have also shown that elderly people have elevated levels of atrial natriuretic peptide, further blunting their renin response. This reduced capacity to conserve sodium renders older patients with fever, diarrhea, and other causes of fluid loss particularly vulnerable to hypovolemia and dehydration. Common disorders of water and electrolyte balance will be addressed individually below.

WATER HOMEOSTASIS

Maintaining the composition and volume of the extracellular fluid compartment is central to the well-being of an individual. Disturbances of osmolality or water and electrolyte balance are common and, often, life threatening in the elderly. The presenting symptoms tend to be nonspecific and include malaise, weakness, apathy, disorientation, agitation, loss of appetite, and cognitive decline. Careful assessment of water intake, electrolytes, renal function, and circulating volume should be made in any older patient who presents with a change in functional status, cognitive status, or behavioral change.

Total body water decreases with normal aging. Young adults have a body composition that is about 60% water, and this drops to around 50% in older persons, and may drop a further 5% in the frailest elderly. This drop is greater in women, as they generally have more fat and less lean body mass. Thus gains and losses of water have more effect in older people, particularly in older women. Superimposed on this underlying vulnerability are age-related functional changes in the ability of the kidneys to handle water deprivation or a water load. Studies have shown that older persons experience less thirst than younger persons when deprived of water for 24 hours and are much slower to correct their increased osmolality when given free access to water. This makes the elderly especially vulnerable to dehydration. Maximal concentrating ability of the urine declines with age, resulting in a mild chronic diuresis that probably has a role in the nocturia that is so common in older adults. The maximum concentrating power of the kidney falls to around 400 to 500 mOsm per kilogram in the over 80-year-old person, compared to 1,100 to 1,200 mOsm per kilogram in a young adult. Since antidiuretic hormone (ADH) levels are usually elevated in older people, this is thought to reflect a decline in tubular function with a diminished capacity to reabsorb water. These factors all contribute to the older patient's susceptibility to dehydration and low intravascular volume. Careful attention should be paid to maintaining fluid volume in the acute hospital setting where losses related to various diseases or their treatments can result in a hyperosmolar state. Institutionalized elders are particularly vulnerable to dehydration, since they are dependent on others for access to fluids. Even the healthy independent senior is vulnerable to dehydration as intercurrent illness limits his or her drive and ability to replace free-water loss.

Older people also exhibit a decline in their ability to excrete a fluid load. Studies comparing older individuals with younger adults show that older subjects took 2-4 times longer to excrete a water load. Renal diluting ability is impaired with age, and during water diuresis older subjects are unable to reduce urine osmolality to levels comparable to younger subjects. This results in vulnerability to fluid overload with attendant pulmonary and peripheral edema, and special care is advised when giving

i.v. fluids to older patients.

SODIUM HOMEOSTASIS

Sodium levels are normally maintained across a fairly wide range from 137 to 150 mEq per liter and are important for maintaining the intravascular volume. Older patients have an impaired ability to conserve sodium due to reduced levels of renin release in response to sodium loss or sodium deprivation. They also have high circulating levels of atrial natriuretic peptide with suppression of the renin–angiotensin–aldosterone axis. Older people suffer from a mild and chronic form of salt wasting. Both hyper- and hyponatremia are common in the elderly.

HYPERNATREMIA

Hypernatremia is defined as a plasma sodium <150 mEq per liter and occurs in about 3% of hospital admissions. It is associated with a mortality rate of around 50%. The incidence of hypernatremia is higher in woman than in men because woman have lower total body water. Hypernatremia may be present on admission or occur during the hospital stay. Although the causes of hypernatremia are similar in elderly patients to those seen in younger people (see [Chapter 145](#)), the frequency with which these are found is quite different. Primary hyperaldosteronism and Cushing's disease are extremely rare in the over-80 age group, whereas dehydration is quite common. The causes of hypernatremia are somewhat different for those patients who are found to be hypernatremic on admission as compared to those who become hypernatremic while in hospital ([Table 461.1](#)). Patients who are hypernatremic on admission are likely to be older, more likely to reside in a nursing home, and are more likely to exhibit cognitive impairment. The most common underlying cause of their hypernatremia is dehydration secondary to increased insensible loss associated with infection. In contrast, those patients who become hypernatremic in hospital are younger, more likely to have uncontrolled diabetes mellitus or to have undergone aggressive diuresis with inadequate free-fluid replacement. About 50% of inpatients who develop hypernatremia do so in an intensive care unit while being intubated.

Infections (pneumonia, urinary tract infection, urosepsis, sepsis)
Diuretic use or solute diuresis
Uncontrolled diabetes mellitus
Enteral losses
Lack of free access to water
Impaired mental status (delirium, dementia)
Malignancy
Impaired renal concentrating ability
Diabetes insipidus
Hypercalcemia
Loss of thirst drive
Enteral feeding with high osmotic load
Gastrointestinal bleed
Diuresis following acute renal failure or relief of obstruction

TABLE 461.1. CAUSES OF HYPERNATREMIA

A patient with hypernatremia will show signs of dehydration. Skin turgor can be hard to assess in the frail elderly, and a better assessment can be made by using the skin on the trunk rather than the limbs. Mucosal surfaces will be dry. Neck veins will fail to fill when the patient is lying down. Blood pressure will be lower than normal for the patient with an orthostatic drop. Daily measurement of orthostatic pressures and taking of fall precautions are necessary when working with these patients. The best guide to fluid balance is through accurate daily weights. Patients typically show signs of impaired consciousness, ranging from delirium with mild degrees of hypernatremia to profound coma when the sodium concentration is significantly elevated.

Treatment of these patients should focus on prompt normalization of fluid balance and sodium concentrations, as well as correction of the precipitating cause of the dehydration. Careful reversal of the hypernatremia is associated with better outcomes and improved chances for returning mental function to baseline. The free-water deficit should be calculated to guide the physician in appropriate volumes and rates of replacement. It is calculated by multiplying the patient's weight (in kilograms) by 0.6. This gives the current total body water.

$$\text{Water deficit} = \text{desired total body water} - \text{current total body water}$$

Desired body water is calculated using the following formula:

$$\frac{\text{Measured serum sodium} \times (\text{weight in kilograms} \times 0.6)}{\text{Normal serum sodium or 145 mEq per liter}}$$

Approximately one-third of the deficit should be replaced in the first 24 hours, as overly rapid normalization of osmolality can cause swelling in the brain and irreversible brain damage. The remaining two-thirds should be replaced over an additional 24 to 48 hours. If the patient's dehydration is so severe as to cause imminent circulatory collapse, initial rehydration can be given as volume expanders or normal (isotonic) saline. Otherwise water should be replaced with 5% dextrose, supplemented by oral intake. Allowance should be made for insensible loss, keeping in mind that tachypnea, fever, and enteral losses all increase the volume of replacement required. Once the hypernatremia has been corrected, steps must be taken to prevent its recurrence. Adequate access to sufficient water requires more than placing a full jug of water in a patient's room. Elderly persons with impaired levels of consciousness have reduced awareness of thirst and a limited ability to fend for themselves. Patients who are anchored to the bed by multiple tubes, drains, and catheters are restrained just as effectively as those wearing a posey or lap belt. Patients with physical impairments may be unable to open fluids presented in cartons, bottles, or cans. Hospital and nursing home staff are unlikely to be as willing to help a patient who is belligerent, aggressive, combative, or uncooperative with access to adequate fluid intake, so the physician must be alert to the possibility that oral intake may fail again when the intravenous line is removed.

Correction of the precipitating cause for the hypernatremia will depend on the individual circumstances presented by each patient. Hospital-acquired hypernatremia is an iatrogenic problem, and as such it is preventable by careful monitoring of patient weights and adequate replacement of free water. Mortality for a given diagnosis is higher when accompanied by hypernatremia than without it. It is difficult to know how much of this is directly attributable to the hypernatremia itself. Patients who develop hypernatremia may be sicker with a more severe underlying complaint or frailer with more impaired homeostatic functions. Studies have shown that higher serum sodium levels and prolonged periods without correction are both correlated with poorer outcomes.

HYPONATREMIA

Hyponatremia occurs when the serum sodium falls below 137 mEq per liter. Several aging changes in the kidney increase the older patient's susceptibility to hyponatremia. The decreased renal conservation of sodium combined with a decline in the ability to secrete water renders the older patient vulnerable to hyponatremia. Hyponatremia can be found in about 7% of healthy community-dwelling older persons. In nursing homes this figure rises significantly, and longitudinal studies suggest that over the period of a year about 50% of institutionalized older persons have at least one episode of hyponatremia. Hyponatremia is also common in the hospitalized older patient. Most cases of hyponatremia in the elderly are dilutional, resulting from the volume-stimulated retention of water due to a decrease in intravascular volume. Intense salt and water reabsorption in the proximal tubule to maintain circulating volume results in the decreased delivery of solute to the distal tubule and leads to the retention of water. Low circulating volume may be caused by excess loss secondary to aggressive diuretic therapy, gastrointestinal losses, or congestive heart failure where the effective intravascular volume is depleted. Thiazide diuretics are especially prone to causing hyponatremia since they not only cause a diuresis but also decrease the renal dilution capacity.

Nonosmotic release of ADH also occurs when the circulating volume is decreased, further promoting the retention of water. Studies suggest that older persons have increased ADH responses to physiologic or pharmacologic stimuli, compared to younger persons given the same stimulus. This predisposes the older patient to dilutional hyponatremia. Postoperative hyponatremia occurs in more than 4% of older patients undergoing surgery, as a result of high postoperative ADH levels. Older patients may also have the syndrome of inappropriate ADH secretion (SIADH). This may be secondary to a tumor, central nervous system (CNS) lesion, pulmonary disease, or drugs. Many older patients have an idiopathic SIADH, where no underlying cause can be identified. Before the diagnosis of idiopathic SIADH is made, a

very careful review of the patient's medications should be carried out. Common culprits include CNS drugs, such as antipsychotics, anticonvulsants, and antidepressants. Sulfonyl ureas and clofibrate have also been shown to cause hyponatremia. More rarely, chemotherapeutic agents have been implicated.

Dilutional hyponatremia can also occur from the movement of water out of cells into the intravascular compartment. This occurs in hyperosmolar states, the most common of which is uncontrolled diabetes mellitus. As the blood sugar rises, water is pulled from the intracellular compartment to offset the osmotic load. There is a dilutional decrease in sodium concentration of 1.6 mEq per liter for each 100 mg per deciliter rise in glucose concentration.

Far more rarely, hypernatremia in an older patient represents true sodium depletion. This happens most often in nursing home residents who are tube-fed. Most tube feeding preparations have a low salt content, and this, combined with the older patient's decline in salt conservation, can lead to a true depletional hyponatremia. Studies suggest that more than 50% of older adults receiving long-term tube feeding become hyponatremic. Institutionalized patients on low-salt diets can also become sodium-depleted. This depletional state can be very simply corrected by the addition of a little salt to the dietary preparations offered.

Older patients with hyponatremia may present with nonspecific complaints, and changes in mental status are common. Severe hyponatremia can cause swelling of brain cells, with seizures and lasting brain damage. Patients with dilutional hyponatremia may show signs of a reduced circulating volume, such as orthostatic hypotension and dehydration. Management depends on the severity of the hyponatremia, the speed of its onset, and the underlying cause. If a medication appears to be responsible, stopping that agent may be sufficient to address the problem. With uncontrolled diabetes, correcting the hyperglycemia may be all that is required, without the necessity of salt supplements. In cases of profound hyponatremia of acute onset, hypertonic saline should be given intravenously, with care taken not to overload the older person with fluid. Replacement of no more than 12 mEq per liter in any 24-hour period is recommended. In cases of idiopathic SIADH or congestive heart failure, where correction of the underlying abnormality is not possible, patients may be treated with fluid restriction or, in more severe cases, with demeclocycline.

POTASSIUM HOMEOSTASIS

The body normally maintains the serum potassium concentration between very narrow limits of 3.5 to 5 mEq per liter. There is great reserve capacity within the system for maintaining potassium levels, since disorders of potassium can be life threatening. Because of diminished renal function, the older patient is particularly susceptible to disorders of potassium homeostasis.

HYPERKALEMIA

Excluding those patients with end-stage renal disease, hyperkalemia is almost exclusively a disease of the elderly. It is also primarily an iatrogenic condition. Age-related declines in GFR, renal blood flow, and the reduction in distal renal tubular function all combine to make the elderly patient particularly vulnerable to hyperkalemia. Impaired tubular response to acidosis and reduced ability to conserve sodium interfere with potassium exchange. Poor renal perfusion, leading to decreased sodium delivery to the distal tubule as seen in heart failure, will also reduce potassium exchange. Extrarenal changes in the elderly also increase their susceptibility to hyperkalemia. Declines in the renin-angiotensin-aldosterone system with age result in the blunting of the renal tubular response to rising potassium concentrations. The age-related rise of atrial natriuretic peptide, a potent suppressor of aldosterone, may also contribute to the impairment of potassium homeostasis. While none of these changes by itself is sufficient to cause hyperkalemia, they all underlie the predisposition of older patients, particularly those with impaired renal function, to develop hyperkalemia.

Hyperkalemia occurs in up to 10% of elderly hospitalized admissions. After renal failure, the two most common causes are medications and hyperglycemia. In most patients the cause of hyperkalemia is multifactorial and cannot be attributed to a lone factor. The major causes of hyperkalemia are summarized in [Table 461.2](#). As can be seen from the list, the common practice of combining b-blockers or angiotensin-converting enzyme (ACE) inhibitors with potassium-sparing diuretics requires careful monitoring in older patients, especially those with even mild renal impairment. Small increments in serum creatinine in patients with low body mass can signal profound impairment of renal glomerular filtration rates (see "Aging Kidney," above), and special caution is advised in these patients.

Primary
Renal failure
Secondary
Drugs affecting renal-angiotensin activity
Angiotensin-converting enzyme inhibitors
b-blockers
Drugs affecting potassium secretion
Spironolactone
Eplerenone
Tamoxifen
Acetazolamide
Amiloride
Triamterene
Acetazolamide
Amiloride
Triamterene
Acetazolamide

Triamterene

TABLE 461.2. CAUSES OF HYPERKALEMIA

Patients with hyperkalemia usually present with nonspecific complaints, such as weakness, fatigue, and nausea. More frequently, hyperkalemia is a chance finding at the time of routine laboratory testing. Patients may present with cardiac arrhythmias or syncope. Once significant hyperkalemia (potassium levels higher than 6 mEq per liter) is established patients should undergo 12-lead electrocardiography (ECG) to rule out cardiac dysrhythmias. Patients with potassium levels higher than 7 mEq per liter should be on continuous cardiac monitoring. ECG abnormalities include peaked T waves, prolongation of the PR interval, first-degree atrioventricular block, junctional rhythm, widening of the QRS complex, and lengthening of the QT interval. There does not appear to be any relationship between the potassium level and the type or frequency of ECG abnormalities. If ECG abnormalities are found, excitable membranes should be stabilized by the administration of intravenous calcium. An estimate of renal function should be made by measuring the blood urea nitrogen and serum creatinine, and a serum glucose should be obtained. Potassium can be moved intracellularly by the administration of intravenous insulin, together with glucose if the patient is not hyperglycemic. Recently, it was shown that 10 to 20 mg of albuterol administered by nebulizer is also effective at reducing potassium concentrations and has an additive effect when administered with insulin. Sodium bicarbonate has also been used in patients with acidosis but has not been found to be particularly efficacious in patients with advanced renal failure. Potassium can be removed from the body by the administration of exchange resins, either by mouth or by enema. In emergencies, dialysis may be indicated. Once the acute situation has been dealt with, serious attention should be paid to precipitating causes. The medication list should be reviewed and adjusted to match the patient's underlying renal and cardiac function. In the outpatient setting, physicians should obtain frequent potassium levels in older patients on combinations of medications that interfere with potassium excretion, such as potassium-sparing diuretics in combination with ACE inhibitors.

HYPOKALEMIA

Hypokalemia is defined as a serum potassium of less than 3.5 mEq per liter. As with hyperkalemia, the elderly patient is particularly susceptible both to developing hypokalemia and to its consequences. Reductions in GFR and declines in tubular function impair the ability of the older patient to maintain potassium concentrations when the system is challenged. The causes of hypokalemia are no different in older patients than in the general population and have been dealt with at some length in [Chapter 146](#). Extrarenal causes of hypokalemia that are prominent in the elderly include the intracellular movement of potassium that accompanies alkalosis and the hypokalemic response to catecholamine release that accompanies medical emergencies. The older patient frequently develops a mild hypokalemia in response to major surgery, myocardial infarct, stroke, or other medical emergencies. This hypokalemia is usually self-limiting and corrects with supportive therapy. Elderly patients are also somewhat more sensitive to b-agonists and may develop hypokalemia when treated with broncho-dilators.

Low total body potassium is usually caused by renal loss. However, in the elderly patient, poor dietary intake combined with poor renal conservation can result in hypokalemia. Older patients are also susceptible to other causes of loss, such as severe diarrhea and laxative abuse, because of their impaired ability to conserve potassium. By far the most common cause of hypokalemia is the use of diuretics. Careful and regular monitoring of potassium levels is necessary in every older person on diuretics, as even small doses of these agents may result in hypokalemia. Renal potassium loss, such as that of the hereditary conditions associated with renal tubular acidosis, very rarely presents for the first time in the older patients; however, acquired salt-wasting conditions seen after the relief of renal obstruction

may present a similar picture in the older patient. Primary excess of mineralocorticoids and glucocorticoids as a cause of hypokalemia is again rare in the older patient. However, tumors that secrete active peptides, leading to secondary increases in these hormones, should be considered. A recent increase in hypokalemic alkalosis has been related to the surge in popularity of herbal teas. Preparations containing licorice have been shown to cause hypokalemia, and the elderly are particularly vulnerable. A careful assessment of over-the-counter remedies and dietary supplements, including herbal teas, should be made in an older person who presents with unexplained hypokalemia.

The clinical presentation of the patient with hypokalemia is usually nonspecific, with complaints of tiredness, weakness, malaise, and cramps. Tissues that are electrically active are very sensitive to potassium levels, so that muscle, nerve, and cardiac complaints are often part of the picture. Since patients with underlying heart disease or being treated with digoxin are far more likely to develop cardiac arrhythmias, older patients are at far higher risk of adverse consequences from hypokalemia than are younger patients. Ventricular ectopic rhythms are common in hypokalemia. ECG changes include low-voltage complexes with depression of the ST segment and reduced-amplitude T waves and a prominent U wave. If ECG changes are noted, prompt potassium replacement therapy should be initiated, with potassium chloride given either orally or intravenously, to correct the hypokalemia. Very close potassium monitoring of older patients on diuretics should be routine, particularly when there is underlying cardiac disease or the patient is also taking digoxin.

CHAPTER 462: APPROACH TO THE ELDERLY PATIENT WITH FALLS AND IMPAIRED MOBILITY

MARY E. TINETTI

[Incidence and Epidemiologic Factors](#)
[Pathophysiologic Factors](#)
[History and Physical Examination](#)
[Laboratory Studies and Diagnostic Tests](#)
[Strategies for Optimal Care Management](#)

A nonsyncopal fall, the topic of this chapter, refers to an event that results in a person coming to rest inadvertently on the ground or other lower level, for reasons other than as a consequence of sustaining a violent blow, loss of consciousness, stroke, or epileptic seizure.

INCIDENCE AND EPIDEMIOLOGIC FACTORS

About one-third of community persons older than 65 years fall each year; this percentage increases to 50% by age 80 years. Most fallers experience multiple episodes; the frequency of falling is similar in older men and women, at least after age 75 years. Women, however, are about twice as likely to suffer a serious injury during a fall. More than half of ambulatory nursing home residents fall each year. The annual incidence of falling among nursing home residents is 1.5 falls per bed per year.

Falling is a major health problem because of its associated morbidity. Unintentional injury is the sixth leading cause of death in persons older than 65 years. Complications related to falls account for most of these deaths. Moreover, those who survive a fall experience greater decline in activities of daily living and higher level physical and social functioning than nonfallers. This decline is thought to result from several factors, including physical injury, pain, fear of recurrent falls and injuries, and loss of confidence. Almost 10% of persons over age 75 are seen in an emergency department for a fall-related injury each year; 40% of these individuals are hospitalized. Approximately 5% of falls by older persons result in a fracture, most commonly of the humerus, wrist, pelvis, hip, or foot. Serious soft-tissue injuries, including cerebral contusions, subdural hematomas, hemarthroses, joint dislocations, or severe sprain, occur in an additional 5% of falls. Another common fall-related complication is the inability to get up without the help of another person. A small percentage, 2% to 5%, of persons who are unable to get up without help experience a long lying down, which in turn can lead to pressure sores, dehydration, pneumonia, rhabdomyolysis, and renal failure. Falling also increases the likelihood of skilled nursing facility admission, independent of other known risk factors such as age, gender, cognitive impairment, functional disability, and immobility.

PATHOPHYSIOLOGIC FACTORS

Nonsyncopal falls occur when environmental hazards or demands exceed the individual's ability to maintain postural stability. Specific diseases, such as Parkinson's disease, normal-pressure hydrocephalus, Binswanger's disease, and high cervical myelopathy, may result in severe postural instability. Some authors also describe a gait disturbance of unknown central nervous system (CNS) etiology, referred to as senile or essential gait disorder. However, these CNS diseases account for a relatively small percentage of falls by older people.

The pathophysiologic process of nonsyncopal falls can perhaps best be understood by considering falling to be a geriatric syndrome and hence of complex, multifactorial etiology. A fall occurs when an older person who is predisposed because diseases and impairments impede his or her postural stability is exposed to an acute insult or challenge that he or she is unable to withstand. Postural stability requires input from sensory, central integrative, and effector components in a highly integrated manner. These components are overlapping and compensatory. Further, cardiac, circulatory, respiratory, metabolic, and other conditions may influence the functioning of these three primary components. Postural instability and predisposition to falling may not be evident until several of the components are impaired. Indeed, several studies have shown that the risk of falling increases as the number of diseases and impairments increases.

The major sensory modalities responsible for orienting a person in space and identifying hazards include the visual, auditory, vestibular, and proprioceptive systems. These modalities mutually interact and have multiple interconnections. Age-related visual changes include decreased visual acuity, dark adaptation, and accommodation. In addition, ocular diseases, including macular degeneration, glaucoma, and cataracts, are commonplace. Hearing also contributes directly to stability through the detection and interpretation of auditory stimuli, which help to localize and orient the person in space, particularly when other modalities are impaired. More than 50% of elderly individuals have some hearing loss.

The vestibular system contributes to spatial orientation at rest as well as during acceleration and is responsible for visual fixation during head and body movements. Age-related decline in vestibular function has been attributed to changes in the otoconia. Predisposing factors include past aminoglycoside use as well as current use of aspirin, furosemide, quinine, quinidine, and, perhaps, tobacco and alcohol. Head trauma, mastoid or ear surgery, and middle-ear infections are other possible predisposing factors.

The proprioceptive system orients the person in space during position changes, while walking on uneven ground, or when other modalities are impaired. The components of the proprioceptive system include the peripheral nerves, mechanoreceptors located in apophysial joints, the posterior columns, as well as multiple CNS connections. Whether age-related changes occur in peripheral nerves remains unknown. Peripheral neuropathy, however, is common among elderly people. The contribution of cervical mechanoreceptors to proprioception is not widely appreciated. The loss of normal afferent input from mechanoreceptors may result in disturbances of postural sensation (sense of balance) and of kinesthesia (awareness of head and neck movement), on which precise control of voluntary movements, such as walking, depends. Predisposing factors include whiplash injuries and cervical degenerative diseases, such as rheumatoid arthritis or spondylosis.

The CNS channels input from the sensory modalities to the appropriate efferents in the musculoskeletal system. Given the multiple connections and their complexity, essentially any CNS disorder can and will contribute to instability and falling. CNS processes that adversely affect cognition further impede stability because problem solving and judgment are needed to interpret and respond appropriately to environmental stimuli. Dementia is a well-recognized risk factor for falls, even among persons without a clinical gait disorder.

The effector components of mobility include the efferent peripheral nervous system as well as muscles, joints, and bones. Therefore, all orthopedic and neuromuscular conditions predispose to falling. In addition, foot disorders, including calluses, bunions, toe deformities, and large, thick, deformed toenails, may alter gait patterns and/or impair proprioception.

A wide range of acute host, activity-related, and environmental factors may precipitate a fall, particularly among older persons predisposed by the chronic diseases and impairments described above. Any systemic disorder can transiently or chronically contribute to instability and falling through adverse effects on the sensory, central, or effector components. In addition, systemic disorders may result in decreased cerebral blood flow, fatigue, confusion, or shortness of breath. Common examples include anemia, electrolyte disturbances, hypoglycemia or hyperglycemia, acid-base disturbances, hypothyroidism, or hypercapnia associated with chronic lung disease. Falling may be a nonspecific presentation of many acute illnesses, including pneumonia or urinary tract infection. Cardiac dysrhythmias may obviously precipitate a fall associated with loss of consciousness and absence of cerebral blood flow. However, chronic cardiac conditions, such as congestive heart failure, may also predispose to instability and falling both directly, by compromising cerebral blood flow and activity tolerance (endurance), and indirectly, by medication side effects such as dehydration, postural hypotension, or confusion. Carotid baroreceptor hypersensitivity may cause or contribute to both syncopal and nonsyncopal falls.

Postural hypotension may result in transient instability through compromised cerebral blood flow. Prevalence ranges from 10% to 30% in persons older than 65 years. Causes include volume depletion; decreased venous return from lower extremity disorders, such as varicosities; autonomic dysfunction from aging or disorders such as diabetes or Parkinson's disease; deconditioning; age-related physiologic changes, such as decreased functioning of the renin-angiotensin system or decreased baroreceptor sensitivity; and medications. Symptoms may occur on position change or after a few minutes of activity. Not all persons who experience a drop in blood pressure upon standing experience symptoms such as dizziness. Although a systolic drop of 20 mm Hg is often used to define postural hypotension, the degree of drop required to cause a fall is unknown and likely depends both on the abruptness of the drop and on the presence of other contributing factors.

Another, more recently identified abnormality in blood pressure homeostasis is postprandial hypotension. The mechanisms and mediators of postprandial hypotension

remain unknown, although inability to compensate for splanchnic blood pooling after ingestion of a meal has been postulated as a possible cause.

Medications may result in instability and falling through many mechanisms, including impaired cognitive functioning, postural hypotension, fatigue, dehydration, or electrolyte disturbance. Centrally acting medications, including sedative hypnotics (particularly barbiturates and benzodiazepines), neuroleptic medications, and antidepressants, have repeatedly been associated with an increased risk of falling. Recent studies suggest that tricyclic and selective serotonin reuptake inhibitor antidepressants impart a comparable risk of postural instability and falling. Other classes of medications implicated, at least in some studies, include diuretics, antiarrhythmics, anticonvulsants, nonsteroidal anti-inflammatory agents, digoxin, and narcotic analgesics. In addition to specific medications, recent changes in dose and total number of medications have been associated with an increased risk of falling.

Activity-related and environmental factors present challenges to postural stability that must be withstood to avoid falling. The degree to which these factors pose a threat depends on the person's vulnerability. Challenges to stability may be posed by the external environment through hazards (e.g., poor lighting, slippery floors); ordinary activities (e.g., stair climbing or walking on even surfaces); or by movements that place the person's center of mass outside the base of support, such as turning or transferring. Only a small percentage of falls occur during clearly hazardous activities, such as climbing on chairs or ladders or participating in sports. About 10% of falls occur on stairs—well out of proportion to the time spent on them, with descending being more hazardous than ascending. The most commonly mentioned environmental hazards include tripping over objects, slippery floors, and carrying of heavy objects. Slippery or improperly fitting shoes constitutes another potential hazard.

Environmental hazards are thought to be less important among nursing home residents than among community-dwelling older persons. Nursing homes typically are safer environments than the community because many hazards have been removed and the adverse challenges to the elderly person—such as stairs—are fewer. However, even among nursing home residents, environmental contributors, described in the section on management, do exist.

Interest has focused on factors that increase the risk of serious injury, particularly fractures, during a fall. Characteristics of fallers shown to be independently associated with serious injury include white race, older age, female sex, cognitive impairment, more frequent falls, previous fall injury, presence of chronic conditions such as diabetes mellitus or stroke, poor visual acuity, reduced proprioception, impaired balance, impaired muscle strength, decreased body mass index, and reduced bone density. Circumstances of the fall that increase likelihood of serious injuries such as fractures include the direction and impact of the fall, the height of the fall, and the hardness of the landing surface.

HISTORY AND PHYSICAL EXAMINATION

Historical and examination findings among older persons who have experienced, or are at risk for experiencing, a fall are listed in [Table 462.1](#). The specific features seen in individual patients depend on which impairments and diseases are present. However, because several conditions often are present simultaneously in older persons, the signs and symptoms of specific impairments or diseases may be obscured or nonspecific. For example, vertigo may occur with nonvestibular problems, whereas patients with vestibular dysfunction may present only with dizziness or instability. Therefore, patients should undergo screening by history and examination for all of the contributing factors listed in [Table 462.1](#).

TABLE 462.1. CONTRIBUTORS TO INSTABILITY AND FALLING: CLINICAL FINDING AND POTENTIAL INTERVENTIONS

The neurologic diseases that predispose to falls can be diagnosed from a thorough neurologic history and examination. Although most neurologic diseases associated with falling result in postural instability and pathologic gait patterns, these findings are not disease-specific. Common features of gait seen in persons with central neurologic diseases include difficulty with gait initiation, flexed posture, step-to-step variability, path deviation, legs crossing the midline, step length asymmetry, decreased step height that results in shuffling if severe, instability on turning, and easy backward displacement. Some of these findings (e.g., decreased step height, flexed posture) can be seen in individuals with sensory abnormalities as well.

A careful screen and/or assessment of balance and gait is helpful not only for detecting the possibility of central neurologic disease but for identifying sensory or musculoskeletal contributors to falling. All older persons should undergo a simple screen for postural stability. If the individual can stand on one leg or tandem-stand for 30 seconds, or can walk with a tandem gait accurately for 10 feet, postural stability is likely intact and no further evaluation is warranted. For persons failing the screen, several quick and reliable assessments of balance and gait, such as that shown in [Table 462.2](#), are available. In addition to identifying sensory or musculoskeletal impairments, a careful assessment of balance and gait may help to identify conditions under which falls are likely to occur and can be used to determine rehabilitative and environmental interventions that may decrease a person's risk of falling.

TABLE 462.2. ASSESSMENT OF BALANCE AND GAIT

Carotid hypersensitivity should be suspected if the patient gives a history of “just going down” or falling with head turning or upon looking up. Carotid sinus massage should be performed on these patients if there is no evidence of cerebrovascular disease or cardiac conduction abnormalities, and if the procedure is judged safe. The carotid sinus syndrome is defined as greater than a 3-second sinus pause or more than a 50 mm Hg drop in systolic blood pressure during carotid stimulation. If carotid hypersensitivity is suspected or diagnosed, precipitating actions, such as wearing of tight collars or looking up, should be avoided. Cardioinhibitory drugs, such as digoxin, b-blockers, methyl dopa, or calcium channel blockers should also be avoided, if possible, or used in the lowest possible dose.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

The laboratory findings that may be helpful in identifying potential contributors to fall risk are listed in [Table 462.1](#). Because of prevalence, nonspecific presentation,

and potential for modification, all older persons at risk for falling should undergo routine laboratory screening, including complete blood count, thyroid function tests, serum glucose, electrolytes (including blood urea nitrogen and creatinine), and assay of folate and vitamin B¹² levels. Measurement of drug levels may be useful for patients taking antiarrhythmics, anticonvulsants, or tricyclic antidepressants.

Brain imaging with computed tomography or magnetic resonance imaging is indicated only if there are focal abnormalities on the neurologic examination. Cervical spine films may be useful in the patient with impaired gait, lower extremity spasticity, and hyperreflexia, which together are suggestive of cervical spondylosis. Lateral dimension of the spinal canal of less than 12 mm suggests a significant encroachment on the cervical cord. This finding can be confirmed with magnetic resonance imaging, which should be considered only if the patient is deemed a candidate for neurosurgery.

Ambulatory electrocardiographic monitoring is not warranted for the evaluation of nonsyncopal falls. Results are difficult to interpret in older persons because of the high prevalence of asymptomatic arrhythmias that rarely coincide with falling.

The role of computerized posturography in the clinical evaluation and treatment of balance and falling disorders remains to be determined. Posturography may be helpful in determining the relative contribution of visual, vestibular, and proprioceptive abnormalities to postural instability and may reveal how the older person responds to postural perturbations. These findings may help in the development of effective rehabilitative interventions. Finally, as safer and more effective treatments, such as estrogen, bisphosphonates, calcitonin, and exercise, for enhancing bone mineral content are becoming available, assessment of bone mineral density through a variety of techniques is indicated, particularly for postmenopausal women.

STRATEGIES FOR OPTIMAL CARE MANAGEMENT

The clinician's goal should be to minimize a patient's risk of experiencing falls, particularly injurious falls, while maintaining or improving the patient's mobility and functioning. The optimal strategy for reducing the risk of falling depends on the functional level and living situation of the patient. Among very healthy, community-dwelling older persons with no or few diseases or impairments, individual or group activity or exercise programs that improve balance and muscle strength are the most cost-effective strategy. Examples include tai chi, dancing, walking, and resistive muscle-strengthening activities.

Among community-dwelling older persons who have more than one chronic disease or impairment, who have any functional limitations, or who take prescription medications, a multifactorial approach to reducing the risk of falling has proven effective in several recent studies. Because of the overlapping, compensatory nature of the systems affecting stability as described earlier, simple interventions may result in major improvements, even if the interventions are not aimed at the modalities believed to be the most impaired. The risk of falling has been shown to decrease with reduction in the number of contributing factors, such as medications, postural hypotension, muscle weakness, foot disorders, imbalance, and gait abnormalities. Therefore, the optimal management strategy is the identification and modification of as many of the factors listed in [Table 462.1](#) as possible. Even if the person suffers from a known neurologic disease associated with falling, such as Parkinson's disease, the elimination or amelioration of other impairments may decrease the frequency of falls and fall-related injuries.

As shown in [Table 462.1](#), treatment involves standard medical or surgical interventions, as well as rehabilitative interventions and environmental adaptations. The results from balance and gait assessment can help guide the selection of rehabilitative and environmental interventions. Examples are shown in [Table 462.2](#).

Because most falls occur at home and because environmental factors contribute to many falls, a home safety evaluation by the patient, family, physical therapist, or home health nurse or aide is an important component of the treatment strategy. Hazards to be assessed include lighting; tripping hazards such as cords, loose rugs, or small objects in the walking path; low, soft chairs that are difficult to get out of; slippery floors; and stairs in poor repair or without bilateral handrails. Because individual impairments influence whether a particular environmental factor is a hazard, combining physical therapy assessment with a home safety evaluation may be the optimal approach.

A careful review of previous falls may provide clues to preventing recurrences. The presence of environmental hazards, such as those described, should be elicited. A description of the patient's activity at the time of the fall is important as well. If the fall occurred during routine, nonhazardous activities, the goal should be to improve the safety and effectiveness of these maneuvers. If the fall occurred during more hazardous activities, such as climbing on chairs or carrying heavy objects on stairs, the substitution of safer activities and better organization of the home to render the activity unnecessary should be advised.

Physical therapy, aimed at increasing muscle strength and improving balance and gait performance, has been shown effective in reducing the rate of falls. The optimal intensity and duration of muscle strengthening and balance exercises remain to be determined. Physical therapists can also help in managing the consequences of falls by teaching the patient strategies for getting up from the floor and by fostering the patient's confidence regarding performing activities of daily living without falling. This multifactorial approach to fall prevention among at-risk community-dwelling older persons has been proved cost-effective, indeed cost-saving. Not only has this strategy been shown to reduce the rate of falls; it has also been associated with lower subsequent health care costs (hospital plus home care plus skilled nursing facility), even after accounting for the cost of the interventions.

Contrary to experience in the community setting, intensive physical therapy programs targeting strengthening and balance have not proven effective at reducing the fall rate among frail nursing home residents. On the other hand, comprehensive programs that address the environment, assistive devices, and staff interactions with patients have been effective. The minimal essential use of psychotropic medication is a key component of fall reduction programs in nursing homes. Another important component includes careful assessment for residents using wheelchairs to avoid use of poorly maintained or poorly fitted wheelchairs. Instruction of all staff in safe and appropriate transfer and ambulatory assistance techniques is needed, as problems with transfers and ambulation are commonly associated with falls among nursing home residents. Although institutions may offer a safer environment than the community, the residents also tend to be more frail than elderly persons living in the community. Therefore, more subtle hazards, such as ill-fitting shoes, pants that are too long, slippery floors, beds that are too high or too low, or movable bedside tables that residents may lean against, should all be considered. Fall prevention efforts in institutions should also be aimed at reducing the use of restraints through alternatives, such as alarms that are activated when residents try to get out of bed or move unassisted, adjustable side rails and bed heights for residents who climb out of bed, and increased staff/resident ratios.

Treatment and prevention of osteoporosis, a significant risk factor for fall-related fractures, are discussed in [Chapter 465](#). Providing extra padding, through the use of various types of hip protectors, appears to be a promising approach to the prevention of hip fractures.

CHAPTER 463: APPROACH TO THE ELDERLY PATIENT WITH PRESSURE ULCERS

RICHARD M. ALLMAN

[Incidence and Epidemiologic Factors](#)
[Etiologic Factors and Pathogenesis](#)
[Clinical and Laboratory Findings](#)
[Optimal Management](#)

A pressure ulcer is any skin lesion caused by unrelieved pressure resulting in damage of underlying tissue. Pressure ulcers usually occur over bony prominences and are staged to classify the degree of tissue damage observed. Stage I is nonblanchable erythema of intact skin. In stage II lesions, skin loss is limited to the epidermis or dermis. Stage III ulcers manifest as full-thickness skin loss involving subcutaneous tissue. The ulcer may extend down to, but not through, underlying fascia. Stage IV lesions extend into muscle or bone or supporting structures.

INCIDENCE AND EPIDEMIOLOGIC FACTORS

Many patients are at risk for pressure ulcers, with 12% or more of adult hospitalized patients being confined to bed or chair. Such activity limitation is even more common in nursing homes, but most patients with pressure ulcers develop the ulcer during a stay at an acute care hospital. More than half of those with pressure ulcers are older than age 70.

The incidence of stage II and higher ulcers during hospitalization is 1% to 3% of all admissions but can be as much as eight times higher for those with activity limitations. Development of a stage I ulcer is associated with the subsequent occurrence of a stage II or higher ulcer in nearly 60% of cases. In nursing homes, the 3-month incidence of stage II and higher ulcers is about 5%; the figure increases to 13.2% after 1 year.

ETIOLOGIC FACTORS AND PATHOGENESIS

Low-level pressure for long periods or high-contact pressure for short periods leads to skin ulceration. Subcutaneous tissues and muscle are more sensitive to pressure-induced necrosis than the epidermis. The effect of pressure on all tissue layers can be augmented by exposure to shearing forces, friction, and moisture. Shearing forces, which are tangential forces generated in deep sacrococcygeal tissues, can cause occlusion of gluteal vessels or mechanical damage to subcutaneous tissues when the patient is sitting in bed or in a chair. Friction-induced epithelial loss can result from being pulled across a bed sheet, or when similar movements result from spasticity. Urinary and fecal incontinence may lead to maceration or irritation of the epidermis.

When bony prominences are exposed to adequate pressure, blood and lymphatic vessels are occluded. As a consequence, endothelial cell swelling occurs, and plasma, proteins, and blood ultimately leak into interstitial tissues. Cellular metabolites and inflammatory cells accumulate, and intravascular thrombosis and fibrin deposition occur. Muscle and subcutaneous tissue necroses ensue, ultimately leading to dermal and epidermal death.

CLINICAL AND LABORATORY FINDINGS

Identification of at-risk patients should involve the systematic assessment of bed- and chairbound persons for risk factors such as mobility impairment, incontinence, nutritional status, and level of consciousness. This can be accomplished by using a validated risk-assessment tool such as the Braden Scale or the Norton Scale. Among bed- and chairbound patients admitted to an acute care hospital, inability to reposition, dry skin, lymphocyte count 1.5×10^9 or less, body weight less than 58 kg, and nonblanchable erythema of intact skin may help identify those at highest risk. After 3 weeks of follow-up, the cumulative incidence of stage II and higher pressure ulcers is 0% among bed- and chair-bound patients without one of these factors. The incidence with one, two, or three factors is significantly higher (11.4%, 39.6%, and 67.9%, respectively).

Evaluation of a patient with a pressure ulcer should include a complete history and physical examination, identification of complications and comorbid conditions, and assessment of nutritional status, pain, psychosocial factors, and risk of additional ulcers. [Table 463.1](#) lists the characteristics of pressure ulcers that should be evaluated and documented weekly. Within 2 to 4 weeks, the clinician can expect a clean pressure ulcer to show evidence of healing manifested by improvements in such parameters.

Location	
Tunneling	Sinus tracts
Stage	Granulation tissue
Exudate	Undermining
Size	Epithelialization
Necrotic tissue	Surrounding tissue status

TABLE 463.1. PRESSURE ULCER ASSESSMENT

All stage II, III, and IV ulcers are colonized with bacteria, so that swab cultures have no diagnostic value and should not be used. When signs of advancing cellulitis or systemic infection accompany a pressure ulcer, a culture of fluid obtained by needle aspiration or of tissue obtained by ulcer biopsy may be helpful. If evidence of local infection (purulent exudate, odor, necrotic tissue) persists after ulcer care measures ([Table 463.2](#)) have been in place for 4 weeks or longer, then quantitative bacterial cultures of the ulcer base and bone biopsy for culture and histologic examination should be considered. Osteomyelitis should be suspected when an elevated leukocyte count or erythrocyte sedimentation rate or an abnormal bone radiograph is documented.

■ Assessment should include the patient's history, physical examination, and laboratory studies.
■ The patient's history should include the location, duration, and characteristics of the ulcer.
■ The physical examination should include the location, size, depth, and characteristics of the ulcer.
■ Laboratory studies should include a complete blood count, serum albumin, and serum prealbumin.
■ The patient's nutritional status should be assessed using a validated tool such as the Braden Scale or the Norton Scale.
■ The patient's mobility status should be assessed using a validated tool such as the Braden Scale or the Norton Scale.
■ The patient's incontinence status should be assessed using a validated tool such as the Braden Scale or the Norton Scale.
■ The patient's pain status should be assessed using a validated tool such as the Braden Scale or the Norton Scale.
■ The patient's psychosocial status should be assessed using a validated tool such as the Braden Scale or the Norton Scale.
■ The patient's risk of additional ulcers should be assessed using a validated tool such as the Braden Scale or the Norton Scale.
■ The patient's response to treatment should be assessed using a validated tool such as the Braden Scale or the Norton Scale.

TABLE 463.2. RECOMMENDATIONS FOR ULCER CARE

OPTIMAL MANAGEMENT

PREVENTION

After identifying a patient at risk for developing pressure ulcers, a systematic skin inspection should be performed daily. At the time of soiling and at routine intervals, the skin should be cleansed with a mild agent, avoiding hot water and minimizing the force and friction applied to the skin. Moisturizers should be used for dry skin. Skin exposure to moisture due to incontinence, perspiration, or wound drainage should be minimized. If incontinence cannot be controlled after appropriate assessment and treatment, an absorptive brief or underpad should be used. Topical agents that act as barriers to moisture can also be tried.

Skin injury due to friction and shear can be minimized by using proper positioning; appropriate transferring and turning techniques; as well as lubricants such as cornstarch and creams, protective films, dressings, and pads over bony prominences. Rehabilitation efforts should be instituted if consistent with the overall goals of therapy. Massage over bony prominences should be avoided, as it may reduce blood flow and cause deep-tissue injury.

Adequate dietary intake should be provided to prevent malnutrition, and nutritional deficiencies should be corrected in a way consistent with the overall goals of therapy. For malnourished patients with pressure ulcers, nutritional support providing 30 to 35 calories per kilogram per day and 1.25 to 1.5 g protein per kilogram per day may be needed to achieve a positive nitrogen balance. A daily high-potency vitamin and mineral supplement is recommended for all patients suspected of having vitamin deficiencies.

At-risk patients in bed should be repositioned every 2 hours if consistent with overall patient goals. In addition, a pressure-reducing device, such as a foam, static air, alternating air, gel, or a water mattress, should be used. Although pressure-reducing support surfaces may decrease the frequency of intermittent repositioning required, patients should be carefully monitored for evidence of erythema over bony prominences. Such evidence would indicate the need for more frequent repositioning or a more effective pressure-reducing device.

When repositioned, patients should be alternately turned from the supine position to the side-lying position at 30 degrees to the support surface. When positioned on the side at this angle, direct pressure on the trochanter and lateral malleolus is avoided. Placement of soft pillows between the knees and ankles is also helpful during repositioning. Pillows should be placed under the legs, or another device should be used to relieve heel pressure totally for completely immobile patients.

Because of the shearing forces generated while sitting, at-risk patients should be repositioned at least every hour while in a chair or should be put back to bed. Patients who can move should be taught to shift their weight every 15 minutes while sitting. The use of a pressure-reducing cushion made of foam, gel, air, or a combination is indicated for at-risk patients while sitting. To minimize the impact of shear on patients in bed, the head of the bed should be kept at the lowest degree of elevation and for the shortest amount of time consistent with other medical requirements.

TREATMENT

Pressure ulcer treatment includes the preventive strategies recommended above. During repositioning, no pressure should be put on the ulcer. A static pressure-reducing support surface may be used if the patient can assume a variety of positions without bearing weight on the ulcer and without compressing the support surface or "bottoming out." Positioning devices may be used to raise a pressure ulcer off the support surface. A dynamic support surface, such as an alternating-air mattress, low-air-loss bed, or air-fluidized bed, is indicated if the patient cannot assume a variety of positions without bearing weight on the ulcer, if the patient fully compresses a static support surface, or if the ulcer does not show evidence of healing.

Recommendations for local ulcer care, debridement, wound cleansing, dressings, adjunctive care, and the management of infection are listed in [Table 463.2](#). Once an ulcer is clean and granulating, dressings that provide a moist wound environment should be used to promote healing. Evidence suggests that continuously moist saline gauze, film, and hydrocolloid dressings are similarly effective in achieving this goal, but saline gauze dressings require significantly more caregiver time than film and hydrocolloid dressings because the latter types of dressings need to be changed less frequently than do moist gauze dressings.

Surgical repair can be considered when clean stage III or IV pressure ulcers do not respond to the recommended treatments. Possible candidates are medically stable and adequately nourished patients who can tolerate operative blood loss and postoperative immobility.

Even after 6 months of treatment, as many as 26% of stage II ulcers and 41% of stage III or IV ulcers may fail to heal. These outcomes for pressure ulcer treatment suggest that clinicians should increase the emphasis on preventive interventions while also seeking improvements in ulcer care.

CHAPTER 464: APPROACH TO THE FRAIL ELDERLY PATIENT

LINDA P. FRIED AND JEREMY WALSTON

[Clinical Import of Frailty](#)
[Presentation and Pathophysiologic Factors](#)
[Precipitants of Frailty](#)
[History, Physical Examination, and Differential Diagnosis](#)
[Strategies for Optimal Care](#)

CLINICAL IMPORT OF FRAILITY

Frailty is a clinical status whose incidence increases with age. It is estimated that 10% to 25% of older adults are frail. After the age of 85, according to the American Medical Association's White Paper on Elderly Health, "46% of those living in the community fall into this group of frail elderly." Frailty is of particular clinical interest because frail individuals are thought to constitute those older adults at highest risk for a number of adverse health outcomes, including dependency, institutionalization, falls, injuries, acute illness, hospitalization, and mortality. Frail individuals are also thought to be at risk for slow or blocked recovery from illness. Although a clinical "sense" of frailty exists, there is still no explicit consensus or standard clinical definition of frailty that would assist identification of this high-risk subset prior to the onset of these adverse outcomes. However, some early work characterized the clinical presentation of this high-risk state, along with interventions that might be useful in prevention of progression. Effective interventions would minimize adverse outcomes in this high-risk group. In addition, clinical evaluations suggest that the later stages of frailty may not be modifiable and in fact presage death, whereas the earlier stages might have greater potential for modification. Given these observations, those with earlier frailty may be a subset of older adults who are most likely to benefit from evaluation and preventive interventions.

Despite the difficulty of defining who is frail, it is important to translate clinical instinct into explicit definitions of frailty. These permit development of useful clinical screening methods and definition of underlying etiologic processes and opportunities for intervention. The purpose of this chapter is to briefly summarize the potential definitions of frailty and to highlight evidence regarding cause and treatment.

PRESENTATION AND PATHOPHYSIOLOGIC FACTORS

The literature suggests that frailty and failure to thrive constitute a continuum of a clinical syndrome, with failure to thrive being the most extreme manifestation that is associated with a low rate of recovery. The manifestations of frailty that are most widely agreed upon in the literature are a constellation of symptoms including unintentional weight loss and/or loss of muscle mass, weakness, fatigue, inactivity, and decreased dietary intake ([Fig. 464.1](#)). In addition, signs of frailty are frequently cited as components of the syndrome; these include sarcopenia (decreased muscle mass), balance and gait abnormalities, deconditioning, and decreased bone mass (osteopenia) ([Fig. 464.1](#)). Undernutrition and malnutrition are also cited as characteristics. Each of these clinical characteristics has been shown to be highly predictive of the adverse outcomes clinically associated with frailty, including decline in function, institutionalization, and mortality. Consistent with the definition of a syndrome, the phenotype of frailty appears to include a critical mass of these symptoms and signs, rather than any one being necessarily present or sufficient to define the condition.

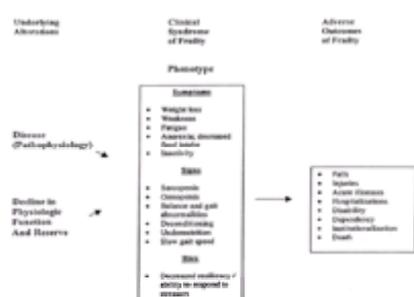

FIGURE 464.1. Modal pathway of frailty. The clinical phenotype of frailty is associated with adverse health outcomes and appears to result from declines in physiologic function and reserve, as well as disease precipitants.

It is well established that undernutrition in older adults, including inadequate protein and micronutrient intake, is a contributor to loss of lean body mass, even in the absence of weight loss. It is also clear that decline in lean body mass leads to declines in strength and exercise tolerance, along with decreased walking speed and overall activity levels, and decreased resting metabolic rate. These latter changes contribute to an overall decrease in total energy expenditure. These established connections suggest, potentially, a vicious cycle involving altered energetics that is consistent with the phenotypic presentation of frailty, described above. Based on preliminary studies, Poehlman et al. have suggested that a subset of older adults manifests dysregulation of energy intake, such that it is inadequate relative to energy output, even at low levels of caloric expenditure. If so, this could complete the hypothesized adverse feedback loop, further exacerbating undernutrition and propelling decrements in this energetics cycle. This clinical conceptualization is displayed in [Fig. 464.2](#).

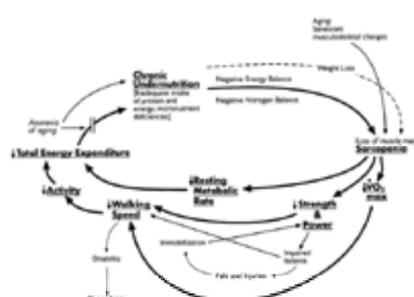

FIGURE 464.2. The cycle of frailty. Key components of frailty that appear to underlie its phenotypic manifestations in a negative feedback cycle are chronic undernutrition; sarcopenia; declines in physical strength, power, and exercise tolerance; and declines in activity and total energy expenditure. Factors that could precipitate or exacerbate this core cycle are indicated with dashed lines. Factors in which a relationship is hypothesized are indicated in italics. (Fried CP, Walston J. Frailty and failure to thrive. In Hazzard WR, Blass JR, Ettinger WH, et al, eds. *Principles of geriatric medicine and gerontology*, fourth ed. New York: McGraw-Hill, 1999: [chapter 109](#), with permission.)

In addition to the clinical manifestations of frailty based on this cycle of adverse energetics, other potential biologic characteristics should be considered. The most widely agreed-upon geriatric definition of frailty from an etiologic perspective is that it represents a state of age-related physiologic vulnerability resulting from impaired homeostatic reserve and a reduced capacity of the organism to tolerate stressors. This could result in the well-recognized decreased ability to tolerate temperature extremes, increased susceptibility to infections, and relatively poor recovery from injuries and infections clinically associated with frailty. It has been suggested that a decline in reserve occurs with aging across multiple physiologic systems. Those systems whose declines are central to the syndrome of frailty

appear to be (a) neuromuscular changes, which result in sarcopenia and thus link this underlying biology to the cycle of energetics and the clinical presentation above; (b) neuroendocrine dysregulation, and (c) immunologic dysfunction. The biologic changes observed in these systems with aging are summarized in [Table 464.1](#). Declines in each of these realms, singly or in combination, can leave the frail older adult especially vulnerable to stressors.

Sarcopenia	Immune Dysfunction	Neuroendocrine Dysregulation
Skeletal muscle mass	Memory cells	Growth hormone
$\dot{V}O_2$ max	Naive cells	Estrogen
Strength and exercise tolerance	IL-2	Testosterone
Thermoregulation	IgG, IgA	Cortisol dysregulation
Energy expenditure	IL-6, IL-18	Sympathetic tone
Insulin resistance	Mitogen response	

IL, interleukin.
 (From Hazzard W, et al, eds. *Principles of geriatric medicine and gerontology*, fourth ed. New York: McGraw-Hill, 1999, Chapter 109, with permission.)

TABLE 464.1. CLINICAL SIGNS AND SYMPTOMS OF AGE-RELATED CHANGES IN PHYSIOLOGIC SYSTEM DECLINES CENTRAL TO THE SYNDROME OF FRAILTY

In fact, age-related declines have been described in a number of organ systems (see [Chapter 16](#)), indexes of which include reduced creatinine clearance, forced expiratory volume, nerve conduction velocity, insulin sensitivity, heart rate variability, lean body mass, $\dot{V}O_2$ max and strength. Some theorize that there are declines in the basic complexity of biologic responses to alterations in the environment that occur with aging and render the organism more vulnerable to internal or external perturbation. It is theorized that when such age-related declines occur in parallel across multiple systems, beyond an aggregate threshold of severity, they may lead to compromised physiologic reserves and ability to maintain homeostasis. This may, in turn, underlie the organism's decreased ability to tolerate stressors. Frailty appears especially to involve age-related compromise in one's ability to respond appropriately in dynamic situations.

Many definitions of frailty are in use. In particular, it is common to consider frailty to be synonymous with comorbidity or disability. However, there is increasing evidence that frailty is a syndrome in and of itself, as described above. It is potentially a cause of mobility- and exercise tolerance-related disability, but it is distinct from (through commonly interacting with) comorbidity as defined by coexisting diseases. Similarly, end-stage disease(s) may lead to frailty, but comorbidity itself is not the same as frailty.

Finally, frailty may itself have an end stage, sometimes termed "failure to thrive." This stage is reached after the occurrence of many of the adverse outcomes of frailty described above. It is thought to be a time of irreversible decline that progresses to death (sometimes called "predeath")—a final, common end-stage process of both the frailty of extreme old age and severe chronic diseases (e.g., congestive heart failure, malignancy, HIV, and dementia). The hallmarks of failure to thrive are unexplained and include progressive weight loss, with malnutrition and resulting loss of fat as well as muscle mass. This syndrome is also described as presenting with social withdrawal; episodes of falling; metabolic abnormalities, including hypoalbuminemia, low creatinine, acquired hypocholesterolemia, and anemia of chronic disease; and decubitus ulcers.

PRECIPITANTS OF FRAILTY

It is thought that frailty and failure to thrive develop as an age-related syndrome that is progressive but that may become clinically manifest in the presence of a trigger event, such as acute illness, injury, an adverse life event, low activity level, and/or bed rest. Incomplete recovery from these events, including failure to regain strength to the pre-morbid level, puts the individual on a stepwise decline that progresses on the cycle of frailty and/or upon the occurrence of a subsequent trigger. Episodic negative energy balance and incomplete recovery from each trigger event may be an important pattern for progression to frailty and initiation of the frailty cycle. Especially central in this pathophysiologic cascade is activation of the immune system ([Table 464.1](#)), which can be triggered by manifold diseases or trauma, and with release of catabolic (and anorexogenic) cytokines initiate a final common pathway of decline.

HISTORY, PHYSICAL EXAMINATION, AND DIFFERENTIAL DIAGNOSIS

The first goal in clinical care is to identify vulnerable individuals with latent frailty before the occurrence of the adverse outcomes for which they are at high risk. Such a clinical approach includes early identification of declines in weight, strength, dietary intake, or activity, each of which might precipitate the cycle of frailty. A number of diseases that are responsive to therapy can cause wasting, including congestive heart failure, diabetes, thyroid disease, tuberculosis and other chronic infections, undiagnosed cancer, and inflammatory conditions such as temporal arteritis. Psychological conditions, such as depression, psychosis, and grief, as well as dementia, can also present in this manner. Whether or not frailty is due to a specific underlying disease, focus should also be placed on prevention of related adverse outcomes, including falls and disability. Evaluation should also include screening for factors that may exacerbate vulnerability to these outcomes, such as medications, with intervention as indicated. Another reality enters the diagnostic picture as well: an underlying disease-specific etiologic process of frailty (e.g., occult malignancy) may not be evident when the syndrome first manifests, and each diagnostic effort in search of such an etiologic process carries its own risk and cost, which may be especially high in the frail patient (who is especially vulnerable to iatrogenic misadventures). Hence, constant subsequent vigilance must be exerted for the emergence of clues to, especially, treatable conditions if appropriate initial diagnostic maneuvers fail to disclose a specific cause of the syndrome.

STRATEGIES FOR OPTIMAL CARE

If other diseases are ruled out as the cause of frailty (if the frailty appears to be primary rather than secondary), a goal should be to institute supportive interventions early. These include targeting the environmental provocations that can trigger or accelerate the manifestations of frailty, especially low activity, inadequate nutrition, and catabolic medications. The purpose of this intervention would be prevention of loss of muscle mass and improvement in strength and energy. This should include prescription of regular exercise, as well as nutritional supplementation, if indicated. There is now firm evidence that resistance exercise to increase the strength of a frail older adult has potential from both a preventive and a therapeutic point of view. In very frail nursing home patients of age 72 to 98 years, progressive resistance exercise training over a 10-week period was shown to improve strength, gait velocity, stair-climbing power, and spontaneous physical activity. The greatest benefit from this weight-lifting exercise was seen in those who were initially weakest but did not have severe muscle atrophy (suggestive of a group with more recent onset of weakness). These findings thus suggest that benefit from exercise can accrue to even the most frail but that improvement is greatest if declines in strength are caught early. At the other end of the spectrum, primary prevention of frailty through regular strength training also has therapeutic potential due to both direct effects on muscle strength and indirect effects resulting from increased overall activity levels in people who are getting stronger. Evans has reported that high-intensity strength training appears to have highly anabolic effects in older adults. He reported a 10% to 15% decrease in nitrogen excretion after initiation of such training, which persisted for the 12-week duration of training. In other words, progressive resistance exercise improved nitrogen balance. As a result, older patients performing resistance training had a lower mean protein intake requirement than did sedentary subjects.

It is notable that such increases in strength from high-intensity training are substantially greater than those seen with growth hormone without concurrent training. Studies to date that have evaluated replacement therapies for prevention or treatment of declines in growth hormone have shown some efficacy in increasing lean body mass, decreasing fat mass, and slowing the catabolic effects of acute and chronic diseases or injuries, such as hip fracture and infections. However, it is not clear that such changes from growth hormone can be sustained, and there is no evidence that supplementation improves the functional status of growth hormone-deficient men. In addition, the long-term risks of growth hormone replacement on tumor development remain unclear. Therefore, there is currently no clear indication for the use of growth hormone in relation to the loss of lean body mass with age.

The role of nutritional supplementation in the treatment of frailty is less well defined than that of exercise. In Fiatarone and colleagues' trial of resistance exercise and nutritional supplementation in frail nursing home patients, total energy intake did not increase spontaneously in those exercising (without nutritional supplementation) or in those receiving nutritional supplementation but not exercising, in comparison with controls. This was the case even though this population had a marginal nutritional intake at baseline. Only with both exercise and nutritional supplementation did energy intake increase to a noticeable extent; these people gained weight but not measurably fat-free mass. Additionally, the research of Poehlman et al. indicates that older men and women have to increase energy expenditure by 1,000

kcal per week to get compensatory increases in energy (food) intake and increases in resting metabolic rate.

Preservation of fat-free mass and prevention of sarcopenia appear key in preventing the decrease in metabolic rate and dysregulation of energetics described in association with frailty. Maintenance of strength should also maintain exercise tolerance, both directly and indirectly because those with improved strength appear to engage more spontaneously in other activities. In the prevention of frailty, this appears to be a critical stage in terms of both the prevention of disability and the downward spiral to failure to thrive and death.

CHAPTER 465: DIAGNOSIS AND MANAGEMENT OF OSTEOPOROSIS IN OLDER ADULTS

KAREN M. PRESTWOOD

[Definition of Osteoporosis](#)
[Epidemiologic Factors](#)
[Review of Bone Remodeling](#)
[Bone Loss with Aging](#)
[Pathogenesis of Osteoporosis in Older Adults](#)
[Diagnosis of Osteoporosis and Prediction of Fracture](#)
[Prevention and Treatment of Osteoporosis](#)

Osteoporosis is a common disease in older adults. In women, the incidence of vertebral fractures begins to increase near the time of menopause; hip fracture incidence accelerates approximately 10 years later. Hip fractures in women are twice as common as in men at age 75 years, but men still suffer more than 75,000 femur fractures annually; the gender ratio of vertebral fractures is 8:1. The direct health care costs related to osteoporosis are estimated to be \$38 million per day, or \$14 billion per year. The number of older adults in this country is increasing rapidly, and the disability and mortality associated with hip and vertebral crush fractures are concentrated in older Americans. Thus, prevention of osteoporotic fractures is a major public health concern.

DEFINITION OF OSTEOPOROSIS

Osteoporosis is a “disease characterized by low bone mass and microarchitectural deterioration of bone tissue leading to enhanced bone fragility and a consequent increase in fracture incidence.” Clinically, osteoporosis can be defined either by the presence of a fragility-related fracture or by bone mineral density (BMD) measurement. In defining BMD criteria for osteoporosis, the World Health Organization (WHO) established the standard as BMD of young adult women who are at the age of peak bone mass. For each standard deviation below peak bone mass (or one-unit decrease in t score), a woman's risk of fracture approximately doubles. For example, a woman with a t score of -3 at the hip would be eight times more likely to suffer a hip fracture than a woman with a t score of zero. As seen in [Table 465.1](#), a t score of less than -2.5 defines osteoporosis; osteopenia (low bone mass) and normal bone mass are also defined. The advantage to diagnosing osteoporosis by BMD is that the disease can be detected prior to incident fracture. In addition, women with osteopenia can be placed on a preventive regimen and followed carefully for additional bone loss. Similar standards for definitions of osteoporosis have not been established for men or for racial and ethnic groups other than whites, although recent data indicate that the standards for Hispanic women are probably similar to those of white women.

	BMC or BMD t score	Recommended Intervention
Normal	>-1	Assure adequate Ca+D intake for age; smoking cessation; regular exercise
Osteopenia	≤ -1 but > -2.5	Use preventive measures (Fig 465.3)
Osteoporosis	≤ -2.5	Use treatment measures (Fig 465.4)
Severe osteoporosis	≤ -2.5 + fragility fracture	Use treatment measures (Fig 465.4)

BMC, bone mineral content; BMD, bone mineral density.

TABLE 465.1. WORLD HEALTH CRITERIA FOR OSTEOPOROSIS AND RECOMMENDATIONS FOR INTERVENTION IN OLDER ADULTS

EPIDEMIOLOGIC FACTORS

In the United States, the estimated numbers of hip and vertebral fractures in women are greater than 250,000 and 500,000, respectively, per year. To this number must be added fragility fractures in men, which occur at about one-third the age-specific rate seen in women. Thus, approximately 1 million Americans suffer fragility fractures each year. The consequences of osteoporotic fracture include diminished quality of life, decreased functional independence, and increased morbidity and mortality. Pain and kyphosis, height loss, and other changes in body habitus of vertebral compression fractures diminish quality of life in women and men. Declines in functional status may result in the inability to bathe, to dress, or to ambulate independently; approximately 50% of women do not recover full function after hip fracture. Finally, a 20% excess mortality occurs in older persons in the year following hip fracture.

REVIEW OF BONE REMODELING

Bone remodeling, the coupled process of bone formation and bone resorption, is the process by which bone repairs microfractures and maintains bone health. Bone remodeling is a normal process that occurs in all adults after peak bone mass is reached. Osteoblasts and osteoclasts are the primary cells involved in bone formation and resorption, respectively. As indicated in [Fig. 465.1](#), the bone-remodeling cycle begins with “activation.” This process may be initiated either by local changes, such as mechanical force and micro-fractures, or by systemic hormones or local factors that influence overall bone turnover. Activation is initiated when factors such as parathyroid hormone (PTH), interleukin-1 (IL-1), prostaglandin E_2 (PGE_2), and 1,25-dihydroxyvitamin D_3 , which are known to stimulate bone resorption, alter molecules on the surface of osteoblast precursors or stromal cells. These surface molecules are variably called osteoclast differentiation factor (ODF), osteoprotegerin ligand (OPGL), and receptor activator of NF Kappa B (RANK) ligand ([Fig. 465.2](#)). The surface molecule on the osteoblast then interacts with a receptor molecule on osteoclast precursors, presumably a form of RANK, and signals are then likely transmitted to both osteoblast and osteoclast precursors. The osteoblast also makes osteoprotegerin (OPG), which can bind to OPGL and block the interaction between the responder cells (osteoblast precursors) and osteoclast precursors. Other cell–cell interactions between osteoblast and osteoclast may also be important in the initial steps of activation and osteoclastogenesis. Furthermore, the interaction between RANK and OPGL is necessary, but not sufficient, for the formation of active functional osteoclasts. At least one other factor, macrophage colony-stimulating factor (M-CSF or CSF-1), which is also produced by osteoblasts, is also important in osteoclastogenesis. M-CSF appears to play a role in the initial replication and activation of the osteoclast precursors, as well as in the subsequent steps of differentiation and fusion that lead to the fully activated osteoclast.

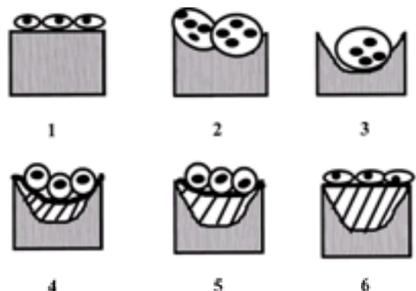

FIGURE 465.1. The bone remodeling cycle. (1) Resting phase. (2) Osteoclast activation. (3) Active resorption by mature osteoclasts. (4) Osteoblasts lay down osteoid. (5) Osteoblasts calcify new bone. (6) Resting phase.

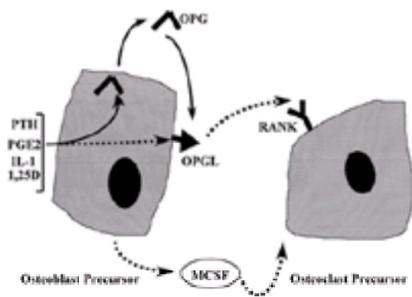

FIGURE 465.2. Schematic illustration of the interaction of osteoblast and osteoclast precursor. On the surface of osteoblast precursors are molecules called osteoprotegerin ligands (OPGLs) (also known as osteoclast-differentiating factors, TRANCE, or RANK-L). These molecules interact with RANK on the surface of osteoclast precursors, resulting in activation of osteoclasts. Parathyroid hormone (PTH), prostaglandin E₂ (PGE₂), interleukin-1 (IL-1), and 1,25-hydroxyvitamin D (1,25D) have a positive effect on OPGL, resulting in increased activation of osteoclasts and, thus, bone resorption. Osteoblasts also make osteoprotegerin (OPG), which can bind to OPGL and block the interaction of osteoblast and osteoclast precursors. PTH, PGE₂, IL-1, and 1,25D have a negative effect on OPG production, resulting in increased bone resorption. Osteoblast precursors also produce macrophage colony-stimulating factor (M-CSF), which acts by another pathway to activate osteoclasts. It appears that both types of osteoblast–osteoclast interactions are necessary for activation of the bone remodeling cycle to take place. Solid lines represent negative effects and dotted lines represent positive effects.

Once the osteoclasts are fully differentiated, bone resorption occurs. One important question in control of bone remodeling is how the depth and breadth of osteoclastic resorption are regulated. The limited extent of osteoclast resorption may be due to the finite life span of osteoclasts, whose nuclei undergo apoptosis. Hormones can regulate the life span and mortality of the osteoclast, but the details of this regulation are not fully understood. Following osteoclastic resorption, the reversal phase of remodeling occurs, during which mononuclear cells are present on the bone surface. The function of these cells is not understood; however, they may be involved in further degradation of bone matrix, in the formation of the so-called cement line that is present between old and new bone, or in signaling of osteoblasts to migrate and differentiate and begin new-bone formation at the resorption site. The initiation of the formation phase is probably dependent not on cell–cell interactions but on local release of growth factors either from the matrix or from the various cells involved in the resorption and reversal phases. These growth factors stimulate the subsequent replication, migration, and differentiation of new osteoblasts in successive waves, which may also depend on signals from the differentiated osteoblasts themselves. In younger individuals, the amount of new bone formed during the coupled phase of bone remodeling is approximately equal to that resorbed; however, the capacity of the osteoblast population to multiply and to lay down new bone decreases with aging. Therefore, the amount of new bone on a trabecular surface, as measured by mean wall thickness, is decreased. In cortical bone, the consequence of impaired osteoblast renewal is incomplete filling in of the haversian canal, resulting in formation of a porotic cortex.

BONE LOSS WITH AGING

Bone mass changes over the life span of an individual. In women, bone mass increases rapidly from the time of puberty until approximately the mid-twenties to mid-thirties, at which time peak bone mass is reached. Once women reach peak bone mass, a few years of stability are followed by a slow rate of bone loss beginning well before the onset of menopause. After menopause, the rate of bone loss is quite high—from 3% to 7% per year—for up to 7 years, due to estrogen deficiency. In later life, bone loss continues, albeit at a slower rate, perhaps 1% to 2% per year; the data strongly suggest that terminating bone loss at any time will decrease fracture risk. Further, investigators estimate that a 14% increase in bone density in 80-year-old women would halve hip fracture risk. This 14% increase would also be realized if bone loss were prevented in 70-year-old women.

Men also lose bone with increasing age. Cross-sectional studies have detected a slower rate of bone loss in men than in women, but in longitudinal studies, rates of bone loss in men equaled those of older women. In spite of similar rates of bone loss in older men and women, vertebral fracture rates are lower in men. Both men and women lose predominantly cancellous bone, which is concentrated in the vertebral spine. Cortical bone accounts for 45% to 75% of the mechanical resistance to compression of the vertebral spine, and men actually gain cortical bone through periosteal bone deposition. Men also undergo an increase in the cross-sectional area of their vertebrae by 15% to 20%, increasing maximum load levels until the age of 75 years. The increased bone strength seems to be reversed by thinning of the cortical ring by age 75, the age at which men begin to present with vertebral fractures. Bone loss at the hip has not been extensively studied in men, but cross-sectional studies indicate that healthy men lose 30% to 40% of femoral neck BMD between the ages of 20 and 90 years. On iliac crest biopsies men demonstrate trabecular thinning, but they perforate the trabeculae less often than women, thereby preserving strength and providing greater potential for repair. In both femur and tibia, men and women showed endosteal resorption of bone and medullary expansion with aging; but only men had concurrent periosteal bone apposition and expansion, potentially compensating for the loss of endosteal bone.

PATHOGENESIS OF OSTEOPOROSIS IN OLDER ADULTS

A number of mechanisms may lead to bone loss and osteoporosis in older women and men. One mechanism may be related to calcium deficiency, producing secondary hyperparathyroidism. PTH is a potent stimulator of bone resorption when chronically elevated. Aging skin and decreased exposure to sunlight reduce the conversion of 7-dehydrocholesterol to cholecalciferol (vitamin D₃) by ultraviolet light and result in vitamin D insufficiency in older adults. Vitamin D insufficiency, in turn, reduces the absorption of calcium. Furthermore, older adults tend to ingest inadequate amounts of vitamin D and calcium. As a result of decreased serum levels of calcium, PTH increases, which leads to increased bone resorption.

The pathogenesis of osteoporosis in women is complex. Factors that affect the level of peak bone mass, the rate of bone resorption, and the rate of bone formation need to be considered. Peak bone mass appears to be 75% to 80% genetically determined, although the genes involved are not clearly known. At this time, candidate genes include vitamin D receptor, estrogen receptor, transforming growth factor, IL-6, IL-1 receptor 2, type I collagen genes, and collagenases.

After menopause, and with estrogen deficiency, a variety of factors that act locally on bone may lead to increased bone resorption. Factors thought to play a role in the postmenopausal bone include IL-1, IL-1 receptor antagonist, IL-6, and tumor necrosis factor, as well as their binding proteins and receptors. The exact mechanism by which estrogen deficiency leads to increased bone resorption and bone loss is not fully understood.

Androgens are important determinants for peak bone mass in men. Bone accretion is closely related to sexual maturity, and men who have abnormal puberty or delayed puberty have reduced bone mass. In addition, men with estrogen deficiency or resistance have decreased bone mass and failure of epiphyseal closure. Late-onset hypogonadism may also play a role in osteoporosis in men, although further study is required to determine the exact mechanism.

Osteoblast activity appears to decrease with aging, compounding the bone loss that results from increased resorption seen with aging and menopause. Growth factors such as transforming growth factor b and insulin-like growth factor I may be impaired with estrogen deficiency or with aging, resulting in decreased osteoblast function.

DIAGNOSIS OF OSTEOPOROSIS AND PREDICTION OF FRACTURE

RISK FACTORS

Risk factors for osteoporosis and osteoporotic fracture have been identified and have been used to determine who should be placed on preventive or therapeutic regimens. Risk factors, however, are mediocre predictors of low bone density and fractures, and it is more useful to identify modifiable risk factors and to implement

change as part of a treatment or prevention program ([Table 465.2](#)).

Potentially Modifiable	Nonmodifiable
Current cigarette smoking	Personal history of fracture
Low body weight (< 127 lb)	History of fracture in first-degree relative
Estrogen deficiency	Advanced age
Early menopause (< 45 y)	Female sex
Prolonged premenopausal amenorrhea (> 1 y)	Dementia
Low calcium intake (lifelong)	Poor health/frailty
Alcoholism	
Impaired eyesight despite adequate correction	
Recurrent falls	
Inadequate physical activity	
Poor health/frailty	

(Modified from National Osteoporosis Foundation. Physician's Guide to Prevention and Treatment of Osteoporosis.)

TABLE 465.2. RISK FACTORS FOR OSTEOPOROTIC FRACTURE

SECONDARY CAUSES OF OSTEOPOROSIS

The diagnosis of idiopathic or primary osteoporosis is made by bone density measurement prior to fracture or by incident fracture. Exclusion of diseases that may present as fracture or with low bone mass is important in the evaluation of women and men with osteoporosis. The major secondary causes of osteoporosis are listed in [Table 465.3](#), along with laboratory tests used to exclude each disease. These laboratory tests should be considered in persons who present with acute compression fracture or who present with a diagnosis of osteoporosis by BMD measurement. Men are more likely to have a secondary cause of osteoporosis than women. The most commonly reported secondary causes of osteoporosis in men include hypogonadism and malabsorption syndromes. Some medications may have a detrimental effect on bone and should be identified to allow dose adjustment or discontinuation of the medications. Medications that have been shown to adversely affect BMD include glucocorticoids, excess thyroid supplement, anticonvulsants, methotrexate, cyclosporine, and heparin. In older adults, glucocorticoids and thyroid hormone are used quite commonly; accordingly, clinicians should consider the effects these medications may have on the already increased risk of fracture when prescribing them to older adults.

Disease	Laboratory Tests
Primary hyperparathyroidism	Ionized calcium
Multiple myeloma	Serum and urine protein electrophoresis
Paget's disease	Alkaline phosphatase
Osteomalacia	Alkaline phosphatase, 25(OH)D ₃
Hypert thyroidism	T ₄ , TSH
Hypogonadism (men only)	Bioavailable testosterone, prolactin

T₄, thyroxine; TSH, thyroid-stimulating hormone; 25(OH)D₃, 25-hydroxycholecalciferol.

TABLE 465.3. RECOMMENDATIONS FOR EVALUATION OF SECONDARY CAUSES OF OSTEOPOROSIS

BONE DENSITY MEASUREMENT

Bone mineral density (BMD), or bone mass measurement, is the best predictor of fracture. BMD of the hip, spine, wrist, or calcaneus may be measured by a variety of techniques. The preferred method of BMD measurement is dual-energy x-ray absorptiometry (DXA). BMD of the hip, anteroposterior spine, lateral spine, calcaneus, and wrist can be measured using this technology. Quantitative computed tomography (QCT) is also used to measure BMD of the spine. Specific software can adapt CT scanners for BMD measurement. The advantages of DXA over QCT include lower cost, lower radiation exposure, and better reproducibility over time. Newer techniques, such as peripheral DXA (measures wrist BMD) or ultrasonography of the calcaneus, may be useful for general osteoporosis screening, and they have the advantage of reduced cost and portability. The cost of DXA is approximately \$200, and Medicare covers approximately two-thirds of the cost. Current recommendations for measurement of BMD are as follows: (a) all postmenopausal women under the age of 65 years with one or more additional risk factors (other than menopause); (b) all women over 65 years, regardless of additional risk factors; (c) all postmenopausal women who present with fracture (to confirm diagnosis and determine severity); (d) women considering therapy for osteoporosis, if BMD testing would facilitate the decision; and (e) women who have been on hormone replacement therapy for prolonged periods of time (even with long-term hormone replacement therapy, women may have low BMD).

BMD may also be used to establish the diagnosis and severity of osteoporosis in men, and should be considered in men with low-trauma fracture, radiographic criteria consistent with low bone mass, or diseases known to place an individual at risk for osteoporosis. Data relating to fracture risk are derived from studies completed in women, but data also suggest that similar associations may be valid in men as well.

BIOCHEMICAL MARKERS OF BONE TURNOVER

Serum and urine biochemical markers of bone turnover have been used successfully to assess rapid turnover states, such as Paget's disease and primary hyperparathyroidism. Bone turnover changes in osteoporosis are generally smaller and require more sensitive methods. Over the last few years, new markers have been developed that reflect collagen breakdown (or bone resorption) and bone formation. Some markers are associated with increased risk of hip fracture, decreased bone density, and excess bone loss in older adults. In addition, markers of bone resorption and formation decrease in response to antiresorptive treatment. However, the use of markers in clinical practice is controversial because of the substantial overlap of marker values in women with high and low bone density or rate of bone loss. Furthermore, few studies have compared the response of a particular marker (or combination of markers) and bone density to therapy to determine the magnitude of decrease of a biochemical marker necessary to prevent bone loss or, more importantly, fracture. Urinary deoxypyridinoline cross-links and N-telopeptides of type I collagen and serum N-telopeptides of type I collagen are commercially available markers of bone resorption that may be useful in monitoring response to treatment in older women. The advantage of the serum versus urinary markers is that the intrapatient variability tends to be lower with serum markers, thus reducing error. Further evaluation of the clinical use of markers in older women is ongoing.

PREVENTION AND TREATMENT OF OSTEOPOROSIS

Osteoporosis develops in older adults when the normal processes of bone formation and resorption become uncoupled or unbalanced, resulting in bone loss. Therefore, osteoporosis prevention and treatment programs should focus on strategies that minimize bone resorption and maximize bone formation, as well as strategies that reduce falls. A number of nonpharmacologic and pharmacologic options are available to health care providers. Modification of risk factors ([Table 465.2](#)) is an important first step in preventing osteoporotic fractures in older adults.

ROLE OF EXERCISE

Exercise is an important component of osteoporosis treatment and prevention programs. Data in older men and women suggest a positive association between current exercise and hip BMD. Among regular exercisers, those who reported strenuous or moderate exercise had higher BMD at the hip than those who reported mild or less than mild exercise. Similar associations were seen for lifelong regular exercisers and hip BMD. In a randomized study of women at least 10 years past menopause, the group receiving calcium supplementation plus exercise had less bone loss at the hip than those assigned to calcium alone. Furthermore,

high-intensity strength training effectively maintains femoral neck BMD and improves muscle mass, strength, and balance in postmenopausal women, in comparison with unexercised controls, suggesting that resistance training would be useful to help maintain BMD and to reduce the risk of falls in older adults.

Marked decrease in physical activity or immobilization results in a decline in bone mass; accordingly, it is important to encourage older adults to be as active as possible. Weight-bearing exercise, such as walking, can be recommended for older adults, who should be encouraged to start slowly and gradually increase both the number of days and the actual time devoted to walking. Physical therapy is an important part of osteoporosis treatment programs, especially after acute vertebral compression fracture. The physical therapist can provide postural exercises, alternative modalities for pain reduction, as well as information on changes in body mechanics that may help prevent future fracture.

CALCIUM AND VITAMIN D

Calcium and vitamin D are required for bone health at all ages. A consensus conference recommended 1,500 mg per day of elemental calcium for postmenopausal women and men over age 65 in order to maintain a positive calcium balance. The amount of vitamin D required is between 400 and 800 IU per day. Calcium plus vitamin D at different doses has been shown to increase or maintain bone density in pre- and postmenopausal women and to prevent hip as well as all nonvertebral fractures in older adults. Adequate calcium and vitamin D intake should be recommended to all older adults, regardless of BMD, in order to maximize bone health.

PHARMACOLOGIC OPTIONS (Fig. 465.3 and Fig. 465.4)

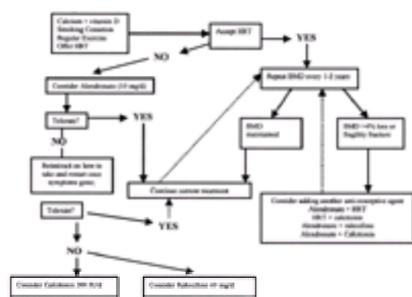

FIGURE 465.4. Algorithm for treatment of osteoporosis in postmenopausal women.

EVIDENCE LEVEL: B. Reference: National Osteoporosis Foundation. Physicians guide to prevention and treatment of osteoporosis. Belle Meade, NJ: Excerpta Medica, 1998.

Estrogen Replacement Therapy

Estrogen replacement therapy remains an important choice for the treatment and prevention of osteoporosis. In case-control and cohort studies, estrogen replacement therapy is associated with 30% to 70% reduction in the incidence of hip fracture. Multiple studies have demonstrated that postmenopausal estrogen use prevents bone loss at the hip and spine when initiated within 10 years of menopause, and other studies suggest that older women with low initial bone mass gain more bone than younger women.

Few studies have evaluated the use of estrogen in truly older women (women in their seventies, eighties, and nineties); however, small short-term studies suggest that older women are responsive to estrogen treatment. Other studies suggest that low-dose estrogen, in combination with calcium and vitamin D, has an additive effect on bone turnover in women over 70 years of age. Data from the Study of Osteoporotic Fractures support current estrogen use as protective against hip fracture, even in the oldest women. Furthermore, more and more data are accumulating to suggest that lower doses of estrogen are effective in reducing bone resorption and bone loss in older women; the lower doses also result in fewer side effects than the usual replacement doses typically used by clinicians. Although estrogen confers benefits to several organ systems, side effects and concerns about increased cancer risk associated with estrogen therapy have limited its use by postmenopausal women. Unopposed estrogen replacement therapy in women with a uterus has been associated with endometrial hyperplasia at a rate of about 30% per year, with endometrial cancer at a lower rate; concurrent progesterone therapy greatly reduces the incidence of both conditions. Hormone replacement therapy also has been associated, in some studies, with an increased incidence of breast cancer. Multiple case-control and cohort studies have variously suggested both increased and decreased breast cancer risk with estrogen replacement. Prospective data regarding the relationship between hormone replacement therapy and the incidence of breast cancer are not currently available; however, the Women's Health Initiative is addressing this issue. The various preparations of estrogen are listed, along with dosing regimens, in Table 465.4. Estrogen may be given in either continuous or cyclical fashion, depending on the preference of the woman. Because of other potential health benefits (cardiovascular, cognitive, genitourinary), hormone replacement therapy remains a primary consideration in women in whom estrogen is not contraindicated.

Medication	Dosage	Special Considerations
Estrogen replacement therapy:		
(1) Conjugated equine estrogen (Premarin)	0.3-0.625 mg/d*	In older women continuous administration usually preferred; lower doses effective in older (>70 y) women
(2) 17 β -Estradiol (Estrace)	0.5-1.0 mg/d	
(3) Transdermal estrogen (Estraderm)	0.05-0.1 mg biweekly	
Alendronate (Fosamax)	10 mg/d for treatment; 5 mg/d for prevention	Strict adherence to dosing instruction required
Raloxifene (Evista)	60 mg/d	Currently approved for prevention
Calcitonin, nasal spray (Miacalcin)	200 IU/d	Used for treatment of osteoporosis; metered spray; once spray given daily, dose alternate nostrils each day to reduce side effects; injectable useful in some patients
Calcitonin, injection (SC or IM) (Miacalcin, Calmarin)	50-100 IU 3-5 times/week	

*For cyclical therapy, estrogen is given on days 1-25 and then stopped. In women with a uterus, progesterone must be given with the estrogen to prevent endometrial hyperplasia. Mestranolone (Provera) is given 2.5-5.0 mg/d continuously or 1 or 10 mg/d on days 16-25 for cyclical treatment. Micronized progesterone is also available (200 mg/d on days 14-25, continuous dose probably lower but no studies have so demonstrated).

TABLE 465.4. APPROVED MEDICATIONS USED FOR THE PREVENTION AND TREATMENT OF OSTEOPOROSIS

Bisphosphonates

Alendronate sodium is a bisphosphonate that was approved for osteoporosis treatment several years ago. When compared with placebo, alendronate increased bone density of the spine and hip, and decreased the vertebral fracture rate in women with osteoporosis. In women with low hip bone density and prevalent vertebral fractures, a decrease in both vertebral and hip fracture was seen with alendronate, in comparison with placebo. Women with two or more vertebral fractures at baseline had the best response to alendronate therapy, suggesting that alendronate is effective in preventing fractures in women at highest risk for fracture. In women with low hip bone mass without previous vertebral fracture, bone density of the spine and hip also increased, and the vertebral fracture rate decreased by 51% with alendronate, in comparison with placebo. Another study in women 60 to 85 years of age indicated that an even lower dose of alendronate may be effective in older women. Recently, alendronate was also approved for prevention of osteoporosis in early postmenopausal women. The dose for prevention is a lower dose than that given for the treatment of osteoporosis ([Table 465.4](#)). Alendronate should be considered in women with osteoporosis, either by bone density or by the presence of a fragility-related fracture, who are unwilling or unable to take hormone replacement therapy. Alendronate is also effective in prevention of bone loss and fractures in men and women with glucocorticoid-induced osteoporosis.

The major side effects of alendronate are gastrointestinal, including abdominal pain, dyspepsia, esophagitis, nausea, vomiting, and diarrhea; musculoskeletal pain may also occur. Esophagitis, particularly erosive esophagitis, may be seen most frequently in patients who do not take the medication properly. For this reason, it is extremely important to provide specific and detailed instructions for patients receiving alendronate therapy.

Intermittent etidronate therapy was shown to increase spinal bone mass and decrease vertebral fractures in women with osteoporosis. However, etidronate is not approved for use in osteoporosis treatment or prevention and should be considered only if all other options have been exhausted. A recent study indicated that etidronate was also effective in preventing bone loss in patients requiring long-term glucocorticoids.

Calcitonin

Calcitonin is a peptide hormone that is used to treat osteoporosis. It is available as a subcutaneous injection and as a nasal spray. The advantages of a nasal spray over injectable calcitonin are fewer reported side effects and greater patient acceptance. Calcitonin has been shown to increase bone density in the spine and to reduce vertebral fractures. In epidemiologic studies calcitonin has been shown to reduce hip fractures, although in clinical trials hip bone density does not increase. A recent 5-year study demonstrated a decrease in vertebral fracture in women on nasal spray calcitonin (200 IU per day), in comparison with those on placebo. Calcitonin, however, does not appear to be as effective in preventing fractures as estrogen replacement therapy or alendronate; therefore, its use should be limited to those women who are unable to tolerate other treatments. In some studies, calcitonin therapy has also been associated with an analgesic effect in acute compression fractures, in Paget's disease of bone, and in bone pain attributable to metastatic disease.

Selective Estrogen Receptor Agonists

The selective estrogen receptor modulators (SERMs) are agents that act as estrogen agonists in bone and heart but act as estrogen antagonists in breast and uterine tissue. These medications have the potential to prevent osteoporosis or heart disease without the increased risk of breast or uterine cancer. Tamoxifen, an agent used in breast cancer treatment, has been shown to have beneficial effects on bone in several studies but has stimulatory effects on the uterus; it is not approved for treatment or prevention of osteoporosis. Postmenopausal osteoporotic women treated with raloxifene had decreased bone turnover and maintenance of proximal femur and total body bone density as well as fewer vertebral fractures, in comparison with women who received placebo. There were no differences among groups in breast abnormalities or endometrial thickness. In a short-term study, raloxifene had effects on bone histomorphometry and bone turnover that were similar in direction to conjugated equine estrogen (CEE) but were lower in magnitude than CEE. Raloxifene is currently approved for prevention of osteoporosis. Its use for treatment of osteoporosis is still being evaluated, although recent data suggest that raloxifene is effective in preventing vertebral fractures in postmenopausal women with osteoporosis.

THERAPEUTIC APPROACHES IN MEN

Very little is known about successful treatment or prevention of osteoporosis in men. Although the data are scarce, reasonable therapeutic approaches, based on successful outcomes in women or understanding of the differences in pathophysiologic factors, can be undertaken until more information is available. Thus, adequate calcium and vitamin D intake and exercise would be part of a prevention and treatment program in older men. Calcium intake is less than 800 mg per day in 60% of adult men in the United States, and approximately 900 mg per day is required to ensure calcium balance in men. Antiresorptive agents, which are effective in women, hold promise but have not been investigated in men. Treatment of osteoporosis due to secondary causes should focus on treatment of the underlying cause.

INVESTIGATIONAL AGENTS FOR OSTEOPOROSIS TREATMENT AND PREVENTION

A number of medications are currently under investigation for use in osteoporosis treatment and prevention, including additional bisphosphonates and SERMs, as well as PTH and fluoride. Other bisphosphonates under investigation for osteoporosis include risedronate, tiludronate, pamidronate, and ibandronate. Additional SERMs currently under evaluation include idoxifene and droloxifene.

PTH, while leading to increased bone resorption when chronically elevated, increases bone mass, trabecular connectivity, and mechanical strength in rodents when administered intermittently; in uncontrolled studies, it has been shown to increase spinal BMD in osteoporotic men and women. In a 3-year randomized study of postmenopausal women with osteoporosis, the group receiving estrogen plus intermittent PTH had a continuous increase in spinal bone mass over the study period, as well as a decreased rate of vertebral fracture. Bone mass of the hip and total body also increased significantly in the estrogen plus PTH group, in comparison with estrogen alone.

The use of fluoride to treat osteoporosis is appealing, since fluoride results in a large increase in spine BMD; however, the increase in BMD was not associated with a decrease in vertebral fractures. In fact, the group receiving fluoride had a higher rate of appendicular fractures. Recently, slow-release intermittent fluoride administration has been associated with an increase in spine BMD, as well as decreased incidence of vertebral fractures. Additional studies are required before slow-release fluoride can be recommended for the treatment of osteoporosis.

CHAPTER 466: DEMENTIA, INCLUDING ALZHEIMER'S DISEASE

CHRISTOPHER M. CLARK

[Alzheimer's Disease](#)
[Other Common Conditions That Produce Late-Life Dementia](#)
[Summary](#)

ALZHEIMER'S DISEASE

Alzheimer's disease (AD) is the most common form of late-life brain failure. It is a heterogeneous, neurodegenerative, dementing illness that produces progressive memory loss, changes in behavior and personality, psychotic symptoms, and impairments in insight, judgment, and executive abilities as well as the ability to perform complex motor and visual tasks (e.g., apraxia).

Pathologically it is defined by extensive neuron loss, numerous amyloid plaques, and abundant neurofibrillary tangles (NFTs) in selectively vulnerable regions of the brain, including the hippocampus, entorhinal cortex, and association areas of the neocortex. The hallmark clinical features of memory loss, behavioral changes, and confused thinking are a direct consequence of these pathologic changes. While there has been considerable progress in understanding the pathologic mechanisms responsible for this late-life neurodegenerative disorder, at present the specific factors responsible for producing these changes in the brain remain obscure. Only a few risk factors have been well established. These include age, presence of an ApoE e4 allele, female gender, history of head trauma, and having a first-degree blood relative with an AD-like dementia.

A small number of patients have an autosomal dominant form of AD. To date, more than 59 mutations have been identified that are capable of causing AD in this group. Twelve are on the *amyloid precursor* gene on chromosome 21, forty-five are on the *presenilin-1* gene on chromosome 14, and two are on the *presenilin-2* gene on chromosome 1. How these mutations produce the pathologic changes of AD has not been definitively established.

Most patients will have either a "sporadic" or "familial" (non-autosomal dominant) form of AD. For these individuals, the conditions capable of initiating and contributing to the pathologic changes in the brain are even more obscure, but they are certain to be multiple and to involve complex biological and environmental interactions.

PREVALENCE

Epidemiologic studies document the relationship between AD and advancing age. For individuals whose age is between 65 to 74 years, the prevalence is about 3%. This climbs to 47% for individuals over age 85. Because of the debilitating nature of the illness, its prolonged duration (6 to 12 years on average, with a range of 4 to 23 years), the high cost associated with care during its terminal stages, and the fact that individuals at highest risk are among the most rapidly growing segment of the United States population, AD is now recognized as a serious and escalating public health problem.

CLINICAL DESCRIPTION AND DIAGNOSTIC EVALUATION

AD is characterized by the insidious onset of memory failure. Symptoms most commonly begin between the ages of 70 and 85, but can occur as early as 40 and as late as 90. During the first several years, patients may also have difficulty with problem solving and word finding. They often exhibit subtle personality and behavioral changes. Frequently, they develop symptoms that mimic mild depression as they withdraw from social situations and lose enthusiasm for participating in activities that they find confusing and/or anxiety provoking. While they may be aware that their memory is failing, they usually do not appreciate the extent of the problem and rarely seek medical help. Thus, it is almost always a family member (spouse or adult child) who brings them to medical attention.

A clinical diagnosis of AD is best made using the consensus criteria developed in 1994. The main elements are listed in [Table 466.1](#).

Probable Alzheimer's disease
Dementia with onset between ages 40 and 90
Cognitive deficits in two or more areas
Progressive memory and cognitive deterioration
No other illness that could account for the dementia
No disturbance of consciousness
Possible Alzheimer's disease
Variations in the onset or clinical course
Presence of a secondary disorder sufficient to produce dementia but not felt to be the primary cause
Definite Alzheimer's disease
Clinical criteria for probable Alzheimer's disease
Neuropathologic evidence sufficient for the diagnosis

NINDS, National Institute of Neurological and Communicative Disorders and Stroke; ADRDA, Alzheimer's Disease and Related Disorders Association.

TABLE 466.1. DIAGNOSTIC CRITERIA FOR ALZHEIMER'S DISEASE BASED ON THE 1984 NINCDS-ADRDA CONSENSUS CRITERIA

A key feature is the documentation of memory loss as the earliest manifestation of the illness. Elements that strengthen the diagnosis but do not confirm or, in their absence, refute a diagnosis of AD include a family history of one or more first-degree relatives with a similar late-life dementia (especially if autopsy-proven AD), normal routine blood studies (including those for thyroid disease and B₁₂ deficiency), presence of one or more ApoE e4 alleles, elevated cerebrospinal fluid tau level, and a magnetic resonance image that either is "normal for age" or shows mild generalized cortical atrophy.

Findings that cast doubt on the diagnosis include the following: parkinsonism (slow gait, decreased arm swing, en-bloc turning), presence early in the course of the illness of a language impairment and/or mental confusion that is more prominent than the patient's memory impairment, prominent symptoms or signs of frontal lobe dysfunction (e.g., disinhibition, perseveration, delusions, psychosis and/or hallucinations) within the first several years of illness, the finding of any focal neurologic signs on examination, and seizures or myoclonus early in course.

TREATMENT

There are several components of treatment. First and foremost is the education of the primary caregiver about the illness, the need for long-range planning, how to maintain a living environment that will maximize the patient's ability to function, how to avoid precipitating behavior problems, and how to handle the problems that do occur despite the efforts of all concerned. Over the past several years, donepezil (Aricept) has become the standard symptomatic treatment. Its benefits are modest and are not seen in all patients. High-dose vitamin E (α-tocopherol) has also been adopted as the standard disease-slowing treatment. Treatment for the behavioral, psychotic, anxiety, and mood changes that occur with AD is generally accomplished through the gentle and short-term use of psychotropic, antianxiety, and hypnotic medications.

OTHER COMMON CONDITIONS THAT PRODUCE LATE-LIFE DEMENTIA

FRONTAL DEMENTIA

The diagnostic category of frontal dementia ([Table 466.2](#)) includes several pathologically defined conditions that cannot be distinguished with certainty during life.

These include Pick's disease, frontotemporal dementia, and dementia lacking definitive histopathology. In general, the presentation of a neurodegenerative frontal dementia takes one of two forms. In each case the onset is gradual, with the first symptoms often beginning before age 65 years.

Diagnosis	Frequency (%)
Alzheimer's disease	58
Mild cognitive impairment	9
Frontal dementia	5
Dementia with Lewy bodies	3
Parkinson's dementia	3
Ischemic vascular dementia	3
Depression	3
Miscellaneous*	15

* includes undefined dementia, Creutzfeldt-Jakob disease, corticobasilar degeneration, multisystem atrophy, and other uncommon conditions.

TABLE 466.2. CLINICAL DIAGNOSIS IN PATIENTS EVALUATED BY A UNIVERSITY-BASED MEMORY DISORDERS CLINIC (N = 1,072)

The most common presentation involves early changes in social behavior. Patients in this grouping undergo the insidious onset of personality and behavioral changes that are clearly out of character. These include impaired interpersonal conduct, as manifest by a disregard for manners, social graces, and decorum; as well as disinhibited verbal, physical, or sexual behaviors. They may demonstrate difficulty with goal-directed behavior as manifest by apathy, passivity, inertia, or, alternatively, hyperactivity without clear purpose. Frequently, they exhibit emotional blunting, with indifference and lack of empathy. In general, they are unconcerned about or unaware of these mental changes. These changes usually begin at a time when there is relative preservation of memory.

The next most common presentation involves the early development of language impairment, characterized by one or more of the following: nonfluent, hesitant, and effortful speech; sentences with missing words; mispronunciation of words; and word-finding difficulties, impaired repetition of phrase, decreased fluency, and impaired reading and writing.

A diagnosis of frontal dementia is supported by a family history of a similar disorder; a decline in personal hygiene and grooming; the presence of mental rigidity and inflexibility; easy distractibility; hyperorality, such as binge eating; perseverative or stereotyped speech, including a tendency to repeat utterances; incontinence without concern early in the course of the illness; and an imaging study result showing focal frontal and/or temporal atrophy.

There is no disease-specific treatment. Behavioral difficulties are common, and management often requires a combination of caregiver education and the gentle use of psychotropic medication.

DEMENTIA WITH LEWY BODIES

The neurodegenerative dementia known as dementia with Lewy bodies shares clinical and pathologic features with AD and Parkinson's disease. Despite the symptom overlap, it is pathologically distinct from AD in that there are no cortical neurofibrillary tangles. It differs from routine Parkinson's disease in that patients have psychotic symptoms (hallucinations, delusions, paranoia) early in the course of their illness. The response to standard antiparkinsonian medication is often poor, and patients have a low threshold for the psychosis-inducing side effects of these drugs. The clinical distinction between the Lewy body variant of AD, dementia with Lewy bodies, and Parkinson's dementia is difficult. However, the distinction is important as the primary treatment strategy differs among these three conditions.

The typical clinical picture includes the insidious onset of confusion with psychosis (hallucinations, delusions, and paranoia). The patient's level of alertness and degree of confusion may seem to fluctuate from hour to hour or be episodic. Hallucinations (when present) are often visual, well formed, detailed, and typically involve people. They are often most evident during periods of marked confusion. Parkinsonian features (rigidity, resting tremor, slow movements, and changes in gait and postural balance) usually develop in concert with the cognitive and psychotic features. Memory impairments may not be present in the early stages but are usually evident with progression.

The diagnosis is supported by the presence of repeated falls due to impairments of gait and postural balance, syncope-like episodes, and exquisite sensitivity to the parkinsonism-inducing effects of typical antipsychotic medication.

There is no uniformly satisfactory treatment. The symptoms of parkinsonism may respond to gentle use of carbidopa or other dopamine agonists. The psychotic symptoms may respond to low doses of atypical neuroleptic medications, but these drugs often exacerbate the parkinsonian symptoms. When present, depression may respond to selective serotonin reuptake inhibitor antidepressant.

ISCHEMIC VASCULAR DEMENTIA (MULTI-INFARCT DEMENTIA)

Although cerebrovascular disease is common, autopsy studies on patients with dementia indicate that it is the primary cause in only 3% to 5% of cases. Thus, only rarely will it be the principal diagnosis for patients with insidious progressive cognitive impairment. Nevertheless, ischemic cerebrovascular disease may contribute to symptoms of dementia that are primarily due to other causes (e.g., AD).

The typical clinical picture of vascular dementia involves an abrupt onset of focal cognitive impairment associated with motor and/or sensory signs of stroke. The episodes may be repetitive, and if there is concordance between the location of the infarction and the patient's cognitive deficits, the patient should be treated for cerebrovascular disease with an emphasis on the use of antiplatelet medication, control of stroke risk factors, and adequate treatment of hypertension.

SUMMARY

Neurodegenerative dementia represents a common affliction of late life and is one of the leading causes of severe disability and death in individuals older than 75 years. Clinical diagnostic criteria have recently become available for the more common disorders. Modestly effective treatment is now available for AD. It is important for clinicians to recognize these disorders when the symptoms are at their earliest stage so they can educate family members and begin treatment to reduce the symptoms and slow the progression. Ideally, planning for long-term care should begin at a stage when the patient can still participate in the discussions. From a medical management, public health, and patient benefit standpoint, the most effective treatment strategy will be to identify individuals at high risk who are still free of symptoms and initiate therapy that will delay the onset of clinical manifestations of dementia and slow its rate of progression so that they can live their natural lives free of severe cognitive disability.

CHAPTER 467: BENIGN PROSTATIC HYPERPLASIA/URINARY OBSTRUCTION

J. LISA TENOVER

[Background And Pathogenesis](#)
[Clinical Presentation](#)
[Evaluation](#)
[Strategies For Optimal Management](#)

BACKGROUND AND PATHOGENESIS

Benign prostatic hyperplasia (BPH; historically, incorrectly often called hypertrophy) is a histopathologic entity characterized by stromal and epithelial prostatic cell hyperplasia of the transitional and periurethral zones of the prostate. As a histopathologic diagnosis, the process is nearly universal in the aging human male; greater than 95% of men will demonstrate this prostate pathologic lesion if they live long enough. The prevalence of histologic BPH is comparable across ethnic groups and locales. Progression of histologic BPH to benign prostatic enlargement (detectable by digital rectal examination, or DRE, or by imaging techniques such as ultrasonography) is somewhat selective and occurs in about half of men with histologic BPH. Environmental and genetic factors may play a role. However, since increased prostate size alone does not produce clinical symptoms, not all men who develop an enlarged prostate experience symptoms of urinary tract outlet obstruction. Nonetheless, clinical BPH is a condition that affects the majority of older men, having an impact on morbidity and well-being.

The pathogenesis of histologic BPH is poorly understood. The two major risk factors are aging and the presence of androgens. Thus far, epidemiologic studies have produced no evidence for any association between development of BPH and diet, smoking, caffeine, frequency of sexual intercourse, medications, or other diseases. Androgens are important in prostate development and growth. The fetal surge of testosterone production is needed for prostate imprinting for later development; adolescent growth of the prostate coincides with the increase in testosterone secretion; and the growth of the prostate that begins in the fourth and fifth decades of life is not seen in the setting of castration or profound hypogonadism. The predominant androgen in the prostate is dihydrotestosterone (DHT), a more potent androgen than testosterone and one that is derived primarily at the target organ tissue by conversion of testosterone to DHT by the 5 α -reductase enzyme. While DHT plays a permissive role in the development of BPH, there clearly are other factors involved. The major histologic growth of BPH occurs in a man aged 40 to 70 years, a time when prostatic DHT levels do not change. Other pathogenetic factors that are probably involved include intraprostatic estrogens, intraprostatic growth factors, and stromal–epithelial interactions.

Prostate enlargement due to BPH may lead to varying degrees of symptomatology related to urinary outlet obstruction. Clinically diagnosed BPH, formerly called prostatism, currently is more aptly described as lower urinary tract symptoms (LUTS) due to BPH. It should be noted, however, that not all LUTS in men are due to prostate enlargement (BPH). Urethral stricture is a notable alternative cause. However, there is a steady increase in the age-specific prevalence of LUTS due to BPH; community-based epidemiologic studies estimate the prevalence of LUTS due to BPH to be about 40% to 50% for men in their seventies.

The development of LUTS as a result of BPH is influenced by a number of factors. Increase in prostate size can result in a decreased functional urethral diameter and an increased urinary outflow resistance; the strength of bladder detrusor muscle contractions is important in overcoming urethral resistance and impacts on the degree of bladder outlet obstruction necessary to result in symptoms; the elasticity of the prostatic capsule can also affect the degree to which prostate growth will cause urethral constriction; and the smooth-muscle tone of the prostate can dynamically affect urethral diameter. There is still disagreement about the relative roles of these factors in the development of LUTS, but clearly enlarged prostate size alone does not necessarily lead to development of symptoms.

CLINICAL PRESENTATION

Urinary symptoms related to BPH can be divided into two categories: obstructive and irritative ([Table 467.1](#)). The obstructive symptoms are directly related to the process of partial urinary outlet obstruction, whereas the irritative symptoms have a more complicated etiologic process. For example, some of the daytime urinary frequency and urgency may be due to incomplete bladder emptying, leading to shortened time intervals until the bladder is again “full” and there is a need to void; however, detrusor irritability also occurs in BPH. Nocturia may be a continuation of the daytime urinary frequency process, but it may also be a result of heightened urine production at night. Most evaluations of therapy for LUTS due to BPH have emphasized the effects of treatment on obstructive symptoms, since these are easier to quantitate objectively (measuring urine flow rates, urine flow patterns, and postvoid urine residual volumes), and because irritative symptoms may be multifactorial, often responding less well to therapeutic interventions. Nonetheless, it is clear that the irritative symptoms are most bothersome to patients.

Obstructive symptoms:

- Decreased caliber and force of urine stream
- Hesitancy and straining to void
- Dribbling at termination of voiding
- Feeling of incomplete emptying

Irritative symptoms:

- Urgency
- Frequency
- Nocturia
- Urinary incontinence

TABLE 467.1. LOWER URINARY TRACT SYMPTOMS DUE TO BENIGN PROSTATIC HYPERPLASIA

Urinary incontinence, which may have both obstructive and irritative components, also is very disruptive to the patient.

It is usually irritative LUTS that bring patients to the attention of the physician. Although LUTS are rarely life threatening, they are associated with significant morbidity (self-reported bother, interference with common daily activities, decreased psychological well-being, worry, and embarrassment). Occasionally, the presence of symptomatic BPH can come to the attention of the physician in a more dramatic presentation. These presentations include (a) acute complete urinary retention; (b) gross hematuria; (c) finding of bladder stones; (d) discovery of large bladder diverticuli and/or bladder wall hypertrophy; (e) recurrent urinary infections; or (f) renal failure.

EVALUATION

The primary goals of initial evaluation, especially for the nonurologist, are (a) to ascertain the presence or absence of LUTS in the male patient, (b) to determine the likelihood that LUTS are due to BPH, (c) to screen for imperative indicators for rapid (usually surgical) intervention, and (d) to establish the degree to which the LUTS are bothersome to the patient. This fourth goal is especially important, since LUTS affect quality of life and the same symptoms may impact different men in different ways. Most treatment recommendations are based on the degree of symptom “bothersomeness,” weighing this against the possible benefits and risks of treatment.

In an attempt to quantify LUTS, the American Urological Association (AUA), in combination with the U.S. Public Health Service, has designed a patient self-administered symptom score sheet ([Fig. 467.1](#)). Also known as the I-PSS (International Prostate Symptom Score), this sheet is in the public domain, may be reproduced without permission, and is used worldwide. This questionnaire is not specific for LUTS due to BPH, but in the correct clinical setting it may be helpful in suggesting who may need treatment and in monitoring therapy. Patients with total scores of 7 or less have “mild” symptoms and rarely need therapy. Scores from 8 to 19 denote “moderate” symptoms, and these patients may or may not need therapy, depending on the impact of the symptoms on their quality of life. Patients with

scores of 20 to 35 are felt to have “severe” symptoms, and most, but not all, of these patients will require some form of treatment.

The image shows the I-PSS symptom score sheet. It is a table with 7 rows of symptoms and 5 columns of response options (None, Mild, Moderate, Severe, Very Severe). The symptoms are: 1. Need to urinate frequently during the day, 2. Need to urinate frequently at night, 3. Difficulty starting urination, 4. Weak or interrupted urine stream, 5. Feeling of incomplete bladder emptying, 6. Pain or burning when urinating, and 7. Blood in urine. Each symptom is followed by a question mark and a box for the patient's response. At the bottom, there are fields for 'Total score (0-35)' and 'Total score (0-35)'. The American Urological Association logo is at the bottom left.

FIGURE 467.1. American Urological Association symptom score sheet for lower urinary tract symptoms (also known as I-PSS).

Both national and international clinical practice guidelines for the diagnosis and treatment of symptomatic BPH have been published. The two guidelines are very similar in both the diagnostic and treatment realms. [Figure 467.2](#) is the diagnosis and treatment guidelines algorithm for BPH from the U.S. Agency of Health Care Policy and Research (AHCPR). In the initial evaluation of possible clinical BPH, a medical history is very important. Not only should the history ascertain the presence and degree of LUTS symptoms (using I-PSS or similar questions), it should also gather information to assist in the evaluation of diagnoses for LUTS other than BPH. Alternative diagnoses for LUTS in men include concurrent urinary infection; detrusor muscle dysfunction due to pelvic nerve damage from trauma, infections, diabetes mellitus, or neurologic disease; bladder cancer; urethral stricture; or use of medications that can worsen detrusor function or heighten bladder outlet obstruction.

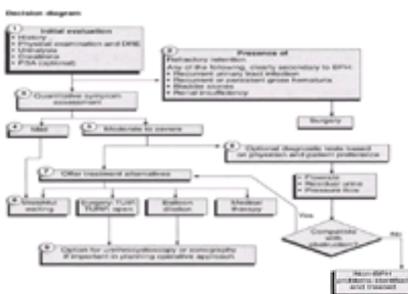

FIGURE 467.2. Benign prostatic hyperplasia diagnosis and treatment guidelines issued by the U.S. Agency of Health Care Policy and Research. DRE, digital rectal examination; PSA, prostate-specific antigen; TUIP, transurethral incision of the prostate; TURP, transurethral resection of the prostate.

In addition to the medical history, other evaluation recommendations include physical examination, including DRE of the prostate (to evaluate anal sphincter tone, prostate gland size, consistency, and abnormalities suggestive of prostate cancer), urinalysis (to evaluate for hematuria, proteinuria, pyuria, and glucosuria), and serum creatinine level. These evaluations are carried out to assist in discriminating between the differential diagnoses of LUTS, to evaluate whether BPH may have already led to renal insufficiency, and to ascertain if there is a likelihood that concurrent prostate cancer is present. Although the presence of BPH is not a risk factor for prostate cancer and prostate cancer rarely causes LUTS, the two can coexist in the same prostate. The use of prostate-specific antigen (PSA) in the evaluation process is optional and is for the purpose of prostate cancer screening.

STRATEGIES FOR OPTIMAL MANAGEMENT

If from the evaluation it seems likely that a patient has LUTS due to BPH, then management decisions will arise as noted in [Fig. 467.2](#). If there is uncertainty as to the cause of the LUTS, then a referral to a urologist for other diagnostic tests is appropriate. There are certain situations when immediate therapy is warranted. Usually, because of the urgency of treatment, therapy consists of some type of surgical intervention. Indicators for immediate intervention include (a) recurrent spontaneous acute urinary retention felt secondary to BPH; (b) recurrent gross hematuria felt secondary to BPH; (c) bladder stones due to BPH; (d) large bladder diverticuli; (e) recurrent urinary tract infections felt secondary to BPH; and (f) renal failure due to outlet obstruction from BPH. In the absence of these complicating situations, the decision to treat should be based on patient preference.

According to the guidelines, if the symptoms are mild, then no therapy except for “watchful waiting” should be recommended. This is the only definitive treatment recommendation in the guidelines and is based on epidemiologic data that show that mild LUTS are unlikely to lead to significant health problems in the immediate future. In fact, about 75% of men aged 40 to 79 years who have mild symptoms at first presentation will continue to have mild symptoms 4 years later without therapy.

Watchful waiting, although it implies initiation of no specific therapy, does require that there be some patient education. Watchful waiting will be much more successful if the patient is counseled about medications to avoid and lifestyle changes that may improve symptoms. Medications that can worsen symptoms include α -sympathomimetics, such as those found in over-the-counter cold remedies; antihistamines; and medications with anticholinergic effects. If diuretics are not needed for the purpose of fluid management, the patient may also benefit by avoiding their use (alternative treatments for hypertension should be considered). Consideration of the amount, timing, and type of fluid ingested is also important; caffeine-containing products and alcohol can worsen BPH symptoms, and large amounts of any type of fluid should be avoided within hours of bedtime. In addition, avoiding long intervals between voiding may be helpful, as a large, full, and nearly optimally stretched bladder contracts with less force than a less full bladder. If watchful waiting is the management approach taken for symptomatic BPH, yearly evaluations that mimic the initial evaluation should be done to confirm that symptoms are still not bothersome and that no complications have developed.

If patient symptoms are moderate or severe but there are no complicating situations, then patient treatment preference, obtained after counseling on the alternatives, should be the deciding factor. [Table 467.2](#) lists the treatment options for these men. Again, watchful waiting is one of the possible treatment approaches. Data from community-based epidemiologic studies and from the placebo treatment arms of drug trials have shown that men with more severe symptoms at first presentation are more likely to need medical or surgical therapy within the next 4 years than men with mild symptoms. On the other hand, it has also been shown that, in an individual patient with moderate to severe LUTS symptoms, these symptoms can remain stable or even improve over that same time period. In terms of the development of spontaneous acute urinary retention (retention not precipitated by surgery, anesthesia, medications, or alcohol), having moderate to severe BPH symptoms does not predict occurrence, although the prevalence of acute urinary retention in men with LUTS due to BPH increases dramatically with age after the age of 60 years, with an incidence of 8 to 14 events per 1,000 person-years.

Watchful waiting
 Medical therapy
 Pharmacologic:
 - Adrenergic receptor antagonists (doxazosin, tamsulosin, terazosin)
 5- α -Reductase inhibitors (finasteride)
 Phytotherapy:
 Saw palmetto
 Surgical/procedural interventions
 Transurethral prostatectomy
 Open prostatectomy
 Radiofrequency therapy:
 Transurethral needle ablation
 Microwave therapy:
 Transurethral
 Laser:
 Transurethral laser incision
 Side-fire laser coagulation
 Holmium: YAG laser resection
 Electroresection:
 Transurethral incision or vaporization
 Other:
 Water-induced thermotherapy
 Balloon dilatation
 Prostatic stents

YAG, yttrium-aluminum-garnet.

TABLE 467.2. TREATMENT OPTIONS FOR MEN WITH LOWER URINARY TRACT SYMPTOMS DUE TO BENIGN PROSTATIC HYPERPLASIA

In the last decade, medical (pharmacologic) management has become the principal initial therapy for most men with LUTS due to BPH. In general, medical management results in less change in symptom scores and urine flow rates than do the surgical interventions, but pharmacologic therapy is noninvasive, results in long-term sustained improvements, and is satisfactory to a large number of patients. At the current time, there are two classes of medications for the treatment of symptomatic BPH: α -adrenergic receptor antagonists and 5 α -reductase inhibitors. There are a number of factors to consider when selecting medical therapy, including mode of action, prostate size, and adverse-effect profiles of the medications.

Prostatic smooth-muscle tone contributes to outlet obstruction, and contraction of the prostate and urethral smooth muscle is mediated by α -adrenergic receptors. There are several subtypes of α -adrenergic receptors present in varying amounts at the bladder neck, prostatic urethra, prostatic capsule, and in the prostatic stroma; the majority of these are of the α -1A subtype. It has been shown that men taking α -adrenergic receptor antagonists experience smooth-muscle relaxation in these areas and, in addition, have a down regulation of expression of the myosin heavy chain gene in smooth-muscle cells. Currently, three selective α -adrenergic receptor blockers have been approved for the treatment of BPH in the United States. These agents are the two α -1-selective long-acting agents terazosin and doxazosin, and the more α -1A selective agent, tamsulosin. The “uroselectivity” of α -blockers is important from the perspective of trying to avoid side effects, such as orthostatic hypotension, which are due to interactions with vascular smooth muscle.

α -Adrenergic receptor antagonists have a relatively rapid onset of action (agents can be titrated to effectiveness within days) and have been shown to remain effective in the treatment of LUTS due to BPH for at least 4 years. The most common adverse effects from these agents include postural hypotension (4% to 8%), fatigue (1% to 12%), dizziness (3% to 10%), flu-like syndrome (2% to 6%), and headache (2% to 12%). All three of the α -adrenergic receptor antagonists approved for the treatment of BPH have been shown to be efficacious in improving symptoms, urine flow rates, and quality of life. Differences between the agents, such as the claimed decreased occurrence of orthostatic hypotension with the more α -1A-selective agent, tamsulosin, have not yet been tested in head-to-head studies.

Finasteride is the 5 α -reductase inhibitor currently available for the treatment of BPH, and it blocks the conversion of testosterone to DHT, thus decreasing intraprostatic DHT levels by about 90%. Associated with this decline in intraprostatic DHT is a marked decrease in epithelial cell size and function, and a decrease in prostate size by about 20% to 25%. With the decline in prostate size there is an improvement in urine flow rate, symptom score, and quality of life. The onset of clinical symptom improvement with finasteride is slower than with the α -adrenergic receptor antagonists, taking 3 to 6 months for improvement to begin, and reaching maximum improvement at about 24 months. Both symptom improvement and prostate size have been maintained with finasteride for at least 5 years of treatment. Prostate size is important in selecting medical therapy because finasteride is less effective than the α -adrenergic antagonists in those prostates that are smaller. On the other hand, finasteride has been shown to reduce the risk of development of acute urinary retention and the need for prostate surgery, especially in men with larger prostates.

Adverse effects of finasteride include impotence (3.7%), decreased libido (3.3%), and gynecomastia (0.4%). In addition, it should be noted that the medication leads to about a 50% reduction in serum total PSA, but does not change the percentage of free PSA. Estimation of the “true” PSA for men taking finasteride should be done by multiplying the obtained value by a factor of two. To date there is no evidence that finasteride masks detection or progression of prostate cancer.

There are currently about 80 plant extracts available as phytotherapeutic compounds for the treatment of BPH. These are nonprescription unlicensed dietary supplements. The most widely used is an extract from the dried ripe fruit of the American dwarf saw palmetto plant. The mechanism of action of saw palmetto is uncertain, but is said to include antiestrogenic, antiandrogenic, and anticholinergic effects. Studies on the use of saw palmetto in the treatment of symptomatic BPH are limited by short duration (4 to 48 weeks), the different preparations evaluated, and the outcomes measured. Nonetheless, a 1998 published meta-analysis of the literature on the use of saw palmetto for BPH concluded that saw palmetto, at least in the short term, seemed to produce similar improvement in symptom scores and urine flow rates as compared to the licensed pharmaceuticals for BPH.

Surgical intervention for BPH is the treatment of choice for refractory urinary retention, renal failure secondary to outlet obstruction, or recurrent hematuria due to BPH. In addition, surgery for symptoms would be necessary in men who fail, or cannot tolerate, pharmacological therapy. Transurethral resection of the prostate (TURP) has been the gold standard surgical treatment for BPH. Although its use has declined dramatically in this decade due to the availability of pharmacologic agents and the development of alternative surgical interventions, it is the procedure of comparison for treatment outcomes. It is very effective in improving LUTS symptoms due to BPH and improving urine flow but is associated with a 3% to 18% morbidity. The most common complications are blood loss, retrograde ejaculation, urinary incontinence, epididymitis, urinary tract infection, urethral stricture, and sexual dysfunction. Other surgical/procedural approaches, many of which can be done in the outpatient setting using local anesthesia, are listed in [Table 467.2](#). As with pharmacologic management, prostate size is an important determinant in the selection of surgical therapy. TURP does not work optimally for small prostates, as it can lead to bladder neck contractures in that setting. Transurethral microwave thermotherapy (heating the prostate to cause coagulation necrosis) and transurethral needle ablation do not work well if there is medial lobe enlargement, and transurethral incision does not work well in large prostates.

CHAPTER 468: GERIATRIC ASSESSMENT

DAVID B. REUBEN

[Principles of Geriatric Assessment](#)
[Putting Geriatric Assessment into Practice](#)
[Comprehensive Geriatric Assessment](#)

PRINCIPLES OF GERIATRIC ASSESSMENT

Geriatric assessment differs from the more traditional medical assessment by recognizing that the health status of older persons is dependent on influences beyond the manifestations of their medical conditions. Among these are social, psychological and mental health, and environmental factors. Geriatric assessment also places high value on functional status, both as a dimension to be evaluated and as an outcome to be improved or maintained.

Although in the strictest sense geriatric assessment is a diagnostic process, many use the term to include both evaluation and management. Moreover, geriatric assessment is sometimes used to refer to evaluation by the individual clinician and at other times to refer to a more intensive interdisciplinary process, i.e., comprehensive geriatric assessment (CGA). In fact, as geriatric assessment has evolved, the multidimensional principles of CGA are increasingly being incorporated into routine practices of individual clinicians.

When caring for older patients who are younger and are in good health or have few chronic conditions, the emphasis is placed on preventive geriatrics (lifestyle modifications, chemoprophylaxis, immunizations, and screening for diseases, including potential geriatric syndromes). In contrast, for those older than 85 years and those with multiple complex health and social problems, a more extensive assessment is indicated. This assessment extends beyond the traditional medical evaluation of older persons' health to include assessment of cognitive, affective, functional, social, economic, environmental, and spiritual status, as well as a discussion of patient preferences regarding advance directives.

Assessment instruments can be used to guide these evaluations but must be interpreted in the context of their limitations. They are rarely, if ever, diagnostic tests. Rather, they indicate the need for further evaluation. Nor do they substitute for good clinical skills and judgment, including the skill of eliciting important information from the patient's history and physical examination. Nevertheless, information obtained from assessment instruments can be used to quickly direct the clinician's attention to issues that are particularly relevant to an individual patient.

Geriatric assessment differs according to the setting in which the patient is being evaluated. In the hospital setting, the initial assessment is usually directed at the acute medical problem that precipitated the hospitalization. As the patient begins to recover and plans are initiated for discharge, other components (e.g., social support, environment) assume increasing importance in the assessment. The inpatient setting can also be problematic for geriatric assessment because of the rapidly changing status of several key dimensions. For example, a patient's functional status may temporarily be "dependent in all tasks" when the patient is acutely ill and gradually improve prior to discharge. Because patients may overestimate their functional status based on their previous level of functioning, alternative sources (e.g., by nurses or physical or occupational therapists) may be necessary for an accurate assessment. Similarly, the patient's full potential to participate in rehabilitation may not be ascertained until near the time of discharge.

Nursing home geriatric assessment requires that closer attention be directed to some aspects of assessment (e.g., risk of falling, nutritional status), whereas others, such as functional status at the level of the instrumental activities of daily living, are less relevant. In contrast, geriatric assessment conducted in the patient's home provides an opportunity for a substantially different type of assessment, where environmental (often including social) factors can be directly assessed but other aspects of the traditional examination (e.g., the gynecologic examination) are much more difficult to assess.

Since the primary site of most clinicians' practices is the office, assessment techniques utilized in this setting are emphasized in this chapter. When appropriate, differing or particularly important information about assessment in other settings is included.

MEDICAL ASSESSMENT

In addition to the standard medical history and physical examination, the clinician should systematically search for specific conditions that are common among older persons and might have considerable impact on function. These disorders include impairments of vision, hearing, and mobility, as well as the geriatric syndromes of malnutrition and urinary incontinence. Assessment instruments or simple screening questions have been developed and validated for each of these disorders ([Table 468.1](#)). Polypharmacy and inappropriate prescribing may be assessed by several methods. Because older persons often receive care from multiple providers who may not communicate with each other and because prescriptions might be filled at several pharmacies, each patient should be instructed to bring all current medications to each office visit. Office personnel can check these against the medication list in the medical record and discrepancies can be brought to the clinician's attention at the time of the patient's visit. Several drug interaction programs are commercially available to check for potential drug–drug interactions.

Depression	Geriatric Depression Scale	5	Sheikh, 1986

TABLE 468.1. COMMONLY USED ASSESSMENT INSTRUMENTS AND APPROXIMATE PERFORMANCE TIME

COGNITIVE ASSESSMENT

Because the prevalence of Alzheimer's disease and other forms of dementia rises considerably with advancing age, the yield of screening for cognitive impairment is highest in the 85 and older group. The most commonly used screen is the Mini-Mental State Examination, a 30-item interviewer-administered assessment of several dimensions of cognitive function. Several shorter screens have also been validated, including recall of three items at 1 minute, the clock drawing test, the serial 7's test (patients are asked to subtract 7 from 100 five times), and the Time and Change Test. Although normal results on these tests vastly reduce the probability of dementia and abnormal results increase the likelihood that the patient has dementia, these tests are neither diagnostic for dementia, nor do normal results exclude the possibility of this disorder. Shortcomings of mental status screens include their lack of relevance to functional activities of daily life and their failure to account for educational level, languages other than English, and cultural differences.

Among hospitalized patients, mental status should be assessed at the time of hospital admission and then again periodically because older persons are especially prone to develop delirium during the hospital stay. Abnormal findings on the mental status examination in hospitalized patients must be interpreted in the context of

change from baseline and the clinical situation. The Confusion Assessment Method provides a guide to interpreting such changes. Other valuable tests when evaluating for delirium include those that measure attention (e.g., the "A" test and physical examination for asterixis).

AFFECTIVE ASSESSMENT

Although major depression is no more common in the elderly population than in younger cohorts (see [Chapter 460](#)), symptoms of depression and other affective disorders are common and cause considerable morbidity. A simple inquiry such as, "Do you often feel sad or depressed?" can be used as a screen. This single question, however, tends to be overly sensitive and may be better used in tandem with a second screen, such as the Geriatric Depression Scale, which has 15- and 30-item versions.

ASSESSMENT OF FUNCTION

Measurement of functional status is an essential component of the assessment of older persons. The patient's ability to function can be viewed as a summary measure of the overall impact of medical conditions in the context of his or her environment and social support system. Moreover, for each older person, the ability to function consistently within the context of his or her personal lifestyle should be an important consideration in all care planning. Therefore, changes in functional status frequently prompt further diagnostic evaluation and intervention. Measurement of functional status can also be valuable in monitoring response to treatment and may provide prognostic information that will be helpful in the planning for long-term care.

Functional status can be assessed at three levels: basic activities of daily living (BADLs), instrumental or intermediate activities of daily living (IADLs), and advanced activities of daily living (AADLs). BADLs assess the ability of the patient to complete basic self-care tasks (bathing, dressing, toileting, continence, feeding, and transferring). IADLs measure the patient's ability to maintain an independent household (shopping for groceries, driving or using public transportation, using the telephone, preparing meals, doing housework, doing handyman work, doing laundry, taking medications, and handling finances). AADLs measure the patient's ability to fulfill societal, community, and family roles as well as participate in recreational or occupational tasks. These advanced activities vary considerably from individual to individual, but may be exceptionally valuable in monitoring functional status prior to the development of disability.

Questions about specific BADL and IADL function have also been incorporated into a variety of more generic health-related quality-of-life instruments (e.g., the Medical Outcomes Study, Short Form 36).

ASSESSMENT OF SOCIAL SUPPORT

The older patient's family structure can be assessed by a few questions during the social history; however, the quality of these relationships should also be determined. For very frail older persons, the availability of assistance from family and friends is frequently the determining factor as to whether a functionally dependent older person remains at home or is institutionalized. If dependency is noted during functional assessment, the clinician should inquire as to who provides help for specific BADL and IADL functions and whether these persons are paid or voluntary help, and whether such help is available only periodically or is sustainable over the long term.

ECONOMIC ASSESSMENT

Although some clinicians may feel uncomfortable in assessing the economic status of their patients, insurance status is routinely collected by office staff. The patient's income can also be assessed and eligibility for state or local benefits to provide services for the functionally impaired can be determined. For the frail and functionally impaired, physicians may need to begin discussions of planning to mobilize savings and other resources to provide personal-attendant care. Referral to a social worker can be exceptionally valuable in such planning.

ENVIRONMENTAL ASSESSMENT

Environmental assessment encompasses two dimensions: the safety of the home environment and the adequacy of the patient's access to needed personal and medical services. Particularly among the frail and those with mobility and balance problems, the home environment should be assessed for safety. The National Safety Council has developed a Home Safety Checklist that patients and their families can complete. For those receiving home health services, in-home safety inspections can be performed, including recommendations for installation of adaptive devices (e.g., shower bars, raised toilet seats).

Older persons who begin to develop IADL dependencies should be evaluated for the geographic proximity of necessary services (e.g., grocery shopping, banking), their need for such services, and their ability to utilize such services in their current living situation.

SPIRITUALITY

Spirituality, whether expressed through affiliation with a formal religious denomination or nonreligious intangible elements, has increasingly been recognized as an important dimension that can affect health. Formal instruments assessing spirituality have not yet been developed, but asking older persons whether religion or spirituality is important to them may provide insights that will facilitate their care. Especially in hospital settings, involvement of pastoral or professional care may be valuable in supporting the patient and in framing medical decisions in the context of the patient's personal belief system.

ADVANCE DIRECTIVES

Discussions of advance directives are important for all patients and should be initiated early on (though usually not on the initial office visit) to elucidate patients' goals and preferences for care should they become unable to speak for themselves due to progressive cognitive impairment or acute illness. A particularly important time in which to discuss such preferences is prior to surgery because of the possibility of surgical complications or postoperative delirium, which may preclude discussions following the procedure. The durable power of attorney for health care, which asks the patient to designate a surrogate to make medical decisions if the patient loses decision-making capacity, is often less emotionally laden than the specifying of treatments that the patient may or may not want. Such discussions should also be revisited any time there are significant changes in a patient's medical condition or a better understanding about prognosis becomes available; patients may revise their thoughts about the benefits and burdens of treatment.

PUTTING GERIATRIC ASSESSMENT INTO PRACTICE

In an attempt to improve clinician efficiency without sacrificing comprehensiveness in geriatric assessment, many clinical practices have begun to use previsit questionnaires that can be completed by the patient or a family member (or other proxy) in advance of the clinical encounter. These questionnaires typically gather information on medical history, medications, preventive measures, and functional status (including information on who helps when the patient is functionally dependent). As a result, they can markedly reduce the time needed to conduct an initial assessment and can ensure a consistent level of comprehensiveness for every patient. By including validated screening instruments, previsit questionnaires can also be used to detect geriatric syndromes.

A second method of streamlining the office visit is by delegating the administration of screening instruments for many of the important geriatric problems to trained office staff. Thus, the clinician may spend a short time reviewing the results of these screens and then decide which dimensions, if any, need greater evaluation. Recently, researchers have demonstrated the feasibility and yield of utilizing office staff to administer case-finding and screening instruments ([Table 468.2](#)) that assess many of the dimensions described above.

Screening Package Characteristics			
Problem	Screening Question	Response Options	Prevalence Sensitivity Specificity
Hearing	1. Do you have difficulty hearing or understanding what people are saying or hearing parts of what they say?	Yes to either question No to both questions	0.75 0.80
	2. Do you have trouble hearing when you are in a noisy place?	Yes to either question No to both questions	0.75 0.80
Hearing	3. Do you have trouble hearing when you are in a noisy place?	Yes to either question No to both questions	0.75 0.80
	4. Do you have trouble hearing when you are in a noisy place?	Yes to either question No to both questions	0.75 0.80
Hearing	5. Do you have trouble hearing when you are in a noisy place?	Yes to either question No to both questions	0.75 0.80
	6. Do you have trouble hearing when you are in a noisy place?	Yes to either question No to both questions	0.75 0.80
Hearing	7. Do you have trouble hearing when you are in a noisy place?	Yes to either question No to both questions	0.75 0.80
	8. Do you have trouble hearing when you are in a noisy place?	Yes to either question No to both questions	0.75 0.80
Hearing	9. Do you have trouble hearing when you are in a noisy place?	Yes to either question No to both questions	0.75 0.80
	10. Do you have trouble hearing when you are in a noisy place?	Yes to either question No to both questions	0.75 0.80

TABLE 468.2. MULTIDIMENSIONAL SCREENING INSTRUMENT

COMPREHENSIVE GERIATRIC ASSESSMENT

Comprehensive geriatric assessment (CGA) began with the notion that a systematic evaluation of frail older persons by a team of health professionals could uncover treatable health problems and lead to improved health outcomes. Early randomized clinical trials provided convincing evidence that such programs conducted in hospital-based and rehabilitation units, which typically required several weeks of treatment, could lead to better survival rates, improved functional status, and more desirable placement (e.g., home rather than nursing home) following discharge from the hospital. Conceptually, comprehensive geriatric assessment is a three-step process: (a) screening to target appropriate patients, (b) assessment and development of recommendations, and (c) implementation of recommendations, including monitoring physician and patient adherence with recommendations. Each of these steps is essential if the process is to be successful in achieving health and functional benefits.

Within this broad conceptualization, CGA has been implemented using many different models in various health care settings. Because of changes in length of hospital stays, an increasing number of CGA programs are relying on postdischarge and community-based assessment. Furthermore, most of the early programs focused on restorative or rehabilitative goals (tertiary prevention), whereas many newer programs are aimed at primary and secondary prevention. These new models of CGA have assumed responsibility for primary care temporarily or permanently or have utilized consultative programs that have included patient empowerment and physician education methods. Most have used some type of identification of high risk (targeting) as a criterion for inclusion in the program. Such targeting criteria have included conditions such as functional impairment, falls, depressive symptoms, urinary incontinence, and expected high health care utilization.

The principles of comprehensive geriatric assessment have also been incorporated into programs that have applied CGA approaches, such as standardized assessment and interdisciplinary teams, to individual conditions (e.g., falls and congestive heart failure) and to improving the care of hospitalized patients (e.g., acute care for the elderly units). Undoubtedly, additional generations of CGA-like interventions will be forthcoming.

CHAPTER 469: GERIATRIC CLINICAL PHARMACOLOGY

JANICE B. SCHWARTZ

[Pharmacokinetics](#)
[Pharmacodynamics](#)
[Adverse Drug Effects and Drug Interactions](#)
[Over-The-Counter Drugs and Nutraceuticals](#)
[Pharmacoepidemiology and Pharmacoeconomics](#)
[Summary](#)

Although representing only slightly more than 12% of the population, older patients consume more than 25% of therapeutic drug prescriptions in the United States. In the older patient, altered pharmacokinetics, pharmacodynamics, and multiple disease states with multiple drugs consumed combine to increase the complexities of optimal medication prescribing and the risk of adverse drug-related events. The purpose of this chapter is to review general principles of clinical pharmacology and age-related changes in pharmacokinetic and pharmacodynamic parameters as they relate to optimizing drug therapy for older patients.

PHARMACOKINETICS

Pharmacokinetic processes determine the rate of appearance, distribution throughout tissues, and elimination of drug from the body. As shown in [Fig. 469.1](#), the major pharmacokinetic terms that describe these processes are (a) bioavailability, (b) distribution, and (c) clearance.

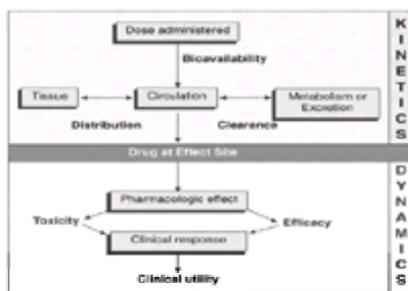

FIGURE 469.1. Schematic representation of the pharmacokinetic and pharmacodynamic processes that relate a drug to its effects.

BIOAVAILABILITY

Bioavailability is defined as the fraction of drug reaching the circulation after administration. Intravascular (i.v.) administration of a drug results in a bioavailability of 1 or 100%. Bioavailability for extravascular routes of drug administration is estimated by comparing the area under the curve (AUC) of drug concentration vs. time after extravascular administration divided by the AUC vs. time data after intravascular dosage (AUC extravascular/AUC intravascular). The result is often expressed as a fraction or a percentage. Bioavailability defines the dose adjustment between intravascular and extravascular drug administration. Low-bioavailability drugs require much greater extravascular, as compared to intravascular, doses. Low bioavailability is frequently found for drugs that undergo oxidative metabolism by the cytochrome P450 system, which has recently been identified in the intestine as well as the liver. Both hepatic and intestinal metabolism can decrease the amount reaching the circulation after oral dosing. Examples of drugs with low bioavailability include cyclosporine, nifedipine, metoprolol, midazolam, propranolol, and verapamil. Interactions with nutrients and dietary factors also are most common for drugs that undergo intestinal metabolism by the same cytochrome P450 isoform. Examples include the increased bioavailability of felodipine when administered with grapefruit juice.

Age-related changes in bioavailability depend on route of drug administration, age-related changes in the organ of absorption (bowel vs. skin), and changes in hepatic drug metabolism during the first pass of the drug through the liver after oral drug administration. Gastric pH, gastrointestinal (GI) motility, blood flow, and active membrane transport processes are altered to a variable extent by aging. There is decreased acid secretion, decreased perfusion of the GI tract, and possibly decreased membrane transport activity. These changes are, however, counterbalanced by longer GI transit time, providing longer times for drug absorption to take place. Studies of traditional oral formulations suggest little clinically significant age-related changes in the rate or extent of drug absorption from the GI tract. Data regarding slow-release preparations, transdermal, transbuccal, and transbronchial drug administration are too limited to allow conclusions regarding age-related changes in drug absorption via those routes.

DISTRIBUTION

Volume of distribution terms relate the amount of drug in the body to the concentration measured. The volume of distribution does not represent a “real” volume or physiologic compartment but an approximation of the volume that would be present if drug were distributed equally throughout the body. Thus, although the total body water for a 70-kg human is about 42 L, distribution volumes of drugs range from 7 to 30,000 L per 70 kg.

Major determinants of drug volume of distribution are plasma protein and tissue binding. Drugs that are highly bound to plasma proteins (albumin or a γ -acid glycoprotein) form a drug–protein complex that is large and less able to cross membranes into tissues. In general, highly protein-bound drugs have smaller volumes of distribution that are more closely related to vascular volumes. An example of such a drug is warfarin. If a drug is highly bound to tissue proteins, distribution volumes will be large. An example of such a drug is digoxin, which distributes into and binds to muscle. Volume of distribution is an important concept for drugs administered with loading doses. Clinically, the volume of distribution defines the loading dose of a drug since:

$$\text{Loading dose} = (\text{concentration desired}) \times (\text{volume of distribution of the drug})$$

This simplification assumes immediate and uniform distribution of drug in the total drug volume of distribution. Clinically, it is often more desirable to administer a loading dose over a period of time or by infusion to avoid toxicity due to high concentrations before distribution is complete.

Age-related changes in volume of drug distribution result from body composition changes with senescence. Important gender-related differences in body composition also exist. Lean body muscle mass decreases with aging, and this decrease results in less creatinine production. Total body water is also somewhat decreased with aging, leading to decreased volumes of distribution for some drugs ([Table 469.1](#)). The clinical consequence of a reduction in distribution volume is a higher drug concentration for any given dose of drug. An illustrative example is the calculation of loading doses of antibiotics (polar drugs that usually distribute only in body water). For aminoglycosides, much of the toxicity is related to peak concentrations, and age and weight adjustments of loading doses are necessary to avoid toxicity. Another example of the impact of distribution volume changes is that seen with alcohol. Increased effects of alcohol (or decreased tolerance) seen in older individuals, and in women compared to men, are attributable to reduced distribution volumes leading to higher alcohol concentrations for an amount consumed.

Enzyme	Substrate	Inhibitor	Inducer
CYP1A2	Caffeine, Nicotine, Theophylline	Fluoroquinolones, Fluorinated quinolones, Fluorinated quinolones	Rifampin, Rifampin
CYP2C9	Warfarin, Phenytoin, S-warfarin	Fluoroquinolones, Fluorinated quinolones, Fluorinated quinolones	Rifampin, Rifampin
CYP2D6	Debrisoquine, Dextromethorphan, Mephenytoin	Fluoroquinolones, Fluorinated quinolones, Fluorinated quinolones	Rifampin, Rifampin
CYP3A4	Amiodarone, Cyclosporin, Ergotamine, Ergotamine	Fluoroquinolones, Fluorinated quinolones, Fluorinated quinolones	Rifampin, Rifampin

TABLE 469.1. CYTOCHROME P450 (CYP) SUBSTRATES AND DRUG INTERACTIONS^a

An important determinant of drug distribution is plasma protein binding. Total protein binding of drugs usually is not altered by aging in healthy individuals. In the presence of disease, serum albumin concentration may decrease, but the decrease in albumin is usually counterbalanced by an increase in a α_2 -acid glycoprotein with acute illnesses. The net result is that clinically important age-related changes in total drug protein binding are largely absent and, in general, not a clinical consideration. Protein binding can, however, be altered by competition for binding by coadministered drugs. Since administration of multiple drugs is more common in the elderly, this becomes a clinical issue. It is especially important during administration of warfarin, which is about 99% protein-bound. Displacement of warfarin from albumin by other highly bound drugs, such as amiodarone, phenytoin, sulfonamides, fluoroquinolones, or azole antifungal agents, among others, can also cause marked increases in anticoagulation. The influence of drug transporters, such as P-glycoprotein, in determining tissue drug distribution and concentrations is currently being investigated but potential age-related changes are largely unexplored at this time.

CLEARANCE

Total Body Drug Clearance

Total body drug clearance is the net rate of removal of drug from the body. It is usually described as a unit of volume cleared of drug per unit time. To maintain a constant drug concentration, input must equal output or clearance. Clinically, clearance defines the drug dosing rate. For most currently prescribed drugs, the major organs of clearance are the kidney and liver. As newer drugs come to more closely resemble hormones, receptor antagonists and agonists, peptides, and intracellular messengers, routes of biotransformation at other sites will assume more importance. For now, knowledge of renal and hepatic elimination provides sufficient background for understanding clearance of most drugs administered to the older patient.

Renal Drug Clearance

Drugs can undergo three processes of elimination in the kidney: (a) glomerular filtration, (b) tubular secretion, and (c) tubular reabsorption. Glomerular filtration can be approximated by estimates of creatinine clearance. Protein binding can influence renal drug clearance because only unbound drug can be filtered. Renal tubular secretion is detected in vivo when renal clearance of a substance exceeds clearance by filtration. Secretion is an active process, with separate processes for acids and bases. Secretion efficiently eliminates protein-bound drugs. Tubular reabsorption is detected when urinary excretion of a compound is less than filtration rates. For most drugs, reabsorption is passive and can be affected by both urine flow and changes in pH.

Alterations in renal function are the most consistent and well-described changes associated with aging. Renal blood flow is decreased, resulting in delivery of less drug to the kidney for clearance. Renal blood flow may also be more dependent on prostaglandin regulation in older individuals than in younger individuals, and renal mass is decreased. These changes lead to an average decrease in creatinine clearance of about 10% per decade after age 20 years. Algorithms designed to estimate creatinine clearance based on subject's age, gender, and serum creatinine level have widespread clinical applications, especially for dosing of renally eliminated drugs, such as digitalis glycosides, aminoglycosides, and lithium, which have narrow therapeutic ranges and toxicities that are closely related to concentration. One commonly used formula is as follows:

$$\text{Creatinine clearance} = \frac{140 - \text{age(y)} \times \text{lean body weight(kg)}^{\wedge}}{72 \times \text{serum creatinine}}$$

It is important to note that serum creatinine concentrations alone do not accurately reflect creatinine clearance in the elderly and that the serum creatinine may be normal when significant reduction of creatinine clearance or glomerular filtration is present.

Age-related changes in the sensitivity to drugs that further impair renal function warrant mention. Nonsteroidal anti-inflammatory drugs (NSAIDs) can decrease production of vasodilating renal prostaglandins, and NSAID inhibition of cyclooxygenase has been postulated to be the mechanism for the variable azotemia seen during administration of NSAIDs in older patients. NSAIDs may also decrease potassium excretion and can cause hyperkalemia when administered to older patients, especially when given in combination with other drugs which decrease potassium excretion. Angiotensin-converting enzyme (ACE) inhibitors may reduce renal perfusion that can lead to significant reductions in renal clearance in the presence of renal artery disease. ACE inhibitors also block production of angiotensin II, which is responsible for dilatation of the efferent arteriole, and alter the balance between afferent and efferent arteriolar resistance such that glomerular perfusion decreases. These effects of ACE inhibitors can result in clinically significant decreases in glomerular filtration and increases in serum potassium in the elderly patient.

Hepatic Drug Clearance

The rate and extent of hepatic drug metabolism depends on both extrahepatic and intrahepatic factors. Hepatic blood flow determines the delivery of drug to the liver, and hepatic enzyme type, numbers, affinity, and activity rate determine hepatic drug metabolism. A simplified view of hepatic drug clearance divides drugs into "high" clearance or "low" clearance drugs. A high-clearance drug is rapidly metabolized by the liver such that the clearance rate is limited only by the rate of drug presentation to the liver (hepatic blood flow). Examples of high-clearance drugs are lidocaine, morphine, propranolol, and verapamil. For a low-clearance drug, the rate of removal is limited by hepatic enzymatic processes. Hepatic disease leading to decreased liver enzyme content, damage, or fibrosis will have a major impact on hepatic metabolism of low-clearance drugs. Examples of low-clearance drugs are amlodipine and phenytoin.

Most hepatic drug clearance results not in removal of drug from the body but in drug metabolism to a more polar compound for renal excretion or to an inactive compound by oxidative biotransformation, largely via cytochrome P450 pathways (Table 469.1). The supergene family of enzymes, responsible for the majority of oxidative metabolism of drugs, environmental chemicals, a number of hormones, foods, and toxins, is called the cytochrome P450 (CYP) family. Approximately 100 variations of the cytochrome P450 protein have been identified in plant and animal species, yet human liver CYP protein content is largely from three major groups—the CYP1, CYP2, and CYP3A families. It is estimated that 50% to 55% of hepatically cleared drugs undergo metabolism by the CYP3 family, and CYP3 proteins compose about 25% of protein in the liver. CYP3 metabolizes amiodarone, astemizole, many b-blockers, most benzodiazepines, carbamazepine, cisapride, clarithromycin, cortisol, most dihydropyridine calcium channel blockers, dapsone, diltiazem, erythromycin, estrogens, 3-hydroxy-3-methylglutaryl reductase coenzyme A (HMG-CoA) inhibitors, itraconazole, ketoconazole, lidocaine, nefazodone, quinidine, rifampin, tamoxifen, terfenadine, troglitazone, verapamil, and warfarin, among others. CYP2D6 is estimated to be responsible for metabolism of 25% of hepatically metabolized drugs, including debrisoquine, dextromethorphan, dehydroepiandrosterone, haloperidol, mexiletine, propafenone, most selective serotonin reuptake inhibitors (SSRIs), testosterone, and tricyclic antidepressants. Five percent to ten percent of whites and 1% of Asians are deficient in 2D6. CYP2C9 accounts for another 20% of hepatic drug metabolism, and substrates are losartan, phenytoin, S-warfarin (the active enantiomer), and many NSAIDs. CYP1 in humans is designated as CYP1A2 and accounts for 5% of human hepatic drug metabolism. Acetaminophen, caffeine, nicotine, tacrine, and theophylline are metabolized via this pathway.

Genetic polymorphisms have been described for CYP 2D6, 2C9, and 2C19, whereas no functional ones have been described for CYP3A4. It appears that 7% to 10% of whites are phenotypically deficient in the CYP2D6 isoform, whereas only 1% to 3% of Asians are deficient. Genetic probes do not exist for all pathways, and in vitro investigations of liver content and substrate affinities do not always correlate with in vivo drug metabolism. Validated in vivo probes for the phenotyping of CYP2D6 are debrisoquine and dextromethorphan. Sparteine and dapsone are in vivo probes for CYP2C. Mephenytoin is a CYP2C19 substrate, and caffeine and nicotine have

been used as probes for CYP1A2. There remains disagreement regarding the best in vivo probes for the CYP3A4 pathway. Endogenous cortisol to 17-hydroxycortisol urinary ratios, erythromycin clearance as estimated by the ¹⁴C-erythromycin breath test, and midazolam clearance have all been used for this purpose.

Genetic polymorphisms have also been described for conjugation by acetylation, sulfotransferases, and hepatic uridine diphosphonate glucuronosyltransferases (UGTs). The first widely recognized genetic polymorphism for drug biotransformation appeared with the description of slow- or rapid-acetylator status for isoniazid. Additional drugs that undergo acetylation for which clinically important polymorphisms have been identified are procainamide and hydralazine. A clinical example of accumulation of an endogenous substrate due to low UGT(1A) activity is bilirubin in individuals with Gilbert's syndrome. It has been suggested that individuals with low UGT(1A) activity have an increased risk for toxicity of a cancer agent metabolized by UGT(1A). Model substrates of glucuronidation that have been administered to humans include paracetamol, menthol, lorazepam, oxazepam, clofibrate, and fenofibric acids.

While definitive evidence for genetic polymorphisms for CYP3A has not emerged, Asians have been reported to have slower clearance of several CYP3A-metabolized drugs, and women have variably been reported to have faster CYP3A-mediated clearance than men. It also appears that CYP1A clearance is higher in men than in women; and conjugative biotransformation is more rapid in men than in women.

Hepatic drug metabolism is far more variable than renal drug clearance, and reliable algorithms to estimate hepatic drug clearance are not available. The marked variability of factors influencing hepatic clearance, such as hepatic blood flow, hepatic size, enzyme inducibility and inhibition, genetic polymorphisms in cytochrome P450 isoforms, and cumulative and differential exposures to modulating environmental influences, contributes to the wide variability in hepatic drug clearance between individuals and with aging.

Age-related Changes in Hepatic Drug Clearance

Although conclusions from studies of potential age-related changes in hepatic drug metabolism vary, there is agreement regarding extrahepatic changes. In general, hepatic blood flow decreases with aging. Decreased hepatic blood flow usually results in decreased hepatic clearance of high-clearance drugs. In most studies, reduced clearance of high-clearance drugs has been seen with increasing age. Variability is marked, however, and gender and smoking history may influence results.

There is agreement on several age-related changes in hepatic factors. Hepatic size decreases with aging. Data from in vitro experiments with tissues from male rodent models of aging also show marked and consistent declines in hepatic enzyme affinity and oxidative metabolic rates, whereas in vitro experiments with human liver biopsy tissues from men fail to demonstrate age-related declines. Differences in hepatic enzyme content and cytochrome P450 isoforms in the male rodent versus human potentially explain discrepancies related to in vitro measures of hepatic enzyme activity. Most in vivo studies of aging effects in humans show decreases in oxidative drug metabolism by the cytochrome P450 system. Examples include α -blockers (doxazosin, prazosin, terazosin), anti-infectious drugs (clarithromycin, erythromycin, itraconazole, ketoconazole), antihistamines (terfenadine), most benzodiazepines, some β -blockers (metoprolol, propranolol, timolol), the calcium channel blockers (dihydropyridines, diltiazem, and verapamil), several HMG-CoA inhibitors (atorvastatin, fluvastatin), sex hormones (estrogen, progesterone, testosterone), several H₂ blockers (cimetidine), and proton pump inhibitors (lansoprazole, omeprazole). In contrast, in vivo studies of drugs metabolized by the conjugative reactions of glucuronidation (e.g., acetaminophen, morphine, diazepam), sulfation (e.g., steroids, methyldopa), and acetylation (e.g., sulfonamides, isoniazid, dapsone, clonazepam) have not found significant effects of aging.

Hepatic enzyme activity induction and inhibition form the basis for many drug–drug interactions. Drugs metabolized by a common CYP isoform often compete for biotransformation and interact, but drugs may also affect pathways that do not appear to be their primary route of metabolism. Inducibility of hepatic enzyme activity is relevant to the use of several drugs that may be prescribed for the very elderly or the nursing home population. The antituberculous drug rifampin has recently been shown to be the most potent inducer of the microsomal oxidase system activity (CYP1A and CYP3A). It is far more potent in this effect than phenobarbital. When rifampin is administered to patients, profound increases in drug clearance occur, and concentrations of coadministered drugs may become negligible. Dosages of drugs cleared by CYP1A and CYP3A that are coadministered with rifampin may need to be increased, and then decreased upon discontinuation of rifampin. Other potent hepatic enzyme inducers include dexamethasone and phenytoin (CYP2C), caffeine, cigarette smoke, lansoprazole, and omeprazole (CYP1A), and St. John's Wort (CYP3A). Considerations regarding hepatic drug enzyme inhibitors are also pertinent. One of the first drugs to be shown to influence hepatic clearance of drugs, cimetidine, both decreases hepatic blood flow and inhibits microsomal oxidase system activity (CYP1A2, CYP2C, and CYP3A) and can profoundly decrease hepatic drug clearance. Marked elevations of serum lidocaine and propranolol concentrations occurred in elderly patients receiving these drugs in combination with cimetidine. Newer antihistaminergic blocking drugs, such as ranitidine, famotidine, and nizatidine, have little or no inhibition of hepatic drug metabolism. More recently, clinically significant decreases in drug clearance accompanying the use of amiodarone (all CYP isoforms), the antifungal drugs itraconazole and ketoconazole (CYP3A), erythromycin (CYP3A), protease inhibitors (CYP3A), and terfenadine (CYP3A) have been reported.

Nonrenal, Nonhepatic Drug Metabolism

Although the liver and kidney are the major sites for clearance of currently available therapeutic drugs, metabolism by both non-CYP processes and CYP-mediated metabolism can occur at other sites. Cloning of the genes for the CYP isoforms and use of cDNA probes has led to the discovery of CYP in organs other than liver, including the mucosa of the GI tract, kidney, lung, brain, or skin. CYP3A intestinal metabolism following oral drug administration probably contributes to the low bioavailability of CYP3A substrates, such as cyclosporine, lorazepam, midazolam, propranolol, verapamil, and other highly metabolized drugs (alcohol, clozapine, ergotamine, fluorouracil, isosorbide dinitrate). CYP1A1 has also been detected in the duodenum, and the CYP2B family has been found in the brain. Hydrolyzing enzymes, glutathione S-transferases (GSTs), UDP-glucuronosyltransferases, N-acetyltransferases, and methyltransferases are also found extrahepatically. Nonspecific esterases are widely distributed in tissues of the body (including blood, liver, and GI tract). Adenosine is an example of a drug that has a very rapid inactivation/clearance because it is metabolized and inactivated by an esterase present in blood. Pentoxifylline, hydralazine, and fluorouracil are metabolized to some extent in blood. Other circulating esterases include acetylcholinesterase and carbonic anhydrase. GSTs and UDP-glucuronosyltransferases are found in the kidney and lung, as well as in the liver. Protease and peptidase enzymes are found in many tissues and cause biotransformation of polypeptides. Potential age-related changes in nonrenal, nonhepatic drug metabolism have not been elucidated.

Elimination Half-life

A half-life ($t_{1/2}$) of a drug is described as the time it takes for the amount of drug in the body to decrease by half. This term is used clinically to refer to the time for drug concentrations to decrease by half after drug distribution has occurred throughout the body. This terminal drug elimination $t_{1/2}$ is described by:

$$t_{1/2} = 0.693 (\text{volume}) / \text{clearance}$$

Half-life, therefore, is a dependent variable, and changes in drug $t_{1/2}$ can occur secondary to changes in drug distribution volume, drug clearance, or combined changes in distribution and clearance.

The $t_{1/2}$ defines the time required to reach steady-state drug concentrations in the body during both drug initiation and after drug discontinuation. It takes approximately 3.3 drug half-lives to eliminate 90% of drug from the body or to reach 90% of steady-state concentrations after drug initiation. Therefore, the $t_{1/2}$ provides information necessary for determination of the time between dosage adjustments or the time necessary for stabilization or reduction in effects of the drug related to drug concentrations. Sustained-release preparations do not alter the drug half-life or the time necessary for stabilization or for reduction of drug concentrations.

Age-related Effects on Elimination Half-lives

The elimination $t_{1/2}$ has been reported to increase with age for a number of drugs (Table 469.1). When age-related increases in terminal elimination $t_{1/2}$ occur, it is important that the time between dosage adjustments be increased to allow evaluation of the full effect of a given drug dosage. It is also important to allow increased time for complete drug elimination before concluding possible adverse effects to be irreversible or non–drug-related.

A summary of the literature available on drugs commonly prescribed in older patients with suggested dosage adjustments are found in Table 469.2.

TABLE 469.2. COMMONLY PRESCRIBED DRUGS BY THERAPEUTIC CLASS AND REPORTED ALTERATIONS IN PHARMACOKINETICS, AND SUGGESTED DOSE ADJUSTMENTS IN OLDER PATIENTS

PHARMACODYNAMICS

Pharmacodynamic models relate drug dose or concentration to the intensity of response or “effect.” The most commonly used models have evolved from drug receptor theory and assume steady-state conditions.

E_{MAX} MODELS

The maximum effect model (E_{max}) is one of the simplest which describes drug (or agonist or antagonist) effect over a range of concentrations. It predicts no effect when there is no drug and maximum effect when “infinite” drug is present. It is based on the premise that drug combines reversibly with a receptor to form a drug receptor complex which then produces an effect and by the equation:

Effect

$$= \frac{(E_{\text{max}})(\text{drug concentration})}{(\text{drug concentration}) + (\text{concentration at 50\% } E_{\text{max}} \text{ or } C_{50})}$$

The measured effect is proportional to the fraction of occupied receptors. Graphically, this relationship is a hyperbola. A minor modification of the E_{max} model creates the sigmoidal E_{max} model, where

$$\text{Effect} = (E_{\text{max}}) \frac{\text{concentration}^n / C_{50}^n}{1 + \text{concentration}^n / C_{50}^n}$$

The sigmoidal E_{max} model predicts a sigmoidal response curve whereby no effect is seen at zero drug concentration or at lower concentrations until a concentration is reached at which a steep rise in the effect vs. response curve is seen. The steeply rising portion of the response curve is approximately linear throughout the 20% to 80% response range and then slowly approaches maximal effect. This model is qualitatively similar to physiologic or clinical circumstances wherein a threshold concentration must be reached to produce an appreciable effect, with increasing concentrations then producing increasing effects; however, as near-maximal effect is reached, increasing concentrations produce only slight changes in effect. The derived parameters have clinical applications. The E_{max} can estimate maximal effects for comparisons between drugs or between individuals. The concentration for half-maximal effect (C_{50}) can be an estimate or representation of the sensitivity of an individual or group to a drug (or affinity for a receptor). The slope factor describes the steepness of responses and amount of change anticipated due to changes in drug concentration and, to some extent, the wideness or narrowness of a drug's therapeutic range. These models can take more complex forms for the known physiologic conditions of tolerance, nonproportionality of response, multiple drugs and multiple receptors, and non-steady-state conditions.

Administration of drugs at dosages that produce maximal effects are often impractical in humans because of potential toxicity or undesired effects. In pharmacodynamic studies not attaining maximal effect, the linear portion of the relationship is often approximated using simple linear regression, where effect = (slope)(concentration) + basal value or $y = mx + b$. This model estimates the steepness of response (slope) and can be used as an index of sensitivity to the drug for between group and between drug comparisons and desired concentration guidelines.

For many compounds found in nature, such as quinidine (cinchona bark) or digitalis (foxglove), and local anesthetics (cocaine), a linear concentration vs. response relationship with toxicity at increased concentrations is frequently observed. For receptor agonist and antagonist drugs (a- and b-adrenergic and calcium receptor-blocking drugs) and enzyme-inhibiting drugs (ACE inhibitors), the E_{max} type of models better approximate the concentration vs. response relationship. New concepts in drug design based on targeted organ delivery or inhibition of intracellular phenomena will require new pharmacodynamic models.

INDIRECT DRUG EFFECTS/REFLEX RESPONSES

The pharmacodynamic models described above assume that effects are directly related to the drug concentration alone. This assumption is valid in vitro, but in vivo homeostatic or reflex mechanisms often counter “direct” drug effects. Reflex responses can be considered “indirect” drug effects. A more realistic representation of effects produced after drug dosing in humans is as follows:

$$\text{Total or net effect} = \text{direct effect} + \text{indirect effect}$$

The contribution or lack of contribution of reflex responses to net drug effect is of especial importance in understanding responses to drugs, such as potent vasodilators, in the older patient. Few tools are available to measure reflex responses, but studies of variability of heart rate, blood pressure, or respiration may provide a measure of vagal or baroreceptor activation.

AGE-RELATED CHANGES IN RECEPTOR SYSTEMS

Dynamic responses to autonomic stimuli have been a focus of investigation and have documented age-related changes. One of the most consistent age-related findings in all species and tissues is the decline in b-adrenergic responsiveness. Decreased responses of white blood cells, platelets, heart rate, atrioventricular conduction, cardiac contractility, and vasodilatation are seen following isoproterenol or other b₁-adrenergic stimuli in animal and human models of aging. Decreased b₁-adrenergic responsiveness with aging results in a shift of the concentration vs. response relationship to the right; higher concentrations are necessary for any given effect and the C_{50} (concentration for half-maximal effect) is higher. The maximum effect is also reduced. The mechanism for the age-related decrease in b-adrenergic responsiveness results from both decreased receptor numbers and altered G-protein coupling to the b-adrenergic receptor and G-protein-mediated signal transduction. Physiologically this results in decreased heart rate responses to b-adrenergic stimulation, such as exercise or stress, and a decrease in the maximal heart rate, which is directly related to age. This decreased b₁-adrenergic responsiveness contributes to the blunted baroreflex responses seen with aging.

Age-related changes of other adrenergic receptor systems are less uniform. For the a receptor, data from humans support the lack of age-related a-adrenergic mediated changes in human hand vein responses. Data from humans also support the presence of age-related decreases in a-adrenergic platelet receptors and decreased a-adrenergic-mediated arterial vasoreactivity of forearm blood vessels in healthy men that are similar to the decreased b-adrenergic-mediated blunting of responses seen with aging. For dopaminergic receptors, there are convincing data for decreased dopaminergic receptor content and dopaminergic transporters with healthy aging in humans. In brain tissue from animals, dopaminergic mRNA, as well as receptor and transporter content, decreases with aging. Cardiac responses to dopaminergic stimulation vary by the effect end point. Contractile responses may be blunted with aging, whereas chronotropic and dromotropic responses are

preserved or enhanced in models of aging.

Disparity in age-related changes in peripheral versus central dynamic responses to muscarinic parasympathetic stimulation or blockade also exist. Decreased sensitivity and responses to parasympathetic stimulation are commonly seen in cardiac and vascular tissues, whereas increased central nervous system effects are frequently seen in the elderly. The physiologic consequences are blunted heart rate responses to atropine but increased anticholinergic central nervous system effects, including delirium, in older subjects. Greater sensitivity may also explain the increased incidence of adverse effects, such as urinary retention, constipation, and fecal impaction in the elderly who receive drugs with anticholinergic properties.

The vascular wall has become a target for pharmacologic manipulation of blood pressure and blood flow. Age-related decreases in vasodilatation in response to acetylcholine have been shown in both normal and diseased coronary and peripheral arteries. Coronary vascular responses to endothelin are also blunted with aging. Vasodilatation in response to non-endothelium-dependent agents, such as nitrates or nitroprusside, do not appear to be altered by aging.

BAROREFLEX RESPONSES

In intact humans, age-related alterations in stimulation and suppression tests of baroreceptor function have been well documented. Blunted responses to vasodilators, vasoconstrictors, postural maneuvers, and the Valsalva maneuver have been shown with aging in the absence of detectable disease. Diseases and deconditioning further decrease responses. Pharmacodynamic alterations at many levels (sensing, signal transmission, central processing, autonomic b-adrenergic and parasympathetic pathways, and vessel receptor content and responsiveness) contribute to the blunted baroreceptor responses seen with aging in humans.

Blunted baroreflex responses help to explain the greater postural hypotension and even syncope after potent nitrate or vasodilator administration to older patients. The lack of evidence for increased vascular responses suggests the mechanism for the greater hypotension following vasodilator drug administration in older individuals is primarily due to blunted baroreflex responses to the hypotension. A similar mechanism can be postulated for greater postural hypotension with tricyclic antidepressant drugs in older versus younger patients.

ADVERSE DRUG EFFECTS AND DRUG INTERACTIONS

The prevalence of chronic and multiple diseases increases with age and contributes to polypharmacy. The most common chronic diseases or conditions are arthritis, hypertension, hearing impairments, heart disease, orthopedic impairments, cataracts, sinusitis, and diabetes. The categories of drugs most frequently prescribed in both hospitalized and community-dwelling older patients are cardiovascular and antiarthritis drugs. Therapeutic classes cited in 32% of outpatient encounters involving older patients are antihypertensives, b- and a,b-blockers, coronary vasodilators, calcium channel blockers, digitalis preparations, diuretics, anti-infectives, ophthalmics, analgesics, antiarthritics, antidiabetics (oral therapy and insulin), psychotherapeutics, bronchial therapeutics, corticoids, antispasmodics, nutrients/supplements, and cough/cold products. It has been estimated that older community-dwelling North Americans take an average of 4.5 medications at any one time and that most patients use both prescription and over-the-counter drugs. The institutionalized elderly are prescribed from three to eight drugs daily, with a somewhat higher use of psychotropics than older outpatients.

Although the frequency of adverse drug reactions had often been thought to correlate with the age of the patient, consistent observations demonstrate that age is not the major determinant of adverse drug effects. Rather, it is the number of drugs administered that is directly related to the risk of adverse drug-related events. Studies have correlated increasing numbers of medications consumed with increased rates of adverse drug effects and hospital admissions, as well as a decrease in the incidence of adverse drug reactions with reductions in the number of medications consumed. Most studies suggest that the chronic administration of two drugs is associated with a risk of adverse effects of about 15%. The risk of interactions rises to 50% to 60% with the administration of five drugs per day. While drug interactions can be minimized by reducing the number of drugs prescribed, multidrug regimens for single diseases and the presence of multiple diseases may make this an unrealistic goal in many older patients. Therefore, a framework for understanding and preventing adverse drug interactions is necessary.

Drug interactions can result from a pharmacokinetic or pharmacodynamic interaction. Interactions of drugs that are metabolized by a similar route can be anticipated. Routes of elimination are discussed in the renal and hepatic clearance sections, as are pharmacokinetic drug interactions that both increase and decrease drug clearance and concentrations. Pharmacodynamic drug interactions have been less well studied. Pharmacodynamic interactions can lead to either potentiation of drug action or decreased drug effects. In the elderly, common types of pharmacodynamic interactions include those that lead to postural hypotension (direct vasodilators or nitrates combined with a-blockers, b-blockers, calcium channel blockers, ACE inhibitors, diuretics, or sildenafil) or bradycardia (b-blockers combined with digoxin, verapamil, or amiodarone).

The highest probability of problems in the older patient will be in connection with drugs that have narrow therapeutic ranges, and these should be particularly closely monitored (i.e., digitalis, theophylline, warfarin, lithium, lidocaine, quinidine, aminoglycoside antibiotics, tricyclic antidepressants). Central nervous system effects or side effects may be more common in older patients and may significantly affect quality of life, mentation, and functional status (i.e., long-acting hypnotics, histaminergic and a-blocking drugs, and drugs with anticholinergic effects, such as disopyramide and antihistamines). Adverse drug effects may present "atypically" as a change in mental status in the older patient, and a high index of suspicion must always be present (i.e., digitalis excess presenting as altered mental status).

OVER-THE-COUNTER DRUGS AND NUTRACEUTICALS

A number of drugs are currently available without prescription or over the counter. Although patients may not report using them, such drugs may produce significant pharmacologic effects and can interact with prescription drugs. A common example is the use of NSAIDs and GI bleeding. Aluminum-containing antacids interfere with the absorption of drugs and calcium. Ingestion of mineral oil inhibits absorption of fat-soluble vitamins. Vitamin K intake can reverse warfarin effects.

The term "nutraceuticals" has been coined for a diverse group of substances, such as dietary supplements, vitamins, herbs, and herbal teas, that are becoming increasingly popular with older populations for the self-treatment of depression, memory impairment, sleep disorders, and other common disorders. Two that appear to have widespread use are St. John's wort and ginkgo biloba. St. John's wort is taken for mild depression. It is similar in action to SSRIs, produces additive effects, and should not be combined with SSRIs. It also produces photosensitivity and should not be used in combination with other photosensitizing drugs. Ginkgo biloba has long been advocated for memory loss and as a vasodilator. It inhibits coagulation, can cause bleeding, and interacts with warfarin. Vitamin E also interacts with warfarin to increase anticoagulant effects. Nutraceuticals are not regulated as to purity, health claims, labeling, or bioequivalency, and limited efficacy data are available. Rigorous evaluation of these and other alternative therapies is just beginning.

Dietary exposure can also influence drug concentrations or effects. Alcohol interferes with the absorption of calcium, folate, and thiamine. Ingestion of char-broiled meat has been shown to induce CYP1A2, leading to increased clearance of substrates metabolized by this pathway. High-salt diets increase clearance of quinidine; and cabbage and Brussels sprouts have been shown to increase hepatic clearance of antipyrine. Recently, grapefruit juice has been shown to be a selective and potent inhibitor of intestinal CYP3A. Ingestion of 150 ml of reconstituted grapefruit juice in combination with a number of dihydropyridines leads to markedly increased drug concentrations and increased antihypertensive effects. The role of diet and nutrients in drug metabolism is only now being recognized, and there are no data on potential age-related changes in these processes.

PHARMACOEPIDEMIOLOGY AND PHARMACOECONOMICS

The challenges of evaluating drug utilization and outcomes associated with therapeutic drug use has stimulated the development of new models and fields for pharmacologic study. Two such fields are pharmacoepidemiology and pharmacoconomics.

PHARMACOEPIDEMIOLOGY

Pharmacoepidemiology applies epidemiologic methods to the study of drug utilization and effects (both beneficial and adverse) in the clinical setting. Basic tools include survey methods for epidemiologic database review, case-control and cohort studies to address the effects of patient variables on clinical outcomes, unexpected drug effects, drug utilization, and individualization of therapy. Examples of these types of analyses in older subgroups are Medicaid database reviews that identified an increased risk of hip fractures in elderly subjects receiving sedative drugs and increased risk of peptic ulcer disease in elderly patients receiving NSAIDs. The pharmacoepidemiologic factors involved in urinary tract infections in patients in long-term care facilities has also been addressed with Medicaid database analysis. Although the field is not fully developed, it is evolving rapidly, with efforts focused on standardization of methodology, development of methods to deal with

confounding of effects by indication, and development of the capacity to adjust accurately for disease severity.

PHARMACOECONOMICS

Pharmacoeconomics incorporates cost considerations into the analyses of drug utilization, benefits, and outcomes. The purpose is to define methods or therapies that accomplish an objective in the least costly manner. Cost/benefit analyses compare the cost of a therapy to its benefit. Cost-effectiveness analyses compare the cost of a therapy in monetary terms with its effectiveness, measured in clinical units—either outcomes or surrogate markers—and are usually reported as a ratio of cost to benefit. Cost/utility analyses estimate cost in monetary units and outcomes in terms of the value patients gain from the therapy. Cost/identification analysis estimates the cost of therapy. Results are expressed in cost per unit of service provided and do not calculate clinical outcomes. This field is newer than pharmacoepidemiology, and few studies of cost-effectiveness have stratified by age. One such study found the cost-effectiveness benefit for thrombolytic therapy with streptokinase to be greater in elderly patients than in younger patients with myocardial infarction. A subsequent study of tissue plasminogen activator in patients after acute myocardial infarction reached the same conclusion. Analyses to date have largely focused on costs per day or costs per year of life saved, and have not typically incorporated multidimensional outcomes that include social function, employment, rehospitalization, paid and unpaid assistance in the home for management of health care problems, symptoms, quality-of-life measures, or drug-related morbidity and mortality.

SUMMARY

Age-related changes have been reliably found and estimated for renal drug clearance; however, changes in hepatic drug clearance, half-life, bioavailability, and volume of distribution are less predictable. In general, one should reduce drug dosages in elderly individuals and titrate drug dosages slowly ([Table 469.3](#), [Fig. 469.2](#)). The current state of knowledge is limited by the paucity of investigations in women, minority groups, the old-old, and patient populations with multiple diseases. Age-related changes in responses have been less extensively studied than changes in drug metabolism and clearance but contribute to clinical effects following drug administration. The increasing use of drugs that act as receptor agonists and antagonists will render investigations of age-related changes in the dynamics of receptor-based systems of growing importance to drug therapy in the elderly. Because the co-administration of multiple medications is the single most important factor in the risk for adverse drug effects, the fewest number of drugs possible should be used in patients. When multiple-drug regimens are necessary, drug interactions should be anticipated based on metabolic route or mechanism of effect and adjustments in drug administration made to avoid adverse drug interactions. Newer tools of pharmacoepidemiology and pharmacoeconomics may help to identify drug efficacy and adverse effects in larger clinical populations.

- Introduce drug at low dosage
- Increase dosages slowly
- Use as few drugs as possible
- Avoid interacting drugs if possible
- Monitor for adverse effects
- Consider effects of over-the-counter drugs, diet, and dietary supplements

CHAPTER 470: GERIATRIC CLINICAL NUTRITION, INCLUDING MALNUTRITION, OBESITY, AND WEIGHT LOSS

JEFFREY I. WALLACE AND ROBERT S. SCHWARTZ

[Nutritional Requirements and Recommended Daily Dietary Allowances](#)
[Malnutrition and Weight Loss](#)

Much of the intense scientific interest in the field of nutrition stems from the hope that an ideal diet, while not necessarily increasing maximal life span, may prolong the active and useful life expectancy within the genetically determined maximal life span. Defining nutritional adequacy, much less an ideal diet, is a formidable task in the elderly because aging can affect each of the processes that together make up good nutrition: the procurement, consumption, assimilation, and use of the substrates necessary to sustain life. In addition, the wide physiologic variation found within this age group greatly influences the nutritional requirements of the elderly.

NUTRITIONAL REQUIREMENTS AND RECOMMENDED DAILY DIETARY ALLOWANCES

The recommended daily dietary allowances (RDAs) are standards for good nutrition that are set to be safe and to meet or exceed the nutritional requirements of all but the 2.5% of the population considered whose needs are the highest. The majority of current RDAs have not been updated since 1989 and are inadequate with regard to the elderly because they divide physiologically mature adults into one group 19 to 24 years old, a second group 25 to 50 years old, and a third group that includes all those older than 51 years. Further, it should be noted that the RDAs were established to prevent dietary deficiencies rather than to prevent or control chronic conditions (including those that may stem from dietary excesses, notably obesity). Moreover, they have been extrapolated from research conducted primarily in younger, healthier populations. Hence, judgments regarding dietary intake in the elderly must be tempered by recognition of the inadequacy of present RDAs for this group. However, recently updated recommendations (referred to as dietary reference intake, or DRI) from the Food and Nutrition Board of the National Academy of Sciences–Institute of Medicine have attempted to address some of these shortcomings for selected vitamins and minerals (B-complex vitamins, vitamin D, calcium, phosphorus, magnesium, and fluoride) and are considered in greater detail below.

ENERGY INTAKE

Energy intake declines significantly with aging. Of the 600-kcal disparity in daily intake between 30- and 80-year-old men noted in the Baltimore Longitudinal Study of Aging, about one-third could be accounted for by a reduction in basal energy expenditure, attributed to a decrement in lean body mass. The remaining two-thirds was associated with a decline in physical activity with aging. A still greater reduction in caloric intake below the RDA, particularly among persons of low socioeconomic status, has been one of the most consistent findings in surveys of nutritional status in the elderly. The first National Health and Nutrition Examination Survey (NHANES I) found that over 50% of older adults with incomes below the poverty level consumed less than two-thirds of the RDA for energy intake and that 15% of the elderly consumed fewer than 1,000 kcal per day. In the NHANES II study, the mean energy intake for the study population 65 to 74 years old was about 1,600 kcal for men (70% of the RDA) and 1,200 kcal for women (63% of the RDA). Smaller studies using superior assessment methods have generally found higher energy intakes, pointing out potential problems with the use of the NHANES dietary recall methodology, but most studies confirm that caloric intake decreases with age.

The observed fall in energy intake with aging may be an important predisposing factor for malnutrition because if noncaloric (“micronutrient”) requirements remain constant or increase with age, then the elderly would be required to consume essentially the same amounts of noncaloric nutrients within the constraint of a reduced overall energy intake. Thus, the inactive elderly are compelled to choose a more nutrient-dense diet if nutritional deficiency is to be avoided. This task is especially difficult because the elderly as a group are the least knowledgeable about nutritional matters, and social, psychological, and biologic forces frequently conspire to inhibit adequate food intake in those of advanced age. Accordingly, many experts recommend multivitamins to help supplement micronutrient intake in older adults, a practice supported by a number of randomized trials whose results indicate that multivitamins can improve nutritional parameters, enhance immunity, and, in one study, reduce episodes of clinical infection. Moreover, the ingestion of one or more over-the-counter vitamin or mineral preparations is very common, especially among generally healthy older adults of middle- and upper-income status in the belief that their health and longevity will be further enhanced, confounding scientific assessment of the rationale for “megavitamin” intake.

PROTEIN INTAKE

Absolute protein intake is closely linked to energy intake and, thus, declines with age. Nonetheless, most adults in Western societies normally consume more than twice the RDA for protein (0.8 g per kilogram), and diminished protein intake alone is unlikely to account for the large reduction in total body protein in the elderly. Studies reveal a mean 40% decline in muscle mass in elderly men compared with young controls, the cause of which is most likely related to excessive muscle catabolism and in the extreme produces sarcopenia and related weakness (see [Chapter 464](#)). Visceral protein is also affected by aging, as evidenced by a small reduction in albumin concentration and a defective regulation of albumin synthesis in response to changes in dietary protein intake. However, an albumin concentration below 3.5 mg per deciliter should not be considered a normal finding in an elderly person.

Different studies that attempt to determine the minimal protein intake necessary for protein balance in the elderly are contradictory, variously supporting protein needs less than, equal to, or greater than the RDA. These discordant findings are not surprising, considering the number of possible factors that affect nitrogen balance (acute and chronic illness, energy balance, and exercise) and the methodologic problems of the nitrogen balance technique. Some studies indicate that increased protein intake can enhance healing of pressure ulcers, and recently published guidelines recommend protein intakes of 1.0 to 1.5 g per kilogram per day for these patients. Similarly, acutely ill or injured patients may benefit from increased protein intakes of up to 1.2 to 1.8 g per kilogram per day, depending on the severity of the stressor. Still other studies suggest that higher than normal RDA intakes of protein (1.0 to 1.2 g per kilogram) may be required for older subjects to accrue significant lean body mass during a strength training program.

CARBOHYDRATE, FAT, AND FIBER INTAKE

Carbohydrate and fat intake are usually inversely related (in the caloric steady state), and the increase in fat consumption in the American diet this century has been paralleled by a reduced consumption of carbohydrates, especially complex carbohydrates. Epidemiologic data have demonstrated that excessive dietary fat intake is associated with increased risks for obesity, coronary heart disease, and certain cancers. Although data indicate that fat consumption has declined in recent years from nearly 40% to around 34% of total energy intake in the face of widespread public education on the risks of high-fat diets, the prevalence of obesity has continued to rise, with more than 40% of persons age 60 to 74 being classified as overweight in the NHANES III study. Dietary fiber has been another area of intense interest because high intakes of dietary fiber have been associated with reduced risks for coronary heart disease, and high-fiber diets may have positive effects on lipids, glucose tolerance, and blood pressure. However, a recent, randomized, double-blind study noted no difference in the parameters in individuals receiving diets supplemented with high- or low-fiber foods. The observed small reduction in cholesterol in the high-fiber group was thought to be secondary to a reduction in the intake of cholesterol and saturated fatty acids. Although high-fiber diets can be recommended for treatment of constipation and diverticulosis, a recent large trial did not find an inverse association between fiber intake and the risk for colorectal cancer, casting doubt on the purported protective role of fiber in colon cancer. Despite these and other areas of controversy, there is general agreement that healthy diets for adults should include adequate dietary fiber (20 to 30 g per day) and more than five daily servings of fruits and vegetables, and should restrict total and saturated fat intake to less than 30% and more 10% of energy intake, respectively.

VITAMIN AND MINERAL INTAKE

Numerous studies have examined vitamin and mineral nutriture in the elderly. Most of these studies have been cross-sectional and have estimated nutrient adequacy by the level of dietary intake of specific nutrients in comparison to the RDA, direct or indirect measurements of blood nutrient concentrations, or cell or tissue nutrient concentrations. Despite frequent dietary or laboratory evidence for inadequacy, clinical evidence for classic vitamin deficiency syndromes in the absence of general malnutrition is rarely documented in the elderly in America.

Water-Soluble Vitamins

Thiamine (Vitamin B₁)

Thiamine is a key coenzyme in the metabolism of sugars by the pentose phosphate pathway; thus, its requirement depends on the caloric intake. A mandatory enrichment of food with vitamin B₁ (especially flour) ensures that the RDA is met in most elderly persons in the United States. In alcoholics, however, interference with active absorption in combination with poor dietary intake can induce the classic clinical triad of thiamine deficiency that defines the Wernicke–Korsakoff syndrome: confusion (acute and chronic), ataxia, and ophthalmoplegia. Heart failure and peripheral neuropathy are also occasionally seen in patients suffering from beriberi. At least 3% to 4% of the population older than 65 years suffers from alcoholism, with higher rates observed in widowers, hospitalized elderly, and nursing home patients. Accordingly, a high level of suspicion for thiamine deficiency in the elderly must be maintained, especially among those at risk for alcohol abuse or with diseases that produce anorexia. Because of the danger of acutely precipitating sequelae of thiamine deficiency, alcoholic and malnourished elderly patients receiving intravenous glucose solutions should also receive thiamine.

Ascorbic Acid (Vitamin C)

Vitamin C is necessary for the hydroxylation of proline and the formation of collagen, and it is a major antioxidant of dietary origin. Although the overt clinical syndrome of scurvy (weakening of collagenous structures, poor wound healing, and hemorrhage) is seldom seen in the United States today, the NHANES I survey found that 23% to 42% of the population studied have intakes of vitamin C that are less than half of the RDA. The lowest intake was found in the poorest socioeconomic group. Other studies have found much lower rates of dietary deficiency, a difference explained mainly by the higher socioeconomic status of the subjects studied. Vitamin C in blood and tissue is diminished in the elderly, and although low levels in hospitalized elderly are enhanced by vitamin C supplementation, little or no clinical improvement has been detected after this intervention. The potential utility of vitamin C in patients with wounds and pressure ulcers has been an area of particular clinical interest, perhaps due to an older, small, placebo-controlled study that found that ascorbic acid 500 mg twice daily improved pressure sore healing rates among surgical patients, many of whom were vitamin C–deficient. However, a recent, much larger, randomized trial of ascorbic acid (500 mg vs. 10 mg, twice daily) in nursing home patients found that higher intakes of vitamin C did not enhance pressure ulcer healing, even among patients with lower baseline vitamin C levels. This result is consistent with extensive evidence that 10 to 20 mg of ascorbic acid per day is sufficient to correct scurvy-related delayed wound healing and that additional supplementation does not appear to further accelerate healing. Thus, although vitamin C in doses of 500 mg twice daily is nontoxic and inexpensive, there is no evidence that such supplements accelerate wound healing among patients who are not vitamin C–deficient.

The ingestion of megadoses of vitamin C has been suggested to reduce the incidence of viral upper respiratory infection, but double-blind studies have repeatedly failed to support this contention. Similarly, although epidemiologic data suggest that vitamin C may protect against atherosclerosis, malignancy, and cataracts (perhaps related to antioxidant properties of ascorbic acid), prospective and randomized studies have not consistently supported these associations. Despite all of the negative or inconclusive studies, vitamin C remains the most common dietary supplement in adults (with up to 60% of some retirement populations taking vitamin C supplements), and it is often taken in megadoses. Megadose vitamin C (more than 10,000 mg per day) may be associated with significant risks: oxalic acid renal calculi, malabsorption of vitamin B₁₂, increased absorption of iron, false-negative tests for occult blood in the stool, rebound scurvy, and possibly bone calcium loss secondary to buffering of the added acid load. In addition, the increment in plasma concentration is only 0.2 mg for a dietary intake of 1,000 mg of ascorbic acid, with up to 90% of the vitamin being excreted unchanged in the urine. Therefore, massive supplementation should not be endorsed. However, several common conditions, such as smoking and stress, negatively affect vitamin C nutriture, and additional intake (250 mg per day) may be warranted under these conditions.

Folate

Folate is essential for the synthesis of nucleic acids and the metabolism of certain amino acids, and a deficiency state is associated with impaired cell division and protein synthesis. It is most abundant in liver, leafy green vegetables, fruit, and yeast. Although a large percentage of older adults do not consume even half of the current DRI for folate, low serum folate levels are unusual in nonalcoholic elderly people. Nonetheless, there is currently a great deal of interest in increasing the folate intake of all adults, in part due to this vitamin's pivotal role in the metabolism of homocysteine, a purportedly important independent risk factor for atherosclerotic cardiovascular disease. Strong epidemiologic evidence indicates that elevated homocysteine levels are associated with cardiovascular disease and that increasing folate intake to at least 400 µg per day can reduce serum homocysteine levels. However, to date no randomized trials have demonstrated that lowering homocysteine by increasing folate intake reduces cardiovascular events.

A folate fortification program for grain products started in 1998 (140 µg of folate per 100 g) increased folate intake by 100 µg per day on average. However, the main impetus for this program was the prevention of neural tube defects in fetuses in pregnant women, and it appears that further increases in folate intake are necessary to optimally reduce serum homocysteine levels. Other evidence that increased folate intake might be beneficial includes prospective data indicating that folate might be protective against colon cancer. Although further study is clearly needed in these areas, the Food and Nutrition Board recently increased the RDA for folate from 200 to 400 µg per day based on many of the above potential benefits of higher folate intakes.

Vitamin B₁₂

Vitamin B₁₂ functions as a coenzyme for methyl transfer reactions [converting homocysteine to methionine and methylmalonyl coenzyme A (Coa) to succinyl-CoA], and deficiency states cause hematologic and neurologic abnormalities. Although the classic presentation of vitamin B₁₂ deficiency includes macrocytic anemia, it has been well documented that patients can develop significant irreversible neurologic complications, including dementia, in the absence of anemia or macrocytosis. Vitamin B₁₂ is found in foods of animal origin, and despite median intakes in the United States (4 µg for older men, 2.5 µg for women) that exceed the recently revised RDA for B₁₂ (2.4 µg per day), studies of community-dwelling elderly individuals demonstrate that 10% to 15% of older adults have metabolic evidence of vitamin B₁₂ deficiency. The high prevalence of vitamin B₁₂ deficiency in older adults appears to be attributable, in large part, to a reduced ability to absorb food-bound vitamin B₁₂ (food–cobalamin malabsorption). Because 10% to 30% of older adults may be unable to absorb naturally occurring food-bound vitamin B₁₂, the recently updated RDAs for B-complex vitamins advised that persons over the age of 50 meet their B₁₂ requirement by taking foods fortified with B₁₂ or by taking B₁₂-containing supplements. Individuals with B₁₂ deficiency caused by a lack of intrinsic factor (e.g., pernicious anemia) require medical treatment with pharmacologic doses of vitamin B₁₂. However, it appears that pernicious anemia is a very uncommon cause of vitamin B₁₂ deficiency in older adults. Because of its high prevalence and potential for irreversible neurologic sequelae that can occur without hematologic warning signs, routine screening of older adults for vitamin B₁₂ deficiency is recommended.

Fat-Soluble Vitamins

Retinol (Vitamin A)

Vitamin A is important in the maintenance of normal dark-adapted vision and mucosal membranes, and deficiency can cause night blindness, dry skin, and dry mucous membranes. The prevalence of dietary deficiency of vitamin A varies from 12% in study of a healthy white population to 60% in the NHANES I survey. However, even in the NHANES study, serum concentrations were normal in more than 99% of the subjects tested. Epidemiologic data support an inverse relationship between dietary vitamin A consumption and cancers of the lung, bladder, upper gastrointestinal tract, and breast. Possible protective effects of vitamin A and its precursors on age-related macular degeneration and coronary heart disease have also been observed, perhaps related to their antioxidant properties. It is unclear, however, whether these potential protective effects are caused by retinol itself or by carotenoid precursors (e.g., beta carotene) in the diet that are capable of quenching free oxygen radicals (or by other substances and effects associated with diets rich in fruits and vegetables). The possible protective effects of vitamin A and its precursors have spurred the frequent use of these vitamins in megadoses. However, four recent randomized controlled trials failed to demonstrate beneficial effects (or even found detrimental effects) of beta carotene (with and without vitamin A) on cancer or cardiovascular outcome events. Furthermore, recent studies suggest that preformed vitamin A in doses as low as 5,000 to 10,000 IU per day may have adverse effects, including reduced bone mineral density and higher hip fracture rates among women consuming more than 5,000 IU per day and teratogenic effects of doses exceeding 10,000 IU per day. In contrast, several studies have shown that beta carotene is safe for humans and that carotenoids do not cause hypervitaminosis A even when ingested in large amounts (but, as noted above, beneficial effects of carotenoids have not been demonstrated).

a-Tocopherol (Vitamin E)

a-Tocopherol comes mainly from vegetable and seed oils. Clinical deficiency of vitamin E in human beings is limited to cases of severe, longstanding fat malabsorption. The amount of vitamin E in the diet of most elderly people in the United States is probably adequate to meet the RDA of 30 IU, but vitamin E supplements are needed to achieve the high levels of vitamin E intake that have been studied in most randomized trials. The major contemporary interest in vitamin E concerns its antioxidant properties, particularly its potential role in decreasing atherogenesis by decreasing oxidized low-density lipoprotein particles. Adding support to this biologic hypothesis, two epidemiologic studies and two randomized controlled trials have found that high doses of vitamin E (from 50 to 800 IU per day) are associated with reduced risks of primary and recurrent coronary heart disease events. Other randomized trials indicate that vitamin E supplements may slow the progression of Alzheimer's disease (2,000 IU per day) and can enhance immune function (200 to 800 IU per day). Most randomized trials concerning the relationship of vitamin E to cancer have produced negative results, except for some encouraging data indicating that vitamin E (50 IU per day) may reduce the incidence of clinically relevant prostatic cancer. Little toxicity has been noted in adults taking pharmacologic doses of vitamin E; however, there is some concern that vitamin E may increase bleeding risks through its antiplatelet effects, and caution has been suggested for patients taking warfarin. While recommendation of widespread supplementation should await further trials of sufficient size and duration to more fully assess risks and benefits, evidence is mounting that vitamin E supplements are safe and may offer important clinical benefits.

Vitamin D

Hypovitaminosis D is common among older adults and is an important, and remediable, risk factor for osteopenia and bone fractures. Prevalence rates of low vitamin D levels in older adults range from 5% to 15% in the Framingham cohort to over 50% of hospitalized and institutionalized elderly. Reasons for these high prevalence rates include poor dietary intake, inadequate sun exposure, chronic liver and renal diseases, and therapy with drugs that can impair vitamin D activity (e.g., phenytoin, corticosteroids). A recent U.S. trial involving healthy older men and women demonstrated that supplemental vitamin D and calcium (700 IU and 500 mg, respectively) can reduce bone loss and decrease fracture rates. Other data suggest that vitamin D may also play an important role in muscle function, immune function, and osteoarthritis progression, and a recent trial demonstrated functional improvements after vitamin D replenishment in frail vitamin D-deficient older adults. The Food and Nutrition Board recently recommended a doubling of the previous RDA for vitamin D to 10 µg per day (400 IU) for adults age 51 to 70 and a tripling to 15 µg per day (600 IU) for adults over age 70. Because mean intake in community-dwelling elderly is approximately 2.5 µg per day, low-dose supplementation (10 µg per day) should be considered for all older adults. However, in one study of hospitalized patients, hypovitaminosis D was still highly prevalent despite the common daily use of vitamins that contained, on average, 10 µg vitamin D. Accordingly, some experts recommend that higher doses of supplements (15 to 20 µg) be considered, particularly for chronically ill, homebound, or institutionalized people with infrequent exposure to sunlight. Such doses appear to have a considerable margin of safety.

Minerals

Calcium

Osteopenia is a very common and costly disorder in the United States that affects 25% of elderly women and, at a given age, half as many men as well. The cause is multifactorial, with several nutritional factors playing important roles in calcium balance. Almost all nutritional surveys indicate that calcium intake in the elderly is far less than the RDA (which was recently increased from 800 mg to a DRI of 1,200 mg for persons over age 50). Still higher intakes of 1,500 mg per day were recommended for men and women over age 65 by a 1994 National Institutes of Health consensus panel on optimal calcium intake. The NHANES II study found mean calcium intakes of 596 and 475 mg per day in older men and women, respectively, and NHANES III found that virtually all elderly had intakes below 800 mg per day. Calcium intake is also inadequate in younger women, with 66% of women 18 to 30 years old and 75% older than 35 years similarly consuming less than 800 mg per day. Reduced consumption at these early ages may be critical because peak bone mass is attained during early adulthood. Of interest, a recent large randomized trial found that supplemental calcium (1,200 mg per day) also decreased the risk of colorectal adenomas, providing another potential rationale for calcium supplementation beyond its beneficial effects on bone. Absorption of calcium supplements appears to be most efficient at individual elemental calcium doses of 500 mg or less and when taken between meals (except for persons with reduced gastric acid production, in whom calcium citrate may be preferable to more commonly used calcium carbonate supplements).

Zinc

Estimates of zinc intake from large surveys reveal that the elderly consume about 10 mg per day of zinc (zinc RDA for women is 12 mg per day, men 15 mg per day). The lowest intakes were in poor elderly women, who consumed less than half the RDA. There appears to be only a small decline, if any, in blood zinc concentration with aging, but the relationship between blood and tissue levels is poor. Zinc nutrition is especially meaningful in the elderly because of its relationship in animal models with immune function, wound healing, and taste perception. A number of small studies suggest that zinc supplementation in doses of 15 to 25 mg may increase the number of circulating T lymphocytes, improve delayed hypersensitivity in elderly subjects, and decrease clinically relevant infections. Interest in the potential role of zinc in wound healing was spurred in part by a small older study whose results indicated that zinc supplements in higher dose (220 mg zinc sulfate t.i.d.) accelerated the healing of excised pilonidal-sinus tracts in young healthy airmen. However, subsequent studies indicate that the benefits of zinc supplementation on wound healing appear limited to patients with baseline zinc deficiencies. Zinc supplementation (zinc sulfate 220 mg t.i.d.) has been demonstrated to promote healing of venous stasis leg ulcers in older subjects with documented low serum zinc levels in double-blind studies. Although clinical zinc deficiency is unquestionably associated with anorexia, the appetite response to zinc supplementation in the elderly has been unimpressive. One double-blind, placebo-controlled study demonstrated that zinc supplementation (zinc sulfate 100 mg twice daily) reduced the progression of macular degeneration, but this intriguing result was not confirmed in a subsequent study. Zinc supplements can cause side effects that include gastrointestinal irritation; paradoxically, high serum zinc levels may inhibit healing and impair immune function, as well as interfere with copper metabolism.

Multivitamins

Most older adults do not consume fruits and vegetables in recommended quantities (more than five servings per day), and their frequently reduced energy intakes often result in diets that are deficient in one or more micronutrients. Studies show that 30% to 60% of older adults already take multivitamins, and there is some evidence that even healthy elderly persons may benefit from such supplements. Most standard multivitamins contain quantities of vitamins and minerals in the RDA range, and such doses appear to have little to no toxicity. Although supplementation is not a substitute for a healthy balanced diet (which may contain beneficial nutrients that remain to be identified), the use of a standard multivitamin appears to be a safe and reasonable approach to ensure adequate micronutrition in the elderly.

MALNUTRITION AND WEIGHT LOSS

BARRIERS TO ADEQUATE NUTRITION

The socioeconomic, psychological, and physiologic variation found in the elderly has a profound influence on the risk for malnutrition in any given person. Further, although undernutrition has been frequently observed in virtually all older-adult populations studied, prevalence rates and the implications of malnutrition vary considerably across the spectrum of health, from well community-dwelling to frail hospitalized or institutionalized elders. Many of the common and often interacting factors that can act as barriers to adequate nutrition in the elderly are listed in [Table 470.1](#). These, along with the drugs listed in [Table 470.2](#), must be considered and addressed in any effort to assess and reduce the risk of malnutrition in older adults.

Socioeconomic:
 Fixed income/poverty
 Access to food
 Isolation or lack of transportation
 Lack of storage facilities (refrigerator, freezer)
 Lack of adequate cooking facilities (oven, microwave)
 Poor knowledge of nutrition
 Dependence on others (institutions, caretakers)
 Elder abuse and neglect

Psychologic:
 Depression
 Dementia
 Loss of mealtime companions
 Anxiety, fear, paranoia

Physiologic:
 Reduced mobility or dexterity producing decreased ability to prepare food or feed oneself
 Arthritis
 Stroke or other neurologic impairment
 Decreased metabolic requirements and reduced food intake
 Inactivity
 Reduced lean body mass
 Impaired sensory input (sight, smell, taste)
 Poor or no dentition
 Alcohol and other drugs (Table 470.2)
 Gastrointestinal disorders (e.g., dysphagia, malabsorption)
 Chronic illnesses that affect nutrient intake, appetite, or utilization

TABLE 470.1. BARRIERS TO ADEQUATE NUTRITION IN THE ELDERLY

Enhance catabolism
 Corticosteroids
 Cancer chemotherapeutic agents

Inhibit intake
 Clonidine
 Glucocorticoids
 Cause dry mouth/impair gastrointestinal motility
 Anticholinergics
 Antihistamines
 Tricyclic antidepressants
 Antipsychotics
 Cause nasopharyngeal edema
 Narcotics
 Kaposin
 Ergotans
 Antidiarrheals
 Serotonin reuptake inhibitors
 Dopaminergics (L-dopa)
 Neurosteroid anti-inflammatory agents
 Reserpine
 Cancer chemotherapeutic agents
 Cause malabsorption of nutrients
 Corticosteroids (calcium)
 Proton pump inhibitors, metformin (vitamin B₁₂)
 Laxatives (energy)
 Bile acid binders (fat-soluble vitamins)
 Antibiotics (fat, calcium)
 Aluminum-containing antacids (calcium)
 Alcohol (folate, vitamins, calcium)
 Cause abnormal nutrient metabolism
 Epinephrine/adrenaline, phorbolmyristate, corticosteroids (vitamin D)
 Isoniazid (vitamin B₆, vitamin B₁₂, niacin)
 Cimetidine (vitamin D)

TABLE 470.2. DRUGS THAT FREQUENTLY AFFECT NUTRITIONAL STATUS

INVOLUNTARY WEIGHT LOSS IN THE ELDERLY

Definition and Clinical Significance

Although no clear consensus exists on the degree of unintentional weight loss that should prompt concern and investigation, most studies on weight loss have used decrements in the range of 5% of body weight, over 6 to 12 months, to signify clinically important weight loss. Available data indicate that this degree of weight loss occurs not infrequently (prevalence (5%) among community-dwelling elderly, commonly (32%) in institutionalized elderly, and is associated with increased morbidity and mortality.

Etiologic Factors

Explanations for weight loss in the elderly have ranged from physiologic changes associated with aging to an increased prevalence of poverty, psychosocial problems, chronic disease, and medication use (Table 470.1 and Table 470.2). Although limited, current data provide some insight into the causes of involuntary weight loss in older adults (Table 470.3).

	Study (Study Size)				
	Martin et al. (N = 91)	Rabinovitz et al. (N = 154)	Wertz et al. (N = 50)	Thompson et al. (N = 42)	Levine (N = 102)

TABLE 470.3. DIAGNOSTIC SPECTRUM OF INVOLUNTARY WEIGHT LOSS

Pathogenesis

Anorexia with diminished caloric intake is often the pathway through which disease, dysfunction, and psychosocial problems lead to weight loss. Possible common underlying pathophysiologic mechanisms that might account for changes in intake and metabolism in the elderly include alterations in neurohumoral regulators of feeding drive and satiety (e.g., endogenous opioids and cholecystokinin); increases in cytokines [e.g., cachectin (tumor necrosis factor), interleukin-6 and other interleukins]; decreases in anabolic factors (e.g., growth hormone, androgens, and insulin-like growth factors); and diminished senses of taste and smell.

Diagnostic Evaluation of Weight Loss

Losses of 5% or more of body weight over 6 to 12 months should prompt clinical evaluation. Actual weight loss should be verified (e.g., medical record, observer corroboration) because in one study almost half of the patients claiming significant weight loss had stable weights, as recorded in their charts. Careful clinical evaluation, with special attention paid to factors listed in Table 470.1, reveals the cause in most cases. Whether the patient has adequate caloric intake may help focus the investigation further (Fig. 470.1). If the basic initial evaluation is unrevealing, it is probably best to enter a period of "watchful waiting" rather than continue extensive testing. If a serious physical disease is present, the diagnosis usually becomes evident within 6 months.

FIGURE 470.1. Weight loss algorithm.

Management and Prognosis

Treatment should be directed at the specific cause (albeit often complex or multifactorial) and hence may require multidisciplinary assessment and longitudinal case management (Fig. 470.1). The availability of adequate food supply, meal preparation, and appropriate assistance for dependent patients needs to be ensured. Depression and nonmalignant gastrointestinal disorders appear to be the most common, specific, remediable causes of weight loss.

Strategies to overcome anorexia and improve oral intake include assessing and meeting food preferences to the highest degree possible and providing frequent small meals and high-calorie snacks. Anecdotally, the use of favorite high-calorie foods (e.g., sweets) has proved useful in helping to overcome anorexia in some hospitalized patients, and a few controlled studies suggest that flavor enhancement of foods can improve food intake. Multivitamins and protein-calorie supplements are generally recommended to improve nutritional status, but there are no widely available diets to promote weight gain. When nutritional supplements are used, those with higher caloric density (1.5 to 2.0 kcal per milliliter) should be favored over standard (1 kcal per milliliter) formulas. Costs are only slightly higher, and as these supplements deliver higher caloric content per milliliter ingested, patients need not drink as much volume to improve caloric intake. Also, supplements should be provided between, rather than with, meals to minimize their potential for reducing usual mealtime intakes. Pharmacologic approaches to stimulate appetite may also be considered, but the few agents (megestrol acetate, dronabinol, cyproheptadine) that have been shown to improve intake in some patient populations (e.g., cancer, HIV, anorexia) have the potential to cause important side effects and are virtually unstudied in the elderly. Cyproheptadine, a serotonin antagonist, has anticholinergic and antihistaminic properties, and thus its use in the elderly may be problematic. Megestrol acetate can cause fluid retention, thromboembolic phenomena, and impotence, and dronabinol can cause confusion and hallucinations. Although a trial of an appetite stimulant might be considered in selected cases where other approaches have failed, in general their use should await clarification of safety and efficacy in studies of older adults. In patients unable to increase their oral intake despite attention to the preceding measures, tube feedings may be considered if deemed appropriate by the physician and patient. Long-term goals should be specified before tube feeding is begun, and periodic reassessment and reconsideration are essential.

OBESITY IN THE ELDERLY

There is no more hotly debated issue in all nutrition than the consequences of obesity in the elderly. There are two separate issues of disagreement: is obesity an independent risk factor for cardiovascular disease in the elderly, and is mild to moderate obesity in the elderly protective or a risk factor for overall mortality? The answers to these questions are of importance because, although the prevalence of obesity in our society peaks between 55 and 65 years of age, obesity rates are increasing in persons of all ages, with the most recent large national study (NHANES III) classifying 41% of men and women age 60 to 74 as overweight [body mass index (BMI) greater than 27.8 kg per square meter in men and greater than 27.3 kg per square meter in women].

Cardiovascular disease is significantly related to obesity when assessed by univariate analysis; however, the independence of this relationship is more ambiguous using multivariate analyses that factor out other known medical concomitants of obesity, such as non-insulin-dependent diabetes mellitus (NIDDM, also known as type 2 diabetes), hypertension, and dyslipidemia. The relation between obesity and overall mortality is even more controversial. Animal studies in several species demonstrate that leanness prolongs and obesity curtails life span. A review of several large epidemiologic studies in human beings, however, indicates that the relationship between obesity and mortality is not linear and that the weight range associated with the lowest mortality may increase with age. The suggestion that mild to moderate obesity in older adults might be associated with reduced mortality has provoked intense dissenting responses, stressing that the inverse relationship between body weight and smoking, not considered in many of the epidemiologic studies, accounts for the apparent increased mortality at lower weight ranges; low-weight nonsmokers as a group have a reduced mortality risk in all age groups from 30 to 62 years; the independent association between obesity and mortality occurs only after a latency period of up to 16 years and would be missed in short-term follow-up studies; and obesity is known to be correlated to several important morbid conditions in human beings (NIDDM, hypertension, dyslipidemia, and cancer), whereas few, if any, protective effects of obesity have been defined (osteoporosis being one notable exception). A recent national study of white nonsmokers found that thinness (BMI 19.0 to 21.9 kg per square meter) was associated with the lowest rates of cardiovascular and all-cause mortality up to age 75. However, the relationship between increasing BMI and increased mortality diminished with age, and after age 75 the BMI range associated with the lowest mortality risk was much higher at 27.0 to 28.9 kg per square meter. Thus, protective effects of mild to moderate obesity in the elderly are possible. For instance, the increases in both energy reserves and lean body mass associated with obesity might benefit the elderly during an acute illness. Increased body weight might also reduce osteoporosis and subsequent fractures, a condition associated with significant mortality (and morbidity) in the elderly. The role of adipose tissue in prevention of pressure sores seems clear. It is unclear, however, as to whether these or any other proposed benefits of obesity in the elderly could outweigh its well-known deleterious effects, perhaps most notably osteoarthritis and problems with mobility, and most experts agree that weight maintenance and avoidance of obesity are appropriate goals in adults of all ages.

CHAPTER 471: EXERCISE IN THE ELDERLY

ALICE S. RYAN AND ANDREW P. GOLDBERG

[Exercise Physiology/Body Composition and Aging](#)
[Exercise in the Prevention and Treatment of Disease](#)
[Exercise Rehabilitation in Chronic Disease](#)
[Exercise Guidelines for the Elderly](#)
[Summary](#)

A sedentary lifestyle results in numerous physiologic and functional declines with aging that increase the risk for disease. Obesity and the special propensity for weight gain in the abdominal region with aging in sedentary older people are strongly associated with the development of hypertension, dyslipidemia, and insulin resistance—all risk factors for cardiovascular disease (CVD). There is increasing evidence that exercise training benefits the health of older persons. The reduced risk for age-related CVD with regular physical activity suggests that people should sustain activity habits as they age. Evidence is emerging that, in addition to its preventive benefits, regular aerobic exercise effectively rehabilitates older people with chronic cardiovascular and musculoskeletal diseases. The focus of this chapter is to provide a clinical framework to guide the clinician in prescribing regular exercise to prevent and treat common diseases in the elderly, as well as to increase functional capacity and independence in older persons disabled by cardiovascular and musculoskeletal complications. Understanding the potential for physical activity to provide health benefits and functional gains not only can enhance the quality of life in older adults but also carries substantial impact for the health care system, considering the rapid growth in the elderly population projected over the next 20 years.

EXERCISE PHYSIOLOGY/BODY COMPOSITION AND AGING

EXERCISE AND THE CARDIOVASCULAR SYSTEM

Aging is associated with numerous changes in the cardiovascular system. As detailed by Lakatta (and reviewed in [Chapter 16](#)), these include a decrease in b-adrenergic stimulation of myocardial contractility, an increase in arterial stiffness and total peripheral vascular resistance, a rise in systolic blood pressure (BP), moderate hypertrophy of the left ventricle, and prolongation of myocardial contraction. These changes in cardiac function are accompanied by a decline in maximal oxygen uptake (VO_2max) and maximal heart rate with age in men and women. VO_2max , the highest rate of oxygen consumption attained during maximal exercise, is a function of maximal cardiac output and maximal tissue oxygen extraction, measured as the arteriovenous oxygen difference. In healthy people, VO_2max is generally believed to be not limited by pulmonary function, blood flow, or oxygen uptake by skeletal muscle. Although stroke volume during exercise does not decline with aging in healthy individuals, there is a smaller increase in left ventricular ejection fraction during exercise in older individuals. Changes in cardiac structure and vascular properties also contribute to the reduction in left ventricular reserve in the elderly.

Cross-sectional data suggest that in healthy subjects the decline in VO_2max is 8% per decade in men and 10% per decade in women. However, longitudinal studies performed in healthy sedentary individuals confirm that VO_2max declines with aging at a rate of 10% to 13% per decade in men and 7% to 11% per decade in women. In older athletes who maintain their physical activity levels and do not change their body composition, the decline is somewhat smaller (5% to 9%) per decade, suggesting that maintenance of exercise training programs attenuates the age-related decline in VO_2max . These older endurance-trained athletes have VO_2max values nearly twice those of sedentary age-matched peers, and similar to those of 30-year-old sedentary individuals. Endurance exercise training can increase VO_2max between 10% and 30% in older individuals, primarily due to an increase in the ability of skeletal muscle to extract oxygen and a rise in cardiac index and left ventricular ejection fraction measured at peak exercise. Older women do not appear to undergo an increase in central cardiac function similar to that of older men; this is possibly related to estrogen deficiency associated with the menopause.

EXERCISE AND BODY COMPOSITION

Body weight and the components of body composition are altered in the aging process ([Fig. 471.1](#)). Body weight is the combined weight of a variety of tissues; the largest component is body water, which composes approximately 60% of body weight. Body water can be further divided into intracellular (40%) and extracellular (20%) components. The remaining cellular components of the body are lipid, proteins, glycogen, and minerals. At the tissue level, these body components are adipose tissue, skeletal muscle, visceral organs, and bone. In healthy people, body weight and fat mass increase gradually from early adulthood until the fifth to sixth decade, after which weight tends to plateau even as fat mass continues to rise, at least until advanced old age. Aging is especially associated with body fat accumulation in the abdominal region, with increases in both subcutaneous and visceral fat. This change is somewhat greater in men than women. In contrast to the increase in fat mass during the aging process, skeletal muscle, body water, and bone mass decline. A number of studies have demonstrated an average loss of fat-free mass (FFM) of approximately 16% between the ages of 25 and 70 years peak. FFM in men is reached in the midthirties and then progressively declines. In females, FFM remains relatively stable until approximately age 50 years, at which point the decline in FFM occurs, but at a slower rate than in men. The muscle mass loss, muscle fiber loss, and decline in motor units with aging are referred to as sarcopenia. The loss of muscle mass is strongly associated with a loss of total body water, which begins to occur after age 70 in women and somewhat earlier in men, with a nadir in the eighth decade of life.

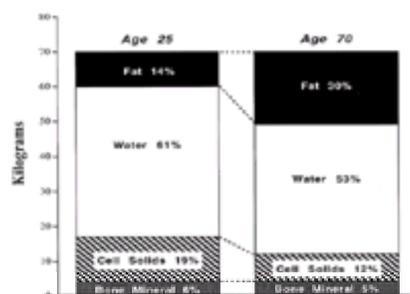

FIGURE 471.1. Age and body composition in adults.

In addition to the losses of FFM and total body water with age, a loss of bone mass is consistently documented. Peak bone mineral mass is reached at age 30 to 35 years in both sexes, followed by a progressive decline. Menopause is a period of more dramatic loss of bone mass in women. By age 70, spinal bone mineral density (BMD) is diminished by approximately 20% in women, slightly less than the 25% loss observed in the femoral neck. Men lose BMD at a rate two-thirds that of women in the spine and one-fourth in the femur, which may explain the reduced fracture risk and rate in males (see [Chapter 465](#)). The loss of muscle mass and muscular strength with age may influence both falls and disability in the elderly, and thus increase fracture risk, especially in women.

The significant changes in body weight and composition that occur during the aging process affect health and can increase the propensity for disease. Chronic morbidity is related to these changes, and accelerated weight loss in the elderly predicts death. The health implications of overweight and obesity generally support a higher relative risk with aging, at least until age 70. Specifically, the increase in obesity is associated with increased prevalence of CVD, dyslipidemia, hypertension, insulin resistance, and diabetes. Moreover, the loss of muscle mass with age results in reductions in muscular strength and aerobic fitness in older individuals. These age-associated declines in VO_2max , FFM, and leisure time physical activity, as well as age itself, contribute to the declines in both resting metabolic rate and energy expenditure seen with aging. Results of cross-sectional as well as longitudinal studies suggest that older subjects can modify their daily energy requirements by increasing physical activity habits to raise total daily energy expenditure. This would counter the age-related tendency for weight gain and obesity-associated cardiovascular risk by allowing older subjects to consume more calories while maintaining their weight. Thus, some of these changes in body composition with aging

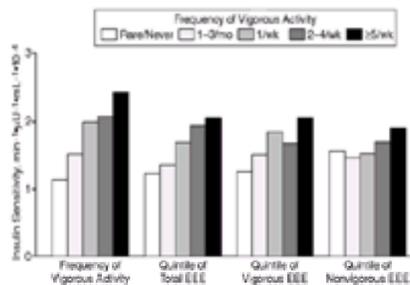

FIGURE 471.3. The Insulin Resistance Atherosclerosis Study. Average, unadjusted values of insulin sensitivity, according to reported participation in physical activity. EEE, estimated energy expenditure.

In longitudinal aerobic exercise training studies, glucose metabolism in healthy older individuals was shown to improve by approximately 20% (13% to 36%). Resistive training also increases glucose uptake and improves insulin action in healthy older men and women. Intensive aerobic exercise normalizes glucose and insulin levels in patients with IGT and mild type 2 diabetes, and increases insulin-mediated glucose disposal and glucose transporter (GLUT-4) levels in glucose-intolerant older men and women. The mechanisms for improvements in glucose metabolism after exercise training include (a) reductions in body fat; (b) increases in muscle mass, GLUT-4, and the enzymes responsible for the phosphorylation, storage, and oxidation of glucose; (c) changes in muscle morphology (increase in conversion of fast-twitch glycolytic IIb fibers to fast-twitch oxidative IIa fibers); (d) an increase in capillary density; and (e) an enhanced blood flow to muscles. Exercise training may also reduce hepatic glucose production, adipose tissue lipolysis and free fatty acid production. This suggests that regular exercise should be an integral part of an individual's lifestyle, as a deterioration in glucose tolerance is observed shortly after cessation of training in older as well as young athletes.

HYPERTENSION

Hypertension is particularly prevalent in the elderly and is present in over 50% of some subsets of older Americans. The risk of hypertension, defined as systolic BP greater than 160 mm Hg and diastolic BP greater than 95 mm Hg in adults aged 45 to 75 years, is twofold higher in overweight than non-overweight individuals. Nonpharmacologic measures, such as weight loss, sodium restriction, and regular physical activity, are beneficial in the treatment of mild essential hypertension in the elderly. Several studies have shown that athletes have lower BP levels than sedentary individuals. There is also a direct relationship between physical inactivity and BP, and the development of hypertension among Harvard male alumni was independently related to the lack of regular strenuous exercise. A regular aerobic endurance exercise training program is recommended for persons with hypertension and results in a decrease in systolic and diastolic BP of 5 to 10 mm Hg in hypertensive individuals. These improvements may be independent of weight loss, but the addition of weight loss to aerobic training further lowers BP in older men. In contrast, resistive training does not generally result in improvements in BP in normotensive individuals, though it can lower both systolic and diastolic BP in mildly hypertensive individuals. There are no studies of the effects of resistive training and weight loss, or on the combined effects of aerobic and resistive training, on BP in normal or hypertensive older subjects.

DYSLIPIDEMIA

The risk of CVD is higher in the elderly and even more so in the overweight and obese. Regional obesity with preferential deposition of body fat in the truncal region is independently associated with CVD and related mortality. Numerous studies have shown that increased body weight associated with aging, as well as the abdominal fat distribution, is associated with abnormal lipid concentrations, thus increasing the risk for CVD in the elderly. Total cholesterol, low-density lipoprotein cholesterol (LDL-C), and triglyceride (TG) levels all rise across the age span through middle age, while high-density lipoprotein cholesterol (HDL-C) remains stable. In addition to abdominal obesity, the sedentary habits and physical inactivity associated with aging, along with such age-associated common diseases as diabetes, hypothyroidism, renal failure, and medications often taken by older people (e.g., thiazide diuretics, b-blockers, corticosteroids), have a detrimental effect on lipid profiles. Thus, dyslipidemia is an important contributing factor to the development of atherosclerosis in the elderly.

Cross-sectional studies indicate that higher levels of physical activity and fitness in both men and women are associated with higher HDL-C and lower LDL-C and plasma TG levels. This less atherogenic lipoprotein profile may be partially due to the lower total and abdominal body fat observed in trained, as opposed to sedentary, individuals. Although acute aerobic exercise increases HDL-C in women, the effects of chronic aerobic exercise on lipoproteins is of greater clinical importance. Longitudinal training studies show that aerobic training raises HDL-C (specifically HDL-2 levels), apolipoprotein A-I levels, and reduces LDL-C and TG concentrations. However, the beneficial effects of exercise on HDL-C are more dramatic in leaner subjects, whereas a combination of exercise and weight loss is most effective in reducing LDL-C and raising HDL-C in obese subjects with hyperlipidemia. Thus, some of the beneficial effects of exercise on lipids are influenced by weight loss and the loss of total and abdominal body fat.

In young and middle-aged adults, resistive training without weight loss does not improve lipoprotein levels; however, there are no longitudinal studies in the elderly. Some studies show a gender difference in the effect of exercise training on HDL-C and LDL-C levels in the elderly. In one study, hormone replacement therapy accentuated the effects of aerobic exercise by raising HDL-C and lowering LDL-C and TG levels more than exercise or hormone replacement alone. Collectively, these findings indicate that exercise benefits lipoprotein lipids in the elderly. Special populations, such as obese subjects, diabetics, or patients on medications or those with chronic diseases, may require additional treatments to maximize these effects.

OSTEOPOROSIS

Osteoporosis (see [Chapter 465](#)) is one of the most prevalent chronic health conditions among the elderly. A reduction in physical activity that occurs in aging may also contribute to osteoporosis. The few longitudinal exercise studies in osteoporotic women that report increases in regional BMD suggest that weight-bearing exercise is not only a beneficial treatment for osteoporosis but also an effective preventive measure.

EXERCISE REHABILITATION IN CHRONIC DISEASE

OSTEOARTHRITIS

Osteoarthritis (OA) afflicts the elderly and is present in more than 60% of individuals 65 years and older. It is characterized by progressive loss of cartilage and bony overgrowth, joint distention, and stretching of periosteal nerve endings, all of which contribute to the pain, stiffness, and reduced range of motion observed in persons with OA. OA of the knee is linked to obesity and inactivity, which in turn are associated with CVD, type 2 diabetes, dyslipidemia, and stroke. As of yet, there is no cure for OA. However, pharmacologic strategies to alleviate pain and disability could improve the quality of life in individuals with this disease. Weight loss, as well as aerobic and resistive exercise, are recommended in the treatment of OA. Preliminary studies showed that both aerobic and resistive exercise reduce pain and disability in this population and also improve physical fitness and reduce depression. In the Fitness Arthritis and Seniors Trial (FAST) randomized control trial conducted by Ettinger's group, an 18-month regimen of either aerobic or resistance exercise training resulted in greater improvements in self-reported pain and disability, as well as physical performance (6-minute walk, stair climb, lift-and-carry task, peak $\dot{V}O_2$, and knee flexion strength), than health education in older men and women with knee osteoarthritis. Although there is some evidence to suggest that exercise may accelerate the progression of OA, the results of the FAST indicate that moderate exercise does not worsen the disease, as there was no change in the x-ray scores.

STROKE

Cerebrovascular accidents, or strokes, occur in more than 700,000 persons each year in the United States; the vast majority are reported in persons older than 55 years. A stroke leads to persistent neurologic deficits that impair functional ability, balance, and mobility, and promotes physical inactivity and, ultimately, disuse muscle atrophy. The increase in body fat and a loss of FFM that occurs in normal aging accelerates functional disability in stroke patients, where a sedentary habitus due to functional immobility compounds sarcopenia. The low endurance, muscular weakness, and impaired functional mobility in stroke patients are potentially modifiable with treadmill exercise training. Improvements in peak aerobic capacity, gait, strength, and functional mobility were seen in selected studies of hemiparetic

stroke patients following 6 months of this training. Cycle ergometry also increases $\dot{V}O_2\text{max}$, and in wheelchair-bound stroke patients, myocardial oxygen demand decreased and peak exercise left ventricular ejection fraction and fractional shortening improved after wheelchair ergometry training.

Treadmill exercise training reduced the energy expenditure and cardiovascular demands of walking and increased quadriceps strength in older (65 years and up) stroke patients in both the paretic and non-affected limb. In addition to the use of treadmill and cycle exercise training programs designed to promote functional improvements in stroke patients, other programs have used Proprioceptive Neuromuscular Facilitation Patterns (PNFs) and Therabands (elastic bands of varying elasticity that provide resistance) with success. Home-based exercise programs also improved lower extremity motor function and gait speed in individuals with stroke. None of these programs reported excessive injuries, morbidity, or patient intolerance to the exercise training. In general, patients were enthusiastic, and compliance rates were greater than 80% in most reports. Thus, aerobic exercise in the stroke patient not only reduces disability but may also reduce the risk of a second stroke and provide such psychological benefits as improving self-esteem and depression, and reducing caregiver burden.

CONGESTIVE HEART FAILURE

Congestive heart failure (CHF) secondary to reduced left ventricular systolic function is common in the elderly, and as such the most frequently assigned Medicare diagnosis-related group (DRG) in older beneficiaries. The prevalence of CHF increases nearly 50-fold from age 40 to age 65 due to the increasing prevalence of coronary artery disease and hypertension in older people. Furthermore, age- and disease-related declines in cardiovascular, renal, and musculoskeletal function make the elderly particularly susceptible to the functional declines associated with left ventricular dysfunction. Many physicians limit the physical activity of older patients with CHF out of concern for precipitating myocardial ischemia, worsening heart failure, or eliciting serious arrhythmias in these disabled, high-risk patients.

Recent studies, however, show that young and middle-aged New York Heart Association/American Heart Association class II and III heart failure patients derive substantial physiologic, functional, and lifestyle benefits from aerobic exercise training. Significant increases in systemic arteriovenous oxygen difference, peak exercise limb blood flow, neuroendocrine hormones, and muscle capillary density and oxidative capacity were associated with increased maximal treadmill exercise time and peak $\dot{V}O_2$. These functional changes translate into increased free-living activity, improved quality of life, reduced hospitalizations, and lower mortality in middle-aged patients. Few studies have examined these effects in older CHF patients, but some show significant improvements in 6-minute walk distance, submaximal treadmill exercise duration, and peak $\dot{V}O_2$. However, longitudinal follow-up of exercise training outcomes is not yet available in older heart failure patients.

PERIPHERAL ARTERIAL OCCLUSIVE DISEASE

Peripheral arterial occlusive disease (PAOD) is present in approximately 6% of persons older than 65 years. It is a major disabling medical problem because it frequently coexists with coronary and cerebrovascular disease in these patients and severely limits their functional mobility and independence. Patients with PAOD often experience intermittent claudication that impairs their walking ability and curtails physical activities. These patients have an approximately 60% lower functional capacity, measured as maximal attainable oxygen consumption, than age-matched individuals without the disease. This reduced aerobic capacity may be a function of disease severity, sarcopenia, smoking status, general health, and other comorbidities. Thus, exercise rehabilitation is recommended for patients in Fontaine stage II with intermittent claudication, or even those with less severe PAOD.

Aerobic exercise training increases physical fitness, increases the time and distance to onset and maximal claudication pain, and improves exercise economy in PAOD patients. Resistance training increased muscular strength but did not change onset of claudication pain, peak walking time, or peak $\dot{V}O_2$ in these patients. The mechanisms for the improvement in physical conditioning after aerobic exercise training are both hemodynamic and peripheral adaptations. Some studies report that exercise rehabilitation increases calf blood flow, reduces blood viscosity, red cell aggregation, and fibrinogen levels in PAOD patients. More research is needed to elucidate the structural and enzymatic adaptations in muscle and the vascular changes associated with exercise training in this population. At the present time, exercise seems to be the most cost-effective, efficacious treatment for reduction of the progressive disability associated with this disease in the elderly.

EXERCISE GUIDELINES FOR THE ELDERLY

EXERCISE PRESCRIPTION

An exercise test with BP and heart rate monitoring is recommended for men over age 40 and women over age 50, as well as for older patients with and without CVD, prior to commencement of an exercise program. Whether a maximal, submaximal, intermittent, or continuous exercise test is used, the mode of testing (treadmill, cycle, step test, field test) employed depends on the purpose of the test. The test could be performed for the development of an exercise prescription, an evaluation of baseline cardiovascular data and progress of an exercise participant, motivation purposes, education regarding the individual's fitness status, risk stratification, and for clinical applications (e.g., pre-discharge exercise testing after myocardial infarction, or post-discharge testing after myocardial infarction, coronary artery bypass grafting, and percutaneous transluminal coronary angioplasty, for diagnostic testing, functional testing, and testing for disease severity and prognosis). In addition, depending on the medical history of the individual being tested, a medical evaluation carried out prior to the fitness test could include a physical examination as well as measurement of BP, serum cholesterol and lipoproteins, blood chemistry profiles, and pulmonary function. There are numerous contraindications to exercise testing (Table 471.1). Patients with absolute contraindications should not undergo an exercise test until those conditions have been stabilized, whereas patients with relative contraindications may be tested after careful assessment of the risk/benefit ratio of exercise training.

Absolute Contraindications	
1.	A recent significant change in the resting ECG suggesting infarction or other acute cardiac event
2.	Recent completed myocardial infarction (unless patient is stable and pain-free)
3.	Unstable angina
4.	Uncontrolled ventricular arrhythmias
5.	Uncontrolled aortic aneurysms that compromise cardiac function
6.	Third degree atrioventricular heart block without pacemaker
7.	Acute congestive heart failure
8.	Recent aortic dissection
9.	Unstable or known dissecting aneurysm
10.	Recent or suspected myocarditis or pericarditis
11.	Dissecting aortic or intracranial aneurysm
12.	Recent splenic or splenohepatic embolism
13.	Recent thrombotic disease (stroke)
14.	Significant arrhythmias (syncope)
Relative Contraindications	
1.	Resting diastolic blood pressure ≥ 115 mm Hg or resting systolic blood pressure ≥ 200 mm Hg
2.	Advanced valvular heart disease
3.	Recent electrolyte abnormalities (hypokalemia, hypomagnesemia)
4.	Recent or suspected coronary artery disease
5.	Frequent or complex ventricular ectopy
6.	Myocardial infarction
7.	Uncontrolled metabolic disease (e.g., diabetes, thyrotoxicosis, or hyperparathyroidism)
8.	Chronic obstructive disease (e.g., emphysema, bronchitis, asthma)
9.	Hemorrhagic, thrombotic, or rheumatoid disorders that are exacerbated by exercise
10.	Advanced or complicated pregnancy

TABLE 471.1. CONTRAINDICATIONS TO EXERCISE TESTING

The exercise prescription is composed of the intensity, duration, frequency, mode of exercise, and progression of physical activity. Both an appropriate warm-up to stretch the muscles and tendons and a cool-down to return the body to its resting level are necessary precautions to avoid injury and muscle soreness and are integral to every exercise session. The exercise prescription should be individualized to meet personal goals and integrated into each individual's lifestyle to enhance and maintain compliance. Maximal oxygen uptake or $\dot{V}O_2\text{max}$ improves with aerobic exercise that involves large muscle groups and is continuous and rhythmic in nature (e.g., running, walking, swimming, bicycling, rowing, cross-country skiing). To improve cardiorespiratory fitness, the heart rate during exercise should be raised by 60% of the heart rate reserve (HRR), or the difference between the maximal and resting heart rate ($HR_{\text{max}} - HR_{\text{rest}}$). The training or target rate is calculated by multiplying the difference between the maximal and resting rates by 0.60 and adding the result to the resting heart rate. An exercise intensity between 50% and 70% of HRR is safe and effective for developing cardiorespiratory fitness in older adults. Recently, it was shown that the HRR method is not recommended in older women because it results in an inappropriately high exercise intensity (higher % $\dot{V}O_2\text{max}$ than expected). Rather, the exercise intensity prescription, which includes heart rate expressed as a percentage of maximal heart rate, was more appropriate for older women. Several studies show that high-intensity training for more than 6 months at a frequency of three times a week is necessary to increase $\dot{V}O_2\text{max}$ by more than 15% in older individuals. It should be emphasized that moderate levels of physical activity can be used to attain cardiorespiratory fitness and high-intensity exercise is not necessarily appropriate for all individuals. Exercise prescriptions may need to be modified for patients on medications that could affect heart rate (e.g., β -blockers) or BP responses to exercise. If persons are on medications that contribute to postural hypotension, they need to be advised to be well hydrated and learn to return gradually to the upright position from supine posture to avoid an episode of postural hypotension. The final components of the exercise prescription are the duration and frequency of exercise. The sedentary beginner should initially start a gradual program of 5- to 10-minute exercise bouts interspersed with 3- to 5-minute rest periods for 2 weeks. Every 2 weeks thereafter, an additional 5 minutes of

exercise could be added to reach the final goal. The American College of Sports Medicine (ACSM) and the U.S. Centers for Disease Control recent recommendation published suggested that persons engage in moderate physical activity for 30 minutes or more most, if not all, days of the week to gain important health benefits.

In contrast to aerobic exercise, resistive training does not typically improve $\dot{V}O_2\text{max}$, but it enhances muscular strength and muscular endurance. A resistive training program for the elderly should begin with minimal resistance and with proper supervision. The first two or three training sessions should be performed without any weight or load to ensure proper lifting technique and avoidance of breath holding during lifting. An individual can begin with one set of eight to ten exercises that train all the major muscle groups, including quadriceps, gluteals, hamstrings, latissimus dorsi, pectorals, deltoids, biceps, triceps, and abdominals, and then progress to two sets of exercises. Use of alternating arm and leg exercises is advantageous for older individuals beginning resistance training programs because this allows for some recovery of the muscles between exercises. As an individual progresses, the number of repetitions should first be increased, followed by an increase in the resistance. Each set should involve 8 to 15 repetitions, with the entire training session completed within 30 minutes. Lastly, resistance training should be conducted at least twice a week, with at least 48 hours of rest between exercise sessions.

Increasing flexibility is another important goal of an exercise program although it is often overlooked. Ten to twenty minutes of stretching before or after aerobic or resistive exercise increases range of motion and flexibility. Furthermore, abdominal exercises are important to include in any exercise program because weak abdominal muscles can contribute to poor posture and lower back pain. Chair stands are recommended to build coordination, strength, balance, and trunk stability. For these exercises, individuals can progress from supporting their body weight with their hands to crossing their arms to stand and eventually holding their hands out in front as they stand from the chair. Ankle strength and flexibility are also important for reducing fall risk.

DISEASE-SPECIFIC RECOMMENDATIONS

Diabetes

Specific guidelines exist for the evaluation of a diabetic patient before enrollment in an exercise program, with special considerations for symptoms of the disease and other comorbidities. We recommend exercise testing with cardiac monitoring prior to training due to the greater risk for arrhythmias and silent ischemia in this patient population. Some types of exercise are not recommended for diabetic patients with moderate or severe retinopathy, including high-impact running and aerobics, racquet sports, boxing, and resistive training. Non-weight-bearing exercise (e.g., swimming, cycling, arm ergometry) is advocated for patients with loss of protective sensation. Patients with proliferative retinopathy are at risk for hemorrhage and retinal detachment during isometric exercise. Older diabetic individuals or those with a long history of the disease should avoid high-intensity resistive training, although light-weight lifting with high repetitions may be performed in most patients with diabetes. Hydration status must be carefully monitored to avoid dehydration, which affects blood glucose and BP levels. Diabetics should drink isotonic or hypotonic fluids (preferably water) prior to exercise and take precautions when exercising in very hot or very cold temperatures. To avoid a hypoglycemic reaction during exercise in patients treated by insulin, such individuals should eat a meal containing complex carbohydrate 1 to 3 hours before exercise, consider a complex carbohydrate snack at least every 30 minutes during exercise of long duration, carry a source of monosaccharide during exercise, and increase food intake during the 4 to 6 hours following exercise. Special care and attention to the feet is especially important to prevent blisters and other foot injury in diabetic individuals. Recommendations include the use of silica gel or air midsoles and polyester or cotton-polyester socks. Feet should be dried carefully and moisturizer used as needed to maintain skin turgor.

Stroke

Exercise programs should be individualized. They should begin slowly and gradually increase in intensity and duration for patients disabled by stroke. Stretching, range-of-motion exercises, and muscle-strengthening exercises should also be incorporated into the stroke patient's exercise prescription. Depending on the severity of each individual's stroke and the use of assisted devices, swimming, aqua-aerobics, and cross-country skiing may be other aerobic options. Resistance training is currently not recommended for stroke patients without medical supervision and guidance. Additional information as to how to start an exercise program and how to safely exercise for stroke survivors is available in *Stroke: Your Complete Exercise Guide* as part of the Cooper Clinic and Research Institute Fitness Series. Treadmill aerobic exercise is effective in improving ambulatory function, but careful screening is necessary before the appropriate prescription can be designed.

Cardiovascular Disease

Cardiac rehabilitation is important for the patient who has suffered a myocardial infarction or undergone coronary artery bypass graft surgery to decrease overall and cardiovascular mortality. In addition to the peripheral and cardiac adaptations that occur after exercise training, maximal work capacity increases and the intensity of work increases at the ischemic threshold for those who achieve a higher workload or $\dot{V}O_2\text{max}$ after training. Preexisting cardiac conditions must be considered before patients embark on an exercise regimen. Guidelines for both inpatient and outpatient programs for cardiac patients is available in the ACSM's *Handbook for Exercise Testing and Prescription*. For patients with hypertension, BP should be monitored before, during, and after the exercise session. As there are no longitudinal studies in moderate/severe hypertension, exercise should be low intensity, with regular BP monitoring as the intensity and duration of exercise are increased.

Peripheral Arterial Occlusive Disease

Exercise programs developed for the patient with intermittent claudication and PAOD have relatively specific guidelines. Patients should walk on a level surface or hill, or use a treadmill to walk intermittently beyond the onset of claudication as long as they can safely tolerate near-maximal claudication pain for an initial duration of 15 minutes, and progress to 40 to 50 minutes at least three times per week. The walking should be intermittent to a claudication pain score of 3 using a 4-point pain scale at an initial intensity of 50% of peak exercise capacity and progressing to 80% by the end of 6 months, as suggested by Gardner. Stair climbing could also be used as the main mode of exercise training, whereas cycling could be used for the warm-up and cool-down periods. There are no specific exercise guidelines for resistance training in this population because aerobic training may be the best option for conferring improvements in daily activities with little or no claudication pain.

Osteoporosis

Exercise programs designed to enhance BMD should involve weight bearing and be of moderately high intensity since the loading forces are a considerable component of the osteogenic response. Animal studies suggest that loading should be high with minimal repetitions. There is some evidence that the effects of exercise may be site-specific such that particular exercises designed to load a specific skeletal site result in improvements in BMD at that site. In general, the aerobic or resistive exercise prescriptions in the prevention or treatment of osteoporosis are similar to that prescribed to improve cardiovascular function and/or to improve muscular strength in the elderly. For older women, hormone replacement therapy when combined with weight-bearing exercise could have additive and independent effects on BMD. The benefits of exercise, such as increased physical fitness, strength, and muscle mass, as well as improvements in balance and coordination, may be just as important as increases in BMD in the prevention of fracture.

Osteoarthritis

The goal of an exercise program for persons with OA is to reduce pain and improve the quality of life. Therefore, it should be enjoyable and as such incorporated into the individual's lifestyle so as to be maintained. As always, appropriate warm-up and cool-down are necessary with range-of-motion and flexibility exercises. However, no specific modifications to an exercise prescription of moderate intensity aerobic or resistive training programs appear to be necessary for individuals with OA. In addition to cycling and walking, swimming is another excellent aerobic exercise that persons with OA can enjoy. Lastly, application of ice after exercise is recommended to control postexercise inflammation. Individuals who have OA and are overweight or obese should be strongly encouraged to lose weight to enhance their health.

SUMMARY

We recommend the large-scale implementation of combined aerobic and resistive exercise programs with flexibility training for the elderly. Although there are some contraindications to exercise that should be addressed in a thorough medical evaluation and exercise test in older patients, as well as possible complications during exercise training, such as tendonitis, falls, sprained joints, broken bones, muscle soreness, and even sudden death, we strongly advocate exercise as being of vital importance to the well-being and health of the elderly. The elderly should be encouraged to exercise, and practitioners should advise their patients of the benefits of exercise. The public should be made aware of the positive health benefits of regular exercise programs for the elderly and be urged to develop pleasant, easily accessible, comfortable environments in which older adults can exercise. The elderly should be given every opportunity to incorporate both aerobic and resistive exercise into their lives, and the maintenance of regular activity should be a priority for our society. It is likely that regular exercise training can improve the quality of

life in older persons, and that preventive and rehabilitative exercise training programs could reduce health care expenditures and chronic morbidity and mortality in high-risk as well as disabled older patients.

CHAPTER 472: GERIATRIC REHABILITATION

KENNETH BRUMMEL-SMITH

[Evaluation of Rehabilitation Potential](#)
[Sites for Rehabilitation](#)
[Rehabilitation of Patients with Common Geriatric Conditions](#)

Rehabilitation is a basic component of geriatric care. While there may be few diseases that can be cured in geriatrics, there is almost always something that can be done to enhance an older person's ability to function more safely and live more independently. Functional assessment and rehabilitation are inextricably linked. Through functional assessment we determine what sort of rehabilitation the patient needs. All primary physicians should have an understanding of the role of rehabilitation interventions when dealing with older persons.

Rehabilitation links the traditional biomedical model of disease to the functional orientation used in geriatrics. That link is illustrated in the definitions promoted by the World Health Organization ([Table 472.1](#)). Disability is very common in the older age group. Approximately 40% of all disabled persons are over age 65 years. The rate of disability increases markedly with age. While 14% of all ages are disabled, the prevalence increases to 47% for those over 65 and 53% for those over 75. Twenty-two percent of those over 75 years of age cannot carry out at least one basic activity of daily living, such as dressing, feeding, or toileting.

Disease: An intrinsic pathology or disorder.

Impairment: Loss or abnormality of structure or function at the organ system level. At this stage the person becomes aware that she or he is unhealthy.

Disability: A restriction or lack of ability to perform an activity in a normal manner; a disturbance in the performance of daily tasks.

Handicap: A disadvantage resulting from impairment or disability that limits or prevents fulfillment of a role that is normal.

TABLE 472.1. WORLD HEALTH ORGANIZATION CLASSIFICATIONS

EVALUATION OF REHABILITATION POTENTIAL

Though the basic principles of rehabilitation are the same regardless of age, the application of those principles may change when one is dealing with an older person ([Table 472.2](#)). The first step in providing rehabilitation is recognizing who needs it. There have been no randomized trials to establish the best method for assessing rehabilitation potential, regardless of the cause of disability. The proper clinical approach is to consider rehabilitation in *any* patient who has had a recent significant loss of functional abilities, who has enough cognitive capacity to follow two-step commands, and who can retain information from day to day. A strong social support system is perhaps the most important factor determining good outcome. Those with better functioning prior to development of the disabling condition also do best in rehabilitation. A comprehensive geriatric assessment clarifies underlying medical, psychological, and socioeconomic conditions that may affect the course of rehabilitation.

1. Stabilize the primary disorder.
2. Prevent secondary disabilities (e.g., pressure sores, contractures, shoulder subluxation, or depression).
3. Restore lost functional capabilities.
4. Promote adaptation—the patient to his or her disability, the family to the patient, and the environment to the patient's needs.

TABLE 472.2. PRINCIPLES OF REHABILITATION

Often it is necessary to provide a trial of rehabilitation to determine whether the patient will benefit. If the primary care provider is asked to approve rehabilitation therapies, he or she should expect the therapist to provide very specific goals and outcomes that will be measured and reported. The proper duration of a trial is dependent on the condition being treated and the outcome expected, and so it must be individualized. The provider should carefully review the progress of the patient, and if none is seen, the cost-effective and ethical approach would be to discontinue the intervention.

SITES FOR REHABILITATION

Rehabilitation can be provided in the hospital, home, skilled nursing facility, or outpatient center. Inpatient rehabilitation is usually reserved for those who can tolerate 3 hours of therapy per day and requires close physician supervision. The use of this modality has declined with the advent of managed care. Recent studies of rehabilitation in skilled nursing facilities have shown excellent outcomes in stroke and hip fracture rehabilitation. There it can be provided 5 to 7 days per week and can be less intense than that provided in hospital settings. Some managed care programs have promoted the use of short-stay, subacute units in the hospital for rehabilitation. Outpatient rehabilitation is helpful for those with good cognition and available transportation. Home rehabilitation is especially useful with frail patients, but such patients must have a good support system to assist with his or her practice of newly learned activities.

REHABILITATION OF PATIENTS WITH COMMON GERIATRIC CONDITIONS

STROKE

Stroke is the most common diagnosis for which older persons receive rehabilitation. Early rehabilitation interventions are important in the acute care setting as they can prevent secondary disabilities and set the stage for functional recovery. Proper bed positioning, turning, range-of-motion exercises, and attentiveness to hydration, nutrition, and maintenance of an appropriate blood pressure (higher than 135/85) is emphasized in the acute hospital.

The patient and family need information about outcomes and plans ([Table 472.3](#)). Overall, about 85% of persons survive (90% with the more common infarction and 50% with hemorrhage). Certain features allow further prognostication. Those with less severe paralysis, less perceptual neglect, no (or only receptive) aphasia, less sensory loss, no pseudobulbar palsy, and good cognition usually have better outcomes and can often return home. Most gains in motor function are seen in the first month. Virtually all motor recovery is completed by 6 months. Speech, swallowing, and sensory return may be seen up to 2 years after the stroke. Guidelines have

been developed for selecting the appropriate site of care ([Fig. 472.1](#)).

Outcome	Incidence (%)
Complete recovery	10
Minor disability	40
Major disability	40
Total dependency	10

TABLE 472.3. FUNCTIONAL OUTCOMES OF STROKE

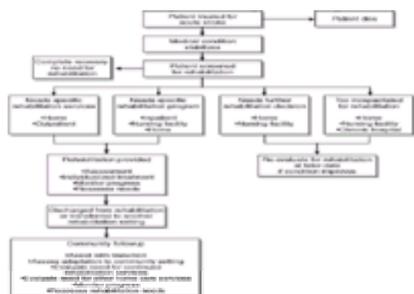

FIGURE 472.1. Choosing a site to provide rehabilitation. (See Gresham GE, Duncan PW, Stason WB, et al. *Post-stroke rehabilitation: assessment, referral, and patient management*. Clinical Practice Guideline No. 16: Quick Reference Guide for Clinicians. Rockville, MD: US Department of Health and Human Services, Public Health Service, Agency for Health Care and Policy Research. AHCPR Publication No. 95-0663, May 1995.

The Interdisciplinary Team

The appropriate approach to rehabilitation of the geriatric patient is inherently interdisciplinary. Each member of the team must not only understand and appreciate the roles and contributions of every other member but must also collaborate and communicate effectively to promote an optimal outcome.

Physical therapy (PT) is devoted to promoting both static and dynamic balance, first while the patient is sitting on the bed, then during transfers, and finally during ambulation. In bed mobility, transfers from bed to wheelchair and from chair to toilet are taught. Gait training can begin when the person can maintain standing balance, support his or her weight on the unaffected side, and advance the affected limb somewhat. Depending on the person's strength and balance, some sort of walking aid is usually provided.

Straight canes are rarely used because they are not stable. A hemiwalker is used when more assistance of the upper extremities is needed. A four-pronged cane is used when less support is required. Regular walkers may be very difficult to use because the arm is often weak. Any assistive device is often resigned to the closet once the patient goes home if training has been inadequate or the emotional response to these devices has not been addressed. Wheelchairs are often provided for negotiating longer distances even to those who can walk. A wheelchair, when provided, should be fitted by a physical therapist, who can ensure that it is the right height and width. Steering the chair with the unaffected leg allows propulsion with one arm. Braces are commonly used and the PT is helpful in choosing appropriate types. Two main types are used. A metal ankle-foot orthosis (AFO) is heavy, unattractive, and difficult to don, but it is the brace of choice for those with muscle spasticity or ankle instability. The plastic posterior AFO is often more acceptable to older persons. It supports those with muscle weakness but has limited use in the presence of spastic muscles.

The occupational therapist provides training in the activities of daily living. New methods of dressing, feeding, and grooming are addressed early. Attention is given to the improvement of sensory, perceptual, and cognitive deficits. A wide variety of adaptive equipment may be offered, such as rocker knives for one-handed cutting, dressing sticks, or buttonhooks ([Table 472.4](#)). Grooming adaptations include the use of special bathroom equipment, such as bath benches, shower hoses, and raised toilet seats.

- Feeding—rocker knives, cutting boards, plate retainers
- Dressing—button hooks, Velcro closures, tilted mirrors, reachers
- Toileting—grab bars, arm frames, raised seats
- Bathing—tub bench, shower hose, grab bars, long-handled brush
- Grooming—tilt mirror, built-up handles
- Safety—"Lifeline" service, remote control lights, telephone dialers, stair rails, removal of throw rugs

TABLE 472.4. AIDS FOR ACTIVITIES OF DAILY LIVING

Speech and language pathologists provide much more than retraining in communication. Cognitive reorganization, training in the use of alternative communication techniques (such as picture boards), and evaluation and retraining for swallowing problems are all pursued. With a recreational therapist the patient may experience skill advancement during play that could not have occurred in the more task-oriented gym setting. The rehabilitation nurse is the coordinator of care. Besides regular nursing duties, she or he provides reinforcement of techniques learned in therapy, teaches families caregiving skills, and observes for signs of complications or problems. In skilled nursing facilities and home settings, the nurse plays a crucial role in providing most of the care.

The role of the primary physician varies with the site of care. In the inpatient setting he or she usually works with a physiatrist and is responsible for medical management and patient advocacy. All drugs that may cause confusion or depression must be removed or reduced. Depression must be recognized early to provide optimum results. Malnutrition due to swallowing dysfunction may require temporary tube placement, though it must be remembered that neither nasogastric tubes nor gastrostomy tubes significantly reduce the risk of aspiration over oral feeding. Anticoagulation for deep venous thrombosis is controversial. Many authorities recommend it for those with infarctions during the immobile period of recovery. Once the patient is ambulatory it can be discontinued. All patients with atrial fibrillation should be anticoagulated after an infarction unless a specific contraindication is present.

AMPUTATION

Amputations occur primarily in older patients. Almost 75% of all amputees are older than 65 years. Peripheral vascular disease is the most common cause, and that presents special problems. First, there is a high incidence of contralateral amputations later in the patient's life. Second, the patient is likely to have underlying cardiac disease as well. This is important because ambulating with a below-the-knee (BK) amputation and a prosthesis requires approximately 10% to 40% more energy than bipedal ambulation. Nevertheless, more than 75% of geriatric amputees eventually achieve independent ambulation after a BK procedure. However, the energy cost of walking with an above-the-knee amputation is so great (approximately 65% to 100% above normal) that few such older patients ever walk again. Therefore, when an amputation is being considered, the physician should advocate for BK procedure (or less) whenever technically feasible.

After the operation, the patient's bed must not be raised higher than a few degrees and pillows must not be placed under the knees, in order to prevent hip or knee flexion contractures. A patient who needs to be upright should sit in a chair, not in the bed. Exercises can begin on the second postoperative day. Single-limb standing and transfers must be learned. Once the stump has healed the patient must be trained in stump care. Massage, wrapping, and inspection for signs of skin breakdown or irritation are needed on a daily basis.

In order to allow the stump to shrink completely, a permanent prosthesis is usually fitted about 6 to 8 weeks after the surgery. Most older patients will use a solid-ankle, cushioned heel (SACH). In addition to a fitted socket, a waist belt is also used for attachment. Proper fitting is important because prostheses can cost more than \$2,500. Wheelchair training is also important. Most older patients also make use of a wheelchair for long distances. The patient for whom a functioning prosthesis is inappropriate (e.g., moderate cognitive deficits, severe contralateral vascular disease or weakness, or joint disease) may nevertheless desire a cosmetic prosthesis.

Although phantom limb sensation occurs frequently, pain is uncommon. Such pain is best treated with a combination of analgesic drugs, massage, and, sometimes, local anesthetic injections. Skin breakdown is usually attributable to poor stump care and an improperly fitting prosthesis.

HIP FRACTURES

All patients should be medically stabilized before surgery. The uninvolved limb can be exercised while the patient awaits surgery. On the day after surgery, the patient can sit up and begin quadriceps exercises. With a total hip arthroplasty the joint should not be flexed more than 90 degrees or excessively adducted. Good pain management is required.

Geriatric patients benefit from rehabilitation after a hip fracture. Recent studies have demonstrated improved outcomes in those receiving PT. Patients with special need for rehabilitation include those with underlying arthritis or cardiopulmonary disease, or those for whom unsupervised exercise may be contraindicated. Severe cognitive deficits may preclude rehabilitation, but patients with mild deficits should be offered a trial.

Generally, the earlier the patient can begin ambulation, the better the long-term prognosis. Some surgical procedures, such as percutaneous pinning, require the patient to only use "partial weight bearing" for up to 8 weeks postoperatively. Most older people have difficulty with partial weight bearing and choose not to walk at all unless strongly encouraged to do so. Many therapists feel that even after hip pinning a patient should be allowed to weight-bear to tolerance. With a compression screw or a prosthetic replacement the patient can begin ambulation after 2 or 3 days.

The patient can commence supervised ambulation by using a walker or cane to "unweight" the affected leg. The walker should be fitted in such a way that the patient's arms are bent 20 to 30 degrees when at his or her side, resting on the grips. The patient should advance the walker 20 to 30 cm, then move the weak leg forward first. No more than 20% to 25% of the patient's weight should be placed on the walker or a fall is likely. Moreover, the energy costs are extreme. Special walkers are needed to go up stairs. The patient should go up first with the good leg, then come down first with the affected leg ("up with the good, down with the bad"). A basket or bag on the walker allows the patient to transport objects. Older patients have been shown to have a more functional gait and more consistently utilize walkers if they are provided the newer, four-wheeled, rolling type of walker.

CHAPTER 473: PHILOSOPHICAL AND ETHICAL ISSUES IN GERIATRICS

CHRISTINE K. CASSEL

[Justice and the Allocation of Resources](#)
[Clinical Decisions to Limit Therapy](#)
[Patient Choice](#)
[Futility](#)
[How Death Occurs](#)
[Conclusion](#)

The special ethical issues facing physicians as they care for aged patients and the moral challenges for health policy in our aging society stem from the increase in life expectancy in this century, which is unprecedented in human history. It presents dramatic challenges to existing models of social structure, expectations of life events and family relationships, and the fundamental meaning of the life cycle.

Before the middle of the twentieth century and throughout the previous existence of the human race, only a small, biologically and socially privileged group of people could expect to survive into old age. However, currently close to 80% of persons born in the United States can expect to live past their sixty-fifth birthday, and a large fraction of those can expect to live into their ninth and tenth decades. This shift, which is largely attributable to decreased mortality in childhood and adulthood before old age, has coincided with advances in medical science that make it possible to treat diseases that are common in old age, some of which are intrinsically linked with the degenerative senescent processes. For example, atherosclerotic heart disease is the number one cause of death in the United States, yet death from heart disease for most people has been postponed by decades. In the first part of this century, death by cardiac disease was unusual in older people, who died primarily from pneumonia, other infectious diseases, and renal failure. The rise in cancer deaths, which is the second leading cause of death, is also linked to increased life expectancy. As one escapes premature death from infectious disease and other causes, the likelihood of the occurrence of cancer increases—particularly breast cancer, prostate cancer, and colon cancer, all of which are linked to aging. As deaths cluster at later and later ages, how are “premature” and “natural” deaths to be distinguished?

Because older persons are susceptible to many more illnesses, it is not surprising that the costs of medical care are much higher for this group (approximately three times greater per year, on average, for those older than 65 years than those younger than 65 years). This high use has led to ethical questions at the societal level and at the individual clinical level. At the societal level, we wonder if it is right to be spending so much money on health care for one sector of the population. At the individual level, should we continue to delay and prevent death in people of advanced age, and how will we know when to stop?

JUSTICE AND THE ALLOCATION OF RESOURCES

Ethicists have long been examining questions pertaining to the values that underlie the allocation of health care resources in society because there have always been inequities in this allocation. The ethical principle of justice is the major one under consideration when we examine the allocation of resources. In the past, some have argued that physicians should not be involved in rationing decisions at the bedside or in their dealings with individual patients, but rather that society should make these decisions and physicians should operate within social guidelines. However, in a diverse and politically complex society such as our own, with a market-driven health system, this fairly straightforward approach has not succeeded. For that reason, physicians have an increasingly important voice in the decision-making process in terms of allocation of resources. Some would argue that it is better to have physicians who understand clinical efficacy involved in allocation decisions, whereas others are concerned that to be so involved conflicts with the physician's Hippocratic responsibility to do everything that is possible for individual patients. Because both perspectives are valid, a balance must be sought.

As many health care systems in the United States are transformed into variations of managed care structures, physicians become critical decision makers about the rationing of care. Indeed, in full-risk capitation systems they are the ones who must decide which clinical expenditures are warranted and which are not. This situation creates important new and challenging ethical problems for physicians and demands more explicit moral guidelines if they are to avoid frank financial conflict of interest. It must be remembered that fee-for-service models also have inherent financial conflicts, often in the direction of overtreatment rather than undertreatment. Both require that serious attention be paid to ethics and professionalism.

Health care has become the subject of much scrutiny as a result of the cost-containment efforts of government, insurance companies, and businesses during the last 20 to 30 years, as health care costs have outstripped inflation for more than three decades. There are three underlying reasons for this dramatic increase in costs: one is advances in medical technology, which are continuing to explode as modern biologic science progresses with exciting new approaches to illnesses that previously were thought untreatable; the second is the patterns of payment of health professionals and prices charged by hospitals and medical technology providers for their services under cost-based, fee-for-service structures common since the beginning of Medicare; the third is the aging of the population. This third reality, which we should acknowledge as a success story, is also of major concern because there are more and more older people who can benefit from the expanding medical armamentarium; in addition, the elderly are the only sector of society enjoying universal publicly funded health insurance, however incomplete the coverage.

When Medicare was established in 1965 as a public system to create health care insurance for older people, it was originally designed as a “safety net,” a catastrophic insurance system that would cover only the very high costs, such as hospitalization, that older individuals and their families could not afford. As health care became more and more complex, as well as less and less affordable, Medicare continually expanded to cover physician payments, outpatient care, and, to some extent, home care. Thus, the combination of increasing numbers of older people and the preexisting societal commitment to insure them through a public system increased the proportion of health care costs paid through general taxation.

This reality has led to concern among some that we are spending too much of the resources of society and of families on the elderly at the cost of other social goods and, in particular, undermining the well-being of the younger generation. This tension has been framed by policymakers and philosophers as the intergenerational equity debate. Demographers in the 1980s noted that at the time Medicare was instituted there were more impoverished elderly people than impoverished children, whereas at the present time, the numbers of impoverished elderly have declined and the numbers of children living in poverty have increased dramatically. In addition, children are dramatically overrepresented among the uninsured and those covered by inadequate public insurance, such as Medicaid. This observation has led to an obvious debate about justice, framed as follows: “Is it fair that society expends so much of its resources on the older generation and is unable, therefore, to support children?” Indeed, at its most stark, this reality has been described as the “wealthy elderly stealing from needy children.”

To evaluate this argument adequately, the following observations must be made:

First, would cutting the funding for Medicare and social security improve the situation of poor children? To fulfill the moral intent of such an exchange, one would have to be confident that the political process will put money into the support of children in poverty—a social commitment that has not been clearly articulated over the decades in which those inequities developed.

Second, the well-being of children is in many ways linked to the well-being of elderly people. It is rarely the case that generations exist in isolation from one another. Indeed, transfer of financial assets is predominantly from the older generation to the younger generation until well into very advanced old age. Thus, it is often the case in multigenerational families that financial support from grandparents helps a young couple to finance their first home or a grandchild to attend college. Even in families that do not have substantial financial resources, it is often the older generation who help with child care and who make possible multigenerational families supporting children of single parents so that the parents can work.

Looking at Medicare specifically as a target for spending reductions does not recognize the overall need for a systematic approach to allocation of resources in health care. Elderly people pay more out of pocket for medical care now than they did before Medicare was instituted, suggesting that rising costs will continue to be a problem and that cuts in Medicare would lead to significant loss of access to care.

It also often is not remembered that a very small percentage of older people, less than 5%, actually have incomes above \$50,000 a year, and that there are still 12% to 15% of elderly people living below the poverty level. Most of these are women, many of whom are widows. One of the unique realities of the continued disparity in life expectancy between the sexes is that women often have inadequate pensions and are subject to greater disability related to advanced old age. Old-age policy is

thus reflective of the historical role of women in our society during an era in which women were at significant financial disadvantage, especially in widowhood.

One must also consider the role of the fabric of society between families and generations. There is a great deal of concern that young people exist in a kind of “futurelessness,” wherein they have little confidence in the stability of the world they are facing. They are concerned about global warfare, about the economy, about environmental degradation, and about declining opportunity for themselves. If they were to see older people devalued within society, this would be another measure of loss of confidence in their own future. These are all reasons why a simple age-based rationing approach to the question of fairness and intergenerational equity is not adequate.

Nonetheless, unprecedented changes in the age structure of our society will require new ways of thinking about resource allocation. The relationship between the generations may indeed be an argument for greater concern about the plight of poor children in our society. The major policy concern for the financing of benefits for the elderly has been in looking ahead to the aging of the baby boomers, expected to begin approximately in the year 2010. This is a group many of whom have benefited from the expanding economy of the 1970s and 1980s. Those who are well off have done well by their children, enabling them often to attend private schools or to live in suburbs where there are good public schools, and to prepare themselves to be productive citizens.

The future for the baby-boomer generation depends in a major way on the strength of the economy in the year 2010 and beyond. No matter what public policies are enacted between now and then, an aging society requires a strong economy to support the inevitably large numbers of frail people and those in need of medical care during those years. In addition, the economy must be strong enough that pension arrangements remain stable and funded. This strength of the economy, however, depends not only on the children and grandchildren of the baby boomers but, perhaps more importantly, on “other people's children.” The 20% of children in poverty are not randomly distributed throughout the population. They are largely children of minority families, many of whom are trapped in the cycle of poverty within inner cities. These children do not have an opportunity to receive the benefits of education, which would allow them to become productive members of society and to contribute to the economy necessary to support those who are elderly in the years 2010, 2020, and 2030. Thus, it would be prudent, as well as fair, for the current baby-boomer generation to consider more actively their responsibility to the support of other people's children who are currently struggling in poverty with poor prospects for the future. The intergenerational equity argument, if framed in this way, could be a way of allocating resources and responsibilities between generations that acknowledges not only the link between the welfare of generations across the life span, but the link in society between the better off and the less well off.

CLINICAL DECISIONS TO LIMIT THERAPY

No one would deny that the responsibility of the physician is to do whatever is reasonably possible to help patients. What is now under scrutiny is how to define those reasonable expectations. Two fundamental principles outline a large gray area. One principle is that the patient always has the right to refuse medical treatment, regardless of its chances of benefit or lack thereof. The other is that the physician is never required to provide futile treatment or treatment that is not medically indicated. The large gray area in the middle comes into play when a patient's preference is not clear or has not been made clear; or when treatment is likely to be virtually, but not necessarily 100%, futile; or when individuals disagree about the futility of treatment or have different definitions of futility.

PATIENT CHOICE

The patient is always the most important one to decide whether to use extensive life-saving or life-sustaining medical measures. Although many older people have given a great deal of thought to this matter and have firm, well-informed views on the subject, others may not have given the issues much attention or may not have specific opinions regarding medical treatments. However, they may have very clear values in terms of which they can clarify a description, sometimes called a *values history*, of the framework within which their life is meaningful to them and the point at which death is acceptable and medical intervention unwarranted. The sorting of these issues requires the physician's willingness to spend time in discussion with the patient and with the family, and to do so periodically over time, because the patient's views may change with accumulated life experience and with personal experience of illness or disability. These discussions are referred to broadly as *advance care planning*. They are best implemented in the ambulatory setting or with a patient in the nursing home, as the physician gets to know that patient in the primary care relationship. This way, discussions can be held in an unhurried way, allowing for reflection and for the bringing out of questions and answers, and providing the opportunity for family members to be involved when the patient feels it is appropriate. The least desirable time for these discussions to occur is during an acute illness or on admission to the hospital, when the patient may be too sick to think clearly or too frightened to process information. Paradoxically, however, because many physicians and patients have not had these advance care planning discussions, decisions about end-of-life care choices often occur at the point of acute illness. In 1990, a federal law, called the Patient Self-Determination Act, was passed, requiring all hospitals and nursing homes to inform patients upon admission of their right to execute an advance directive. This has led to a much broader awareness of the need for more advance care planning.

An advance directive is a document that demonstrates and records the patient's views on advance care planning. The two most common forms of advance directives are living wills, which usually stipulate that some limits be set to heroic medical measures taken in the event of critical or terminal illness, and durable powers of attorney for health care, which specify one or more individuals who are responsible for those decisions in the event of a patient's incapacity. These are discussed in greater detail in [Chapter 2](#). In the event that neither such document exists and that there is no record of advance care planning discussion with a physician, many states now have legislated next-of-kin authority for proxy decision making. Although the purpose of advance directives and advance care planning is, as much as possible, to elicit and respect the autonomous wishes of the patient with regard to end-of-life decisions, the recognition by the states of the role of families reflects what research has shown about the views of many elderly people. Older people often refer to family members as key decision makers or support their reasons for a decision to limit therapy by asserting that they do not want to be a burden on the family. Elderly persons should be afforded the same respect for their individuality as younger persons, but autonomy is not the only—or even the preeminent—value for many people. In seeking respect for autonomy, we must not forget that the connectedness to a family network, be it large or small, is often as important as, or more important than, individual self-determination.

Physicians sometimes are reluctant to bring up discussions of advance care planning with their patients, especially in the absence of an acute life-threatening illness, because they are afraid it will upset the patient. However, most studies show that most elderly people are quite open to such discussions and feel relieved when the physician initiates such a discussion. Indeed, consideration of the finality, expectability, and proximity of death is an attitude of old age that makes such conversations easier and more natural than with a younger patient. At the age of 70, 80, or 90 years, most people have experienced the death of a number of family members and close friends, and undoubtedly have had the stimulus to consider what they would want for themselves as they face the end of their lives. Although these discussions should always occur with appropriate sensitivity and compassion, in most cases it is not unduly upsetting to the patient to have such a discussion, and may indeed empower the patient to raise other questions with the physician.

When describing the risks of medical treatment to a patient, the physician should be able to discuss possible outcomes of intermediate success as well as the chances—if known—of survival or of death. Older people may be more concerned about the risks of survival with major impairment (such as in the event of an intraoperative stroke during cardiac surgery) than about mortality rates. When facing the last stages of one's life, quality of life can become a much more vivid concern than extending the number of years of life if those years entail living with major disabilities.

FUTILITY

Because of society's emphasis on respecting a patient's autonomy, some experts believe that we have gone too far in offering all medical interventions, even to patients of very advanced age, when the chances of their being used with success are extremely slim. This creates a situation where the patient is presented with a menu of options, with no values placed on any of them; often this occurs when the patient is critically ill and, as a result, the family are made to feel that it is their burden to decide whether to attempt to save the person's life or to refuse life-saving medical intervention and allow death to occur. Ethicists and policy makers have begun to articulate an area where life-saving medical treatment may be considered futile and therefore is not offered. An example of this is cardiopulmonary resuscitation in long-term care settings, where the staff are not well trained and the patients are extremely frail and unlikely to survive. Most studies show that there are virtually no survivors of such interventions. When the data show that the outcomes are almost uniformly fatal, then it is acceptable for the physician not to offer the intervention to the family, and to simply write an order not to resuscitate or to make a decision to withhold that treatment.

Unfortunately, in most situations where life-sustaining treatment decisions must be made, there are not such conclusive data. Physicians have the clinical impression that there are patients for whom intensive care, intubation, cardiopulmonary resuscitation, chemotherapy, major surgery, and similar interventions have an exceedingly small chance of promoting meaningful survival. The ethical dilemma is how to weigh the extremely small chance of success. This is a controversial area, but many experts argue that the physician is obligated to tell the patient his or her own opinion about the chances of success and advise, in a way that is comforting, when such interventions should not be instituted. Of course, these discussions are always easier on and more beneficial to the family if there is a preexisting relationship, but even if there is not, the physician can provide great comfort to the family by clearly expressing his or her own views about the expected chances of success or failure. Here is an opportunity to regain some of the paternalistic aspect of the physician's role and its potential to comfort a family that is facing the loss of

an elderly relative.

However, this comforting role can be an empty one if there is no positive alternative to intrusive life-sustaining therapy. Many of our hospitals have not developed the teamwork and skills among physicians, nurses, and others to deliver excellent palliative care with control of symptoms, care during the grieving process, spiritual counseling, and sophisticated approaches to problems such as pain, nausea, vomiting, dyspnea, and other such symptoms that are likely to occur in the face of critical or terminal illness. Patients, families, and physicians alike may find it more difficult to accept the withholding or withdrawal of life-sustaining measures if they believe that the only alternative is abandonment. It is thus the physician's responsibility to ensure that there is a more caring and clinically appropriate alternative. For many people, the best alternative is home hospice care, if there are family members at home who are able to care for the patient and if the patient's illness is one that can be appropriately cared for in that setting. It is still true, however, that 80% of people die in hospitals or in nursing homes, and that for many people, either because of the lack of someone in the home full time or because of other factors, this ideal of home hospice care is not always possible. Thus, we must create within our hospitals and nursing homes the option of aggressive comfort care. This is an important area for training and research, as is health care financing.

The traditional hospice patient has been one with widespread metastatic cancer for whom expectation of survival can be confidently considered quite short. It is now widely accepted that such patients should be treated with extensive pain medication and attention to other symptoms. It is necessary to expand this concept of hospice care, however, and not demand that there be such a demonstrably short survival prognosis to provide extensive comfort care for patients. For example, some demonstrations have now been done with hospice care for patients with advanced Alzheimer's disease. One must make the same conceptual shift that the goal of treatment is not to prolong survival but to enhance comfort, and orient the treatment toward that goal. If treatment of pain or dyspnea by narcotics or sedation unintentionally shortens life when given for the purpose of comfort, then such an outcome is acceptable. The distinction that the goal of treatment is to relieve suffering rather than to prolong life should be applied in the evaluation of any intervention being considered in patients for whom comfort care is the appropriate mode of therapy.

HOW DEATH OCCURS

The fundamental principles that guide the physician and patient through decisions to withdraw or withhold life-sustaining treatments and to provide comfort care in patients facing the end of life are substantively no different if the patient is 58 years old or 98 years old. Specifically, the physician's responsibility is to respect the wishes of the patient, always to relieve suffering, and to not abandon the patient even though the search for ways to prolong life may be foregone. However, there is no doubt that our feelings about decisions and care at the end of life might be quite different for a person of very advanced age, regardless of quality of life. Physicians often acquiesce more easily to withholding life-sustaining treatment in a patient who has far advanced physical or cognitive impairment and for whom life no longer holds any personal meaning, and perhaps especially if the patient is of advanced old age. We must caution the physician to observe the distinction between his or her own values about meaningful further life and those of the patient or family. But beyond this, we must recognize that there is a sense in which human survival and the meaning of it is related to a connectedness to other people and to one's own identity. Within a broad range of personal spiritual perspectives, these realities seem to hold.

It is also logical to most that a person who is 95 or 100 years old is ready for the end of life in a way that a person who is 50 years old is not. We have a sense of the naturalness of the human life span and that it is unseemly to push the frontiers of human life beyond that span. The challenge in our aging society, and with the success of increasing life expectancy, is to find the right definition for that natural human life span. The best definition, as always, reverts back to the patient and the history of his own life and its meaning to him. Writers have described the sense of a "closing biography" for person's who are ready for the end of life, even though they may not be actively seeking it. Patients, too, describe this feeling of being "finished" or "almost finished" with their life's tasks. Physicians who have the privilege to treat patients in advanced old age should make use of the opportunity to explore with them these philosophical viewpoints about the human life span and the sense of meaning and closure that a long life can bring.

In this context, then, a decision to withhold heroic measures may take on a very different meaning than it does in a younger person. In a person who no longer looks forward to his future life or for whom cognitive impairment has erased the ability to identify self or relate to other people, measures such as tube feeding, intravenous fluids, and antibiotics for infections all may be viewed as unnecessarily heroic, and within the framework of ethics may be withheld or withdrawn, if done so in accordance with the values history of the patient. Ideally, these values are ones that have been clearly and explicitly articulated by the patient and the family, but the ability to be explicit may vary enormously depending on the specific situation of the doctor-patient relationship and the level of sophistication of the family. It should not rest on the family to insist on each specific medical treatment that they wish to have withheld or withdrawn. The physician, as advocate for the patient, should work with the family to establish the values framework but may need to act on these values in terms of specific medical treatments without getting "releases" or specific permission from the family for each separate decision.

CONCLUSION

In summary, the ethical principles that apply to other aspects of medical care apply equally strongly and convincingly to the care of elderly patients. In addition, there are perspectives to be gained by understanding the concept of a personal life biography and the role of advance planning as it empowers the older person and his or her family to gain strength in their awareness of facing mortality, a universal human characteristic that younger people can more easily avoid. In addition, the social implications of the aging society will continue to put great pressure on the profession of medicine to demonstrate wisdom in the allocation of resources. Here it is important that we take seriously the physician's part in making sensible use of the resources of society and understanding the importance of the concept of futility, even in situations where it cannot be conclusively proven. It is equally important for the physician not to assume that because someone is old medical care is not indicated and to realize that aiming for functional goals, such as hip or knee replacements in an 85-year-old person who would then be able to walk again, is an entirely justifiable use of medical technology. As our ability to use these techniques advances, we will need to hone further our moral conversations with one another and with our patients to establish the appropriateness of their use. Finally, important clinical skills are necessary to fully meet the requirements of ethics, especially in facing end-of-life care. The first of these is communication skills and the second is palliative care. The secret of patient care, as Peabody said, is in caring for the patient. In addition, it requires attentiveness to the advances in biomedical science that present us with ever more useful and challenging ways to improve the lives of patients well into advanced old age.

HOW TO USE THE RAPID ACCESS GUIDE TO INTERNAL MEDICINE

The Rapid Access Guide to Internal Medicine is an index of the major disease entities and clinical syndromes described in the *Kelley's Textbook of Internal Medicine, 4th Edition*. It is a quick-reference feature of the *Textbook* that is intended to provide a brief summary of the most important facts regarding a specific disease or syndrome at those times when speed is essential.

The Rapid Access Guide includes 149 of the common diseases and clinical syndromes most likely to be encountered in clinical practice. For greater ease of use, the information in each entry is compartmentalized into the following categories: definition, etiology, epidemiology, clinical features, diagnosis, prognosis, and management. Each entry contains a cross-reference to the chapter(s) in *Kelley's Textbook of Internal Medicine, 4th Edition* in which the disease or syndrome is discussed comprehensively. Figures and tables that are contained within the *Textbook* chapters themselves have not been duplicated. Instead, cross-references have been included to direct readers quickly to the location of the figures and tables in the main text.

In order to achieve the promised rapid access, *The Rapid Access Guide to Internal Medicine* is arranged according to the major sections of *Kelley's Textbook of Internal Medicine, 4th Edition*, with the entries listed alphabetically within each section. Moreover, on the inside covers of the *Textbook*, all of the *Rapid Access Guide* entries are listed alphabetically, accompanied by their page number and the *Textbook* section from which they are derived. Though an attempt has been made to minimize the use of acronyms and abbreviations with which readers may not be familiar, the common acronyms and abbreviations that have been employed are listed for easy reference.

The complete *Rapid Access Guide* is also available separately as a pocket handbook companion to *Kelley's Textbook of Internal Medicine, 4th Edition*.

Abbreviations

ABG	arterial blood gas
ACE	angiotensin converting enzyme
ACTH	adrenocorticotrophic hormone
ADH	antidiuretic hormone
AIDS	acquired immunodeficiency syndrome
ANA	antinuclear antibody
A₂	aortic component of the second heart sound
BID	twice each day
BP	blood pressure
CBC	complete blood count
CDC	Centers for Disease Control and Prevention
CHF	congestive heart failure
CMV	Cytomegalovirus
COPD	chronic obstructive pulmonary disease
CPK	creatine phosphokinase
CNS	central nervous system
CSF	cerebrospinal fluid
CT	computed tomography
CXR	chest x-ray
D	day
D_LCO	single-breath diffusing capacity for carbon dioxide
DNA	deoxyribonucleic acid
DBP	diastolic blood pressure
ECG	electrocardiogram
EEG	electroencephalogram
ELISA	enzyme-linked immunosorbent assay
EMG	electromyogram
ERCP	endoscopic retrograde cholangiopancreatography
ESR	erythrocyte sedimentation rate
FEV₁	forced expiratory volume in one second
FVC	forced vital capacity
GFR	glomerular filtration rate
GH	growth hormone
GI	gastrointestinal
GU	genitourinary
h	hour
HLA	human leukocyte antigen
Ig	immunoglobulin
INR	international normalized ratio (of the prothrombin time)
IVP	intravenous pyelogram
JVD	jugular venous distention
LDH	lactate dehydrogenase
LP	lumbar puncture
LV	left ventricular
MI	myocardial infarction
MRI	magnetic resonance imaging
NSAIDs	nonsteroidal antiinflammatory drugs
PO	orally (per os)
PFTs	pulmonary function tests
PND	paroxysmal nocturnal dyspnea
PSA	prostate-specific antigen
PTT	partial thromboplastin time
P₂	pulmonic component of the second heart sound
QID	four times each day
RBC(s)	red blood cell(s)
RNA	ribonucleic acid
RPR	rapid plasma reagin
RV	right ventricular
S₁	first heart sound
S₂	second heart sound
S₃	third heart sound
S₄	fourth heart sound

SBP systolic blood pressure
SLE systemic lupus erythematosus
TID three times each day
TPN total parenteral nutrition
VDRL Venereal Disease Research Laboratory
WBC white blood cell count
WBCs white blood cells

ACUTE MYOCARDIAL INFARCTION

DEFINITION AND EPIDEMIOLOGY

Acute myocardial infarction (MI) is irreversible ischemic injury to the myocardium. In 1997, about 1.5 million persons in the United States experienced MI.

PATHOPHYSIOLOGY AND CLASSIFICATION

Acute MI is almost always associated with a thrombus superimposed on marked coronary atherosclerosis. It is a regional disease limited to the vascular territory of one of the three major vessels or their branches. Irreversible myocardial injury requires at least 15 to 20 minutes of ischemia; it begins in the subendocardium and spreads to the epicardium. MI is more common from 4 A.M. until noon, which corresponds to a time of decreased adrenergic activity, increased plasma fibrinogen levels, and increased platelet adhesiveness.

MI can be classified as Q-wave or non-Q-wave depending on whether Q waves develop in the relevant leads of the electrocardiogram (ECG). This classification has prognostic and therapeutic importance.

CLINICAL FINDINGS

History: The main symptom is prolonged (more than 30 minutes) chest pain, although patients may refer to it as “chest pressure” or “chest tightness.” The pain is generally retrosternal, commonly radiates to the arm and neck, and usually is not relieved by nitroglycerin. Associated symptoms include nausea and vomiting, which are especially common with inferior infarction, diaphoresis, and dyspnea.

Physical examination: The typical patient is anxious, has an ashen face beaded with perspiration, and appears dyspneic. The pulse tends to be increased in anterior MI but decreased in inferior MI. Blood pressure usually is normal. Increased jugular venous pressure may reflect left-sided heart failure but also may be caused by involvement of the right ventricle in inferior MI. Right ventricular dysfunction also causes the Kussmaul sign (lack of the normal decrease in jugular venous pressure on inspiration) among about two-thirds of patients with inferior MI. Within 24 hours, there usually is some abnormality of the precordial pulsations, either a lack of a point of maximal impulse or the presence of a diffuse contraction. An S₄ is heard in almost all patients, and an S₃ in about 25%. The S₃ may be the only manifestation of cardiac decompensation. A systolic murmur from papillary muscle dysfunction occurs at least transiently in most patients within the first 24 hours. Approximately 10% of patients with Q-wave infarction have a pericardial friction rub, generally after about 48 to 72 hours. Patients with previous infarction may come to medical attention with worsening cardiac failure.

DIFFERENTIAL DIAGNOSIS

Conditions that may simulate acute MI include acute pulmonary embolism, acute pericarditis, dissecting aortic aneurysm, esophagitis and esophageal spasm, hiatal hernia, cholecystitis, pancreatitis, and spontaneous pneumothorax.

DIAGNOSIS

Electrocardiographic findings: The ECG findings generally are limited to the leads that reflect a certain anatomic region of the heart (anterior, inferior, posterior, or lateral), although reciprocal changes can occur elsewhere in the ECG. Fewer than one-half of patients have the characteristic profile of ST-segment elevation followed by the development of new Q waves (Q-wave MI). The rest have changes limited to ST-segment elevation or depression or only mild, nonspecific abnormalities (non-Q-wave MI). When the changes are restricted to the ST segment and T waves, confirmation by means of enzymatic and radiologic assessment is essential, because these changes also are associated with ischemia without irreversible injury. The ECG diagnosis of MI is notably difficult among patients with left bundle-branch block or previous MI with residual Q waves, because the development of new Q waves may be masked. When there is suspicion of inferior MI, an ECG with right precordial leads may demonstrate ST elevation that indicates right ventricular infarction.

Cardiac enzymes: Elevations of several myocyte enzymes have been incorporated into the diagnostic approach to MI. The level of plasma total MB isoenzyme of creatine kinase (CK-MB) is elevated (more than 7 ng per milliliter) within 6 to 10 hours of the onset of infarction and peaks between 12 and 28 hours. The level returns to normal after 72 to 96 hours. Troponin T and troponin I are contractile proteins (normal levels less than 0.1 ng per milliliter and 1.5 ng per milliliter, respectively). They are released within 6 to 10 hours of the onset of MI and peak within 24 to 36 hours. A more gradual return to normal levels (10 to 12 days) makes levels of these substances particularly suitable for the late diagnosis of MI. Of these three enzymes, cardiac troponin I appears to be the most specific for cardiac injury. CK-MB and troponin T levels may be elevated in musculoskeletal disorders and renal failure. Although measurement of these various markers is useful in the diagnosis of MI, delay in release makes them less satisfactory in quickly excluding the diagnosis among patients arrive in an emergency department with chest pain (only 10% of whom have MI). The only markers that offer the sensitivity and specificity for diagnosis within the first 6 hours are myoglobin and CK-MB isoforms. The ratio of the two CK-MB isoforms becomes abnormal (CK-MB-2/CK-MB-1 greater than 1.7) well before the total CK-MB levels rise to diagnostic levels. Once a diagnosis is made, infarct size can be estimated with serial determination of CK-MB levels over 48 to 72 hours.

Noninvasive imaging: These techniques are useful when the diagnosis of MI is unclear. Echocardiography shows infarct-associated regional wall motion abnormalities but cannot help differentiate acute MI from prior myocardial scarring. Echocardiography also shows ventricular dysfunction, aneurysm, or thrombus. Thallium-201 imaging shows regions of decreased tracer uptake but does not allow reliable differentiation between prior and current MI.

PROGNOSIS AND MANAGEMENT

Treatment in a cardiac care unit, which provides constant ECG monitoring and highly trained medical and nursing personnel, has been associated with a decrease in the immediate mortality rate from MI to 10% to 15%. Patients generally stay in the unit for 2 or 3 days, after which the risk of ventricular fibrillation and ventricular tachycardia is much reduced. Most deaths are caused by pump failure from myocardial destruction rather than by arrhythmia. The use of thrombolytic therapy limits myocardial destruction and has been associated with a further lowering of the acute death rate to approximately 6%. Q-wave MI and non-Q-wave MI have distinct natural histories. The former confers a high-risk period of 6 to 12 weeks and is followed by a low mortality in subsequent years. Patients with non-Q-wave MI have a low mortality initially but a prolonged high-risk period of 1 to 2 years thereafter. After this interval, the accumulated mortality rate is similar to that of Q-wave MI. [Figure 73.2](#) provides an overview of the treatment of patients with chest pain believed to be caused by MI.

INITIAL ASSESSMENT

Vital signs are checked and the patient is immediately given intravenous saline solution and aspirin. Morphine is indicated for pain relief and lidocaine for the management of ventricular arrhythmias. Supplemental oxygen is necessary only if hypoxemia is present. Continuous ECG monitoring should be established. All patients should be assessed for eligibility for thrombolytic therapy within the first 30 minutes.

Reperfusion therapy: Patients with chest pain who have new ST-segment elevation or bundle-branch block are candidates for reperfusion; those with ST-segment depression or T-wave inversion are not. Thrombolytic therapy with recombinant tissue plasminogen activator, streptokinase, or anistreplase (APSAC) improves ventricular function and decreases both infarct size and risk of immediate death when administered within the initial 4 to 6 hours. Studies show some benefit even among patients treated up to 12 hours. Contraindications to thrombolysis include bleeding tendency, prior stroke, hypertension, peptic ulcer, or recent (within 6 weeks) surgery. Age is not a contraindication. Patients undergoing thrombolytic therapy should receive heparin and aspirin, but to date there has been insufficient evidence to support routine cardiac catheterization after thrombolysis. Patients with recurrent ischemia or those who exhibit ischemia at stress testing before discharge should undergo catheterization for possible angioplasty or bypass surgery.

Primary angioplasty is associated with a vessel patency rate of more than 90% (consistently better than that of thrombolysis) and is an acceptable alternative to thrombolysis, if it can be performed within 45 minutes of the time the patient arrives at the hospital. The long-term comparative efficacy of primary angioplasty in relation to thrombolytic therapy remains to be determined. Among patients with contraindications to thrombolysis, primary angioplasty is the preferred therapy.

Adjunctive medications: The routine use of calcium channel blockers is not indicated for limitation of infarct size. However, diltiazem has been shown to be effective in preventing death and reinfarction among patients recovering from non-Q-wave MI and is recommended for routine use in the care of these patients. Angiotension-converting enzyme inhibitors have been shown to prolong life among patients with left ventricular dysfunction or cardiac failure. Patients with an ejection fraction of 45% or less should routinely receive these agents. Four β -blockers (timolol, propranolol, metoprolol, and atenolol) have been shown to prolong life after Q-wave MI. One of these drugs should be given to patients with Q-wave MI who do not have contraindications to use of such a drug, including uncompensated heart failure, asthma, and conduction disturbances, and who meet one or more of the following criteria: age older than 60 years, ischemia demonstrated at exercise testing, ejection fraction less than 45%, concomitant angina or hypertension, or an episode of sustained ventricular tachycardia or fibrillation during the hospital stay. Aspirin therapy (325 mg each day) has been shown to decrease the risk of nonfatal MI or death among patients who have had an MI. Two recent large trials indicated that magnesium has no benefit in the management of acute MI.

ASSOCIATED COMPLICATIONS

Ventricular arrhythmias: These are common in the first 48 hours after MI and include multifocal ventricular extrasystole, runs of 3 or more ectopic ventricular beats, and 5 or more isolated ectopic ventricular beats per minute. Intravenous lidocaine (1 mg per kilogram, then 2 to 4 mg per minute) is recommended as first-line therapy and for prophylactic use before thrombolytic therapy. Persistent arrhythmias may necessitate addition of procainamide or bretylium. Patients in hemodynamically unstable condition need electrical cardioversion or defibrillation.

Atrial arrhythmias: Sinus tachycardia occurs among 20% to 30% of patients. If caused by ventricular failure, sinus tachycardia responds to therapy for that condition. If associated with minimal myocardial damage and normal hemodynamics, sinus tachycardia should be managed with β -blockers to avoid development of ischemia or more severe arrhythmias. Therapy should not be provided for asymptomatic sinus bradycardia.

Conduction disturbances: Type I second-degree heart block may develop, generally in patients with inferior MI. This type of heart block usually is transient and intermittent and rarely progresses to complete block. Type II second-degree heart block is rare, occurring in fewer than 1% of cases. It is almost always associated with anterior MI and a wide QRS complex. This type of heart block often progresses to complete block and always necessitates use of a pacemaker. The associated mortality rate is more than 80% with or without a pacemaker. Complete block necessitates pacing. Intraventricular conduction disturbances occur in as many as 5% of cases. If more than one of the three fascicles (right bundle, left anterior and posterior fascicles) is blocked, temporary pacing is recommended. The need for a permanent pacemaker among such patients is controversial.

Postinfarction angina: Persistent or recurrent chest pain that lasts more than 24 to 48 hours reflects the presence of viable but ischemic myocardium. It is an adverse prognostic indicator and is much more common after non-Q-wave MI. Pericarditis may be the cause of recurrent chest pain and should be excluded. The condition of a patient with postinfarction angina should be stabilized with nitrates and diltiazem, and β -blockers, if necessary. The patient then should undergo catheterization. More than 90% of patients with postinfarction angina and ECG changes have multiple-vessel disease at coronary angiography.

Early reinfarction: The overall incidence of early reinfarction, confirmed with a secondary elevation in plasma CK-MB level, is 10% to 15% after non-Q-wave MI, 5% to 10% after thrombolytic therapy, and less than 5% after Q-wave MI. Patients recovering from non-Q-wave MI should undergo routine plasma CK-MB analysis every 12 hours throughout the hospitalization. Early reinfarction is an indication for coronary angiography.

Cardiac failure: Cardiac failure develops when more than 25% of the left ventricle is involved, but it is often temporary. Because these patients do not have marked sodium and water retention, loss of fluid into the lungs occurs at the expense of vascular volume and may precipitate hypotension and decreased coronary perfusion. Patients with inferior MI, especially if there is also right ventricular involvement, need high filling pressures to maintain cardiac output. Therefore, diuretics should never be given unless central pressures are measured first. Dobutamine and vasodilating agents such as nitroglycerin are considered superior to diuretics in this setting; dopamine is added in the treatment of patients with marked hypotension.

Cardiogenic shock: Cardiogenic shock occurs among 5% to 10% of patients and is the most common cause of death. The only effective therapy is prevention. Clinical criteria include primary cardiac abnormality, a sustained drop in systolic blood pressure to less than 85 mm Hg, a ventricular filling pressure of 16 mm Hg or more, a cardiac index less than 1.5 L per minute per square meter, and peripheral organ involvement (oliguria, altered mentation). Hypovolemia, right ventricular infarction, pulmonary embolism, and cardiac tamponade must be excluded. Treatment includes discontinuation of vasodilators and negative inotropic agents and infusion of dopamine. Mechanical ventilation may be needed. If problems that can be corrected, such as ventricular septal rupture, are found, mechanical assist devices can help to keep patients alive until specific therapies can be undertaken.

Papillary muscle rupture: In rare instances rupture of the papillary muscle occurs 2 to 7 days after onset of MI. It is characterized by the sudden onset of pulmonary edema caused by acute mitral insufficiency. A new, low-pitched, holosystolic murmur radiates to the axilla and frequently is accompanied by an S_3 or an S_4 . Pulmonary crackles are present. Swan-Ganz tracings show a large v wave. Echocardiography is useful in the diagnosis. The patient's condition is stabilized with an intra-aortic balloon pump. The mortality rate without surgery is about 90%; early surgery has a mortality rate of about 50%.

Ventricular septal rupture: This is a rare complication, usually occurring between the first and fifth days of recovery among patients with a first anterior MI. Rupture initiates a left-to-right shunt that causes biventricular failure, pulmonary edema, and cardiogenic shock. A harsh holosystolic murmur suddenly appears; jugular venous pressure elevation and conduction defects occur frequently. Monitoring with a Swan-Ganz catheter shows a step-up in oxygen saturation at the right ventricular level.

Pericarditis and Dressler's syndrome: Pericarditis develops in 5% to 10% of patients with Q-wave MI, usually more than 48 hours after infarction. It usually is heralded by the appearance of pleural-pericardial pain and a pericardial friction rub. The treatment is aspirin. Dressler syndrome is characterized by fever and pleural or pericardial chest pain and usually occurs within 2 to 6 weeks after MI. It is believed to be autoimmune in origin. Initial treatment consists of salicylates; glucocorticoids are added if necessary.

POSTINFARCTION MANAGEMENT

Medical therapy: See *Adjunctive medications*.

Postinfarction stratification: Patients at high risk are characterized by an ejection fraction less than 40%, ECG evidence of ischemia at exercise testing, and frequent or complex ventricular arrhythmias. All patients surviving MI should, before discharge, undergo assessment of left ventricular function by means of radionuclide ventriculography or echocardiography. Those who have been treated with thrombolytic agents probably should undergo cardiac catheterization only if there are symptoms of spontaneous or exercise-induced myocardial ischemia. Patients who have not received thrombolytic agents and who have had their first episode of MI, have an ejection fraction less than 40%, or have refractory pain or early reinfarction should undergo coronary angiography. All other patients may be

stratified through exercise testing (preferably with thallium imaging), and catheterization can be reserved for those who show considerable ischemia.

Revascularization: Bypass surgery is clearly indicated for left main coronary artery disease or for three-vessel disease associated with decreased ejection fraction (less than 45%). The role of angioplasty is less well defined.

Activity: Patients should stay in bed for the first 24 hours after MI but may use a bedside commode. By the fifth or sixth day, they may walk in the room. After discharge, patients are encouraged to walk daily at home for the next 3 to 6 weeks. They usually can return to work in 6 weeks. Formal cardiac rehabilitation programs sometimes are indicated.

Chapter 73

AORTIC VALVE DISEASE

DEFINITIONS, EPIDEMIOLOGY, AND ETIOLOGY

Aortic Stenosis: Aortic stenosis (AS) implies obstruction of left ventricular (LV) outflow caused by a fixed anatomic abnormality of the aortic valve. In adults, AS may be congenital, rheumatic, or degenerative (calcific). Congenital AS is more common among men and usually is associated with a bicuspid aortic valve. Rheumatic AS may occur in isolation but is more commonly associated with mitral valve disease. Degenerative AS occurs exclusively among older adults.

Aortic regurgitation: Aortic regurgitation (AR) is a condition of LV volume overload caused by incompetence of the aortic valve. Congenital causes include bicuspid aortic valve. Acquired AR may be caused by rheumatic disease, hypertensive and atherosclerotic diseases, infective endocarditis, and nonpenetrating trauma. Diseases of the ascending aorta, such as aortic aneurysm and dissection, Reiter's syndrome, ankylosing spondylitis, syphilitic aortitis, and cystic medial necrosis, also can cause AR.

PATHOPHYSIOLOGY

Aortic stenosis: Increased afterload causes compensatory LV hypertrophy. LV systolic function is preserved until late in the course, although diastolic function may be impaired earlier by the increased LV mass. The increased LV mass and intracavitary pressures can cause mismatch of myocardial oxygen demand and supply and lead to angina. Because cardiac output is relatively fixed, the peripheral vasodilatation that occurs with exercise may cause hypotension and syncope.

Aortic regurgitation: When AR is chronic, volume overload and increased wall tension trigger compensatory LV dilation and hypertrophy. Ejection fraction remains normal until late in the disease. Myocardial ischemia occurs in advanced disease because of the increased LV mass and low coronary perfusion pressure. In acute AR, tachycardia is the only compensatory mechanism, and patients frequently have pulmonary edema and shock.

CLINICAL FINDINGS

Aortic stenosis: A long latent period precedes the development of the classic symptoms of dyspnea, angina, and exertional syncope. Late in the course, a decrease in cardiac output causes congestive heart failure (CHF), the effects of which are fatigue, weakness, and peripheral cyanosis. Peripheral edema, hepatomegaly, and ascites may occur. The classic physical finding is *pulsus parvus et tardus*, a delayed and prolonged arterial pulse of diminished intensity, typically assessed in the carotid or brachial artery. On auscultation, the aortic component of S₂ is diminished. An S₄ usually is audible, and an S₃ may be heard if the patient has CHF. The murmur is a harsh, low-pitched, crescendo-decrescendo systolic ejection murmur that radiates from the base of the heart into the carotid arteries. With increasing severity of AS, the murmur peaks progressively later in systole. The murmur of end-stage AS may have a softer volume because of decreasing cardiac output.

Aortic regurgitation: Most patients have no symptoms for years or decades. Early symptoms include palpitations. Exertional dyspnea may be the first manifestation of LV decompensation; orthopnea and paroxysmal nocturnal dyspnea develop later. Symptoms of more advanced disease include angina, ascites, and peripheral edema. Most physical findings in chronic AR reflect the combination of increased stroke volume and widened pulse pressure, including bobbing of the head (de Musset sign), water-hammer pulse, visible capillary pulsation in the nail beds with gentle nail compression (Quincke pulse), and a diastolic murmur with pressure over the peripheral arteries (Duroziez sign). The aortic component of S₂ may be diminished. The murmur is a high-pitched, blowing, decrescendo diastolic murmur, loudest at the left or right upper sternal border. It may radiate to the cardiac apex (Austin Flint murmur) as a low-pitched diastolic rumble that mimics mitral stenosis. There may be a loud accompanying systolic murmur caused by the large stroke volume. Many of the physical findings associated with chronic AR are absent among patients with acute AR, because there are no acute increases in stroke volume or pulse pressure.

DIAGNOSTIC STUDIES

Aortic stenosis: The ECG may show evidence of LV hypertrophy. The chest radiograph may be normal or show an enlarged cardiac silhouette. Echocardiography with Doppler technique is an accurate, noninvasive means of establishing the diagnosis and determining cause and severity. It also provides an assessment of LV size, mass, and systolic function. Cardiac catheterization should be reserved for patients who have a discrepancy between clinical and echocardiographic data or those undergoing planned aortic valve operations that may include coronary artery bypass if severe coronary artery disease is found. AS is not usually of hemodynamic importance until the valve area is reduced to one-fourth normal. In general, AS is considered severe when the valve area is 1.0 cm² or less and the mean transvalvular pressure gradient is 50 mm Hg or more, although patients with LV dysfunction may have lower gradients because of decreased flow.

Aortic regurgitation: Neither chest radiography nor ECG is very helpful. Echocardiography with Doppler techniques can be used to confirm the diagnosis and determine cause and severity. LV dimensions, mass, and systolic function should be evaluated, as should the size and anatomic details of the aortic root. Cardiac catheterization with coronary angiography is useful when a planned aortic valve operation may include coronary artery bypass if severe coronary artery disease is demonstrated.

PROGNOSIS AND STRATEGIES FOR MANAGEMENT

Aortic stenosis: Mortality is low as long as patients have no symptoms. With the onset of symptoms, the average survival time without intervention is 2 to 3 years. The worst prognosis is associated with symptoms of CHF. All patients should receive prophylactic antibiotics prior to procedures that are likely to cause bacteremia. There is no suitable medical therapy. Medications that decrease preload (nitrates, diuretics) may reduce the cardiac output of patients with LV hypertrophy and must be used with caution. Agents that decrease afterload (calcium channel blockers, angiotensin-converting enzyme inhibitors) may cause marked hypotension in the setting of fixed cardiac output and are best avoided. Valve replacement is associated with symptomatic improvement and an increased survival rate and should be considered strongly in the care of almost all patients with symptoms, even elderly patients or those with LV systolic dysfunction. Use of a mechanical prosthesis has the advantages of a favorable hemodynamic profile and durability but necessitates long-term anticoagulation because of thrombogenicity. Aortic balloon valvuloplasty is important in delaying the need for valve replacement among younger patients or in palliative treatment of patients who cannot undergo surgical therapy.

Aortic regurgitation: Prognosis worsens with the onset of symptoms; the mortality rate is estimated to be more than 10% per year among patients with severe AR and angina and more than 20% per year among those with symptoms of CHF. LV systolic dysfunction and marked LV dilatation also are associated with a worse prognosis, even if patients continue to have no symptoms. Patients should receive prophylactic antibiotics prior to procedures that are likely to cause bacteremia. Patients with chronic mild or moderate AR do not benefit from any other therapy. However, patients without symptoms who have chronic, severe AR benefit from long-term vasodilating therapy with nifedipine or possibly angiotensin-converting enzyme inhibitors. Drug therapy appears to delay the need for valve replacement and to improve outcomes after surgery. Therapy should be limited to patients with systolic hypertension. Aortic valve replacement is indicated in the care of patients with severe AR and symptoms of angina or CHF and for patient without symptoms who have severe AR and decreased LV systolic function (resting ejection fraction less than 50%) or marked LV dilatation. Severe acute AR can be stabilized with diuretics and aggressive afterload reduction, as with nitroprusside, before urgent valve replacement.

Chapter 77

ATRIAL ARRHYTHMIAS

DEFINITION AND CLINICAL PRESENTATION

Cardiac arrhythmias are disorders of the normal heart rhythm. Most commonly, they cause palpitations, an awareness of the heartbeat because of an abnormally strong ventricular contraction, a pause in normal rhythm, or extra beats. Less commonly, they can produce syncope, near-syncope, angina, congestive heart failure, or death.

SPECIFIC ARRHYTHMIAS

Premature atrial complexes: These manifest as a premature P wave morphologically different from the sinus P wave. They usually discharge the sinus node and are followed by a noncompensatory pause. They occur among healthy persons and can be provoked by drugs, alcohol, caffeine, or tobacco. They usually do not necessitate therapy, but patients without symptoms may be given digitalis, propranolol, or verapamil.

Atrial flutter: This rhythm is recognized on an electrocardiogram (ECG) as sawtooth-shaped atrial complexes, usually at rates of approximately 300 beats per minute, with a 2:1 ventricular response among untreated persons. If the atrioventricular (AV) conduction ratio remains constant, the ventricular rhythm is regular; otherwise it is irregular. Atrial flutter usually is associated with underlying heart disease. Reentry is the most probable cause. Synchronous direct-current cardioversion is the initial therapy of choice; rapid atrial pacing also is effective. Therapy with class IA, IC, or III drugs can be tried ([Table 1](#)). Before class I drugs are given, the ventricular rate must be slowed (as described in the section on atrial fibrillation).

Class I: Drugs That Interact Predominantly with the Fast Sodium Channel

Quinidine-like: quinidine, procainamide, disopyramide
Lidocaine-like: lidocaine, mexiletine, tocainide
Flecainide-like: flecainide, propafenone
Phenytoin

Class II: β -Adrenergic Antagonists

Nonselective: propranolol, nadolol, timolol
Cardioselective: atenolol, metoprolol
intrinsic sympathomimetic activity
Nonselective: pindolol
Cardioselective: acebutolol, carvedilol

Class III: Drugs That Prolong Repolarization

Sotalol
Amiodarone
N-Acetylprocainamide (NAPA) (acecainide)
Sotalol

Class IV: Calcium Channel Antagonists

Verapamil
Diltiazem

TABLE 1. DRUGS WITH ANTIARRHYTHMIC ACTIVITY

Atrial fibrillation: Atrial fibrillation is the most common sustained arrhythmia; the incidence increases with age. It also occurs commonly among patients with hypertension, rheumatic heart disease, atrial septal defect, cardiomyopathy, coronary heart disease, or thyrotoxicosis and among those who have undergone cardiac surgery. It can occur among patients without structural heart disease (lone atrial fibrillation). The rhythm is characterized by totally disorganized atrial depolarization without effective contraction and is most commonly sustained by multiple wavelets of reentry. An ECG shows small, irregular baseline undulations of varying amplitude and morphologic characteristics. Because many of the fibrillatory impulses are blocked in the AV node, the ventricular rhythm is irregularly irregular, although this may be difficult to appreciate when the ventricular response is rapid. Among patients with normal AV conduction, the ventricular rate usually is 100 to 160 beats per minute.

If acute cardiovascular decompensation has occurred, electrical cardioversion is the initial treatment. Otherwise, the therapeutic objective is to slow the ventricular rate and then to restore atrial systole. (Atrial fibrillation accompanying Wolff-Parkinson-White syndrome must be treated differently, however.) Drugs that slow the ventricular response (digitalis, β -blockers, and calcium channel blockers) can be used alone or in combination. The adequacy of rate control must be assessed both at rest and with activity; digitalis is often ineffective during exertion. Inadequate rate control can lead to tachycardia-induced cardiomyopathy. If the ventricular rate proves refractory to medical therapy, or if such therapy is poorly tolerated, radiofrequency ablation of the AV node followed by implantation of a pacemaker may be useful. Conversion to sinus rhythm should be considered in the care of patients with symptoms or when the ventricular rate cannot be controlled. Outpatient electrical cardioversion is the most effective technique. Many oral and intravenous drugs are useful, although pharmacologic conversion for patients with structural heart disease should be performed in a monitored, hospital setting. Amiodarone is ineffective at converting atrial fibrillation but does decrease risk for recurrence. Unlike quinidine and flecainide, amiodarone does not appear to increase mortality due to proarrhythmia when used for long-term treatment of patients with extensive structural heart disease. The strongest predictor of recurrent atrial fibrillation is the duration of arrhythmia before cardioversion. Catheter and surgical techniques are being developed for the management of atrial fibrillation.

Patients with chronic atrial fibrillation are at increased risk of stroke. Risk factors, include hypertension, rheumatic heart disease, diabetes, history of previous thromboembolic events, left atrial enlargement, history of congestive heart failure, and age older than 65 years. Long-term anticoagulation with warfarin is effective in reducing this risk. Aspirin can be used to treat patients without risk factors. Electrical and pharmacologic cardioversion are associated with atrial contractile dysfunction (stunning) and thrombus formation. Therefore, unless a contraindication is present, short-term anticoagulation before and after cardioversion is necessary in the care of all patients with atrial fibrillation that persists for more than 2 days or is of unknown duration. Absence of a left atrial thrombus on a transesophageal echocardiogram has been demonstrated to allow safe cardioversion without prior anticoagulation. However, the cardioversion should be preceded by the initiation of heparin therapy and must be followed by 4 weeks of warfarin therapy. Patients who have undergone AV node ablation and implantation of a pacemaker are still at risk of stroke and should undergo anticoagulation.

Atrial tachycardia: Atrial tachycardia can be caused by enhanced atrial automaticity, reentry, or triggered activity. The atrial rate usually is 150 to 200 beats per minute and can be slightly irregular. Vagal maneuvers usually do not stop the tachycardia, even though they may produce transient AV nodal block. Atrial tachycardia occurs most commonly among patients with structural heart disease, such as coronary artery disease or cor pulmonale, or with digitalis intoxication. If digitalis is not the cause, this drug may be given to slow the ventricular response, as may β -blockers and calcium channel blockers. Recurrent atrial tachycardia can be controlled with antiarrhythmic drugs and often can be cured with catheter ablation.

Multifocal atrial tachycardia (chaotic atrial tachycardia): This type of arrhythmia is characterized on an ECG by atrial rates of 100 to 130 beats per minute, marked variation in P-wave structure, and irregular PP intervals. At least three P-wave shapes usually are found. As in atrial fibrillation, ventricular rhythm usually is irregularly irregular. Multifocal atrial tachycardia occurs commonly among patients with pulmonary disease. Therapy is directed at the underlying disease; antiarrhythmic agents often are ineffective in slowing the atrial rate or the ventricular response. Potassium and magnesium replacement may suppress the tachycardia.

AV nodal reentrant tachycardia: This type of arrhythmia occurs when characteristics of conduction pathways near the AV node allow an impulse to travel slowly along one path and then return in a reverse direction along an initially blocked path to reexcite tissue proximal to the site of the block. AV nodal reentrant tachycardia is characterized by regular tachycardia, usually at rates of 180 to 200 beats per minute, a narrow QRS complex and retrograde P waves at the onset of or immediately after termination of the QRS complex. The onset and termination both are sudden. Examination of the jugular veins may reveal constant cannon a waves. This type of tachycardia occurs commonly among patients without structural heart disease. Depending on the duration and rate and the presence of structural heart disease, AV nodal reentrant tachycardia produces symptoms ranging from palpitations, nervousness, and anxiety to angina, heart failure, or syncope. Termination initially involves a vagal maneuver, such as carotid sinus massage, a Valsalva maneuver, or gagging. The drug of first choice is intravenous adenosine (a vagomimetic drug). Alternatives are diltiazem, verapamil or a short-acting β -blocker such as esmolol. Prevention of recurrence with these AV nodal blocking agents may prove more difficult, but radiofrequency catheter ablation of the slow pathway has a high success rate (about 95%) and low risk (less than 2%). The prognosis among patients without heart disease is good.

APPROACH TO THE PATIENT WITH CHEST PAIN

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of chest pain is extensive ([Table 32.5](#)). Rapid assessment is essential to identify whether a patient has acute coronary syndrome and hence is at risk of sudden cardiac death. Most patients with chest pain related to a noncardiac cause have esophageal or anxiety disorders.

HISTORY AND PHYSICAL EXAMINATION

A carefully obtained history is the best initial diagnostic tool ([Table 32.1](#)). Patients may not call their problem *pain*. Morning episodes of discomfort and radiation to the arms, neck, or shoulder both are more frequent with myocardial ischemia than with other disorders. The presence of nausea or vomiting and diaphoresis should heighten the suspicion of ischemia. Symptoms occurring at rest or those related to meals, movement, stress, and respiratory pattern are more likely to have a noncardiac than a cardiac cause. A sensation described as “stabbing” or “fleeting” also is less likely to represent myocardial ischemia.

A detailed cardiovascular examination can provide vital clues, but normal findings do not exclude a cardiac disorder. Detection of a murmur of papillary muscle insufficiency, S₃ or S₄, loud P₂, abnormal precordial impulse, jugular venous distention, rales, or lower extremity edema is associated with organic heart disease and may indicate ischemia or infarction. A diminished A₂ with a crescendo-decrescendo systolic murmur and decreased carotid upstroke suggests hemodynamically significant aortic stenosis. Unequal pulses or blood pressures should be a warning of possible aortic dissection. Detection of a pericardial friction rub, tachycardia, and pulsus paradoxus suggest pericarditis and possible tamponade. A pleural friction rub, evidence of consolidation, and absent or abnormal breath sounds may indicate a pulmonary cause. Persistent sinus tachycardia with tachypnea, a pleural rub, and localized wheezing can indicate pulmonary embolization. Atypical pain that is reproducible with cervical motion probably is caused by C6-7 radiculopathy.

DIAGNOSTIC TESTS

An ECG is essential. About 50% to 60% of patients with acute myocardial infarction have ECG changes that suggest the diagnosis. Normal ECG findings make the diagnosis less likely but do not exclude it. Pericarditis, pulmonary embolism, pulmonary hypertension, and esophageal spasm also can be associated with ECG abnormalities. A rational approach to biochemical testing includes both creatine kinase-MB and troponin I, which is found only in myocardial muscle and can be detected for up to 10 days after myocardial injury. Exercise ECG testing may be useful in the care of patients with a stable pattern of chest pain but is contraindicated in the care of patients at high risk. The addition of imaging techniques, such as thallium 201 or sestamibi scanning and echocardiography, to ECG monitoring is advisable in the care of patients with abnormal resting ECGs and women younger than 40 years. Pharmacologic testing with adenosine, dipyridamole, or dobutamine is helpful in evaluations of patients who cannot exercise adequately.

For patients whose signs and symptoms suggest pain unrelated to myocardial ischemia or whose evaluation does not prove the presence of myocardial ischemia, other specific tests may be warranted. In many cases, however, the diagnosis, such as gastroesophageal reflux disease or panic disorder, can be made clinically.

CORONARY ARTERY DISEASE

EPIDEMIOLOGY

In the United States, atherosclerotic coronary artery disease (CAD) is the leading cause of death among both men and women and is a clinically significant process in about 11 million people. Risk factors include cigarette smoking, hypercholesterolemia, hypertension, diabetes mellitus, male sex, menopause, and family history. Recent studies also implicate elevated levels of plasma homocysteine or lipoprotein(a) and dormant infection with *Chlamydia* or cytomegalovirus organisms.

DEFINITIONS AND PATHOPHYSIOLOGY

Chronic coronary disease: The most common cause of CAD is stenosis of the proximal segments of the left anterior descending (LAD), right, or circumflex coronary arteries by atherosclerotic plaque. For most patients, myocardial ischemia occurs during stress, when progressive increases in myocardial oxygen demand exceed the ability of the coronary circulation to increase blood flow. Endothelial dysfunction of the coronary arteries, even those with plaques that are not themselves flow limiting, contributes to this imbalance. The chief mechanism is a decrease in the production of nitrous oxide, a potent endogenous vasodilator that also inhibits smooth-muscle proliferation and platelet aggregation.

Acute coronary syndrome: Acute coronary syndrome (ACS) is characterized by an increase in the intensity or frequency of angina and is associated with an increased risk of myocardial infarction (MI) and cardiac death. Examples include prolonged rest angina (more than 20 minutes), new onset of angina (pain of less than 2 months' duration), and acceleration of angina. ACS and non-Q-wave MI generally result from the formation of thrombus after rupture of an atherosclerotic plaque, often one that is angiographically insignificant.

Variant angina: Prinzmetal's angina is a syndrome of angina that usually occurs at rest and is associated with reversible ST-segment elevation without enzymatic evidence of acute MI. It is caused by coronary vasospasm and is associated with heavy smoking, migraine headaches, and Raynaud's phenomenon.

CLINICAL FEATURES

Chronic coronary disease: Stable angina is characterized by poorly localized discomfort in the chest or left arm associated with physical exertion or emotional stress and relieved promptly with rest or sublingual nitroglycerin. The pain also can involve the neck, jaw, and teeth. Dyspnea, diaphoresis, nausea, and dizziness may be present. Many patients have no chest discomfort; the only symptoms may be a combination of dyspnea and pain in the neck, shoulder, or arm. An anginal episode may last a few minutes to 15 to 20 minutes. Common precipitants include exercise, sexual activity, and emotional distress. The anginal threshold may be lowered by mental stress, exposure to cold temperatures, meals, cigarette smoking, anemia, and hyperthyroidism. For reasons that are not clear, most ischemic episodes among patients with stable angina are painless, or “silent.” The physical examination helps to exclude valvular heart disease or obstructive hypertrophic cardiomyopathy as the cause of chest pain. Some patients with prior MI may show evidence of LV dysfunction. Vascular bruits suggest diffuse atherosclerotic disease. During an attack of angina, an S₃, an S₄, or the murmur of mitral regurgitation may be present.

Acute coronary syndrome: The chest discomfort of ACS is similar to that of stable angina but is usually more severe and protracted. The discomfort often is associated with diaphoresis, an S₃ or S₄, and a systolic murmur. Electrocardiographic (ECG) findings during a symptomatic attack may show ST-segment depression or elevation or T-wave abnormalities. If they persist for several hours, these abnormalities often are associated with elevation of creatine kinase-MB and the diagnosis of non-Q-wave MI. Elevation of troponin T and troponin I levels is associated with increased risk of death.

Variant angina: Most patients have angiographically significant atherosclerotic CAD and therefore are at risk of MI and sudden death. The chest discomfort usually occurs at rest, although the vasospasm can be triggered by exercise. The duration is somewhat longer than that of stable angina.

DIFFERENTIAL DIAGNOSIS

Several conditions may produce an anginal syndrome indistinguishable from that caused by atherosclerotic CAD. These include aortic stenosis, aortic insufficiency, hypertrophic cardiomyopathy, dilated cardiomyopathy, pulmonary hypertension, and cocaine use. Microvascular angina, or syndrome X, is caused by a reduction in vasodilator reserve of the coronary vasculature. It is common among women and persons with hypertension and is a common cause of chest pain when coronary arteriograms are normal. Other conditions may cause chest pain unrelated to myocardial ischemia. These include aortic dissection, pulmonary embolism, acute

pericarditis, reflux esophagitis, esophageal spasm, peptic ulcer, and biliary disease.

LABORATORY TESTS AND DIAGNOSIS

Chronic coronary disease: Anemia and hyperthyroidism should be excluded, and a serum lipid profile should be obtained. The ECG may be entirely normal or show evidence of prior (possibly silent) MI. Additional diagnostic testing should be reserved for patients with moderate pretest probability of CAD, such as patients with symptoms or several risk factors for CAD. Among patients with a high probability of disease, such as middle-aged men with typical angina and numerous risk factors, the diagnosis is usually well established without further testing. The various noninvasive tests are compared in [Table 72.5](#); cardiac magnetic resonance imaging and electron-beam computed tomography are additional techniques under investigation. Among patients with known or suspected CAD, coronary angiography is performed for diagnosis, for risk stratification, and for the assessment of appropriateness and feasibility of myocardial revascularization with percutaneous transluminal coronary angioplasty (PTCA) or coronary artery bypass grafting (CABG). Angiography is indicated in evaluations of patients classified as being at high risk at noninvasive testing and of patients with stable angina who continue to have evidence of ischemia despite adequate medical therapy.

Acute coronary syndrome: The diagnosis of ACS usually is made on clinical grounds, although additional testing often is helpful in guiding management (see later).

Variant angina: The diagnosis is made on clinical grounds and demonstration of ST-segment elevation during an attack of angina that normalizes with sublingual nitroglycerin. Ambulatory ECG monitoring and exercise testing may be useful in demonstrating ST-segment elevation. All patients should undergo coronary angiography. Intravenous or intracoronary administration of ergonovine in the catheterization laboratory elicits coronary vasospasm in more than 90% of patients with variant angina; a negative test result essentially excludes the diagnosis.

MANAGEMENT

Chronic coronary disease: Acute cardiac events are caused by disruption of atherosclerotic plaques; the plaque need not be stenotic to rupture and cause occlusive thrombosis. The goals of therapy include both improvement of symptoms and prevention of the plaque disruption and growth that can lead to progression and acute cardiac events. Risk factor modification is essential and includes smoking cessation, control of hyperglycemia, and aggressive management of hypertension. The total cholesterol level should be reduced to less than 200 mg per deciliter, the low-density lipoprotein cholesterol level decreased to less than 100 mg per deciliter, and the high-density lipoprotein cholesterol level increased to more than 35 mg per deciliter. HMG-CoA reductase inhibitors have been shown to be particularly beneficial in this setting. Reducing homocysteine levels with folic acid and vitamins B₆ and B₁₂ has not yet been demonstrated to improve clinical outcomes. Correction of contributing conditions (such as anemia, thyrotoxicosis, fever, and hypoxemia) should be undertaken.

Aspirin (81 to 324 mg per day) reduces the risk of MI and sudden death and should be used to treat all patients unless contraindicated. Clopidogrel and ticlopidine also block platelet activation and may be used in place of aspirin.

Nitrates are potent systemic venous and coronary arterial vasodilators that may be used to abort (0.4-mg sublingual capsules or spray) or prevent (long-acting tablets and transdermal patches) attacks of angina. Tolerance develops to the long-acting forms unless there is an 8 to 12 hour nitrate-free period each day. The most common side effects are headache and hypotension.

β -Blockers are among the most important therapies for CAD. These agents decrease the frequency of attacks of angina and improve exercise tolerance. They are at least relatively contraindicated in the care of patients with asthma, atrioventricular conduction defects, profound bradycardia, severe hypotension, peripheral artery disease, and Raynaud's phenomenon. They must be used with extreme caution by patients with overt heart failure, although use of these agents does improve survival in such cases. These drugs should be discontinued gradually over several weeks, if possible, to avoid rebound effects.

Calcium channel blockers relax vascular smooth muscle in the arterial and coronary circulation. The different agents depress myocardial contractility to varying degrees (most with verapamil, least with dihydropyridines such as nifedipine and amlodipine). They may reduce the frequency of angina and increase exercise tolerance and are generally well tolerated. Calcium channel blockers must be used with extreme caution by patients with systolic heart failure. The use of short-acting agents, particularly by patients with hypertension, has been associated with an increased risk of MI. β -Blockers are preferred over calcium channel blockers in the management of stable angina.

Percutaneous coronary revascularization (PCR) is a nonsurgical procedure on a stenotic artery in which the coronary lumen is dilated with a balloon catheter or other intracoronary device. PCR is technically successful about 90% of the time. Indications include a considerable stenosis of a major epicardial artery (other than the left main) in patients with angina that does not respond to medical therapy or with evidence of myocardial ischemia in the territory of the artery to be dilated. The main limitation of angioplasty is coronary restenosis, which occurs among 30% to 50% of patients within the first 6 months after the procedure. Stents and platelet glycoprotein IIb/IIIa receptor blockers may reduce the rate of restenosis. Bypass surgery with saphenous veins and the internal mammary artery is used primarily to treat patients with symptoms that are not responsive to medical therapy or PTCA. Unlike medical therapy, CABG improves the survival rate among patients with left main coronary artery disease, three-vessel disease, or two-vessel disease when one of the two vessels involved is a large LAD artery with severe proximal stenosis. This benefit is particularly evident among patients who have LV systolic dysfunction. Among selected patients with multivessel CAD, PCR and CABG have similar clinical outcomes, although patients undergoing PCR are more likely to have persistent angina and have a greater need for additional revascularization procedures. Patients with diabetes have a significantly lower mortality rate with CABG than with PCR. For patients with disease of the left main coronary artery, multivessel disease involving the proximal LAD, or three-vessel disease with impaired LV systolic function, CABG is preferred over PCR.

Acute coronary syndrome: Patients with suspected ACS should undergo initial risk stratification ([Table 72.11](#)). Patients at low risk can undergo outpatient evaluation. Therapy should consist of aspirin, sublingual nitroglycerin as needed, oral β -blockers, and long-acting topical or oral nitrates. Patients at intermediate or high risk should be admitted to the hospital and undergo serial cardiac enzyme measurements and ECG to exclude acute MI. These patients should be treated with aspirin, intravenous heparin or low-molecular-weight heparin, glycoprotein IIb/IIIa antagonists, nitrates, and β -blockers. Calcium channel blockers should be reserved for patients with hypertension or ischemia refractory to the other agents. Intravenous thrombolytic therapy is not indicated unless there is prolonged rest pain and either elevation of the ST segments in two consecutive leads or a left bundle-branch block. Patients who continue to have ischemia despite medical therapy or who have marked ischemia at stress testing should undergo coronary angiography. Indications for CABG are the same as those mentioned earlier. Treatment of patients with two-vessel or one-vessel disease remains controversial, but revascularization usually is recommended.

Variant angina: Nitrates and calcium channel blockers are extremely effective in preventing coronary artery spasm. β -Blockers should not be used unless there is extensive concomitant atherosclerotic disease. High doses of aspirin may increase the severity of vasospasm. The indications for revascularization among patients with variant angina and significant multivessel atherosclerotic disease are the same as for other patients with chronic CAD.

[Chapter 72](#)

HEART BLOCK

DEFINITION AND CLINICAL PRESENTATION

Heart block is a disturbance of impulse conduction that can occur at any site but is recognized commonly between the sinus node and the atrium (SA block), between the atrium and ventricle (AV block), or within the ventricle (intraventricular or bundle-branch block). The symptoms are those of bradycardia—syncope, near-syncope, angina, and congestive heart failure.

SPECIFIC ARRHYTHMIAS

First-degree atrioventricular block: In this block, the PR interval exceeds 200 milliseconds, but all P waves conduct to the ventricles. The prolonged PR interval can be caused by a conduction delay in the AV node or in the His–Purkinje system. It is almost always asymptomatic.

Second-degree atrioventricular block: Second-degree AV block is divided into type I (Wenckebach) and type II. During type I AV block, there is a regular PP interval, and progressive PR interval prolongation precedes a nonconducted P wave. Because the increment in PR interval conduction delay decreases after the first

cycle, the RR interval progressively decreases. In type II, the PR interval remains constant before one or more nonconducted P waves. If the QRS complex is normal, the block is more likely to be type I; almost always, type II AV block occurs in the setting of a bundle-branch block. As a rule, type I AV block is a more benign conduction disturbance and can occur among healthy persons. Often it produces no symptoms and requires no pacemaker therapy. Type II block usually is located in the His–Purkinje system and is associated more often with syncope and the need for pacemaker therapy. A transient type I block occurs in some patients with inferior wall MI; type II block more often accompanies severe anterior infarction.

Complete atrioventricular block: Complete AV block, or third-degree AV block, occurs when no atrial activity conducts to the ventricles and, therefore, independent pacemakers control the atria and ventricles. When the block occurs at the level of the AV node, usually a congenital condition, the QRS complex is normal and the ventricular rate usually is 40 to 60 beats per minute. Atropine and exercise increase the ventricular rate. Children most often have no symptoms. Acquired complete AV block occurs most commonly distal to the bundle of His. The QRS complexes are abnormal, and the ventricular rate usually is less than 40 beats per minute and fails to increase with administration of atropine or with exercise. Complete AV block can be associated with electrolyte disturbances, endocarditis, tumors, rheumatoid nodules, calcific aortic stenosis, infiltrative processes, drug toxicity, coronary artery disease, and degenerative processes. The patients usually have Adams-Stokes syncope and need pacemaker implantation.

APPROACH TO THE PATIENT WITH HEART FAILURE

ETIOLOGY AND PATHOPHYSIOLOGY

Heart failure is not a disease. It is a wide-ranging expression of left ventricular (LV) dysfunction attributable to diverse etiologic factors. The most common form, systolic LV dysfunction, represents failure of the heart as a pump. It usually is caused by myocardial infarction or hypertension. The clinical expression of heart failure also can be seen without systolic dysfunction among patients with valvular or pericardial disease, abnormalities of cardiac rhythm, or impaired diastolic filling (diastolic dysfunction). Heart failure stimulates a cascade of compensatory responses, including activation of the renin–angiotensin system, increases in sympathetic tone, and enhanced production of antidiuretic hormone. These responses enhance renal sodium and water retention and contribute to the formation of edema.

CLINICAL FINDINGS

History: Most patients seek medical attention because of breathlessness or exercise-induced fatigue. Sometimes the first recognized manifestation of heart failure is orthopnea or paroxysmal nocturnal dyspnea. For other patients, pedal edema may be the first concern.

Physical examination: Tachycardia usually represents chronotropic compensation for the reduced cardiac output. If irregular, the tachycardia most typically reflects atrial fibrillation, the most common atrial arrhythmia in this population. Blood pressure is often low among patients with chronic heart failure. A narrow pulse pressure is consistent with low stroke volume or inadequate diastolic filling time. The magnitude of jugular venous distention provides an estimate of cardiac filling pressure. Pulmonary examination may reveal tachypnea, dyspnea with speech, or crackles. In general, the height of the crackles in the posterior fields is proportional to the severity of LV decompensation. Crackles may be obscured by the presence of pleural effusion, which is more often a marker of chronic decompensation. A diffuse apical impulse displaced away from the midsternal line suggests ventricular enlargement and is typical of heart failure. Cardiac auscultation may show murmurs (mitral regurgitation is common), an accentuated P₂, an S₃, which indicates ventricular dysfunction or decompensation, and an S₄, which indicates abnormal atrioventricular filling characteristics. Abdominal examination findings suggest the presence of hepatomegaly or ascites. Pitting edema of the lower extremities is common.

LABORATORY FINDINGS AND DIAGNOSTIC TESTS

Chest radiograph The cardiothoracic ratio, which is measured on a conventional posteroanterior radiograph, provides an estimate of overall heart enlargement. Pulmonary blood volume often is redistributed to the upper lobes on an upright image, producing cephalization. Perihilar infiltrates suggest cardiogenic pulmonary edema.

Electrocardiogram: The presence of Q waves indicates prior myocardial infarction. The increased voltage of LV hypertrophy may be seen. Various arrhythmias (atrial, ventricular, heart block) are common among patients with heart failure.

Specialized cardiac studies: Ventricular performance can be quantified by means of echocardiography or radionuclide blood pool scanning. An LV ejection fraction less than 45% at rest is considered abnormal. Echocardiography also provides information about valvular function, wall thickness, and regional wall motion. Doppler flow measurements are used to assess the functional significance of observed stenotic and regurgitant valvular lesions. Coronary angiography often is necessary to clarify the cause of heart failure (ischemic or nonischemic). Direct measurement of right atrial, right ventricular and pulmonary artery wedge pressures confirms the diagnosis of heart failure. In difficult cases, an exercise test with monitoring of ECG and gas exchange can help differentiate cardiac, pulmonary, deconditioning, and nonmotivational disability.

PROGNOSIS AND MANAGEMENT

General strategies: The overall 5-year survival of heart failure is less than 50%. Management goals include identification of causes that can be corrected, prevention of disease progression, maintenance of physical activity, reversal of sodium retention, and reduction of the risk of death. Moderation of sodium intake (2 to 3 g per day) helps counteract the tendency toward sodium retention and edema. Dynamic, not isometric, exercise should be encouraged within the limits of tolerance. Associated conditions, such as cardiac arrhythmia, hypertension, chronic lung disease, and diabetes should be managed aggressively. Overweight patients should be encouraged to lose weight.

“Standard” pharmacologic therapy: Angiotensin-converting enzyme (ACE) inhibitors are recommended for all stages of heart failure. By decreasing systemic vascular resistance, these agents improve symptoms, limit progression of LV dysfunction, and reduce mortality. The dosage should be small at first and gradually escalated (e.g., to 40 mg lisinopril per day or 20 mg enalapril twice a day). Diuretic dosage should be reduced if hypotension (symptomatic or systolic pressure less than 80 to 85 mm Hg) or clinically significant azotemia develops. Transient reduction of renal function may occur but should not discourage continued therapy in most cases. Side effects include dry cough, hyperkalemia, and skin rash. Other vasodilators, such as the combination of hydralazine and isosorbide dinitrate, may be given to patients who cannot tolerate ACE inhibitors. Because of a lack of benefit in most trials, no calcium channel blocker has been approved for the management of heart failure.

Loop diuretics reduce intravascular volume and allow reabsorption of edema fluid. The response is monitored by assessing of symptoms, signs of fluid overload, daily weights, and changes in blood urea nitrogen and creatinine levels. Among patients who seem to be resistant to high doses of a loop diuretic, the addition of a thiazide diuretic (which acts at a different location within the nephron) can be helpful. Hypokalemia is a common problem and may contribute to arrhythmia, especially among patients receiving digoxin. Replacement may be difficult if there is a coexisting magnesium deficiency. Digoxin has been shown to have some benefits, including a decreased rate of hospitalization, in the care of patients with normal sinus rhythm. No effect on mortality has been demonstrated.

Supplemental therapy: Angiotensin II antagonists are not approved for the management of heart failure but have been beneficial in some trials. Some clinicians have substituted them for ACE inhibitors when ACE inhibitors were suspected of causing a bothersome cough. In the recent RALES trial, the aldosterone antagonist spironolactone produced a highly significant reduction in mortality when added to standard therapy (ACE inhibitor, diuretic, and digoxin). The effective dose was 25 mg per day, much lower than the historical dosage.

b-Blockers have emerged as important therapy despite initial concerns about their negative inotropic effect. b-Blockers exert favorable effects through reduction of heart rate, suppression of the renin–angiotensin system, and resetting of abnormal sympathetic nervous system abnormalities. Trials of three different agents all showed significant reductions in mortality when b-blockers were added to standard therapy. One should start with the lowest possible dose and gradually advance over 1 to 3 months, as tolerated, to target doses (e.g., 100 mg metoprolol twice a day and 25 mg carvedilol twice a day).

Because sudden death accounts for 35% to 70% of the mortality in published studies of heart failure, the use of antiarrhythmic agents has been investigated. A mortality benefit with amiodarone has been reported but not conclusively established. For patients with symptomatic ventricular arrhythmia, implantation of a cardiac

defibrillator has been shown to be most effective in preventing sudden death.

Advanced heart failure: “Refractory” heart failure is progressive decompensation despite optimal medical therapy. In some cases, patients may respond to intravenous diuretics or intravenous dobutamine. Ventricular assist devices are being used as a bridge to cardiac transplantation, which is now a practical option limited chiefly by a shortage of donor hearts.

Chapter 66

APPROACH TO THE PATIENT WITH HYPOTENSION AND SHOCK

DEFINITIONS AND PATHOPHYSIOLOGY

Hypotension is the reduction of systemic blood pressure below the usual range. It becomes clinically important only when it elicits symptoms of decreased organ perfusion or when it is a manifestation of an underlying disease, such as hemorrhage or myocardial infarction. *Orthostatic hypotension* is defined as a reduction in systolic blood pressure of at least 20 mm Hg within 3 minutes of standing. It represents a failure of the usual circulatory compensations to upright posture (increases in heart rate, myocardial contractility, and vasoconstriction). *Shock* is a syndrome of inadequate organ and tissue perfusion due to extreme circulatory failure. The pathophysiologic mechanism may be hypovolemia, increased vascular capacitance, cardiac failure, or obstruction of blood flow. If the condition remains uncontrolled or progresses despite the maximal recruitment of compensatory mechanisms (those noted above, as well as an increase in renal salt and water retention), the patient enters a stage of tissue dysfunction, which eventually leads to cell injury and death.

CLINICAL FEATURES AND DIFFERENTIAL DIAGNOSIS

Orthostatic hypotension: Patients often have postural symptoms such as light-headedness, dizziness, blurred vision, or headache. Common causes include dehydration, effects of medications (such as phenothiazines, tricyclic antidepressants, diuretics, and antihypertensive drugs), autonomic dysfunction, blood loss and anemia, hypokalemia, deconditioning, and malnutrition. The history should focus on prior medical problems, medications use, alcohol consumption, and dietary habits. Patients with autonomic dysfunction also may have a history of constipation, urinary difficulties, sexual dysfunction, or night blindness. The physical examination should include evaluation of positional changes in heart rate. Patients whose pulse does not increase when they stand may have autonomic dysfunction. Careful cardiac and neurologic examinations also are essential.

Shock: The pulse may be rapid and faint. Because systemic hypoperfusion provokes intense dermal vasoconstriction, the skin appears pale to light blue and becomes cool to the touch. The palms are frequently moist. Myocardial ischemia is likely to occur. Ventilation–perfusion mismatches reduce the arterial oxygen content; hypoxemia is markedly exacerbated if adult respiratory distress syndrome develops. Cardiogenic forms of shock may cause pulmonary edema due to high left ventricular filling pressure. Renal hypoperfusion decreases urine output and increases the blood urea nitrogen (BUN) to creatinine ratio to more than 10:1. If acute tubular necrosis develops, the urine output decreases further (less than 20 mL per hour), the BUN to creatinine ratio decreases to less than 10:1, and the urine sodium concentration usually exceeds 40 mEq per liter. Gastritis and stress ulcers are common. Intestinal infarction can occur. Hepatic hypoperfusion increases serum liver enzyme levels. The liver injury may evolve into hepatic necrosis in severe cases. Icterus is common. The patient's mental status may range from anxiety in mild shock to confusion, disorientation, and somnolence in moderate cases to obtundation and coma in prolonged or severe shock. Disseminated intravascular coagulation commonly accompanies terminal stages. Metabolic acidosis usually is caused by lactate production by underperfused muscle. A classification of shock according to causative factors is presented in [Table 71.2](#).

STRATEGIES FOR MANAGEMENT

Orthostatic hypotension: Reversible causes should be treated. Patients should be counseled to rise slowly and to perform isometric exercises of the extremities beforehand. Increasing dietary salt intake may improve symptoms by expanding intravascular volume. If these measures fail, salt tablets or fludrocortisone acetate may be effective in increasing intravascular volume. Patients with supine hypertension and orthostatic hypotension may respond to nonselective β -blockers, such as propranolol, which reduce the vasodilating effect of β -adrenergic stimulation.

Shock: The evaluation and management of shock are outlined in [Fig. 71.1](#). The physician must perform the initial evaluation and the initial treatment simultaneously. The choice among the possible diagnostic and therapeutic options is guided by the evolving clinical suspicion.

Chapter 71

MITRAL VALVE DISEASE

DEFINITIONS, EPIDEMIOLOGY, AND ETIOLOGY

Mitral Stenosis: Mitral stenosis (MS) implies valvular obstruction of left ventricular (LV) inflow. MS among adults is predominantly of rheumatic origin. Women are affected more than men.

Mitral regurgitation: Mitral regurgitation (MR) is an acute or chronic process of LV volume overload caused by incompetence of the mitral valve. Regurgitation due to abnormal leaflet anatomy can be caused by congenital or rheumatic disease, myxomatous degeneration, connective tissue disease, or infective endocarditis. Ischemic MR is caused by incomplete coaptation of the mitral leaflets due to ischemic changes in the function or geometric features of the LV. Any myopathic process that causes LV dilatation can cause MR by a similar mechanism. Acute, severe MR is caused by infective endocarditis, acute myocardial infarction with papillary muscle rupture, or prosthetic valve dysfunction.

Mitral valve prolapse: Mitral valve prolapse (MVP) is a fairly common syndrome of myxomatous degeneration of the mitral valve that produces redundant leaflets and elongation of the chordae tendineae. It occurs in 2% to 6% of the adult population, more commonly in women. There is evidence of an autosomal dominant inheritance pattern and an association with connective tissue diseases.

PATHOPHYSIOLOGY

Mitral Stenosis: The normal mitral valve area is 4.0 to 5.0 cm². Symptoms occur with exercise or tachycardia when the area is approximately 2.0 to 2.5 cm² but do not usually occur at rest until the area is 1.5 cm² or smaller. Obstruction to LV inflow causes left atrial (LA) dilatation, pulmonary venous and arterial hypertension, and right ventricular (RV) hypertrophy.

Mitral regurgitation: Blood is ejected from the LV into both the low-pressure LA and the high-pressure aorta. LV volume overload results. Forward cardiac output is maintained by means of compensatory LV dilation. The volume overload eventually leads to LV systolic dysfunction and pulmonary congestion. Because LV emptying does not rely on overcoming high aortic pressure, the stroke volume and ejection fraction remain normal despite progressive systolic dysfunction.

Mitral valve prolapse: Patients with MVP have a propensity to premature valve degeneration, leaflet flail, and mitral regurgitation. There is prolapse of the mitral valve into the left atrium during ventricular systole.

CLINICAL FINDINGS

Mitral stenosis: The first symptoms of rheumatic MS typically occur decades after an episode of rheumatic fever that may have been unrecognized or forgotten. There is usually another long period during which symptoms are present but mild. Early symptoms include fatigue or dyspnea precipitated by events with associated tachycardia (such as exercise, emotional stress, fever, pregnancy, or surgery). Later, dyspnea occurs with less strenuous activity and eventually at rest. Pulmonary edema may lead to orthopnea and paroxysmal nocturnal dyspnea and the production of frothy, pink sputum. Patients may notice palpitations caused by ectopic beats, paroxysmal atrial tachycardia, or atrial fibrillation. Late symptoms include hemoptysis (caused by rupture of small bronchial vessels in the setting of pulmonary

hypertension) and peripheral edema, ascites, and pleural effusion (from RV failure).

Neck vein distention is found at physical examination. The LV apical impulse is diminished or nonpalpable. Auscultation reveals accentuation of S₁ and usually an increase in P₂. The classic high-pitched opening snap occurs soon after the A₂. A low-pitched diastolic rumble occurs after the opening snap and is heard best at the LV apex with the patient in the left lateral decubitus position. Presystolic accentuation occurs in sinus rhythm. As the severity of MS increases, the opening snap occurs sooner after A₂, and the duration of the murmur increases. Late findings include hepatomegaly, ascites, pleural effusion, and peripheral edema.

Mitral regurgitation: Chronic MR remains asymptomatic for an extended period. Fatigue and exertional dyspnea eventually develop, followed by more overt symptoms of congestive heart failure, including orthopnea and paroxysmal nocturnal dyspnea. Patients with acute, severe MR almost always have fulminant symptoms of pulmonary edema. At examination, patients with chronic MR have a hyperactive precordium and a displaced LV apical impulse. An S₃ is often present and is not necessarily indicative of ventricular failure. The classic murmur is a loud, blowing, holosystolic murmur that may obliterate S₁ and S₂. It usually is loudest at the apex, and there is radiation to the axilla or back. The large volume of blood crossing the mitral valve in diastole may cause a diastolic rumble in the absence of mitral stenosis. In acute MR, the systolic murmur may be decrescendo rather than holosystolic because of early equilibration of LA and LV pressures in the presence of an LA of normal size.

Mitral valve prolapse: MVP can remain asymptomatic. Some patients have palpitations, usually from isolated ectopic beats or supraventricular tachycardia, or atypical, nonexertional chest pain. There are controversial associations between MVP and both transient ischemic attacks and panic attacks. The symptoms of MR also may be present. Patients with MVP classically have a thin body habitus, and there is an association with pectus excavatum. Auscultation reveals one or more high-pitched mid-to-late systolic nonejection clicks. If the patient has MR, the murmur begins in systole after the click.

DIAGNOSTIC STUDIES

Mitral stenosis: MS is associated with broadened, notched P waves in the inferior leads are caused by enlargement of the LA (P mitrale). Atrial fibrillation is common, and right axis deviation and RV hypertrophy may be evident. A chest radiograph shows apical redistribution and prominent vascularity in the lung parenchyma, interstitial edema, and peribronchial and perivascular cuffing. The cardiac silhouette has prominent pulmonary arteries. LA enlargement straightens the left heart border and splays the bronchi with elevation of the left main stem bronchus. The diagnosis is confirmed with echocardiography, including Doppler techniques. This modality also can be used to assess severity and associated cardiac abnormalities, such as LA and RV hypertrophy and pulmonary hypertension. Cardiac catheterization with coronary angiography is useful when a planned mitral valve operation may also include coronary artery bypass if severe coronary artery disease is demonstrated.

Mitral regurgitation: For patients with chronic MR, the ECG and chest radiograph may contain show evidence of LA or LV enlargement. Echocardiography with Doppler technique is the diagnostic test of choice and can be used to define severity and causation. Cardiac catheterization is useful for assessment of coronary anatomy in the care of patients at risk of coronary disease who are undergoing a mitral valve operation and in the care of patients with MR believed to be ischemic in origin.

Mitral valve prolapse: Echocardiography with Doppler techniques is the preferred diagnostic test.

PROGNOSIS AND STRATEGIES FOR MANAGEMENT

Mitral stenosis: The 10-year survival rate is more than 80% among patients with MS who are asymptomatic or have mild symptoms. Once debilitating symptoms occur, usually with associated pulmonary hypertension, prognosis is poor. The estimated survival rate becomes less than 3 years among patients who do not undergo surgical treatment. Mortality is related to progressive heart failure, pulmonary embolization, and infection. Patients should receive prophylaxis against endocarditis prior to procedures likely to cause bacteremia. Those with evidence of rheumatic heart disease should receive secondary prophylaxis against recurrent infection, usually with monthly intramuscular injections of 1.2 million units of penicillin G benzathine. Patients in sinus rhythm with symptoms at rapid heart rates may benefit from calcium channel blockers or b-blockers. Pulmonary congestion is treated with salt restriction and diuretics. Patients with atrial fibrillation or a history of prior embolization should receive long-term anticoagulation.

Mitral valve surgery is indicated for patients with moderate or severe MS along with intolerable symptoms, pulmonary hypertension regardless of symptoms, or recurrent thromboembolism despite adequate anticoagulation. Mitral valve replacement is indicated only for patients who should not undergo percutaneous valvotomy or open commissurotomy, such as those with marked mitral regurgitation, left atrial thrombus, or extensive fibrosis of the mitral valve leaflets. Mechanical prostheses have greater durability but high thrombogenicity. Tissue prostheses have lower thrombogenicity, and thus no independent requirement for anticoagulation, but more limited durability than do mechanical prostheses.

Mitral regurgitation: Appropriate antibiotic prophylaxis should be used prior to procedures likely to cause bacteremia. Afterload-reducing agents may decrease the severity of MR by reducing the resistance to anterograde flow from the LV. Mitral valve surgery is indicated to treat patients with severe MR and either symptoms of heart failure or evidence of LV systolic dysfunction. Because preoperative LV systolic function is an important predictor of postoperative survival, patients without symptoms should be evaluated with echocardiography once a year and be referred for surgical intervention before the onset of systolic dysfunction. (Stroke volume and ejection fraction are poor markers of systolic function, however, because regurgitant flow allows LV emptying to be maintained despite progressive systolic dysfunction). The choice of surgical procedure includes mitral valve repair and mitral valve replacement with or without chordal preservation. Repair minimizes the use of prosthetic material and is associated with more favorable hemodynamics and a lower mortality rate, but it is a more technically demanding procedure and may not be feasible for all valves.

Mitral valve prolapse: Patients who have associated MR or leaflet thickening at echocardiography should receive antibiotic prophylaxis prior to undergoing procedures likely to cause bacteremia. Patients without symptoms need no additional therapy. b-Blockers often are useful for the management of palpitations. Patients who have had focal neurologic events who are in sinus rhythm and have no LA thrombus should receive antiplatelet therapy with aspirin. Longterm anticoagulation with warfarin is recommended for patients with no contraindications who have had a stroke or who have recurrent transient ischemic attacks while receiving aspirin.

[Chapter 77](#)

PERICARDIAL DISEASES

CLASSIFICATION

There are three broad pericardial syndromes—acute pericarditis, pericardial effusion and tamponade, and constrictive pericarditis.

PATHOPHYSIOLOGY AND DIFFERENTIAL DIAGNOSIS

Acute pericarditis: Most cases are of unknown origin and are assumed to be related to an unidentified viral infection. Bacterial, mycobacterial, fungal, and parasitic infections are relatively rare in the United States. Many cases are noninfective and occur after surgery (postpericardiotomy syndrome), myocardial infarction (Dressler syndrome), irradiation, or trauma. Other associations are with renal failure, collagen vascular disease, especially lupus erythematosus, and myxedema.

Pericardial effusion tamponade: Pericardial effusion often occurs as part of a general increase in extracellular fluid volume, as in congestive heart failure and nephrotic syndrome. It also occurs as a feature of almost every form of pericardial disease. Neoplasm accounts for about one-half of cases. The clinical consequences depend on the quantity of fluid and rate of accumulation. Cardiac tamponade occurs when the increased pressure within a pericardial effusion is sufficient to compress the heart and impede its diastolic filling. Acute tamponade is caused most frequently by hemopericardium associated with trauma, cardiac surgery, aortic dissection, or myocardial rupture.

Constrictive pericarditis: In constrictive pericarditis, the heart is compressed by solid tissue surrounding the heart. The solid tissue is usually scar tissue but can be malignant solid tumors and organizing blood. Any of the causes of pericardial disease can produce sufficient scarring to cause constriction. The most common causes

are irradiation therapy and cardiac surgery.

CLINICAL FEATURES AND DIAGNOSTIC EVALUATION

Acute pericarditis: Idiopathic or viral acute pericarditis often is preceded by a low-grade fever, sore throat, and myalgia. Anterior chest pain is the most prominent symptom. It is classically substernal and pleuritic, often sudden in onset and severe, and is partially relieved by sitting up. The corresponding finding at examination is pericardial friction rub. Definite pericardial rubs have both systolic and diastolic components, and the classic rub also has a third component in late diastole that is caused by atrial contraction. The characteristic ECG abnormalities are diffuse ST-segment elevation from subepicardial inflammation without reciprocal ST-segment depression and PQ-segment depression. Creatine kinase levels generally remain normal unless there is accompanying myocarditis. Erythrocyte sedimentation rate and white blood cell count often are elevated. Initial diagnostic studies should focus on ruling out bacterial infection. A tuberculin skin test usually is indicated. Cultures of blood and other tissue are indicated when the degree of fever and leukocytosis and the severity of the illness suggest that purulent pericarditis is a reasonable possibility. Screening tests for rheumatic conditions, hypothyroidism, and renal failure may prove useful.

Cardiac tamponade: Hemopericardium generally manifests with sudden hypotension and elevation of venous pressure. Tamponade associated with medical conditions such as idiopathic or infective pericarditis, neoplasm, renal failure, or collagen vascular disease usually manifests in a less acute manner. The principal symptom is dyspnea, which occurs despite clear lungs. Pleural effusion often is present. Jugular venous pressure is nearly always elevated. The other key finding is the paradoxical pulse, an inspiratory decline of more than 10 mm Hg in systolic blood pressure. An electrocardiogram (ECG) often shows low amplitude of the complexes. Beat-to-beat alternation in the amplitude of the QRS complexes (electrical alternans) often is a specific sign. Except in very acute cases, a chest radiograph shows enlargement of the cardiomeastinal silhouette. Echocardiography is the most valuable diagnostic procedure for detecting pericardial effusion. Specific findings, such as collapse of the right atrium and ventricle in early diastole, also suggest tamponade.

Constrictive pericarditis: Patients usually have at least mild dyspnea and impaired exercise tolerance. Ankle edema, ascites, congestive hepatomegaly, and pleural effusion may occur. Because these patients often are younger and have less venous insufficiency, they frequently have less ankle edema than patients with more common forms of heart disease. Examination reveals elevated jugular venous pressure in almost every case. The venous pulsation shows a prominent brief dip in early diastole and an increase with inspiration (Kussmaul sign). Auscultation shows a pericardial knock, an abnormal extra heart sound in early diastole. Paradoxical pulse is not prominent in most patients. The ECG findings are not distinctive. The chest radiograph usually shows normal heart size and clear lungs.

Echocardiography is helpful chiefly in excluding cardiac disease or pericardial effusion. Computed tomography and magnetic resonance imaging have better resolution than echocardiography and provide a more accurate assessment of the thickness of the pericardium. Findings at cardiac catheterization can support the diagnosis and indicate severity. The classic finding is diastolic pressure equalization in all cardiac chambers and dip-plateau pressure waveforms in the right ventricle. Some patients with amyloidosis or idiopathic restrictive cardiomyopathy have findings at cardiac catheterization and angiography that closely resemble those of constrictive pericarditis. A myocardial biopsy or exploratory thoracotomy may be necessary.

MANAGEMENT

Acute pericarditis: Idiopathic or viral pericarditis usually is self-limited. Treatment is directed primarily at symptom relief. After initial use of narcotics to relieve the pain, aspirin should be prescribed for its analgesic and anti-inflammatory effects. In severe cases, glucocorticoids may be necessary. Bacterial forms must be managed with antibiotics and surgical drainage. Cases associated with uremia, malignant tumors, and rheumatic disease respond to specific therapies for the underlying condition.

Pericardial tamponade: Although the circulation may be supported temporarily by fluid infusion, only removal of pericardial fluid is consistently effective. Needle pericardiocentesis is less traumatic than surgical drainage, but surgical drainage is more likely to be effective and provides a specimen for pericardial biopsy.

Constrictive pericarditis: In mild cases, fluid retention can be controlled with diuretics alone. In general, however, surgical pericardiectomy is the only effective treatment. It can be a difficult operation with high morbidity and mortality.

Chapter 79

PULMONARY HYPERTENSION AND COR PULMONALE

DEFINITIONS

Pulmonary hypertension is defined as a mean pulmonary artery pressure exceeding 25 mm Hg at rest or 30 mm Hg during exercise. Cor pulmonale is best defined as pulmonary hypertension in the setting of chronic respiratory disease. Right-sided heart failure is a late manifestation.

ETIOLOGY AND DIFFERENTIAL DIAGNOSIS

The causes of pulmonary hypertension can be categorized according to the primary circulatory site affected. Postcapillary pulmonary hypertension is caused by obstruction of pulmonary venous return (e.g., left ventricular failure, mitral or aortic valve disease, left atrial myxoma, and pulmonary veno-occlusive disease). Precapillary pulmonary hypertension is caused by obstruction, constriction, or obliteration of a substantial component of the pulmonary arterial tree (e.g., parenchymal lung diseases, sleep apnea and hypoventilation syndromes, high altitude disease, intracardiac septal defects, massive or chronic pulmonary embolism, pulmonary vasculitis, and primary pulmonary hypertension). Primary pulmonary hypertension is a rare disease in which there are substantial elevations in pulmonary artery pressure in the absence of known causative factors. It is characterized by a spectrum of vascular lesions, from medial hypertrophy of small pulmonary arteries and intimal proliferation of pulmonary arteries to more severe destructive vascular abnormalities such as fibrinoid necrosis. Primary pulmonary hypertension occurs with greater frequency among women, particularly during the childbearing years, and in some families. An association with the diet drugs fenfluramine and dexfenfluramine has been demonstrated.

CLINICAL FEATURES

Symptoms: The symptoms of pulmonary hypertension usually are nonspecific. Patients with chronic respiratory disease in whom cor pulmonale develops may come to medical attention merely with a worsening of their previous symptoms. Exertional dyspnea, tachypnea, chest pain, and light-headedness are common and are related to the increase in right ventricular (RV) work. Syncope, pedal edema, and ascites are indicative of more critical impairments in RV function. Hemoptysis, from small-vessel rupture, occurs occasionally among patients with precapillary pulmonary hypertension but is more common among those with postcapillary pulmonary hypertension. Hoarseness can be caused by compression of the left recurrent laryngeal nerve by enlarged proximal pulmonary arteries. Some patients with connective tissue disease or primary pulmonary hypertension have Raynaud's phenomenon.

Physical examination: There may be findings referable to underlying diseases. Jugular venous distention may be present (a prominent c_v wave indicates tricuspid insufficiency). RV enlargement may cause a parasternal lift. The P_2 is loud, and there may be a pulmonic ejection click. An S_3 may be heard at the left parasternal region in RV failure and an S_4 in severe pulmonary hypertension. The murmur of tricuspid insufficiency frequently is audible, as is the Graham Steell murmur of pulmonic insufficiency. Venous congestion may cause tender hepatomegaly. Ascites and lower extremity edema indicate overt RV failure in the absence of other causes. Digital clubbing is common among patients with chronic obstructive lung disease, pulmonary fibrosis, cystic fibrosis, and congenital heart disease but is uncommon in primary pulmonary hypertension and thromboembolism.

DIAGNOSIS

The diagnostic approach involves establishing the presence and severity of pulmonary vascular disease and clarifying its cause. Primary pulmonary hypertension may be diagnosed when pulmonary hypertension exists in the absence of significant parenchymal lung disease, thromboembolic disease, or congenital or left-sided cardiac disease.

Cardiac testing: The ECG usually shows RV hypertrophy and P pulmonale, though the latter (a P wave greater than 2.5 mm in amplitude in inferior leads) is not

specific for pulmonary hypertension. Echocardiography is a useful noninvasive procedure. Chamber size and wall motion can be assessed, and Doppler technique allows accurate evaluation of the function of the tricuspid and pulmonic valves. It also provides information about left ventricular and mitral valve function. A right-to-left shunt can be found with a bubble study. Pulmonary artery systolic pressure can be estimated with Doppler techniques, but these measurements are not consistently reliable.

Pulmonary testing: The chest radiographic findings of pulmonary veno-occlusive disease include signs of pulmonary edema and Kerley B lines. Pulmonary function tests and assessment of arterial blood gases are useful in detecting unsuspected or worsening respiratory disease. Sleep studies can be used to exclude sleep apnea syndromes. Ventilation–perfusion scanning is critical. The perfusion scan is essentially normal in primary pulmonary hypertension but may show patchy abnormalities in veno-occlusive disease or multiple defects in recurrent or unresolved thromboembolism. Patients with suspected thromboembolism should undergo pulmonary arteriography to clarify the diagnosis and determine the extent and site of the clot. The role of lung biopsy in the evaluation of unexplained pulmonary hypertension is controversial. Biopsy findings can establish the presence of subclinical interstitial disease, pulmonary vasculitis, or small-vessel thromboembolism.

Laboratory tests: A low titer of antinuclear antibody occurs among about 25% of patients with primary pulmonary hypertension. The presence of polycythemia suggests hypoxemia. Detailed coagulation studies should be performed for patients with recurrent or unresolved thromboembolism.

PROGNOSIS AND MANAGEMENT

Coexisting pulmonary hypertension in the setting of chronic respiratory disease is a poor prognostic sign; death commonly occurs within 3 to 5 years of the onset of disease. The median survival time from the initial diagnosis of primary pulmonary hypertension is 2 to 3 years. It depends more on RV function than on pulmonary artery pressure.

Underlying conditions should be treated with agents such as bronchodilators, mucolytics, and glucocorticoids. Supplemental oxygen may be indicated for patients with resting or exertional hypoxemia. Chronic hypoxemia can cause polycythemia and worsening of pulmonary hypertension. Isovolumic phlebotomy is recommended if the hematocrit exceeds 50%. Digitalis is of limited value in isolated RV dysfunction but may be useful therapy for biventricular failure or control of supraventricular tachyarrhythmias. Diuretics must be used cautiously, because the RV is sensitive to reductions in preload. Unless use of anticoagulants is contraindicated, patients with pulmonary hypertension due to thromboembolism and primary pulmonary hypertension should be treated with anticoagulants, usually warfarin, for life. The use of anticoagulants to manage other causes of pulmonary hypertension is controversial.

Vasodilators: A variety of vasodilators have been used cautiously with mixed results. They usually increase cardiac output but produce little change in pulmonary artery pressure. Most patients notice improvement in symptoms when cardiac output increases. Therapy must be discontinued if systemic hypotension, an increase in pulmonary artery pressure, or worsened hypoxemia develops. Prostaglandin I₂ (PGI₂) is a potent, short-acting, titratable vasodilator that is administered intravenously. Patients who respond to PGI₂ infusion with decreases in pulmonary artery pressure or pulmonary vascular resistance seem to have similar responses to therapy with orally active drugs such as nifedipine and diltiazem. PGI₂ has been used in continuous infusion for the management of severe pulmonary hypertension and may be particularly useful as a bridge to transplantation. Inhaled nitrous oxide, the endothelium-derived relaxing factor, has been used to test vascular reactivity initially and to treat patients with severe pulmonary hypertension for brief periods.

Transplantation: Combined heart–lung transplantation has been performed successfully on patients with primary pulmonary hypertension or Eisenmenger syndrome. Single- or double-lung transplantation has been performed successfully on patients with less severe impairment of RV function.

Chapter 80

APPROACH TO THE PATIENT WITH SYNCOPE

DEFINITION AND PATHOPHYSIOLOGY

Syncope is a sudden transient loss of consciousness associated with a loss of postural tone and a spontaneous recovery. Most episodes are the result of reduced blood flow to the brain centers responsible for the maintenance of consciousness. Decreased cerebral blood flow is usually the result of one of four physiologic abnormalities: disorders of vascular tone or blood volume, cardiopulmonary mechanical disorders, cardiac arrhythmias, and cerebrovascular disease. Syncope can occur with normal cerebral blood flow when there is a lack of essential nutrients required for cerebral metabolism (e.g., hypoglycemia and hypoxemia). Some of the causes of syncope are presented in [Table 69.1](#). Vasovagal syncope, a common cause of syncope among otherwise healthy persons, is thought to be caused by inappropriate bradycardia and vasodilation in the face of declining arterial pressure.

DIFFERENTIAL DIAGNOSIS

Seizures can mimic syncope. They account for loss of consciousness among 5% to 10% of patients in most studies. Seizures often can be differentiated from syncope by the presence of an aura, the maintenance of muscular tone during the episode, and the presence of drowsiness and confusion after an episode. Tongue-biting may occur. Hysterical fainting and other neuropsychiatric disorders also can mimic syncope. These episodes usually occur in the presence of observers, typically in emotionally charged situations, and rarely result in physical injury. Anxiety with hyperventilation may decrease cerebral blood flow owing to hypocapnea. Diagnostic clues include digital and circumoral numbness and tingling and lack of relief from light-headedness with recumbency. Unlike most patients with syncope, those with metabolic disorders such as hypoglycemia, hypoxemia, and hypercapnea typically have both a gradual onset of symptoms and a gradual recovery.

CLINICAL FEATURES

The interview is the cornerstone of the evaluation. Specific historical issues and key elements of the physical examination are summarized in [Table 69.4](#).

Vasovagal syncope: Vasovagal syncope often is preceded by a prodromal period that lasts for as long as a few minutes. The person, who is almost always sitting or standing, experiences weakness, nausea, diaphoresis, light-headedness, and often a sense of impending darkness. Tachycardia, decreased blood pressure, and pallor usually occur at the beginning of the episode. Cardiac slowing ensues, as does diaphoresis, pupillary constriction, and syncope. The duration of unconsciousness rarely is longer than a few minutes. A variety of factors may precipitate vasovagal syncope, including a hot or crowded environment, the effects of alcohol consumption, extreme fatigue, hunger, long-term recumbency, prolonged standing, and emotional or stressful situations.

Cardiac arrhythmias: Syncope is uncommon unless the heart rate drops to less than 30 beats per minute or exceeds 180 beats per minute. Syncope associated with tachyarrhythmia or bradyarrhythmia often occurs with little or no warning. Supraventricular arrhythmia rarely causes syncope in the absence of associated cardiovascular disease.

DIAGNOSTIC EVALUATION

Laboratory findings: Serum electrolyte and plasma glucose levels and the hematocrit sometimes help to establish the cause of syncope. The presence of hypokalemia makes arrhythmia more likely. Cardiac enzymes should be evaluated for patients with a history that suggests myocardial infarction. Blood and urine toxicology screens may reveal the presence of alcohol or other drugs.

Electrocardiogram: The electrocardiogram (ECG) at the time of evaluation may reveal arrhythmia, but it more commonly shows a sinus rhythm. Nevertheless, an ECG may provide clues such as a prolonged QT interval or Q waves. Hospitalized patients should undergo continuous ECG monitoring unless the suspicion of cardiac arrhythmias is very low. Holter monitoring is appropriate for patients undergoing outpatient evaluation, although the diagnostic yield diminishes dramatically after the first 24 to 48 hours of monitoring. It is important to correlate any arrhythmias with a diary of the patient's symptoms. Event recorders are small ECG monitors that the patient can carry for weeks, if necessary. The recorder can be activated by the patient when symptoms of palpitation or light-headedness occur.

Other tests: Other diagnostic tests may be indicated for selected patients. A signal-averaged ECG can help identify electrical signals that indicate a substrate for ventricular tachycardia; it is most useful in the care of patients with a history of myocardial infarction. Exercise testing may help detect ischemia or exercise-induced arrhythmias but should not be used in the care of patients who may have aortic stenosis or hypertrophic cardiomyopathy. Electrophysiologic studies are invasive tests

that can provide diagnostic and prognostic information about sinus and atrioventricular node function, conduction pathways, and a variety of types of arrhythmia. Depending on the group studied, electrophysiologic studies can help identify the cause of syncope in 12% to 70% of cases. Echocardiography with Doppler examination is useful for diagnosing or excluding many cardiac mechanical causes of syncope, such as valvular and pericardial disease, atrial myxoma, and hypertrophic cardiomyopathy. Patients with regional wall motion abnormalities and diminished left ventricular function are at higher risk of ventricular arrhythmias than those with normal echocardiograms. The upright tilt-table test often induces syncope among patients with vasovagal events (sensitivity 75%, specificity 93%). The addition of intravenous isoproterenol increases the sensitivity of the test at the cost of some of its specificity. Cardiac catheterization is necessary in the care of some patients to determine the presence and severity of coronary artery disease or the anatomic basis for an abnormality detected by noninvasive means. Electroencephalography, carotid ultrasonography, and computed tomography of the head rarely are helpful.

OPTIMAL MANAGEMENT

Treatment depends on the specific cause of the syncope and the frequency and severity of the episodes. Until it is clear that the syncope has been effectively controlled, patients should avoid operating automobiles or heavy mechanical equipment. Therapy for vasovagal syncope includes β -blockers and disopyramide, which are thought to act by decreasing myocardial contractility. Other agents that have been used include theophylline, scopolamine, and ephedrine. Mineralocorticoids, salt loading, and support stockings may be effective for patients in whom hypovolemia or venous pooling initiates, vasovagal syncope.

Chapter 69

SYSTEMIC HYPERTENSION

DEFINITION

Chronic elevations in blood pressure to more than 140/90 mm Hg are regarded as hypertension. However, the relation between blood pressure and morbidity is continuous rather than dichotomous, and the optimal blood pressure has not been established conclusively.

EPIDEMIOLOGY

The prevalence of hypertension ranges from about 20% among white Americans to almost 40% among blacks. Blood pressure increases with age; more than 60% of Americans older than 65 years have hypertension.

ETIOLOGY

Genetic and environmental factors may interact to increase blood pressure. A hereditary risk has been well demonstrated. Some persons also seem to have a sensitivity to high sodium intake, alcohol consumption, oral contraceptives, nonsteroidal anti-inflammatory agents, exogenous glucocorticoids, and the sympathomimetic agents in decongestants and appetite suppressants.

PATHOGENESIS AND PATHOPHYSIOLOGY

Primary, or essential, hypertension: Primary hypertension accounts for more than 90% of cases. It results from an alteration in one or more of the following: extracellular fluid volume, renal function, vasoactive factors and peripheral resistance, and cardiac output.

Secondary hypertension: Uncommon, but potentially curable, causes of hypertension include two forms of renal vascular hypertension: an atherosclerotic narrowing of one or both renal arteries (common among older patients) and stenosis from fibromuscular dysplasia (more common among young women). Decreased renal perfusion stimulates renin release, raises peripheral resistance, and prompts reabsorption of sodium and water. Primary aldosteronism, usually from an adrenal adenoma or hyperplasia, also induces salt and water retention. In pheochromocytoma, hypertension is caused by increased production of catecholamines, usually norepinephrine, and consequent increased cardiac output and peripheral vasoconstriction. Cushing's syndrome is produced by excessive adrenal corticosteroid production. Secondary hypertension also can be produced by coarctation of the aorta, hyperthyroidism, and the medications listed earlier.

CLINICAL FINDINGS

Most patients have no symptoms, and the only finding is the elevated blood pressure reading itself. The major effects of chronic hypertension can be separated into those caused directly by the increased pressure (cerebral hemorrhage, retinopathy, vascular rupture, left ventricular hypertrophy, and congestive heart failure), those caused by atherosclerosis (increased coronary, cerebral, and renal vascular resistance), and those caused by decreased blood flow and ischemia (myocardial and cerebral infarction and renal nephrosclerosis). A physical examination therefore may reveal nicking of retinal arterioles, a loud A_2 , and an S_4 . Malignant hypertension is rarely encountered at levels less than 160/110 mm Hg. Manifestations can include central nervous system effects (headaches, blurred vision, altered mental status, hemiparesis, seizures, and papilledema), cardiac effects (angina or acute pulmonary edema), and acute renal failure. The various forms of secondary hypertension should be considered when a patient has severe hypertension in an accelerated phase or when blood pressure control is difficult despite appropriate combination therapy and patient compliance. Paroxysmal headaches, sweating, and tachycardia suggest pheochromocytoma. Thyromegaly, cushingoid appearance, and midepigastriac bruit also suggest secondary forms of hypertension.

LABORATORY FINDINGS

Screening tests include urinalysis and measurement of blood urea nitrogen and creatinine to detect renal disease, fasting glucose because diabetes often coexists with hypertension, serum potassium when the patient is not taking diuretics (low value suggests hyperaldosteronism or renal artery stenosis), and electrocardiography (left ventricular hypertrophy suggests long-standing hypertension). Specific imaging studies and laboratory tests are used to diagnose the secondary forms of hypertension.

MANAGEMENT

Nonpharmacologic therapy: The most recent recommendations of the Joint National Committee on High Blood Pressure are to use nonpharmacologic interventions, including weight loss, exercise, and reduction of sodium and alcohol intake, when blood pressure reaches a persistent level of 140 mm Hg systolic or 85 mm Hg diastolic. In the absence of target-organ damage, concomitant cardiovascular disease, or diabetes mellitus, these interventions also can be used to manage mild hypertension (diastolic pressure 90 to 95 mm Hg).

Pharmacologic Therapy: One approach to the initiation of antihypertensive therapy is presented in [Fig. 30.1](#) Because some side effects are dose dependent, it often is wise to add a second drug before reaching the maximum dose of the initial agent. Combination therapy is more effective when drugs of different classes are used. Diuretics are the first choice for patients who are sensitive to sodium, particularly blacks and elderly persons. The starting dose of hydrochlorothiazide is usually 12.5 to 25 mg per day. Potassium or a potassium sparing agent can be added. β -Blockers reduce blood pressure by reducing cardiac output and are most useful in the treatment of young patients with hyperdynamic circulation. Labetalol combines α - and β -blockade and is particularly useful in the emergency management of hypertension. Centrally acting sympatholytic agents such as α -methyldopa and clonidine can be useful adjuncts but are used infrequently because of side effects such as fatigue, depression, sleepiness, and dry mouth. Calcium channel blockers, angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers, and peripheral α -blockers reduce vascular resistance, usually without promoting tachycardia or fluid retention. Direct-acting vasodilators, including minoxidil and hydralazine, are used chiefly to manage refractory hypertension owing to their tendency to induce salt and water retention.

Special situations: Secondary forms of hypertension have specific therapies. Recent evidence supports reduction of blood pressure to levels at or below 130/85 mm Hg among patients with diabetes for preservation of renal function. For pregnant women with preexisting hypertension, dosages may have to be reduced because blood pressure normally drops in the first two trimesters. Pregnancy-induced hypertension usually occurs among young primigravidas after the twenty-seventh week. Centrally acting sympatholytic agents, peripheral α -blockers, and short-acting β -blockers can be used. ACE inhibitors and angiotensin receptor blockers are contraindicated during pregnancy.

VENTRICULAR ARRHYTHMIAS

DEFINITION AND CLINICAL PRESENTATION

Cardiac arrhythmias are disorders of the normal heart rhythm. Most commonly, they cause palpitations, an awareness of the heartbeat caused by abnormally strong ventricular contraction, a pause in normal rhythm, or extra beats. Less commonly, they can produce syncope, near-syncope, angina, congestive heart failure, or death.

SPECIFIC ARRHYTHMIAS

Premature ventricular complexes: A premature ventricular complex (PVC) is characterized by occurrence of a QRS complex that is bizarre in shape and has a duration usually exceeding the dominant QRS complex (typically more than 120 milliseconds). A large T wave opposite in direction to the major deflection of the QRS is present. A premature P wave does not precede the QRS, but a sinus P wave that occurs at its usual time may be present. A PVC usually does not discharge the atria and sinus node; therefore a fully compensatory pause follows it (a pause that exactly makes up for the prematurity of the PVC so that the R wave of the following, normal QRS falls when it otherwise would have). An aberrantly conducted supraventricular complex can mimic a PVC, PVCs with different contours are called *multiform* or *polymorphic*.

The prevalence of PVCs increases with age. Symptoms include palpitations, discomfort in the neck or chest from the supranormal contractile force of the postextrasystolic beat, or the feeling that the heart has stopped during the compensatory pause. PVCs can be produced by direct mechanical, electrical, and chemical stimulation of the heart. Coronary artery disease, myocarditis, medications, electrolyte imbalance, tension states, caffeine, tobacco, alcohol, and autonomic stimulation all can provoke PVCs. In the absence of underlying heart disease, PVCs have little importance, and patients do not have to be treated. Among patients with known heart disease, PVCs are a marker for higher mortality. Despite this fact, antiarrhythmic therapy with flecainide and encainide has been shown to increase mortality even as it suppresses PVCs. Thus PVCs may be only a marker for risk and not themselves the cause of the risk. When they produce intolerable symptoms, PVCs can be controlled with radiofrequency ablation or the medications used to manage ventricular tachycardia (VT).

Ventricular tachycardia: VT arises distal to the bifurcation of the His bundle. It is defined as three or more consecutive PVCs. The rate and duration of VT and the presence of associated heart disease help determine the symptoms, as does the location of impulse formation. Ischemic heart disease is the most common cause. VT can be nonsustained (stopping spontaneously in less than 30 seconds) or sustained. Atrioventricular dissociation may be present, during which atrial activity is independent of the VT, or the atria may be activated by retrograde conduction through the AV node. QRS complexes can be uniform or vary. The finding of wide-QRS tachycardia is not specific for VT; supraventricular tachycardia with aberrance (bundle-branch blocks and conduction over accessory pathways) is another cause. [Table 76.2](#) lists several electrocardiographic features that are useful in differentiating these two diagnoses. Prior probabilities must be considered; a wide QRS tachycardia occurring for the first time in a middle-aged man with a history of myocardial infarction has a greater than 90% chance of being VT. Torsades de pointes is a form of VT characterized by prolonged QT intervals and QRS complexes of changing amplitude that appear to twist about the isoelectric line and occur at rates of 200 to 250 beats per minute. Predisposing factors include severe bradycardia, potassium depletion, and use of class IA and IC antiarrhythmic agents.

VT that does not cause hemodynamic decompensation can be controlled with intravenous administration of lidocaine. Intravenous procainamide or bretylium can be administered next. Amiodarone is effective when given intravenously. Hypokalemia, ischemia, and hypomagnesemia should be corrected. If pharmacologic therapy is unsuccessful or hemodynamic decompensation is present, prompt direct-current electrical cardioversion is indicated. Competitive pacing also can be effective. Recurrent episodes usually are controlled with class I drugs (see *Atrial Arrhythmias*), sotalol, or amiodarone. Combinations of drugs with different mechanisms of action can be successful when single agents fail. Implantable defibrillators have been shown to be more effective than antiarrhythmic drugs for improving survival among patients who have had cardiac arrest or sustained VT. For selected patients, radiofrequency catheter ablation may be indicated. Management of VT with a polymorphic pattern is influenced by whether the QT interval is prolonged. If it is, the VT may be torsades de pointes, which is managed effectively by means of accelerating the ventricular rate, usually with pacing or isoproterenol. Magnesium infusions also are helpful.

Ventricular fibrillation: Ventricular fibrillation (VF) is severe derangement of the heartbeat that usually leads to death within 3 to 5 minutes unless it is terminated. VF probably accounts for more than 75% of sudden cardiac deaths (bradycardia and asystole account for the rest). VF is recognized by the presence of irregular undulations of varying contour and amplitude without distinct QRS complexes, ST segments, or T waves. Sometimes the fibrillatory waves are so small they simulate asystole. VF causes immediate loss of consciousness, seizures, apnea, and death. It occurs most commonly in association with coronary artery disease, administration of antiarrhythmic drugs, hypoxemia, and atrial fibrillation. Immediate nonsynchronized electrical shock with 200 to 360 J is mandatory treatment. Time should not be wasted with cardiopulmonary resuscitation if electrical defibrillation can be done promptly.

WOLFF–PARKINSON–WHITE SYNDROME

DEFINITION AND PATHOPHYSIOLOGY

Wolff–Parkinson–White (WPW) syndrome is a symptomatic preexcitation disorder in which muscular connections of working myocardial fibers exist outside the specialized conduction tissue and connect the atrium and ventricle. The atrial impulse travels through this tissue and activates the ventricle earlier than would be expected if the impulse traveled through the normal conduction pathway. In some cases, the pathway can conduct impulses only retrograde, from the ventricle to the atrium.

Preexcitation is associated with a variety of tachyarrhythmias. The most common is orthodromic reciprocating tachycardia, which occurs when a premature atrial complex conducts to the ventricle over the normal pathway and then returns to the atrium over a previously blocked accessory pathway to cause eccentric reactivation of the atria. Less commonly, the tachycardia can be antidromic, during which anterograde conduction occurs over the accessory pathway and retrograde conduction over the atrioventricular (AV) node. Approximately 15% to 30% of patients have atrial fibrillation.

EPIDEMIOLOGY

It is probable that acquisition of an accessory pathway is congenital. The prevalence is about 0.15% but is higher among relatives with WPW syndrome. WPW syndrome occurs in all age groups, has a higher prevalence among boys and men, and decreases in prevalence with age. Most adults with preexcitation syndrome have normal hearts.

CLINICAL MANIFESTATIONS

The clinical manifestations of these types of tachycardia range from palpitations and light-headedness to syncope, angina, and congestive heart failure. When the atrial impulse prematurely activates the ventricle, two major electrocardiographic (ECG) changes result: (a) the PR interval is less than 120 milliseconds during sinus rhythm and (b) the QRS complex lasts longer than 120 milliseconds and has a slurred, slowly rising QRS onset in some leads (delta waves). These abnormalities are not present, however, in patients who have concealed accessory pathways that are not capable of anterograde conduction. In orthodromic tachycardia, the QRS complex appears normal, but the retrograde P waves may have an unusual contour. In antidromic forms of tachycardia, the QRS complex is abnormal (as described earlier) owing to ventricular activation over the accessory pathway. Patients with atrial fibrillation have the characteristic ECG abnormalities of that rhythm, although conduction over the accessory pathway usually broadens the QRS and increases the ventricular rate.

PROGNOSIS AND MANAGEMENT

The prognosis is excellent among patients without tachycardia or an associated cardiac abnormality. For these patients, no therapy is indicated. For most patients with tachycardia, the prognosis is good, but sudden death does occur. Termination of the acute episode of orthodromic tachycardia should be as for AV nodal reentry

(vagal maneuvers, adenosine, calcium channel blockers, or short-acting b-blockers). For atrial flutter or atrial fibrillation conducted over the accessory pathway, drugs that prolong refractoriness in that pathway (class 1A, 1C, and amiodarone) must be used. For some patients with very rapid ventricular rates, electrical cardioversion should be the initial treatment of choice. Verapamil, digitalis, and lidocaine may increase the ventricular rate during atrial fibrillation in a patient with WPW syndrome, and intravenous verapamil can precipitate ventricular tachycardia. Atrial fibrillation among patients with a concealed accessory pathway is managed in the same manner as if the pathway were not present, because anterograde conduction is preceding only over the AV node and not the accessory pathway. Radiofrequency catheter ablation usually is the initial treatment of choice for patients with symptoms because it has an excellent success rate (95%) and a low complication rate (less than 2%).

APPROACH TO THE PATIENT WITH ABDOMINAL PAIN

CLASSIFICATION

There are three major types of abdominal pain—visceral, parietal, and referred. Visceral pain (e.g., pain from intestinal or ureteral obstruction or biliary colic) is perceived as dull, gnawing, or burning pain that is poorly localized. It may be elicited by numerous stimuli, such as muscle contractions or spasms, mural distention, ischemia, or necrosis. It is often described as an uncomfortable feeling rather than as pain and is frequently accompanied by autonomic disturbances such as nausea, vomiting, pallor, and diaphoresis. Patients often feel restless and attempt to move about to relieve the discomfort. Parietal pain (e.g., pain from peritonitis) is sharp, well-localized, and more intense. It is not usually associated with autonomic disturbances. Patients attempt to lie still, because even small movements often exacerbate the pain. Referred pain combines features of both visceral and parietal pain and is felt at sites distant to the involved organ. It is usually well localized and increases in intensity as organ damage progresses.

DIFFERENTIAL DIAGNOSIS

A list of causes of acute and chronic abdominal pain is presented in [Table 96.3](#). Disorders of the chest can mimic abdominal disorders and must be considered. Upper abdominal pain is common among persons with cholecystitis, pancreatitis, or peptic ulcer disease. Midabdominal pain may represent appendicitis, intestinal obstruction, or mesenteric vascular occlusion. Lower abdominal pain is commonly caused by appendicitis, diverticulitis, ureteral colic, ectopic pregnancy, or ovarian cyst torsion.

HISTORY

A carefully obtained history is the best initial diagnostic tool. [Table 96.2](#) characterizes some of the important types of acute abdominal pain. The presence of other symptoms also is useful for diagnosis. Acute viral gastroenteritis usually is accompanied by nausea and vomiting early in its course. Patients with small-bowel obstruction often vomit only after the onset of abdominal pain. Anorexia is an early symptom of appendicitis. Patients with mesenteric ischemia often have persistent anorexia and subsequent weight loss. Diarrhea often accompanies gastroenteritis and colitis. Bloody diarrhea usually suggests severe colitis caused by infection, ischemia, nonsteroidal anti-inflammatory drugs (NSAIDs), or inflammatory bowel disease. Alternating diarrhea and constipation is a classic presentation of irritable bowel syndrome. Lower abdominal pain and constipation together may be a sign of colonic neoplasm. Fever occurs with gastroenteritis, abscesses, cholangitis, and diverticulitis. Jaundice suggests biliary tract disease or hepatitis. Neurologic disturbances and photosensitivity occur with porphyria.

PHYSICAL EXAMINATION

The general examination may disclose findings that suggest certain etiologies factors. Such findings include fever, hypotension, jaundice, atrial fibrillation, and weak distal pulses. The abdominal examination begins with inspection for hernias, surgical scars, and distention. Diffuse peritonitis usually obliterates bowel sounds, whereas early intestinal obstruction produces tinkling, highpitched sounds. A succussion splash may be detectable in patients with gastric outlet obstruction. A midabdominal bruit may be audible in patients with an aortic aneurysm.

Palpation should begin lightly at an area distant from the region of greatest pain. It is important to increase pressure slowly and not abruptly. Rebound tenderness suggests peritoneal irritation, as does guarding. Percussion is useful to detect fluid or gas within the abdominal cavity and can be used to estimate the size of the liver and spleen.

Rectal and pelvic examinations always should be included in evaluations of acute abdominal pain. Intraabdominal disorders such as appendicitis may not initially involve the anterior abdominal wall and may first be detected during rectal examination. Stool should be tested for occult blood. Among women, a pelvic examination may reveal ovarian cysts or the cervical motion tenderness characteristic of pelvic inflammatory disease.

DIAGNOSTIC TESTS

The presence of anemia often suggests gastrointestinal bleeding, which may be occult. A complete blood cell count with differential should be obtained. The finding of leukocytosis with immature forms suggests infection, and eosinophilia suggests an allergic reaction or a parasitic infection. Urinalysis may suggest pyelonephritis or renal calculi. A urine pregnancy test should be performed for all women of childbearing age who have acute abdominal pain. Serum levels of electrolytes should be measured, and renal function tests should be performed. Amylase, lipase, and liver enzymes should be measured selectively. Elevated amylase and lipase levels suggest pancreatitis, whereas marked elevation of liver enzyme levels occurs with biliary obstruction and hepatocellular injury. Patients with ascites who have abdominal pain should undergo diagnostic paracentesis to determine whether they have spontaneous bacterial peritonitis.

Radiographic evaluation should be guided by the clinical signs and symptoms and the laboratory results. A series of plain abdominal radiographs is essential in the care of all patients with an acute presentation. These radiographs can depict abnormal gas patterns, as in small-bowel obstruction, and the presence of intraperitoneal free air caused by perforation of a viscus. Most renal calculi can be seen, but gallstones usually are radiolucent. An upright chest radiograph adds sensitivity to the detection of free intraperitoneal air and may depict signs of pneumonia or pleural effusion. Ultrasonography is particularly helpful in the diagnosis of cholelithiasis, biliary ductal dilatation, ovarian cyst, and ectopic pregnancy. Abdominal computed tomography is more expensive than ultrasonography but is the preferred method of detecting many intra-abdominal disorders, such as appendicitis and pancreatic cancer. It can also demonstrate changes that occur within the mesentery (e.g., fat stranding due to diverticulitis) or intestinal wall (e.g., ischemia).

Endoscopy should be used selectively. It is appropriate in the evaluation of chronic epigastric pain or lower abdominal pain accompanied by rectal bleeding. Cholangitis caused by an obstructing gallstone or mass may best be managed with emergency endoscopic retrograde cholangiopancreatography with stone extraction or biliary stenting. Diagnostic laparoscopy can be performed as an emergency procedure on extremely ill patients or an elective procedure on patients with chronic abdominal pain when the diagnosis remains elusive despite all noninvasive testing.

MANAGEMENT

Therapy for chronic abdominal pain of known causation is focused on management of the underlying pathologic condition and relief of the pain with medications, nerve block (e.g., celiac plexus block), or nerve stimulation. NSAIDs are less effective in the management of chronic abdominal pain than they are in that of musculoskeletal pain. Antidepressants and opioids have been used successfully. For patients who have chronic functional abdominal pain (no identifiable cause despite appropriate evaluation), the goal should be to improve quality of life, not necessarily to eliminate pain. A multidisciplinary approach is recommended. Continued diagnostic evaluation is unlikely to be fruitful.

[Chapter 96](#)

APPROACH TO THE PATIENT WITH ABNORMAL LIVER CHEMISTRIES

DEFINITIONS

Liver disease can be categorized into four main types—cholestatic, immunologic, hepatocellular, and infiltrative. Cholestasis can be categorized further as either a functional defect in bile formation at the level of the hepatocyte (intrahepatic cholestasis) or a structural impairment in bile secretion and flow (extrahepatic cholestasis). Depending on the target of the immune response, immunologic injury causes either cholestasis (the bile ducts are involved preferentially, as in primary biliary cirrhosis) or a hepatocellular form of injury (the primary insult is to the hepatocyte membrane, as in viral and autoimmune hepatitis).

There are three categories of liver tests. *Hepatic function tests* reflect the synthetic and excretory capabilities of the liver. They include measurement of albumin, immunoglobulins, clotting factors, bilirubin, and serum bile acids. *Serum markers* of hepatobiliary dysfunction serve as markers of hepatocellular necrosis, cholestasis, or infiltrative processes. They include measurement of transaminases (aspartate aminotransferase [AST] and alanine aminotransferase [ALT]), lactate dehydrogenase (LDH), alkaline phosphatase (AP), and other enzyme markers of cholestasis (g-glutamyl transpeptidase [GGTP] and serum leucine aminopeptidase [SLAP]). Evaluation of *disease-specific markers*, such as viral serologic testing, immunologic testing, measurement of ceruloplasmin, assessment of iron storage characteristics, measurement of α_1 -antitrypsin, and liver biopsy, helps determine the specific cause of any laboratory abnormalities.

MARKERS OF HEPATOBILIARY DYSFUNCTION

Transaminases: The AST and ALT are important markers of hepatocellular injury, but the levels are not predictive of histologic findings. AST is present in various tissues ([Table 104.3](#)), but ALT is limited to the liver, and elevation of the level of this enzyme therefore is a more specific indicator of hepatic injury. The highest levels of these enzymes are present in patients with viral, toxin-induced, or ischemic hepatitis. Smaller elevations (less than 300 U) occur with alcoholic hepatitis. As a rule, transaminase levels greater than 400 U indicate hepatocellular injury. In contrast, milder degrees of elevation are of little diagnostic benefit; they occur with cholestatic disorders as often as with acute and chronic hepatocellular disease. An AST/ALT ratio greater than 2 is highly suggestive of the existence of alcoholic liver disease. In most other conditions, a ratio less than 1 is typical.

Lactate dehydrogenase: Total LDH level has limited specificity for liver disease. Moderate elevations in LDH level often occur with hepatocellular disorders such as viral hepatitis and cirrhosis and are less common in cholestatic disorders. Fractionation of LDH to determine levels of the hepatic isoenzyme (LDH-5) is occasionally useful.

Alkaline phosphatase: In the liver, AP is produced by cells that line the bile canaliculi. Hepatocellular injury causes increases in AP level, but elevations more than four times normal are typical with cholestatic syndromes. AP activity is not specific to the liver; the enzyme also is produced in bone, placenta, intestine, kidney, and leukocytes. However, liver and bone are the predominant sources among healthy persons.

Other markers of cholestasis: Although AP isoenzymes can be separated, alternative approaches are useful in clinical practice. Elevated serum levels of GGTP or SLAP generally establish the hepatic origin of an elevated AP level. These enzymes are produced in biliary tract cells but not in bone. Alcohol consumption increases GGTP level independently of any liver disease.

GENERAL APPROACH

Nonhepatic causes must be considered first ([Table 104.3](#)). Each type of liver disease is characteristically associated with a particular pattern of liver test abnormalities. Hepatocellular necrosis usually is characterized by marked elevations in transaminase levels, a normal or mildly increased level of AP, a normal to markedly increased bilirubin level, prolonged prothrombin time, and a decrease in albumin level if the condition is chronic. Cholestasis usually is associated with normal or mildly elevated transaminase levels, marked elevations in AP level, normal to markedly increased bilirubin level, prolonged prothrombin time responsive to vitamin K, and a normal albumin level. Infiltrative processes generally affect AP, though transaminase and bilirubin levels can be mildly elevated. The diagnosis of selected hepatobiliary disorders is reviewed in [Table 104.5](#). The most direct approach to the differential diagnosis of cholestasis is the use of abdominal ultrasonography to assess bile duct size followed by endoscopic retrograde cholangiopancreatography if biliary ductal dilatation is present. If the presence of infiltrative disease is suspected, imaging with abdominal ultrasound or abdominal computed tomography is an appropriate first step, although liver biopsy may eventually be necessary.

[Chapter 104](#)

ACUTE AND CHRONIC PANCREATITIS

DEFINITIONS

Acute pancreatitis is an acute inflammatory process that starts in the pancreas and variably involves peripancreatic tissues or remote organ systems. Chronic pancreatitis is an inflammatory process involving the pancreas that results in irreversible fibrosis of the gland and atrophy of both exocrine and endocrine tissue.

ETIOLOGY AND PATHOGENESIS

Acute pancreatitis: Gallstone disease and excessive alcohol use account for 70% to 80% of cases in industrialized countries. Other etiologic factors are listed in [Table 117.2](#). Acute pancreatitis is believed to begin as an autodigestive process within the gland that is caused by premature activation of digestive enzyme precursors. The result is acinar cell damage and necrosis and pancreatic edema and inflammation. Extension of the inflammatory process beyond the pancreas leads to local complications (e.g., inflammatory phlegmon, peripancreatic effusion, abscess formation, ileus) or systemic effects (e.g., hypovolemia, hypotension, respiratory failure, azotemia and oliguria, hypercalcemia, metabolic acidosis, and disseminated intravascular coagulation).

Chronic pancreatitis: In industrialized nations, alcohol consumption accounts for about 70% of cases. Other etiologic factors are chronic obstruction of the pancreatic duct, genetic hyperlipidemia, pancreatic trauma, hyperparathyroidism, and cystic fibrosis. The pathogenesis remains uncertain. Gland fibrosis and atrophy often lead to malabsorption and diabetes mellitus. Other complications include pancreatic cancer (10-fold increased risk), splenic venous thrombosis, bile duct or duodenal obstruction, pancreatic ascites and pleural effusion, and pseudocysts.

CLINICAL FEATURES

Acute pancreatitis: Abdominal pain is present in 95% of cases. It is usually epigastric, radiates to the back, and is worsened by ingesting food or alcohol or by vomiting. Cessation of eating and drinking and leaning forward may provide some relief. Nausea, vomiting, and abdominal distention are frequent. Hematemesis, melena, and diarrhea occur infrequently. At examination, abdominal tenderness usually is present; it may be mild and limited to the epigastrium or severe and accompanied by abdominal rigidity and rebound tenderness. An uncommon finding is dissection of blood along fascial planes to subcutaneous tissues, which can cause bluish discoloration of the skin of the periumbilical region (Cullen sign) or flanks (Grey Turner sign). The patient may have fever, tachycardia, tachypnea, hypotension, and other manifestations of the systemic complications listed earlier.

Chronic pancreatitis: Pain is the most common presenting symptom; it is similar to that of acute pancreatitis. Nausea and vomiting may occur. About half of patients

have episodes lasting several days, the other have symptoms almost constantly. For some patients, the pain diminishes or resolves over 5 to 15 years, coincident with the appearance of pancreatic calcifications, steatorrhea, and diabetes (“burnout” of the gland). Patients typically lose weight because of decreased caloric intake, malabsorption due to pancreatic exocrine insufficiency, and poorly controlled diabetes mellitus. Physical examination usually shows abdominal tenderness of a degree less impressive than the amount of abdominal pain.

LABORATORY TESTING AND DIAGNOSIS

Acute pancreatitis: Serum amylase levels are the traditional diagnostic test but are neither fully sensitive nor specific for acute pancreatitis. Serum lipase level is as sensitive as amylase level and has greater specificity. A threefold or greater elevation in serum alanine aminotransferase level suggests gallstones as the etiologic factor. Computed tomography (CT) of the gland almost always has abnormal findings in moderate to severe disease. Dynamic CT has been used, but the criteria have not been standardized. After the diagnosis is established, the Ranson and the modified Glasgow criteria can be used to estimate severity and assess prognosis ([Table 117.4](#)).

Chronic pancreatitis: Chronic pancreatitis should be suspected when a patient has with the typical pattern and character of abdominal pain, particularly if accompanied by symptoms suggestive of steatorrhea or diabetes. Calcifications in the region of the pancreas are depicted on plain abdominal radiographs in about one-third of cases and can establish the diagnosis. Abdominal ultrasonography, CT, and endoscopic retrograde cholangiopancreatography (ERCP), in increasing order of sensitivity, cost, and invasiveness, can be used to confirm the diagnosis for patients without calcifications. The typical findings are tiny calcifications, dilatation of the pancreatic duct, and pancreatic pseudocysts. Endoscopic ultrasonography is the only modality that allows detailed evaluation of both the duct system and the parenchyma. Therefore it can be used to identify subtle changes in early disease not seen with other modalities. An alternative approach is assessment of pancreatic exocrine function by means of measuring the bicarbonate concentration in pancreatic juice collected before and after secretin infusion.

DIFFERENTIAL DIAGNOSIS

Acute pancreatitis: Various intra-abdominal processes may manifest similarly to acute pancreatitis and may even elevate serum amylase levels. These include penetrating duodenal ulcer, perforated gastric or duodenal ulcer, cholangitis, intestinal ischemia or infarction, and ruptured ectopic pregnancy. Ruptured abdominal aortic aneurysm may present with similar symptoms and signs.

Chronic pancreatitis: The differential diagnosis includes peptic ulcer disease, gastric or pancreatic cancer, chronic partial obstruction of the small intestine, and functional abdominal pain syndromes. Steatorrhea from pancreatic insufficiency must be differentiated from that caused by diseases of the small intestine.

MANAGEMENT

Acute pancreatitis: Most patients have a mild, self-limited course that necessitates only bed rest, cessation of oral intake, intravenous hydration, and analgesia (usually with narcotics such as meperidine). Nasogastric suction does not shorten the course but may relieve nausea, vomiting, and abdominal distention. Patients may be fed cautiously once abdominal pain and tenderness have abated and serum amylase and lipase levels have begun to return to normal. In severe cases, vigorous resuscitation with intravenous hydration and electrolytes may be necessary.

Patients with presumed gallstone pancreatitis should undergo urgent ERCP if cholangitis is suspected because of the presence of right upper quadrant pain, fever, or a leukocyte count greater than 20,000 per milliliter. There is no consensus currently on whether urgent ERCP should be performed within 24 to 72 hours of admission for patients with presumed gallstone pancreatitis of moderate to severe degree who do not have cholangitis. Agents that inactivate pancreatic enzymes, decrease pancreatic secretion (e.g., atropine or somatostatin), or reduce inflammation (e.g., glucocorticoids) have not been shown to be beneficial. Prophylactic administration of antibiotics is controversial; current evidence best supports the use of a combination of ciprofloxacin and metronidazole in the care of patients with predicted severe pancreatitis or suspected cholangitis. Pancreatic necrosis or abscess usually manifests more than 1 week after admission with worsening pain or vomiting, fever, or leukocytosis. After confirmation of disease by means of CT, such patients should undergo extensive debridement and drainage. About 10% to 15% of patients have a pseudocyst—an encapsulated collection of inflammatory fluid and pancreatic juice. If they cause only mild symptoms, pseudocysts may be followed with ultrasonography or CT for at least 6 weeks to determine whether they will resolve (about half do) or shrink without surgical intervention.

Chronic pancreatitis: Oral analgesics, including potent narcotics, often are needed for pain relief. Pancreatic enzyme supplementation sometimes reduces pain, presumably by inhibiting pancreatic secretion. Results of celiac plexus and splanchnic nerve blocks have generally been disappointing. Surgical resection usually improves pain but worsens pancreatic exocrine and endocrine insufficiency. Malabsorption is managed with a low-fat diet and pancreatic enzyme supplementation. Symptomatic pseudocysts and expanding pseudocysts larger than 6 cm in diameter should be managed with internal or percutaneous drainage.

[Chapter 117](#)

ALCOHOLIC LIVER DISEASE

DEFINITIONS, EPIDEMIOLOGY, AND ETIOLOGY

Alcohol abuse is one of the most important causes of chronic liver disease. Alcohol liver disease (ALD) includes three major histologic stages—fatty liver (or steatosis), hepatitis, and cirrhosis. Two or more of these stages often coincide. The peak incidence of ALD is at 40 to 55 years of age; the male to female ratio is about 3:1. Only about 35% of heavy drinkers contract alcoholic hepatitis and only about 20% develop cirrhosis. Both the amount of ethanol ingested and the duration of intake are important factors; the pattern of drinking and the type of beverage are not. Other factors postulated to increase susceptibility to ALD include female sex and an enhanced sensitivity of cytokine metabolism to the effects of alcohol. There is also a high prevalence of hepatitis B and C infections among persons with alcoholism and cirrhosis, suggesting an interaction between viral infection and the effects of ethanol.

PATHOGENESIS AND PATHOLOGY

The development of alcoholic fatty liver occurs largely because alcohol alters the hepatic NADH/NAD ratio and inhibits fatty acid oxidation. The effect is most pronounced on perivenous cells. The accumulation of fat is accompanied by an induction of microsomal proteins and fatty acid-binding protein and by the retention of secretory proteins and water. This causes the hepatocytes to swell (ballooning degeneration) and interferes with blood flow to the perivenous zone. The decreased flow coupled with increased oxygen consumption may induce perivenular hypoxia and thus pericentral necrosis and fibrosis. The development of alcoholic hepatitis and cirrhosis has been linked to a number of other pathophysiologic events as well.

The fatty liver is enlarged and firm. Microscopic examination shows great variation in the number of fat droplets found, and there is a distinct tendency toward fat accumulation in the perivenous and middle zones. There generally is little inflammation or necrosis. In alcoholic hepatitis, ballooning degeneration and focal hepatocyte necrosis occur, and a neutrophilic inflammatory infiltrate develops. About 30% of patients have alcoholic hyaline, which is aggregates of perinuclear, eosinophilic, amorphous material. The final stage is cirrhosis, which is characterized by fibrous bands connecting portal triads with central veins and by regenerating nodules, which are typically small and uniform in size.

CLINICAL FINDINGS

Alcoholic fatty liver: Hepatomegaly may be the only initial findings; however, signs of alcoholism (e.g., Dupuytren's contractures, testicular atrophy, loss of the male pattern of body hair, palmar erythema, spider angiomas, and gynecomastia) may be present. More advanced disease, most likely representing incipient progression to alcoholic hepatitis, may be associated with some of the symptoms and signs of alcoholic hepatitis.

Alcoholic hepatitis: Although a few patients have no symptoms, most have anorexia, nausea, malaise, weakness, abdominal pain, icterus, weight loss, and fever. Common physical findings include hepatomegaly, hepatic tenderness, splenomegaly, ascites, jaundice, and fever. Some patients have severe jaundice, ascites, azotemia, and hepatic encephalopathy.

Alcoholic cirrhosis: Alcoholic cirrhosis may be asymptomatic as much 20% of the time, but it more commonly manifests the complications of chronic liver

disease—cachexia, coagulopathy, ascites, spontaneous bacterial peritonitis, hepatorenal syndrome, hepatic encephalopathy, hepatocellular carcinoma, and gastrointestinal (GI) bleeding from esophageal and gastric varices. The physical findings associated with chronic liver disease and alcoholism may be present.

LABORATORY EVALUATION

Alcoholic fatty liver: Serum aspartate aminotransferase (AST) and alanine aminotransferase (ALT) levels usually are less than 300 IU per liter. The ratio of AST to ALT is 2 or more in 80% of cases. In the absence of cholestasis, alkaline phosphatase (AP) level is only modestly elevated (less than 300 IU per deciliter). A g-glutamyl transpeptidase to AP ratio greater than 5 is characteristic of ALD. The serum albumin level usually is normal. Macrocytosis is common among persons with alcoholism.

Alcoholic hepatitis: The laboratory abnormalities are more severe in alcoholic hepatitis. Anemia develops in 50% to 70% of cases and is caused by the toxic effects of alcohol on bone marrow, impaired vitamin B₆ metabolism, folic acid deficiency, iron deficiency from blood loss, or hypersplenism. Leukocytosis occurs in 25% to 75% of cases. Leukopenia and thrombocytopenia are present in 10% to 15%. Serum AST and ALT levels are elevated but rarely exceed 300 IU per liter. AP level is elevated in 80% of cases. Serum albumin level usually is decreased and the prothrombin time often is prolonged. Electrolyte abnormalities may include hyponatremia, hyperchloremia, hypokalemia, hypomagnesemia, and respiratory alkalosis.

Alcoholic cirrhosis: Liver enzyme abnormalities are less pronounced than those of alcoholic hepatitis. With compensated cirrhosis, many of the test results are nearly normal. Abnormalities include mild elevations in AST, ALT and AP levels; depression of serum albumin level; prolongation of prothrombin time; leukopenia; thrombocytopenia; and anemia.

DIAGNOSIS AND MANAGEMENT

There are two pitfalls in the diagnosis of ALD. The first is failure to consider the diagnosis when a patient does not fit the stereotype of a skid-row denizen with alcoholism; the second is the assumption that when an alcoholic patient has abnormalities in liver tests, these results are invariably due to ALD. Alcoholism should be considered for any patient with liver disease, and the interview should include either the CAGE questions or the MAST test as a means of screening for alcohol abuse. A liver biopsy is necessary to reliably differentiate among fatty liver, alcoholic hepatitis, and cirrhosis. Appropriate blood tests (see *Approach to the Patient with Abnormal Liver Chemistries*) and biopsy should be performed to exclude nonalcoholic causes of liver disease and to define the severity of the disease. If tense ascites, severe thrombocytopenia, or a prolonged prothrombin time precludes percutaneous needle biopsy, transjugular liver biopsy may be done.

Alcoholic fatty liver: This condition is benign unless accompanied by perivenular fibrosis or foamy degeneration. If the patient abstains from alcohol and nutritional deficits are corrected, the fatty changes usually regress within 6 weeks.

Alcoholic hepatitis: The early mortality rate varies from about 20% to about 80%. Those who have severe jaundice, encephalopathy, renal failure, ascites, and variceal bleeding have a worse prognosis. Certain laboratory abnormalities are prognostic indicators. For example, patients with Maddrey discriminant function (4.6 X [prothrombin time in seconds – control time] + serum bilirubin in milligrams per deciliter) greater than 32 have a 50% risk of death within 1 month. Other studies indicate that the presence of hepatic encephalopathy is equally predictive. Supportive treatment consists of cessation of alcohol consumption and a nutritious diet. Parenteral amino acid therapy or enteral amino acid–protein therapy have been shown to be beneficial for malnourished patients. Glucocorticoids (e.g., prednisone, 40 to 80 mg every day for 4 to 6 weeks) are indicated in the treatment of patients with hepatic encephalopathy or a Maddrey score greater than 32, excluding those with GI bleeding, active infection, or renal failure.

Alcoholic cirrhosis: The prognosis depends on whether the patient continues to drink, the coexistence of alcoholic hepatitis, and the severity of the disease. In one study, the 5-year survival ranged from 85% among abstainers without jaundice, ascites, or GI bleeding to only 20% among drinkers with GI bleeding. Therapy with glucocorticoids has no effect on survival. Prophylactic nonselective portacaval shunting merely shifts the cause of death from GI bleeding to hepatic coma. Colchicine therapy improved survival in one study and is under investigation. Advanced alcoholic cirrhosis can be managed by means of liver transplantation and now accounts for approximately 25% of liver transplantation procedures performed on adults in the United States.

Chapter 121

APPROACH TO THE PATIENT WITH CHRONIC LIVER DISEASE

DEFINITIONS

Hepatic cirrhosis is a diffuse pathologic process in which the normal structure of the liver is replaced by regenerative nodules of hepatocytes separated by bands of fibrosis. It may result from various hepatic diseases ([Table 105.1](#)).

PATHOGENESIS

The clinical features of cirrhosis occur as a consequence of portal hypertension, hepatocellular insufficiency, and cholestasis. Portal hypertension occurs when resistance to flow causes an increase in blood pressure within the portal vein; the level of the resistance may be presinusoidal, sinusoidal, or postsinusoidal. Hepatocellular insufficiency is a pathologic deficiency of hepatic protein synthesis coupled with the disordered metabolism of certain endogenous proteins and xenobiotics. Cholestasis is caused by impairment of bile secretion and specific defects in the secretion of anions.

CLINICAL FINDINGS

Portal hypertension: When portal pressure increases, collateral vessels (varices) in the lower esophagus, stomach, or rectum may dilate and become prone to hemorrhage. Portal hypertension also causes splenomegaly and hypersplenism, with a consequent sequestration of white blood cells and platelets. Ascites is the accumulation of serous fluid in the peritoneal cavity. Portal hypertension plays a role in the development of ascites, but other factors, such as altered renal sodium handling and a reduction in plasma oncotic pressure from diminished albumin secretion, also play a role. Ascites increases abdominal girth and causes rapid weight gain and occasionally dyspnea and early satiety. It is detected clinically when percussion of the abdominal flanks elicits dullness that moves as the patient changes position (shifting dullness) and when a fluid wave is detected. Small volumes of ascites (less than 1,500 mL) often are clinically undetectable. In such cases, an imaging study such as computed tomography (CT) or ultrasonography is needed for diagnosis. Hepatic encephalopathy occurs because of the transmission of portal blood to the right side of the heart through intra- or extrahepatic shunts. Although patients with encephalopathy often have elevated serum ammonia levels, it is still uncertain which substances are the actual mediators of the syndrome. Patients have a broad range of neuropsychological syndromes up to and including coma.

Hepatocellular insufficiency: Clinical manifestations include coagulopathy and hypoalbuminemia. The clinical manifestations of coagulopathy include easy bruising, bleeding from the gums and nose, and minor degrees of anorectal bleeding. Coagulopathy also may contribute to variceal hemorrhage. Hypoalbuminemia develops because of diminished hepatic synthesis, but malnutrition may play a role for some patients. The clinical consequences of hypoalbuminemia include ascites, cirrhotic hydrothorax, and peripheral edema. The reduced albumin concentration of ascites among patients with cirrhosis is thought to be an important factor in the pathogenesis of spontaneous bacterial peritonitis (SBP). Men may have both androgenic failure and feminization (e.g., gynecomastia); women often have anovulation and amenorrhea. Spider angiomas and palmar erythema are thought to be endocrine features of hepatocellular insufficiency.

Cholestasis: Cholestasis is characterized by pruritus, jaundice, and elevated levels of alkaline phosphatase. Hyperlipidemia occurs because of impaired excretion of cholesterol and phospholipids into bile. Fat malabsorption and steatorrhea may be caused by impaired bile acid delivery. Deficiencies of the fat-soluble vitamins (A, D, E, and K) may occur and cause altered vision, osteoporosis, and worsened coagulopathy.

Miscellaneous complications: Many forms of liver disease are complicated by disorders of bone metabolism. Hepatic osteodystrophy is particularly common in chronic cholestatic disorders such as primary biliary cirrhosis. Patients with cirrhosis also have a higher rate of infection; SBP is the most important among patients with ascites. SBP, which is usually caused by gram-negative aerobes or *Streptococcus pneumoniae*, must be suspected whenever a patient with cirrhosis has a sudden deterioration in hepatic or renal function, worsening malaise, encephalopathy, or unexplained leukocytosis, even in the absence of fever and abdominal pain. The diagnosis is confirmed when more than 250 neutrophils are found per microliter of ascitic fluid; demonstration of an organism is not required. Patients with

cirrhosis are at risk of hepatocellular carcinoma.

APPROACH TO CARE OF THE PATIENT WITH LIVER DISEASE

A careful history and physical examination may allow differentiation of acute from chronic liver disease and should allow the physician to form diagnostic hypotheses (Table 105.6).

LABORATORY EVALUATION

Profiles of serum transaminases, bilirubin, and alkaline phosphatase are not specific for diagnosis but indicate broader categories of liver injury, such as hepatocellular injury or cholestasis, which often coexist in a given patient. Specific serum tests exist for many of the hepatic diseases that can lead to cirrhosis (see *Approach to the Patient with Abnormal Liver Chemistries*). Liver imaging studies include sonography with Doppler technique, CT, magnetic resonance imaging, angiography, and CT angiography. All patients with putative chronic liver disease should undergo at least one baseline structural imaging study. Endoscopic retrograde cholangiopancreatography is the best method to differentiate primary sclerosing cholangitis from other chronic cholestatic processes. Histopathologic examination of liver tissue can be helpful in confirming the presence of cirrhosis or estimating the degree of activity of chronic hepatitis. It also may be helpful in making the diagnosis of specific conditions such as hemochromatosis, Wilson's disease, a₁ antitrypsin deficiency, autoimmune chronic hepatitis and primary biliary cirrhosis.

MANAGEMENT

Acute gastrointestinal hemorrhage, bacterial infection, and multisystem failure (particularly the combination of hepatic and renal failure) are the most common modes of death. Although therapy may control the initial decompensating event (e.g., sclerotherapy for bleeding varices or antibiotics for SBP), the measures do not change the long-term risk of death unless liver failure is corrected. Therapies that reverse liver failure include abstinence from alcohol for patients with alcoholic liver disease, glucocorticoids for autoimmune hepatitis, and specific therapies for metabolic disorders such as hemochromatosis and Wilson's disease. Liver transplantation has become the therapy of choice for end-stage liver disease, but use of this procedure has been limited by cost and by an inadequate supply of donor organs.

Bleeding esophageal varices: Patients with cirrhosis and features of portal hypertension should undergo endoscopy, because prophylactic therapy with noncardioselective b-blockade reduces portal pressure and the incidence of first or recurrent variceal hemorrhage among patients at high risk. Active variceal hemorrhage is always an emergency. Endoscopic ligation banding and injection sclerotherapy are the standard therapies, although balloon tamponade often is used to control persistent bleeding. Intravenous vasopressin (usually given with glyceryl trinitrate to limit cardiac effects) and IV octreotide produce splanchnic vasoconstriction and can help control hemorrhage. If bleeding persists or recurs, a transjugular intrahepatic portosystemic shunt (TIPS) is the treatment of choice.

Ascites: Management is directed at controlling fluid overload without precipitating renal failure and, for selected patients, at providing prophylaxis against SBP. Sodium intake should be limited to 2 g per day. Furosemide and spironolactone (usually in combination) are the diuretics most commonly used. Use of these agents necessitates careful monitoring of results of renal function tests and serum sodium and potassium levels. Intractable ascites is managed by means of intermittent, large-volume paracentesis. Albumin replacement (12.5 g for each liter of ascites removed) is controversial but is probably a reasonable precaution in the care of patients with an elevated serum creatinine levels. It has been shown that a functioning TIPS improves the control of ascites. Prophylactic therapy against SBP with quinolones and trimethoprim-sulfamethoxazole has been studied; a reasonable plan is to limit prophylaxis to patients who are awaiting liver transplantation, are considered to be at high risk of a first episode of SBP (e.g., have an ascites protein content less than 1 g per deciliter), or who have had a previous episode of SBP.

Hepatic encephalopathy: Acute exacerbations should always prompt a search for a precipitating cause, such as gastrointestinal bleeding, new-onset renal failure or electrolyte disturbance, infection, intracranial hemorrhage, or the administration of benzodiazepines and other central nervous system depressants. Lactulose is the mainstay of management. The dose should be titrated to produce two or three soft bowel movements a day. Metronidazole may be useful if lactulose is insufficient. Protein restriction should be reserved for management of disabling, severe encephalopathy.

Chapter 105

COLORECTAL CANCER

EPIDEMIOLOGY AND ETIOLOGY

Cancer of the large intestine (adenocarcinoma in 95% of cases) is the most frequent neoplasm of the gastrointestinal tract and the second most common cause of death from cancer in the United States. It occurs at some time in the lives of 5% to 6% of the population. Colorectal cancer is slightly more common among men than in women but is equal in frequency between blacks and whites. The incidence is very low before 40 years of age; thereafter the risk increases as an exponential function of age. The age-adjusted risk is higher among persons with affected first-degree relatives, especially if the relative had cancer before 45 years of age. That a relative had colorectal cancer after 60 years of age does not add substantial risk. There are many familial colorectal cancer syndromes, including familial adenomatous polyposis, hereditary nonpolyposis colorectal cancer (Lynch syndrome), and Peutz-Jeghers syndrome.

ETIOLOGY, PATHOGENESIS, AND STAGING

Colorectal cancer develops through a multistep accumulation of critical mutations in genes that regulate growth, such as the p53 gene. The tumors probably always evolve from adenomas, although not necessarily from polyps. Diets high in fat and low in fiber have been implicated as a factor in the high incidence of colon cancer in industrialized nations. The incidence is lower among persons who frequently use aspirin and nonsteroidal anti-inflammatory drugs than among persons who do not use these agents. The prognosis is directly related to the penetration depth of the malignant tumor rather than to the total tumor bulk. Colon cancers spread by direct extension through the wall of the intestine into the pericolic fat and mesentery, to the mesenteric lymph nodes, and through the portal vein to the liver. Additional spread may be evident throughout the peritoneal cavity, to the lungs, and to other distant sites. Rectal carcinoma spreads by means of direct extension into the perirectal fat and to the regional lymph nodes. It metastasizes to the liver or other distant sites somewhat less frequently. A number of different staging schemes of colorectal cancer have been used, including the Dukes classification, the Astler-Coller modification, and the tumor-nodes-metastasis (TNM) system.

CLINICAL FINDINGS

Early cancers produce no symptoms. Symptomatic colorectal neoplasia has three characteristic modes of presentation—lower intestinal obstruction (usually tumors of the sigmoid colon or rectum), hematochezia (usually distal tumors), and iron deficiency anemia (most often with cancers of the cecum or ascending colon). At physical examination, an abdominal mass or enlarged liver is found only when the patient has advanced disease. Occult bleeding may be detected by means of rectal examination. In rare instances, colon cancer perforates spontaneously and causes acute abdominal pain.

LABORATORY EVALUATION

Most early colorectal cancers are not associated with any laboratory abnormalities. Advanced cancer, especially from the cecum or proximal colon, may cause anemia. Adenocarcinoma can elevate the level of plasma carcinoembryonic antigen. This finding may help in assessment of residual or recurrent tumor burden, but it is not an effective screening test because it is neither sensitive nor specific for colorectal cancer.

PROGNOSIS AND OPTIMAL MANAGEMENT

Surgical therapy: Some colorectal tumors, particularly those found in adenomatous polyps, can be excised colonoscopically. Most necessitate surgical resection. Cancer of the cecum, ascending colon, and hepatic flexure is best managed with right hemicolectomy and ileocolonic anastomosis. Cancer of the distal transverse colon, splenic flexure, or proximal descending colon can be managed by means of extended right hemicolectomy or segmental resection. Cancer of the distal descending colon or sigmoid colon is managed by means of segmental resection and primary colonic anastomosis. Therapy for rectal cancer is more complex and depends on the location, depth, and size of the lesion. Cancer in the lower rectum may necessitate proctocolectomy and sigmoid colostomy.

Adjuvant therapy: Adjuvant therapy is used to prevent tumor recurrence among patients who have undergone successful resection. It is not indicated in the care of

patients with stage I or II tumors (those limited to the colonic wall and not associated with lymph node metastasis), because the cancer-free survival rate is already more than 80% and is not significantly improved by chemotherapy. Patients with regional lymph node involvement (stage III) should be treated with adjuvant chemotherapy, usually 5-fluorouracil combined with either levamisole or leucovorin. Such regimens improve the disease-free survival rate from about 50% to about 65% and delay the time of recurrence. Rectal cancer are more likely to be associated with the presence of progressive local disease after initial resection, especially resection of high rectal lesions when tumor is left behind in an attempt to preserve the rectum. Radiation therapy has been shown to decrease the recurrence rate in such cases. In some instances, preoperative chemoradiation therapy can be used to convert an apparently nonresectable tumor into one that can be removed surgically.

Metastatic colorectal cancer: If an isolated focus of metastatic disease is found in the liver, it is best managed by means of surgical resection. There are no successful modalities for management of widespread metastatic disease. Chemotherapy with 5-fluorouracil and other drugs may produce partial tumor shrinkage in 15% to 25% of patients but has not been shown to prolong survival. Radiation therapy may also be palliative in some cases.

SCREENING AND SURVEILLANCE

There is evidence that periodic screening with fecal occult blood tests (every 1 to 2 years) and sigmoidoscopy (every 3 to 5 years) decreases the incidence of fatal colorectal cancer. The optimal screening program for persons with a family history of sporadic colon cancer is not known. Annual or frequent colonoscopy for such patients, particularly in those with a single affected relative, has a low yield and a high cost per detected neoplastic lesion. Surveillance of patients who have undergone removal of adenomatous polyps is controversial. It is most important to initiate a follow-up program for patients who have had larger (more than 1 cm in diameter), multiple, or more dysplastic lesions removed. Such patients may benefit from colonoscopic examinations every 3 years.

Chapter 116

APPROACH TO THE PATIENT WITH CONSTIPATION

DEFINITION AND PATHOPHYSIOLOGY

Constipation is the most frequent digestive disorder in the United States. Patients may use the term to describe infrequent defecation (less than 2 to 3 bowel movements a week), dry stools, excessive straining, or a sense of incomplete evacuation. Constipation is caused by obstruction of the flow of luminal contents or by poor colonic propulsion.

DIFFERENTIAL DIAGNOSIS

Causes of constipation are listed in [Table 100.1](#).

HISTORY AND PHYSICAL EXAMINATION

Symptoms of hypothyroidism, collagen vascular disease, or diabetes may be uncovered. A careful medication history is essential. Examination includes anorectal examination for tumors, hemorrhoids, and fissures and assessment of rectal tone.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

Results of laboratory studies can confirm the existence of electrolyte or metabolic disturbances. If the results of initial evaluation suggest obstruction, a barium radiographic study or colonoscopy is performed. Once obstruction is excluded, treatment is attempted. Most patients improve, and no additional evaluation is necessary. Special studies are indicated for the minority of patients with severe constipation. These include marker transit studies, anal manometry, and defecography.

COMPLICATIONS AND MANAGEMENT

Chronic constipation plays a role in the development of rectal prolapse, anal fissures, hemorrhoids, ischemic colitis, and fecal incontinence. Contributing metabolic and pharmacologic influences must be removed; daily exercise should be encouraged. Patients should allocate a limited amount of time for defecation after a chosen meal. Daily fiber supplements taken with water should be tried for 2 to 3 weeks, although flatus and bloating may worsen temporarily. The next step is intermittent or short-term use of saline (magnesium citrate), lubricant (mineral oil), or osmotic (lactulose, polyethylene glycol) laxatives. Stool softeners are of marginal benefit. Stimulant laxatives (bisacodyl, senna) should be used for brief periods if at all, because they can damage myenteric neurons and cause dependency.

Chapter 100

APPROACH TO THE PATIENT WITH DIARRHEA

DEFINITIONS AND PATHOPHYSIOLOGY

Diarrhea can be defined as a stool output of more than 200 g per day. However, patients may use the term to describe bowel movements of increased frequency or that are loose in consistency. It is important, therefore, to differentiate true diarrhea from conditions, such as fecal incontinence or functional bowel disease, in which stools may be frequent or loose but are of normal total daily weight. Diarrhea is caused by two basic mechanisms—increased active anion secretion and decreased absorption of water and electrolytes. The former is caused by bacterial enterotoxins, hormones, neuropeptides, inflammatory mediators, bile salts, laxatives, and medications. The latter is caused by bacterial enterotoxins; ingestion of poorly absorbed, osmotically active solute, such as magnesium or lactose among persons with lactase deficiency; decreased absorptive surface from mucosal damage or intestinal resection; hypermotility and decreased contact time between luminal fluid and the mucosal surface; and impairment of mucosal barrier function that causes back flux of water and electrolytes into the intestinal lumen.

DIFFERENTIAL DIAGNOSIS

Acute diarrhea in normal hosts: Acute diarrhea (less than 2 to 3 weeks' duration) usually is caused by infection or ingestion of toxins, medications, or dietary products. The most common cause is infection due to viruses and food-borne toxins. Viral diarrhea usually occurs among children and their family members, whereas diarrhea due to food poisoning usually occurs within several hours of the meal. Pathogens that cause traveler's diarrhea usually are acquired through the fecal-oral route; these include enterotoxigenic bacteria (*Escherichia coli*, *Vibrio cholerae*), bacterial of genera *Campylobacter*, *Shigella*, and *Salmonella*, viruses, and parasites. Giardiasis is the most common parasitic infection in the United States. Sporadic waterborne outbreaks of cryptosporidiosis have occurred on farms and in cities. Bloody stool has a limited differential diagnosis that includes invasive bacterial enteritis (*Campylobacter*, *Shigella*, or *Yersinia* organisms), *Entamoeba histolytica* infection, exposure to cytopathic toxins (*Clostridium difficile*, *E. coli*, or Shiga toxin), inflammatory bowel disease, and ischemic bowel.

A number of drugs and dietary products cause acute diarrhea. Antibiotics are the most common. Only about 25% of cases of antibiotic-associated diarrhea are caused by *C. difficile* toxin; in the remaining cases, the cause is unknown. Other drugs commonly implicated include antacids, prokinetic agents such as cisapride and metoclopramide, and prostaglandins. Dietary substances that cause diarrhea include lactose (among persons with lactase deficiency), sorbitol (elixirs, dietetic candies, gum), fructose (pears, prunes, apple juice), and Olestra indigestible fat substitute.

Acute diarrhea in other settings: Immunocompromised hosts, such as patients with HIV infection and a CD4 cell count less than 150 per microliter, can acquire any of the infections mentioned earlier and are at risk of infection with cytomegalovirus (CMV), and organisms of *Mycobacterium avium* complex, *Cryptosporidium*, *Isospora belli*, *Microsporidia*, and *Cyclospora*. Diarrhea is common among patients treated with chemotherapy or abdominal radiation. Direct intestinal toxicity is the most common cause. Diarrhea occurs among 30% to 50% of patients in intensive care units and can be caused by antibiotics, other medications, fecal impaction, tube feedings, or the underlying disease. *C. difficile* infection is the most common cause of diarrhea among hospitalized patients; viral infections are the most common cause among nursing home residents.

Chronic diarrhea: Chronic diarrhea can be caused by malabsorption of nutrients or poorly absorbable solute, deranged water and electrolyte transport, or inflammatory disease of the intestine. [Table 99.6](#) lists some of the etiologic factors. Diarrhea due to malabsorption of nutrients or poorly absorbable solute usually is low in volume (less than 1 L per day) and diminishes with fasting. Secretory diarrhea usually is high in volume (more than 1 L per day) and does not improve with fasting. Inflammatory diarrhea with mucosal destruction is associated with the presence of blood and pus in the stool.

HISTORICAL FEATURES

One must first determine whether the patient truly has diarrhea and, if so, whether it is acute or chronic. Persons with irritable bowel syndrome or fecal incontinence often have frequent small stools of normal weight rather than diarrhea. Diarrhea usually is caused by organic illness if it is of recent onset, occurs daily or at night, or is associated with metabolic disturbances.

Associated symptoms: Low-grade fever occurs with viral or toxigenic diarrhea; high-grade fever may complicate invasive bacterial infection, amebiasis, CMV colitis, and inflammatory bowel disease. The existence of orthostatic light-headedness or weakness suggests that the patient has high-volume diarrhea. Weight loss in the setting of acute diarrhea implies fluid loss; in chronic diarrhea, it usually indicates nutrient malabsorption. Nausea and vomiting are associated most often with viral infection or food poisoning. Abdominal cramps can be caused by infection or by carbohydrate malabsorption. Severe abdominal pain occurs with invasive or cytopathic bacterial infection and intestinal ischemia. Blood in the stool indicates an infectious, inflammatory, or ischemic process. Associated neurologic symptoms occur with botulism and exposure to marine toxins (scombroid, ciguatera). Systemic manifestations of enteric bacterial infection include arthritis, urethritis, and conjunctivitis (*Salmonella*, *Shigella*, *Campylobacter*, *Yersinia*) and hemolytic-uremic syndrome (hemorrhagic *E. coli*, *Shigella*).

Settings: The setting in which diarrhea occurs provides important clues. Recent travel, restaurant dining, change in drinking water, or ingestion of imported or poorly cooked foods may point to an infectious cause. Diarrhea may occur with use of new medications, over-the-counter medications, herbal products, or changes in the diet. Associations with particular foods should be identified. Diarrhea due to *C. difficile* infection is common among hospitalized patients and nursing home residents and persons with a history of antibiotic use. Persons with compromised immune function may have diarrhea caused by common organisms or those unique to the impaired host. Among the elderly and persons predisposed to thrombosis, diarrhea with pain out of proportion to physical findings suggests the existence of intestinal ischemia. Questions should be asked routinely about previous abdominal operations, chemotherapy, or radiation therapy.

PHYSICAL EXAMINATION

Attention should be paid to vital signs, volume status, and the abdominal and rectal examinations. High fever raises the suspicion of the presence of invasive organisms. Hyperventilation may be a consequence of metabolic acidosis caused by the loss of bicarbonate in the stool. Patients with chronic diarrhea should be evaluated for signs of malnutrition and evidence of vitamin or mineral deficiency. These include weight loss, muscle wasting, tetany, oral and skin lesions, peripheral neuropathy, ataxia, and edema. The abdomen should be examined for distention, bowel sounds, tenderness, and masses. A stool swab for culture, when necessary, should be obtained before the rectal examination because lubricants contain bacteriostatic agents that can interfere with bacterial growth. The rectum should be examined for stool texture, masses, and sphincter tone. Stool should be tested for occult blood.

LABORATORY FINDINGS

Stool studies for the presence of intestinal inflammation include microscopic examination for fecal leukocytes and evaluation of the stool for occult blood; the former is less sensitive but more specific for inflammatory causes. Results of stool cultures are only positive among 40% to 60% of persons with dysentery; special culture techniques are needed for some pathogens. Stool can be examined for ova and parasites and tested for *C. difficile* toxin. Sudan staining is a qualitative test for fat in the stool; the results are valid only if the patient consumes a high-fat diet. The test is 90% sensitive for fat malabsorption greater than 10 g per day. Measurement of electrolytes in the stool is useful in differentiating secretory from osmotic diarrhea. The stool osmotic gap is calculated as follows: Stool osmotic gap = Stool osmolality – 2 X (stool [Na] + stool [K]). Because stool osmolality can be falsely elevated by laboratory processing delays, plasma osmolality, which is the same, usually is substituted.

Secretory diarrhea is characterized by high stool sodium (more than 90 mmol per liter) and bicarbonate concentrations and the absence of a stool osmotic gap. Osmotic diarrhea, in contrast, is characterized by low stool sodium concentration (less than 50 mmol per liter) and the presence of a stool osmotic gap greater than 100 mOsm per kilogram water. Measurement of stool volume over 24 to 48 hours while the patient fasts also provides useful information about whether the diarrhea is functional (less than 250 mL per day), osmotic (250 to 1,000 mL per day), or secretory (more than 1 L per day). Fluids should be administered intravenously during the fast. A stool pH less than 7.0 can indicate carbohydrate malabsorption or gastrinoma. A 72-hour stool collection for fat while the patient is consuming 70 to 100 g fat per day should be performed if there is a high suspicion of malabsorption despite a negative Sudan stain result. For patients with high-volume secretory diarrhea of undetermined origin, serum levels of gastrin, vasoactive intestinal polypeptide, somatostatin, cortisol, neurokinins, and calcitonin can be considered. For suspected carcinoid syndrome, serotonin and urine 5-hydroxyindoleacetic acid should be measured.

EVALUATION

Acute diarrhea in normal hosts: In cases of uncomplicated acute diarrhea in a normal host, no evaluation is necessary. Stool for ova and parasites should be obtained only when the history suggests exposure to parasites or when diarrhea does not resolve. When diarrhea is associated with fever, a screening test should be used to differentiate inflammatory from noninflammatory causes. A stool occult blood test is the easiest to perform. If there is a high suspicion that the patient has invasive bacterial enteritis, a stool culture should be obtained regardless of the result of stool screening studies. If the patient has bloody diarrhea, a stool culture should be obtained. If the result is negative, colonoscopy with biopsy is the next diagnostic procedure.

Acute diarrhea in other settings: For patients with compromised immune systems, stool should be obtained for culture and detection of parasites and *C. difficile* toxin. If fever is present, blood cultures for bacteria and fungus also should be obtained. When the patient has both blood in the stool and fever, and the result of initial stool studies are negative, full colonoscopy should be performed that includes collection of biopsy specimens of the colon and a stool aspirate for culture, detection of *C. difficile* toxin, and parasite examination. If the stool is watery, upper gastrointestinal endoscopy with duodenal aspiration and biopsy should be performed. Among hospitalized patients, *C. difficile* infection should be excluded and the medication list examined carefully. For patients with blood in the stool and negative results of *C. difficile* toxin tests, flexible sigmoidoscopy can be used to look for pseudomembranes. Stool culture and parasite examination are generally not recommended for patients who contract diarrhea in the hospital.

Chronic diarrhea: An informative history can provide the diagnosis (e.g., lactose intolerance or sorbitol ingestion) or can help streamline the evaluation. Initial tests include measurement of serum electrolytes and serum albumin, complete blood cell count, and the erythrocyte sedimentation rate. Stool should be tested for occult blood, ova and parasites, *Giardia* antigen, fat (Sudan stain), and phenolphthalein (to detect surreptitious laxative use). Flexible sigmoidoscopy with biopsy can be useful in detecting inflammatory (inflammatory bowel disease, microscopic colitis), infectious (shistosomiasis), infiltrative (amyloidosis), and cathartic (anthracene laxatives) lesions. If the diagnosis is still obscure, additional tests are necessary. These may include measurement of fasting stool volume, quantitative fecal fat determination, and colonoscopy with biopsy. One can differentiate osmotic from secretory diarrhea by calculating the stool osmotic gap. If the fecal fat levels are elevated, specific diagnostic tests should be performed on the basis of suspicion of pancreatic disease, bacterial overgrowth, mucosal disease, or lymphatic obstruction. Blood tests for thyroid function and hormone levels (see earlier) may be helpful.

MANAGEMENT

Acute diarrhea: Fluid therapy is most important, especially for infants and the elderly. When large diarrheal losses are replaced with water or oral solutions low in sodium content (e.g., juice, soda, sports drinks), hyponatremia results. Oral rehydration solutions are preferable. In some cases, intravenous saline solution may be necessary. Patients with acute infectious diarrhea should not be treated with antibiotics unless they are travelers or are likely to have invasive bacterial enteritis. Single doses of a quinolone and an antimotility agent at the onset of symptoms relieve traveler's diarrhea in most cases. Patients with severe diarrhea, a high fever, or bloody stools should be given a quinolone to take orally for 3 days. Antimotility agents should not be given to these patients (see later). For patients with *C. difficile* infection, the offending antibiotic should be discontinued (if possible) and metronidazole therapy begun. Oral vancomycin should be reserved for patients with severe or refractory infection.

Chronic diarrhea: Treatment consists of fluid repletion and specific therapy for the underlying condition. Lactase deficiency is managed with a lactose-free diet,

pancreatic insufficiency with pancreatic enzyme replacement, and celiac disease with a gluten-free diet. Bacterial overgrowth and tropical sprue respond to antibiotics. Patients with a limited ileal resection are treated with cholestyramine.

Antidiarrheal agents: These can be grouped into four categories: bismuth subsalicylate, antimotility agents, antisecretory agents, and anti-inflammatory agents. Bismuth has both antimicrobial and antisecretory properties and is used most often in the prevention of traveler's diarrhea. Antimotility agents such as loperamide slow intestinal transit and increase contact time for fluid reabsorption. These agents usually are reserved for patients with mild to moderate diarrhea who do not have fever or blood in the stool. They should not be used or should be used with caution to manage high-volume diarrhea (can lead to underestimation of fluid losses), invasive bacterial enteritis (can delay clearance), or ulcerative colitis (can precipitate toxic megacolon). No agent specifically inhibits intestinal fluid secretion. Octreotide, the long-acting somatostatin analogue, inhibits all gastrointestinal secretions and is effective in decreasing secretory diarrhea from any cause. Steroids and 5-aminosalicylic acid decrease prostaglandin and leukotriene production and are effective in the management of inflammatory bowel disease and microscopic colitis. Indomethacin may decrease diarrhea caused by radiation enteritis.

Chapter 99

APPROACH TO THE PATIENT WITH DYSPHAGIA

DEFINITION

Dysphagia means either difficulty initiating a swallow (oropharyngeal dysphagia) or the sensation that foods, liquids, or both are hindered in their passage from mouth to stomach (esophageal dysphagia). It is important to differentiate dysphagia from odynophagia (pain with swallowing).

HISTORY AND PHYSICAL EXAMINATION

Oropharyngeal dysphagia: Because patients have difficulty initiating swallowing, symptoms occur within 1 second of swallowing. Patients identify the cervical esophagus as the problem area. Associated symptoms include nasal regurgitation, coughing, choking, dysarthria, and nasal speech. Examination usually reveals that a neuromuscular condition is contributing to the symptoms. Oropharyngeal dysphagia should not be confused with globus, a constant sensation of a lump or tightness in the throat that does not interfere with swallowing.

Esophageal dysphagia: The patient describes the problem as food "hanging up" somewhere behind the sternum. Localized to the lower sternum or epigastrium, the lesion is most likely in the distal esophagus. Localization to the lower part of the neck may indicate dysfunction in this area, but often the symptoms are referred from a more distal blockage. It is important to determine whether the symptoms are progressive or intermittent and whether they occur with solids only or with both liquids and solids. Historical features of gastroesophageal reflux, chest pain, and weight loss should be sought. Examination is of limited value. Patients with esophageal cancer may have lymphadenopathy; those with scleroderma may have features of the CREST syndrome.

DIFFERENTIAL DIAGNOSIS

Oropharyngeal dysphagia: Neuromuscular disease, especially stroke, is responsible for about 80% of cases. Other causes are listed in [Table 94.1](#).

Esophageal dysphagia: Causes are listed in [Table 94.1](#). [Figure 94.1](#) shows an algorithm for the evaluation of dysphagia.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

Barium esophagography, preferably with video technique, is the initial diagnostic test for oropharyngeal or esophageal dysphagia. For patients with the former, administration of various consistencies of barium and food products helps ascertain who can swallow safely without aspiration. For patients with esophageal dysphagia, the test outlines irregularities in the esophageal lumen, defines sites of obstruction, and provides information about liquid transit through the esophagus. If there is an obstructing lesion, endoscopy with biopsy can confirm the diagnosis. Endoscopy should not be the initial study, however, because a narrow endoscope tends to miss rings and strictures. If results of barium studies are normal or suggest a motility disorder, esophageal manometry is the next step. This study can help diagnose achalasia and spastic motility disorders, and the findings may suggest scleroderma esophagus.

MANAGEMENT

Modification of diet and instruction in swallowing techniques may benefit patients with oropharyngeal dysphagia. Therapy for contributing conditions such as Parkinson's disease, polymyositis, and myasthenia gravis is indicated. Strictures and webs often can be managed during endoscopy by the use of dilators. Proton pump inhibitors and promotility agents may be helpful to manage strictures and webs associated with gastroesophageal reflux.

Chapter 94

GALLSTONES AND CHOLECYSTITIS

INCIDENCE AND EPIDEMIOLOGY

Cholelithiasis is a common disorder in the United States, particularly among women. By the age of 75 years, approximately 35% of women and 20% of men have gallstones, most of which are asymptomatic. Native Americans and Northern Europeans have particularly high rates of gallstone formation, Asians and Africans much lower rates.

ETIOLOGY AND PATHOGENESIS

In the United States, at least 75% of all gallstones are cholesterol stones. Risk factors for cholesterol stones include obesity, rapid weight loss, spinal cord injury, female sex (risk ratio 2:1), ileal resection or disease, pregnancy, and estrogen use. The presence of biliary sludge (also called *microcrystalline disease*) is believed to be a precursor stage of lithogenesis and is associated with many of the same risk factors. Although it may resolve spontaneously or cause macroscopic stone formation, biliary sludge has been implicated convincingly as a cause of classic biliary pain, acute cholecystitis, and acute pancreatitis.

The spontaneous formation of biliary sludge or cholesterol gallstones is a multistep process. The precipitation of solid cholesterol crystals from supersaturated bile is called *nucleation*. The cholesterol concentration must exceed the capacity of bile salts and phospholipids to hold it in solution. As the bile is progressively concentrated, biliary vesicles aggregate and fuse into larger multilamellar vesicles. Crystals begin to emerge when the balance of nucleator and antinucleator activity favors solid crystal formation. Cholesterol crystals and calcium bilirubinate pigment if sequestered within the gallbladder, may form a stone over time.

About 25% of all gallstones are pigment stones. These stones are categorized as either black or brown depending on their chemical composition and appearance. Risk factors for black pigment stones include chronic hemolysis, cirrhosis, and total parenteral nutrition. The risk factors for brown pigment stones are biliary stasis and chronic biliary infection. Although the pathogenesis of pigment stones is incompletely understood, some degree of elevation in the level of biliary unconjugated bilirubin appears to be important.

PATHOPHYSIOLOGY AND CLINICAL FINDINGS

Asymptomatic stones: Most gallstones remain clinically silent. The frequency of symptomatic stone disease is approximately 1% to 2% per year in the period after the diagnosis of cholelithiasis; this frequency decreases over time.

Biliary Colic: Classic biliary colic is caused by mechanical obstruction of the gallbladder neck by a stone and a resultant increase in intraluminal pressure. It is a discrete episode of a steady, severe pain, typically located in the epigastrium or right upper quadrant. It may radiate to the back or right shoulder region, but the

intensity does not usually fluctuate in the manner that the term *colic* implies. The pain usually comes on rapidly, lasts 30 minutes to 3 hours, and then gradually subsides. The pain is not associated with fever, leukocytosis, or acute peritoneal signs. The presence of these findings or biliary pain lasting longer than 4 to 6 hours should raise the suspicion of acute cholecystitis. True attacks of biliary pain should be differentiated from dyspeptic symptoms such as belching, epigastric burning, bloating, heartburn, flatulence, and intolerance of fatty foods. Abdominal discomfort that is chronically present or fleeting in nature (less than 10 to 15 minutes) should not be attributed to the presence of gallstones.

Chronic cholecystitis: Chronic cholecystitis is a consequence of repeated attacks of discrete biliary pain or acute cholecystitis. These episodes induce a chronic inflammatory process that may be mild and patchy or quite severe and extensive. Over time, the gallbladder wall may become thick and fibrotic, and the gallbladder becomes contracted and nonfunctional. When this is the case, the gallbladder does not opacify during oral cholecystography.

Acute cholecystitis: Acute obstruction of the cystic duct by a stone leads to gallbladder distention and can eventually cause inflammation of the gallbladder. The histologic findings range from edema, erythema, and mild mucosal inflammation to gross infiltration of the wall with neutrophils and evidence of necrosis and perforation. Superimposed bacterial infection may occur and is critical in the development of complications such as empyema, emphysematous cholecystitis, perforation, and the formation of a cholecystenteric fistula, which can lead to gallstone ileus if a large gallstone passes through the fistula and causes small-intestinal obstruction. Patients with acute cholecystitis report continuous upper abdominal pain and a history of similar but self-limited attacks in the past. They may have nausea but generally cannot relieve the pain by vomiting or changing position. Low-grade fever and right subcostal tenderness are typical findings at examination. A classic Murphy's sign may be elicited when the patient's inspiration is abruptly halted because of pain during palpation of the right upper quadrant. Generalized rebound tenderness suggests perforation.

Acalculous cholecystitis (cholecystitis in the absence of stone obstruction) accounts for 5% to 10% of cases of acute cholecystitis. It is most commonly associated with critical illness, major surgery, extensive trauma, or burn-related injury. Elderly men with peripheral vascular disease and patients receiving total parenteral nutrition appear to be at greater risk than other patients. The patho-physiologic mechanism involves a combination of gallbladder stasis, inflammation, and ischemia. Gallbladder infection, such as cytomegalovirus infection in a patient with AIDS, also may be responsible. Patients may not manifest the typical signs and symptoms of acute cholecystitis.

Choledocholithiasis: Stones are found in the common bile duct (CBD) in approximately 10% to 15% of patients with symptomatic gallstones. Obstruction by stones in the distal duct or ampulla may cause jaundice, gallstone pancreatitis, or cholangitis. Cholangitis is bacterial infection of an obstructed bile duct. Patients have biliary pain, fever with chills, and jaundice (Charcot's triad). The infecting organisms commonly include gram-negative aerobic bacteria, enterococci, and intestinal anaerobic bacteria.

DIAGNOSTIC EVALUATION

Laboratory findings: The results of laboratory evaluation of uncomplicated biliary colic usually are unremarkable. In contrast, acute cholecystitis often is associated with mild elevations in peripheral white blood cell count and bilirubin levels. Bilirubin levels of 2 to 10 mg per deciliter, however, suggest obstructive choledocholithiasis. Acute obstruction of the CBD also can elevate serum transaminase levels; if amylase and lipase levels also are increased, gallstone-induced pancreatitis is likely.

Imaging studies: Ultrasonography is the preferred imaging study in the evaluation of acute or recurrent biliary pain. It can accurately depict the presence or absence of gallstones and can show evidence of acute cholecystitis (gallbladder wall thickening more than 3 mm, pericholecystic fluid, and gallbladder tenderness with transducer pressure). Although dilatation of the CBD suggests biliary obstruction due to choledocholithiasis, ultrasonography depicts only about 50% of nonobstructing CBD stones. Radionuclide scanning of the biliary system is helpful in demonstrating cystic duct obstruction in selected patients with symptoms and signs of acute cholecystitis and normal or inconclusive results of ultrasound examinations. Direct cholangiography with either endoscopic retrograde cholangiopancreatography (ERCP) or percutaneous transhepatic cholangiography is performed when additional delineation of the biliary tree is needed or when therapy such as CBD stone extraction or biliary stent placement is being considered.

MANAGEMENT

Asymptomatic stones: Adults with silent or incidental stones should be observed and treated expectantly regardless of age or sex. The course of gallstones in such patients usually is benign, and warning symptoms of biliary pain usually arise before a serious complication occurs.

Symptomatic stones: A patient with an episode of uncomplicated biliary pain has a 30% to 50% chance of having another attack within 1 to 2 years and a 3% per year risk for development of a complication. The decision to proceed with cholecystectomy, usually a laparoscopic procedure, depends on the patient's desires and ability to tolerate a surgical procedure. Nonsurgical intervention, such as bile acid dissolution therapy, plays a limited role and is best reserved for patients with symptoms who decline surgery or have a high operative risk.

Acute cholecystitis: Early laparoscopic cholecystectomy is indicated once the diagnosis is secure and the patient's condition has been optimized, usually with intravenous fluids and antibiotics for 24 to 48 hours. Patients with a major complication such as perforation undergo urgent open laparotomy. Percutaneous cholecystostomy is considered for patients with acute cholecystitis who are deemed to be at excessive risk of a poor surgical outcome, such as many critically ill patients with acalculous cholecystitis.

Common duct stones: When a patient with known gallbladder stones has signs and symptoms of concomitant choledocholithiasis, a number of treatment options exist. The presence of obstructive jaundice with or without fever and abdominal pain generally leads to a preoperative ERCP examination with sphincterotomy and stone extraction, followed by routine laparoscopic cholecystectomy. Patients also can go directly to laparoscopic surgery and undergo intraoperative cholangiography to determine whether a CBD stone is present. If a stone is present, it may be possible to remove it through the cystic duct. Otherwise, the CBD can be opened and then closed over a T tube, or the surgeon can convert the procedure to open CBD exploration or arrange for postoperative ERCP.

[Chapter 124](#)

GASTRODUODENAL ULCER DISEASE

DEFINITION AND EPIDEMIOLOGY

Peptic ulcers are defects in the mucosal lining of the stomach or duodenum that extend through the submucosa into the muscle layer. Duodenal ulcers are common, affecting about 10% of the population at some time in their lives. Women are now affected as often as men.

ETIOLOGY AND PATHOGENESIS

Peptic ulcer disease requires the presence of aggressive noxious substances such as acid and pepsin but rarely is caused solely by excessive acid secretion. Most cases result from a combination of exposure to these noxious substances and factors that undermine mucosal integrity. Chronic gastric infection with *Helicobacter pylori* is the most important predisposing factor to both gastric (70% of cases) and duodenal (90% of cases) ulcers. It has effects on both gastric acid secretion and gastric mucosal integrity. About 15% to 20% of persons with *H. pylori* infection have ulcers during their lifetime. About 75% infected of patients with a single episode of gastric or duodenal ulcer experience repeated ulceration if *H. pylori* is not eradicated. The second most common cause of ulcers is ingestion of nonsteroidal anti-inflammatory drugs (NSAIDs), which undermine mucosal integrity by depleting gastric mucosal prostaglandins. Cigarette smoking has been implicated as a risk factor for duodenal ulcer. Gastrinoma (Zollinger--Ellison syndrome) is a rare cause of peptic ulcer disease.

CLINICAL FINDINGS

Symptoms: Although the characteristic pain is a dull ache in the epigastrium relieved by ingestion of food or antacids, there are many variations, including pain in the right and left upper quadrants. Bleeding ulcers may be painless and manifest as hematemesis, melena, anemia, or even hematochezia. Perforated ulcers typically manifest as severe generalized abdominal pain associated with signs of peritonitis. Patients with ulcer-induced gastric outlet obstruction may have repeated episodes

of vomiting. It usually is impossible to differentiate duodenal and gastric ulcers according to symptoms alone. Duodenal ulcer pain usually is episodic, typically occurs at night, and often is relieved by ingestion of food. Gastric ulcer (or gastric cancer) is suggested by pain that occurs within 30 minutes after eating, continuous rather than episodic pain, anorexia, nausea, vomiting, and weight loss.

Physical examination: Midepigastric tenderness is common but nonspecific. The examination may reveal evidence of other causes of epigastric pain, such as musculoskeletal tenderness, neuropathy, or abdominal masses. Succussion splash, a sign that the stomach contains excessive air and fluid, suggests gastric outlet obstruction. Patients with free ulcer perforation usually have abdominal rigidity and signs of generalized peritonitis.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes nonulcer dyspepsia, gastroesophageal reflux disease, drug-induced dyspepsia and gastropathy, gastric or duodenal tumors (benign or malignant), Crohn's disease of the stomach or duodenum, pancreatic disease (benign or malignant), hepatobiliary disease, and neuromuscular pain. The diagnosis of nonulcer dyspepsia is made when a patient has epigastric symptoms for more than 4 weeks and diagnostic evaluation reveals no obvious cause. Though nonulcer dyspepsia cannot reliably be differentiated from peptic ulcer disease with the history or examination findings, it is suggested by earlier age at onset, female sex, precipitation by ingestion of food, daily occurrence, impaired sleep pattern, and worsening of symptoms during periods of stress.

LABORATORY FINDINGS AND DIAGNOSTIC EVALUATION

Diagnostic studies: During upper gastrointestinal endoscopy, ulcers are seen as depressions with white or yellow bases, often with erythematous or edematous edges surrounded by normal mucosa. Other structural diseases can be excluded, such as erosive esophagitis or gastric cancer, and biopsy and culture specimens may be obtained. Therapy for bleeding ulcers can be administered directly. Most gastric and duodenal ulcers can be diagnosed with barium radiography, especially when double-contrast technique is used, although this method does not allow biopsy, culture, or therapy. Radiography is especially useful for identifying infiltrative diseases, such as lymphoma or linitis plastica, and extrinsic compression of the stomach or duodenum by mass lesions.

Ancillary studies: Routine laboratory studies generally are not useful in establishing the diagnosis, but they can help define the cause. In selected cases, fasting gastrin and acid secretory measurements are useful in excluding gastrinoma. Testing for *H. pylori* is essential for all patients with documented ulceration. This can be done by invasive (histologic identification or rapid urease testing of biopsy specimens) or noninvasive (serum antibody testing or urea breath testing) means. Serologic tests are highly sensitive and specific but cannot help differentiate a previously treated infection from a currently active one. Serologic testing therefore cannot be used to document eradication of the infection after therapy, which is a role well suited to urea breath testing.

MANAGEMENT

Nonspecific measures: Dietary manipulations are not of proven benefit. Because smoking is associated with poor healing and increased recurrence rates, smoking cessation is a reasonable adjunct. The role of alcohol restriction is controversial. Discontinuation of aspirin and NSAIDs is important both for healing and for reducing recurrence rates. If these drugs cannot be discontinued, an NSAID with low ulcerogenic potential, such as ibuprofen, should be used. Studies are currently underway to evaluate specific cyclooxygenase II inhibitors, which are likely to carry a lower risk of peptic ulcer complications than NSAIDs do. Other measures that may decrease ulcer formation in patients who need NSAIDs are eradication of *H. pylori* and long-term therapy with misoprostol or acid-inhibiting drugs.

Cure of *H. pylori* infection: Eradication of *H. pylori* accelerates the healing of *H. pylori*-associated ulcers, greatly diminishes the likelihood of ulcer relapse, and may decrease the frequency of complications. The optimal treatment regimen is not yet established, but consensus is emerging that triple-therapy combinations should be used to ensure adequate cure rates. A 2-week course of standard triple therapy with metronidazole (250 mg three times a day), a bismuth compound (e.g., 2 chewable bismuth subsalicylate tablets four times a day), and tetracycline (500 mg four times a day) with standard doses of antisecretory therapy provides excellent results but is poorly tolerated. Proton pump inhibitor-based tripletherapy regimens are therefore the current regimens of choice. The U.S. Food and Drug Administration has approved 7- to 14-day regimens consisting of lansoprazole (30 mg twice a day) or omeprazole (20 mg twice a day) combined with two of the following three antibiotics: amoxicillin (1 g twice a day), clarithromycin (500 mg twice a day), or metronidazole (500 mg twice a day).

Medical Management: Several drugs are effective for healing active ulcers, and some of these may decrease the rate of recurrence when used for long-term therapy after healing. These drugs work by inhibiting acid secretion, neutralizing acid secretion, or improving cytoprotection in the ulcer environment. Administration of a single daily dose of histamine-2 receptor antagonists (e.g., 300 mg ranitidine or nizatidine, 40 mg famotidine) at bedtime heals 90% of duodenal ulcers within 6 weeks. Gastric ulcers heal more slowly and respond better to 6 to 8 weeks of therapy. Maintenance therapy usually is given as half of the treatment dose. Proton pump inhibitors (20 mg omeprazole or 30 mg lansoprazole each morning) produce more rapid healing than do histamine-2 receptor antagonists and have a better side effect profile. They are the agents of choice for patients with gastrinoma. Low doses of antacids (e.g., 2 tablets four times a day) can heal ulcers effectively at a low cost. Prostaglandins such as misoprostol have cytoprotective properties and may inhibit acid production. They may have a special protective action on damage produced by NSAIDs. Use of prostaglandins is limited by side effects such as abdominal cramps and diarrhea and the ability to cause uterine contraction and abortion. Sucralfate is an aluminum sulfate disaccharide that acts locally on the gastric and duodenal mucosa. It has no specific side effects and produces healing rates comparable to those of the histamine-2 receptor antagonists.

Surgical management: Some complications of ulcer disease necessitate surgical treatment, such as hemorrhage unresponsive to medical management, including endoscopic hemostasis, gastric outlet obstruction not reversed by medical management, perforation, and malignant tumors. The most effective operation for gastric ulcer is simple antrectomy. Partial gastric resection with vagotomy is effective in the management of duodenal ulcer. The procedure may be performed with a Billroth I (gastroduodenal) or Billroth II (gastrojejunal) anastomosis. Perforated ulcers may necessitate only simple closure with an omental patch. Surgical complications include bile gastritis, anastomotic ulcer, dumping syndrome, and malabsorption.

[Chapter 107](#)

GASTROESOPHAGEAL REFLUX DISEASE

DEFINITION, EPIDEMIOLOGY AND PATHOPHYSIOLOGY

Gastroesophageal reflux disease (GERD) is the pathologic manifestation of the movement of gastroduodenal contents into the esophagus. It is probably the most common condition affecting the gastrointestinal tract. More than 40% of adults in the United States experience its primary symptom, heartburn, at least once a month. Pregnant women have the highest prevalence. The pathophysiologic mechanism is a complex interplay of numerous factors, but the common denominator is the development of a common cavity that represents equilibration of intragastric and intraesophageal pressures. Transient lower esophageal sphincter (LES) relaxation is the main mechanism that promotes free reflux of gastric contents. Delayed gastric emptying, increases in intra-abdominal pressure, and dysfunction of esophageal acid clearance are factors in some patients. Most patients with esophagitis have a sliding hiatal hernia, but many persons with hiatal hernias do not have GERD. The mechanism of mucosal damage involves the action of pepsin and the direct effect of acid.

CLINICAL FINDINGS

Heartburn is the classic symptom; it is generally described as retrosternal burning pain that also be felt in the epigastrium, neck, and throat. It often occurs after meals and is exacerbated by recumbency or bending over. Patients may have dysphagia, odynophagia, water brash, and belching. Dysphagia suggests the presence of a peptic esophageal stricture or severe esophagitis. Water brash is the sudden appearance in the mouth of slightly sour or salty fluid from the salivary glands in response to intraesophageal acid exposure. GERD also can manifest with extraesophageal symptoms such as hoarseness, chronic cough, and wheezing.

COMPLICATIONS

Peptic strictures represent the end stage of ongoing reflux, mucosal damage, healing, and fibrosis. They manifest as slowly progressive dysphagia for solids. Barrett's esophagus results when severe esophagitis induces a unique reparative process in which the original squamous epithelium is replaced by metaplastic columnar epithelium. The prevalence is 5% to 10% among patients with symptomatic GERD; higher rates occur among patients with esophagitis or peptic strictures. The

diagnosis is made by means of endoscopy and biopsy. The main concern is a markedly increased risk of esophageal adenocarcinoma.

DIAGNOSIS

In most cases, the history is sufficiently typical to allow a trial of therapy without diagnostic testing. Early investigation should be undertaken when a patient has an atypical presentation of GERD, when symptoms are unresponsive to medical therapy, or when there is clinical evidence of the complications of GERD, such as dysphagia.

Endoscopy: All patients with persistent symptoms or frequent relapses after medical therapy should undergo endoscopy to ascertain the presence of esophagitis or other complications of GERD. Such patients need biopsy to exclude malignant disease and Barrett's esophagus. However, most patients with GERD have no evidence of esophagitis at endoscopy.

Other tests: Barium esophagography is the best first test in the care of patients with dysphagia. It can demonstrate reflux fluoroscopically and depicts signs of erosive esophagitis and peptic strictures. It is less sensitive for mild esophagitis. Prolonged esophageal pH monitoring is the best test for diagnosing GERD. It is helpful when the disease has an atypical presentation, such as noncardiac chest pain or pulmonary symptoms, or causes intractable symptoms in association with normal endoscopic findings. Esophageal pH monitoring has essentially replaced the acid perfusion Bernstein test. Manometric assessment of LES pressure is not sensitive; it is reserved for instances in which another diagnosis, such as achalasia, is suspected.

PROGNOSIS AND MANAGEMENT

In the care of patients who do not have esophagitis, the goal is simply to relieve symptoms. For patients with esophagitis, the goal is to eliminate the inflammation and prevent further complications such as strictures and Barrett's metaplasia. Strategies include lifestyle modifications ([Table 106.3](#)), antacid therapy; administration of prokinetic drugs (of which cisapride is the best for controlling symptoms and healing mild esophagitis), histamine-2 antagonists, or proton pump inhibitors; and antireflux surgery. A general approach is outlined in [Table 106.2](#). Patients with peptic strictures often need dilation of the narrowing with blunt bougies. For patients with Barrett's esophagus, endoscopic surveillance with biopsy is recommended to detect high-grade dysplasia or early cancer and to allow curative resection.

[Chapter 106](#)

APPROACH TO THE PATIENT WITH GASTROINTESTINAL BLEEDING

DEFINITIONS

Gastrointestinal (GI) bleeding may be chronic (manifesting as iron-deficiency anemia or occult fecal blood) or acute. Bleeding from the upper GI tract often manifests as hematemesis (bloody vomitus). This may reflect recent (bright-red vomitus) or previous (coffee-ground vomitus) hemorrhage. Melena consists of black, tarry, malodorous stool caused by the presence of degraded blood in the intestine. Melena generally indicates an upper GI source but can originate in the right colon. Other causes of black stool (iron or bismuth ingestion) must be excluded. Hematochezia is the passage of bright red blood from the rectum; it generally indicates a lower GI lesion. Lower GI bleeding is defined as hemorrhage from below the ligament of Treitz. Occult GI bleeding is bleeding of which the patient is unaware; it manifests as guaiac-positive stools or iron deficiency anemia.

DIFFERENTIAL DIAGNOSIS

Upper GI Bleeding: The three major causes are peptic ulcer disease, gastropathy or gastric erosions, and esophageal varices. Other causes include Mallory-Weiss tears, esophagitis, erosive duodenitis, and neoplasms. Patients with no endoscopic diagnosis (10% to 15%) have an excellent prognosis.

Lower GI Bleeding: Seventy percent to 80% of lower GI hemorrhage is from the right colon. The two major causes of acute lower GI hemorrhage are diverticulosis and angiodysplasia. Diverticular hemorrhage occurs when an artery ruptures into the diverticular sac; therefore diverticulosis is not thought to be a cause of occult GI bleeding or slow bleeding. Other causes include neoplasia, radiation or ischemic colitis, and inflammatory bowel disease. Hemorrhoids and colonic neoplasia are the most common causes of chronic lower GI bleeding.

Occult GI Bleeding: In Western countries, acid-peptic disease accounts for 30% to 70% of cases of occult bleeding (aspirin and other nonsteroidal anti-inflammatory drugs [NSAIDs] often are implicated); however, when the stool occult blood test is used for screening among patients older than 50 years, the goal is early detection of colonic polyps and colon cancer. The specificity of the test for these lesions is quite low. Therefore many positive results must be investigated, usually with colonoscopy, to find one polyp or instance of cancer.

HISTORY AND PHYSICAL EXAMINATION

Upper GI Bleeding: A history of peptic disease or dyspeptic symptoms suggests ulcers; a history of cirrhosis suggests variceal bleeding, although 30% to 60% of patients with cirrhosis have a nonvariceal source of bleeding. Use of aspirin, NSAIDs, and alcohol must be ascertained, and the patient should be asked about recent nose bleeds. Physical examination should focus on signs and symptoms of cirrhosis or evidence of underlying malignant disease, such as lymphadenopathy. Epigastric tenderness is common in peptic disease. Maroon or melanic stool found at rectal examination indicates severe bleeding. In severe cases, the patient may be in a state of shock.

Lower GI Bleeding: A recent history of anorexia or weight loss may indicate malignant disease. Symptoms such as abdominal pain or diarrhea suggest inflammatory bowel disease and ischemic or infectious colitis. In severe cases, the patient may be in a state of shock.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

Serial hemoglobin determinations help determine severity. In the presence of acute hemorrhage, the initial hematocrit is a poor reflection of the amount of hemorrhage.

Upper GI Bleedings: Nasogastric lavage can be used to assess the rate of ongoing blood loss and confirm an upper GI source, although a negative result does not exclude duodenal hemorrhage. Diagnostic endoscopy is the procedure of choice. Angiography and radionuclide scans are used to localize the site of hemorrhage only when endoscopy does not.

Lower GI Bleeding: All patients need a diagnostic evaluation ([Fig. 102.2](#)). When bleeding is rapid, the colonoscopic view may be obscured by blood, and the patient should undergo immediate angiography. Before angiography, nasogastric lavage and even upper GI endoscopy should be considered to rule out an upper GI source.

Bleeding from unknown source: About 5% of patients have no identifiable source despite extensive examination. In most instances, the cause is thought to be vascular ectasia. In the care of young patients, a radionuclide scan for Meckel's diverticulum is valuable. Enteroclysis may identify small-bowel sources. If these modalities are not revealing and the severity of the bleeding is sufficient to warrant transfusion, visceral angiography or small-bowel enteroscopy is indicated.

Occult GI bleeding: In the absence of anemia or GI symptoms, a patient older than 40 years should undergo colonoscopy or the combination of air-contrast barium enema radiographic examination and sigmoidoscopy. A patient younger than 40 years can be observed with repeat hemoglobin levels and stool samples. If the patient has iron deficiency or has upper GI symptoms and is older than 40 years, colonoscopy should be performed first but should be followed by upper endoscopy if the colonoscopic findings are not revealing. If both studies have normal findings, enteroclysis may help identify small-bowel sources. If the severity of bleeding is sufficient to warrant transfusion, visceral angiography or small-bowel enteroscopy is indicated.

PROGNOSIS AND MANAGEMENT

Upper GI Bleeding: About 80% of episodes are self-limited and necessitate only supportive care. The mortality rate is about 10% and increases to about 30% to 40%

with continued or recurrent bleeding. Management begins with resuscitation (saline infusion with or without red blood cell transfusion). Acid-reducing therapy often is started empirically, although conclusive evidence of benefit has been lacking. For variceal hemorrhage, intravenous somatostatin and the combination of intravenous vasopressin and nitroglycerin are helpful. Endoscopic therapies include thermal coagulation of bleeding vessels and sclerotherapy or band ligation of varices. Massive variceal hemorrhage may necessitate balloon tamponade. Bleeding refractory to all of these interventions may necessitate urgent surgery.

Lower GI Bleeding: Episodes resolve spontaneously in 80% of patients. Unlike upper GI bleeding, most lower GI bleeding is slow and intermittent and does not necessitate hospitalization. Management begins with resuscitation (saline infusion with or without red blood cell transfusion). Most patients with bleeding that ceases or is slow need elective treatment of the underlying disorder, such as colonoscopic electrocoagulation techniques for angiodysplasia. Urgent therapy is indicated when a patient needs more than three units of red blood cells. Intra-arterial vasopressin (0.2 unit per minute) after selective catheterization of the bleeding vessels is the best initial therapy; subtotal colectomy and intra-arterial embolization are next in order of effectiveness.

Bleeding from unknown source: A therapeutic trial of estrogen-progesterone therapy for possible vascular ectasia may be worthwhile.

Chapter 102

GIARDIASIS

DEFINITION AND EPIDEMIOLOGY

Giardia lamblia is the organism that causes most instances of protozoal infection of the intestinal tract worldwide. Prevalence varies from 2% to 5% in industrialized nations to 20% to 30% in the developing world. The illness usually is acquired by means of consuming water contaminated with the feces of humans or animals. Streams and wells are common sources. Transmission also is common in day care centers, in institutions for the mentally ill and retarded, and among homosexual men.

CLINICAL FEATURES

Clinical giardiasis ranges from asymptomatic carriage to severe chronic diarrhea and malabsorption. Acute illness is characterized by abdominal cramps, nausea and vomiting, and watery diarrhea. Many cases are short-lived and resolve without therapy. However, giardiasis often becomes chronic and can then manifest as a nonspecific chronic diarrheal syndrome or as a malabsorptive syndrome characterized by abdominal distress, gas bloating, and malaise without much diarrhea. Urticaria and arthralgia also have been reported.

DIAGNOSIS

Diagnosis is made by means of finding trophozoites or cysts in stool or intestinal fluid or tissue. Examination of the stool has a sensitivity of 35% to 50% at best. Duodenal contents can be aspirated directly or by means of a string test. A stool antigen test also is available.

MANAGEMENT

Treatment is with 250 mg metronidazole three times a day for 5 days.

Chapter 113

HEPATIC NEOPLASMS

DEFINITION, EPIDEMIOLOGY, AND PATHOGENESIS

Primary hepatocellular carcinoma (HCC) is a malignant transformation of hepatocytes and is a well-recognized complication of long-standing liver disease of numerous causes. The incidence worldwide is correlated with the prevalence of chronic hepatitis B virus infection. Other risk factors include male sex, hemochromatosis, α_1 -antitrypsin deficiency, Wilson's disease, exposure to aflatoxin B (a by-product of *Aspergillus* infection of grains, rice, and peanuts), androgens, estrogen, and vinyl chloride exposure. Chronic inflammation is thought to expose the liver to genotoxic free radicals that lead to mutations and formation of HCC. Fibrolamellar HCC is a distinct variant that usually occurs among patients who do not have cirrhosis and is associated with a better prognosis.

There are several types of benign hepatic tumors. Hepatic adenoma and focal nodular hyperplasia (FNH) are the most common. The true incidence is unknown. Women are at increased risk of hepatic adenoma, especially during the reproductive years and with the use of oral contraceptives. Hepatic adenoma is made up of normal-appearing hepatocytes without portal triad elements. FNH is composed of all cell populations normally present in the liver and appears as a central vascular scar with fibrous septa radiating from it. The liver is a preferential site for the deposition of tumor metastases, especially from cancers of the pancreas, gallbladder, colon, or breast; malignant melanoma; and neuroendocrine tumors.

CLINICAL FINDINGS

Hepatocellular carcinoma: The presentation depends in part on the presence of associated liver disease, which may cause fatigue, jaundice, weight loss, pain in the right upper quadrant, ascites, or hepatomegaly. HCC should be sought in evaluation of patients with chronic liver disease who have hepatic decompensation with no identifiable precipitating factor.

Benign neoplasms: Patients with hepatic adenoma are of childbearing age and have histories of oral contraceptive use. Symptoms, including abdominal mass or pain, are present in 80% of cases. Patients with FNH are in their fifth to sixth decades of life. The lesion often is found in patients without symptoms during radiographic evaluation of the liver. Only 10% of patients have pain or an asymptomatic hepatic mass at the time of diagnosis.

Metastatic disease: Patients may notice weight loss, anorexia, or right upper quadrant pain. About 50% of patients have hepatomegaly and 15% have jaundice. Ascites occurs among 50% of patients with metastatic gastric, ovarian, or gallbladder carcinoma. Patients with metastasis from primary tumors in the pancreas, stomach, or lung often have no symptoms. At examination, firm, distinct nodules may be felt.

LABORATORY FINDINGS AND DIAGNOSTIC EVALUATION

Hepatocellular carcinoma: Routine laboratory tests should be performed for the evaluation of liver injury and function. Assessment of serum markers for specific diseases should be performed; these include serologic testing for viruses, measurement of ceruloplasmin, calculation of iron-binding ratio, and measurement of ferritin. Serum HCC tumor markers, most notably α -fetoprotein (AFP), can be measured. AFP levels are elevated in 60% to 70% of cases (not in fibrolamellar HCC). Values greater than 400 ng per milliliter are highly specific for HCC. Imaging by means of ultrasonography and computed tomography (CT) is used to identify and characterize the features of the liver tumor, to direct percutaneous biopsy, and to assess the extent of disease. Helical CT facilitates detection of small nodules. Magnetic resonance imaging is especially useful for detection of hemangioma and fatty liver infiltrates.

Benign neoplasms: AFP levels are normal. Hepatic imaging and biopsy are the primary tools used to differentiate benign from malignant disease. If hepatic adenoma is suspected, radiologic evaluation should be performed first, because biopsy carries a significant risk of bleeding. Biopsy is safe in the evaluation of FNH.

Metastatic disease: An elevated alkaline phosphatase level is common. Increased serum bilirubin levels may be a sign of large-duct obstruction. AFP levels are normal. CT can be used to define the location and number of lesions and to identify the presence of a primary, extrahepatic tumor in the abdomen. Percutaneous biopsy may be necessary to confirm the diagnosis.

PROGNOSIS AND MANAGEMENT

Hepatocellular carcinoma: Early detection and resection of HCC nodules smaller than 2 cm in diameter followed by resection, for patients with adequate hepatic reserve, is the optimum approach to definitive cure. The 5-year survival rates range from 30% to 85%. Ultrasound screening every 6 months for patients with long-standing cirrhosis is essential for early detection. When resection is not feasible because of widespread disease, poor hepatic reserve, or evidence of metastases, other noncurative options can be used. These include intra-arterial chemoembolization, percutaneous injection of alcohol, and cryosurgical ablation. Orthotopic liver transplantation has been used to manage HCC.

Benign neoplasms: When a woman is found to have a hepatic mass, discontinuation of any estrogen is the first priority. Large hepatic adenomas occasionally shrink or resolve in the absence of hormone. If hepatic adenoma is suspected because of clinical and radiologic features, surgical resection is the preferred treatment because of the risk of rupture or hemorrhage and the documented potential for malignant transformation. For FNH, no risk of bleeding or malignant transformation exists, and tumors can be removed by means of enucleation or wedge resection to release compression on normal liver tissue or to ameliorate pain.

Metastatic disease: Resection of metastatic lesions from noncolorectal tumors has a dismal prognosis. For selected patients with colorectal carcinoma, resection of metastatic lesions improves prognosis. Favorable factors include the presence of three or fewer lesions, an interval of more than 1 year between bowel and liver resection, and a greater margin of normal resected liver around the tumor.

[Chapter 126](#)

HEREDITARY HEMOCHROMATOSIS

DEFINITION, EPIDEMIOLOGY, AND PATHOGENESIS

Hereditary hemochromatosis is a common disorder of iron metabolism that affects approximately 1 in 200 to 400 persons of Northern European descent. It is caused by an increase in absorption of iron from the proximal intestine and deposition of iron in the liver, pancreas, heart, joints, skin, and endocrine organs. Affected individuals have two copies of the mutant hemochromatosis gene (*HFE*).

CLINICAL FEATURES

Hereditary hemochromatosis is increasingly being identified during the evaluations conducted because routine chemistry panels show abnormal iron levels or because screening iron studies are performed on persons with a family history of hereditary hemochromatosis. Cases diagnosed in this way usually are asymptomatic. Symptomatic cases often manifest as fatigue, right upper quadrant abdominal pain, arthralgia, impotence, decreased libido, symptoms of heart failure, or diabetes. Physical examination findings include hepatomegaly, cirrhosis, extra-hepatic manifestations of chronic liver disease, testicular atrophy, signs of congestive heart failure, skin pigmentation, and arthritis.

LABORATORY FINDINGS AND DIAGNOSTIC EVALUATION

Fasting transferrin saturation (serum iron divided by total iron binding capacity) should be calculated. If the ratio is 45% or more, *HFE* mutation analysis should be performed to confirm the diagnosis. Patients with symptoms also typically have elevated levels of serum ferritin. Patients older than 40 years or with abnormal liver tests, regardless of *HFE* test results should undergo percutaneous liver biopsy quantitative iron studies for histologic interpretation. Patients with symptoms typically have elevated levels of serum ferritin.

MANAGEMENT

Treatment is weekly therapeutic phlebotomy of 500 mL of whole blood. Phlebotomy typically is continued until the transferrin saturation is less than 50% or serum ferritin levels are less than 50 ng per milliliter. Once excess iron stores are depleted, maintenance phlebotomy continues every 2 to 3 months for the duration of the patient's life. If treatment is initiated before complications of liver disease develop, the prognosis is excellent. All first-degree relatives should be offered genetic screening.

[Chapter 123](#)

INFLAMMATORY BOWEL DISEASE

DEFINITION AND EPIDEMIOLOGY

Inflammatory bowel disease (IBD) encompasses at least two forms of idiopathic intestinal inflammation--ulcerative colitis and Crohn's disease (also known as regional enteritis). Ulcerative colitis and Crohn's disease are at least partially distinct in initial pathogenic events, but they have many key pathophysiologic processes in common. Men and women are affected equally, but the prevalence is higher among the U.S. white than the U.S. black and U.S. Hispanic populations. Onset is usually in the second and third decades of life; there is a small increase in incidence in the fifth and sixth decades.

ETIOLOGY AND PATHOPHYSIOLOGY

The precise causes are unknown. Both environmental and genetic factors seem to contribute to the pathogenesis. The clinical manifestations depend on a series of immunologic and inflammatory events. Activation of inflammatory cells produces reactive oxygen metabolites that may serve as the final common pathway of tissue damage.

PATHOLOGY

Ulcerative colitis: The inflammatory process in ulcerative colitis is confined to the mucosa and superficial submucosa of the colon and rectum (neutrophilic microabscesses within the lamina propria and crypts). The inflammatory process typically extends in a continuous manner proximally from the rectum, the length of proximal extension varying among patients.

Crohn's disease: Crohn's disease is much more varied in its manifestations. Active disease is characterized by an infiltrate in which macrophages and lymphocytes predominate. Noncaseating granulomas are found in most patients. Extension of the inflammatory process into the deeper layers of the bowel wall is a distinguishing feature. Transmural involvement is common and may lead to fistula formation and serosal adherence to adjacent structures. Although Crohn's disease may affect any region of the gastrointestinal tract, involvement of the terminal ileum or colon is most common. The inflammation can be patchy, and segmental involvement of different areas is typical.

CLINICAL FEATURES

Ulcerative colitis: The cardinal symptom is bloody diarrhea. Bowel movements are frequent but often small in volume. Additional symptoms can include crampy lower abdominal pain, rectal pain, tenesmus, and fecal urgency. With more extensive colonic inflammation, fatigue, fever, and weight loss are common. Ulcerative colitis typically follows a chronic relapsing course characterized by intermittent acute attacks interspersed with periods of remission. Local complications include colonic perforation or stricture. Toxic megacolon is the most serious complication of acute ulcerative colitis. Extension of the inflammatory process into the muscularis leads to impairment of contraction and colonic distention along with fever, tachycardia, and leukocytosis. Patients with long-standing ulcerative colitis have a markedly increased risk of colon cancer.

Crohn's disease: Crohn's disease is more varied than ulcerative colitis in clinical course, owing to its diversity of anatomic involvement and the presence of

transmural inflammation. Patients most often have the triad of diarrhea, abdominal pain, and weight loss. The onset can be insidious; most patients have had symptoms for months before medical evaluation. Among patients with colonic disease, diarrhea is often small in volume and associated with rectal urgency and tenesmus. Among patients with disease confined to the small intestine, stool volume is larger, especially if disease of the terminal ileum causes secretory diarrhea from bile salt malabsorption. Weight loss may be caused by diffuse intestinal inflammation, malabsorption, or decreased intake of food. Colonic Crohn's disease is more likely than small-intestinal Crohn's disease to be associated with rectal bleeding. Physical examination may reveal evidence of weight loss and muscle wasting. The abdomen often is tender. Laboratory findings include anemia (from chronic inflammation, blood loss, or deficiencies of iron, folate, or vitamin B₁₂), leukocytosis, elevated erythrocyte sedimentation rate, and hypoalbuminemia. Complications include fistulas, usually enterocutaneous or enteroenteric, intra-abdominal abscesses, small-bowel obstruction, and perianal abscesses or fistulas. Free intestinal perforation is rare. Patients have an increased incidence of cholesterol gallstones and calcium oxalate nephrolithiasis. As in ulcerative colitis, the risk of colon cancer is increased among patients with Crohn's colitis.

EXTRAIESTINAL MANIFESTATIONS

Both ulcerative colitis and Crohn's disease are associated with a variety of extraintestinal manifestations. The most common is arthritis (25% of cases). Pauciarticular (fewer than five joints) peripheral arthritis tends to be acute and self-limited and correlates with bowel disease activity. Polyarticular (more than five joints) peripheral arthritis may be independent of the activity of IBD and is associated with uveitis. Sacroiliitis with or without ankylosing spondylitis also can occur and tends to pursue a relentlessly progressive course independent of the bowel disease. Hepatic complications include fatty liver, primary sclerosing cholangitis (more common with ulcerative colitis than in Crohn's disease), chronic hepatitis, and cirrhosis. Dermal complications include erythema nodosum, pyoderma gangrenosum, and rare instances of neutrophilic dermatosis. The principal ocular complications are episcleritis and uveitis.

DIFFERENTIAL DIAGNOSIS AND DIAGNOSTIC STUDIES

The differential diagnosis includes acute infectious colitis, giardiasis, ischemic colitis (among the elderly), diverticulitis, hemorrhoids or anal fissures, irritable bowel syndrome, medication-induced colitis (e.g., nonsteroidal anti-inflammatory drugs and allopurinol) and lymphocytic or collagenous colitis.

In most cases, the diagnosis of IBD is strongly suspected on the basis of a clinical presentation of diarrhea, bloody diarrhea, abdominal pain, or perianal disease. For patients with diarrhea, stool cultures for enteric pathogens and examination for ova and parasites should be performed. The principal techniques to confirm the diagnosis and monitor progression disease are endoscopy (sigmoidoscopy and colonoscopy) and contrast radiography. Endoscopy is useful in defining the extent of mucosal inflammation, detecting mild inflammation, obtaining biopsy specimens, and conducting surveillance examinations for dysplasia. Air contrast radiography is useful in assessing colonic distensibility and detecting fistulas and strictures. Barium enema radiographic studies and colonoscopy are contraindicated in the evaluation of patients with severe ulcerative colitis or Crohn's colitis because of the possibility of precipitating toxic megacolon or colonic perforation. Computed tomography is particularly useful in the evaluation of patients with Crohn's disease because it depicts abscesses and thickening of the bowel wall.

PROGNOSIS AND MANAGEMENT

Supportive therapy includes antidiarrheal agents such as loperamide and diphenoxylate (contraindicated in moderate or severe colitis because of the risk of toxic megacolon), repletion of fluids and electrolytes, and blood transfusions. The value of elemental diets as primary therapy is controversial. Surveillance colonoscopic examinations to detect dysplasia are recommended for patients with chronic ulcerative colitis or Crohn's colitis. There is no specific curative drug therapy for IBD; therapy must be individualized ([Table 111.7](#)). Patients with ulcerative colitis who do not respond to aggressive medical therapy can be cured with colectomy. Most patients with Crohn's disease ultimately undergo operative treatment for indications such as intestinal obstruction, symptomatic fistulas, abscesses, toxic dilatation, perforation, and cancer. The extraintestinal manifestations may necessitate specific therapies.

[Chapter 111](#)

IRRITABLE BOWEL SYNDROME

DEFINITION

Irritable bowel syndrome (IBS) is a group of functional bowel disorders in which abdominal discomfort is associated with features of disordered defecation.

EPIDEMIOLOGY

IBS affects about 10% to 20% of adults in western countries. No ethnic differences have been reported; the prevalence appears to decrease among older persons. Although only 30% those with IBS seek medical attention, it is still one of the most frequently seen disorders in medical settings.

ETIOLOGY AND PATHOPHYSIOLOGY

No unique pathophysiologic mechanism for IBS has been identified. Patients with IBS often have abnormalities of gastrointestinal motility, but the findings are not unique to IBS and correlate poorly with symptoms. Several studies have shown that patients with IBS have lower pain thresholds to rectal distention and experience the urge to defecate at lower rectal volume. Psychological distress can cause prolonged motor abnormalities and a reduction in the threshold at which people experience afferent gastrointestinal symptoms. Patients with IBS have a higher prevalence of comorbid affective disorders, personality disturbances, and psychiatric illnesses. As many as 50% of women evaluated in a gastroenterology referral practice report a history of physical or sexual abuse.

CLINICAL FEATURES

Abdominal pain associated with a change in the consistency or frequency of stools and relieved with defecation is the hallmark of IBS. The pain is often poorly localized and may be migratory and variable. However, it often occurs after a meal, during psychological stress, or at the time of menses. Associated symptoms may include bloating or feeling of distention, presence of mucus in stool, urgency, and a feeling of incomplete evacuation. IBS may be diarrhea predominant, constipation predominant, or a combination of both at different times. The physical examination findings usually are unremarkable, although mild to moderate abdominal tenderness may be elicited.

LABORATORY FINDINGS AND DIAGNOSIS

The diagnosis is made clinically. The initial evaluation to exclude other disorders should include complete blood cell count; erythrocyte sedimentation rate (ESR); blood chemistries; stool examination for ova, parasites, and blood; and sigmoidoscopy. Colonoscopy or barium enema with sigmoidoscopy is recommended if the patient is older than 50 years. The following signs should alert the clinician to other diagnoses and lower the threshold for obtaining additional studies: history of weight loss; onset of symptoms at an older age; nocturnal symptoms; family history of carcinoma of the colon or inflammatory bowel disease; fever; abnormal physical findings, such as abdominal mass or hepatomegaly; or abnormal laboratory results, such as occult blood in stool, anemia, leukocytosis, elevated ESR, or abnormal results of blood chemical analysis. If any of these abnormal results is present, or if an initial therapeutic trial fails, additional testing is necessary. For patients with constipation-predominant IBS, the additional studies may include colonic transit time and anal manometry. For those with diarrhea the additional studies include stool tests (volume, electrolytes, fat, leukocyte count), small-bowel radiography, breath tests to exclude bacterial overgrowth, and colonic biopsy to exclude collagenous or lymphocytic colitis. For patients with bloating and pain, abdominal radiographs to exclude partial obstruction and abdominal ultrasonography may be indicated.

MANAGEMENT

Once the diagnosis has been made, the patient should receive education and reassurance about the condition and its consequences. A specific treatment strategy is based on the nature and severity of the symptoms. Referral for psychological treatment usually is recommended for patients with disabling symptoms or associated psychiatric disorders.

Dietary modifications: Identifying and eliminating offending dietary substances can be useful. These may include lactose for persons with lactose intolerance,

caffeine, fatty foods, alcohol, sorbitol, and gas-producing foods such as cabbage and beans.

Pharmacotherapy: Most patients need no medications. When used, the choice of medication should be based on the predominant symptom. Pain and bloating respond to anticholinergic agents such as dicyclomine hydrochloride or hyoscyamine sulfate, preferably before meals. In severe cases, low doses of tricyclic antidepressants (50 to 150 mg desipramine; 25 to 100 mg amitriptyline) should be considered for their neuromodulatory and analgesic properties and for their psychotropic effects. Fluoxetine or paroxetine may be better tolerated by older patients. When diarrhea is the predominant symptom, agents such as loperamide (4 to 8 mg per day) may help to decrease urgency and stool frequency. For patients with constipation, an increase in dietary fiber (25 g per day) may be effective. If not, osmotic laxatives such as milk of magnesia, sorbitol, or lactulose may be added. Use of stimulant laxatives such as senna should not be prolonged. Proton pump inhibitors such as cisapride may be helpful only to patients with milder symptoms.

Chapter 109

APPROACH TO THE PATIENT WITH MALABSORPTION

PATHOPHYSIOLOGY AND DIFFERENTIAL DIAGNOSIS

Generalized maldigestion and malabsorption: Generalized maldigestion may be caused by a deficiency of pancreatic digestive enzyme secretion. Among adults, the two most common are chronic pancreatitis and pancreatic carcinoma. Among children, cystic fibrosis is the most common cause. Because solubilization of fatty acids requires bile acids, moderate fat malabsorption (steatorrhea) can occur with bile duct obstruction, intrahepatic cholestasis, and diseases or resection of the terminal ileum, which is responsible for bile acid reabsorption. Mucosal diseases such as celiac sprue, tropical sprue, Whipple's disease, radiation enteritis, amyloidosis, and giardiasis can cause generalized malabsorption, as can resection of the small intestine and protein-wasting enteropathy. A combination of maldigestion and malabsorption may occur with Zollinger-Ellison syndrome and with intestinal bacterial overgrowth caused by achlorhydria, small-intestinal strictures, the presence of blind loops of intestine, ileal resection, and motility disorders.

Disorders of specific nutrient assimilation: These disorders are caused by an isolated defect in an enzyme or transport system and are not associated with generalized malabsorption or malnutrition. The most common of these disorders is lactase deficiency, which causes malabsorption of the disaccharide lactose. The deficiency may be primary but is also commonly caused by mucosal diseases or the lingering effects of acute enteritis.

CLINICAL FEATURES

Generalized malabsorption: The major symptoms are caused by loss of calories into the stool (weight loss), an increase in stool volume (diarrhea), colonic fermentation of unabsorbed carbohydrates (abdominal bloating and distention, flatulence), and deficiency of dietary nutrients (a combination of anemia, dehydration, and hypokalemia). The weight loss often occurs despite a normal, or even enhanced, appetite. Although abdominal discomfort is common, severe abdominal pain is unusual. Among patients with steatorrhea, oil or undigested food particles may be present in the stool, which is commonly pale, yellow, sponge-like, and difficult to flush down the toilet. Deficiency of iron, folate, or cobalamin may cause anemia. Excessive bruising or bleeding (vitamin K deficiency), paresthesia or tetany (hypocalcemia or hypomagnesemia), and pathologic fractures due to osteoporosis or osteomalacia (calcium and protein deficiency) are the common initial manifestations of specific nutrient deficiencies.

Clinical examination often reveals pallor, muscle wasting, and hair loss. Follicular hyperkeratosis, cheilosis, and glossitis are common signs of nutritional deficits. The abdomen may have a doughy consistency because loops of small intestine become dilated and filled with fluid. Peripheral edema occurs as the result of hypoalbuminemia.

Deficiency of specific nutrients: Isolated malabsorption of specific nutrients usually produces a narrower clinical spectrum than does generalized malabsorption. Lactose malabsorption, for example, causes osmotic diarrhea but is not associated with weight loss and malnutrition.

LABORATORY TESTS

In generalized malabsorption, the stool usually is semiformal or watery and has an increased volume. It may appear greasy. Anemia is common and may be microcytic, normocytic, or macrocytic depending on the underlying deficiency. Prothrombin time may be elevated because of vitamin K deficiency. Profound electrolyte depletion with hyponatremia, hypokalemia, and a metabolic acidosis may occur with severe disease. Decreases in serum levels of calcium, magnesium, zinc, and phosphorus are common. Hypoalbuminemia and hypocholesterolemia are typical in moderate to severe disease.

DIAGNOSTIC EVALUATION

Generalized malabsorption and steatorrhea: Serum levels of carotene, cholesterol, and albumin are routinely low and can therefore be useful as a screening battery, although these findings are not specific for malabsorption. Measurement of stool pH and total reducing substances is useful to screen for carbohydrate malabsorption. The quantification of fat in a 72-hour stool collection (more than 6 g per day after the patient ingests 70 to 100 g fat per day for at least 3 days) is considered the standard of reference for the diagnosis of steatorrhea. Sudan staining of a single stool specimen has 85% sensitivity for severe steatorrhea (more than 15 g per day) but a low sensitivity for mild to moderate disease. Blunted carbon 14 oxygen production after ingestion of carbon 14 C triolein also suggests fat malabsorption. Once generalized malabsorption is established, the D-[¹⁴C]xylose test is helpful in identifying the pathophysiologic mechanism. D-[¹⁴C]Xylose is normally absorbed passively in the jejunum; its absorption decreases in diffuse mucosal diseases but is typically normal in luminal causes of maldigestion such as pancreatic or bile acid deficiency. Small-bowel radiographs and small-bowel biopsy are useful in differentiating luminal and mucosal causes. The presence of pancreatic secretory insufficiency can be established directly with pancreatic function testing or indirectly by measurement in the urine, plasma, or breath of the pancreatic hydrolytic products of orally administered substrates, such as bentiromide. Patients with protein-wasting enteropathy have a α_1 -antitrypsin leakage into the stool. A simplified approach to the diagnosis of generalized malabsorption is shown in [Fig. 110.7](#).

Tests for bacterial overgrowth and specific nutrient malabsorption: Jejunal cultures are the standard for documenting small-intestinal bacterial overgrowth. Owing to bacterial fermentation, patients with bacterial overgrowth also usually have a prompt increase in breath carbon 14 oxygen after ingestion of D-[¹⁴C]xylose or the radiolabeled bile acid cholyll-L-carbon 14 C glycine. Several breath hydrogen tests can be used to detect fermentation of undigested carbohydrates such as lactose. Cobalamin absorption is classically measured with a dual-labeled Schilling test.

MANAGEMENT

Patients with specific diseases should be treated with therapies such as a gluten-free diet for celiac sprue; antibiotic therapy for Whipple's disease, giardiasis, and bacterial overgrowth; and pancreatic enzyme supplements for pancreatic insufficiency. If the specific cause cannot be adequately controlled, parenteral nutrition may be necessary. Patients with lactase deficiency can discontinue the consumption of milk, ice cream, cheeses, and other dairy products or can take these foods with supplemental lactase.

Chapter 110

APPROACH TO THE PATIENT WITH NAUSEA AND VOMITING

DEFINITIONS

Nausea and vomiting are nonspecific responses to a variety of conditions. Nausea is the sensation of an impending urge to vomit; vomiting is the forceful ejection from the mouth of contents of the upper gastrointestinal (GI) tract.

PATHOPHYSIOLOGY

Vomiting is caused by a coordinated interaction of neural, somatic muscular, and gastrointestinal myoelectric and muscular phenomena. Although the mechanisms

that cause nausea are less well understood than those that cause vomiting, activation of selected cerebral cortical sites seems to be necessary.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of nausea and vomiting is extensive and includes a broad range of conditions that affect the GI tract, the peritoneal cavity, the central nervous system, and endocrine and metabolic functions ([Table 98.1](#)).

HISTORY AND PHYSICAL EXAMINATION

Duration of symptoms: Acute vomiting (1 to 2 days) is most often caused by infection, ingestion of a medication or toxin, or accumulation of endogenous toxins, as in uremia or diabetic ketoacidosis. Vomiting for more than 1 week usually is caused by a long-standing medical or psychiatric condition.

Timing of symptoms: Vomiting soon after a meal may occur with gastric outlet obstruction or psychogenic vomiting. Nausea and vomiting from inflammatory conditions such as cholecystitis or pancreatitis may occur in the first hour after a meal. Vomiting more than 1 hour after eating occurs in gastroparesis. Vomiting before breakfast is typical of early pregnancy, uremia, and alcoholism. Nausea from peptic ulcer disease and esophagitis may be improved by ingestion of food.

Character of the vomitus: Vomiting of undigested food suggests achalasia or a Zenker's diverticulum. Vomiting of partially digested food long after ingestion suggests gastroparesis or gastric outlet obstruction. The presence of bile excludes obstruction proximal to the ampulla of Vater. Blood indicates a process causing mucosal damage, such as an ulcer or malignant tumor, or Mallory–Weiss tear caused by the vomiting itself. Feculent emesis occurs in obstruction of the distal small intestine or colon.

Associated symptoms: Abdominal pain occurs with peptic ulcer disease, small-intestinal obstruction, and inflammatory disorders such as cholecystitis and pancreatitis. Vomiting may relieve the pain of the first two but has no effect on inflammatory conditions. The occurrence of diarrhea and fever suggests gastroenteritis. Weight loss is common for many patients, but not those with a psychogenic cause. Central nervous system lesions and meningitis are associated with headaches, neurologic deficits, or neck stiffness. In these disorders, vomiting may be effortless and are not associated with nausea. Specific symptoms can occur with many of the other conditions listed in [Table 98.1](#), such as pregnancy, hyperthyroidism, and labyrinthine disorders.

Physical Examination: The existence of orthostatic hypotension suggests hypovolemia and the need for intravenous fluids. The absence of bowel sounds signifies ileus, whereas the presence of high-pitched, hyperactive bowel sounds and abdominal distention is consistent with intestinal obstruction. A succussion splash may occur with gastric outlet obstruction. Abdominal tenderness or occult fecal blood are present in many of the disorders listed in [Table 98.1](#).

LABORATORY STUDIES AND DIAGNOSTIC TESTS

A thorough history and physical examination are sufficient in most instances. [Figure 98.2](#) shows a suspicion-based algorithm for the evaluation of nausea and vomiting.

MANAGEMENT

Dietary therapy: Frequent small liquid meals should be prescribed to minimize gastric distention. Fats delay gastric emptying and tend to worsen nausea.

Medical therapy: Specific therapies should be directed at the underlying disorder, such as acid suppression for peptic ulcer disease, hydrocortisone for Addison's disease, and surgery for cholecystitis and small-bowel obstruction. For chronic nausea and vomiting, antiemetic medications provide relief. Dopamine receptor antagonists such as prochlorperazine are the most commonly prescribed. The side effects include drowsiness, dystonic reactions, and hyperprolactinemia-induced galactorrhea and sexual dysfunction. Patients with motor dysfunction of the upper GI tract may benefit from use of prokinetic agents that promote gastric emptying and intestinal transit; these include metoclopramide, domperidone, and cisapride. For the emesis caused by cancer chemotherapy, combination approaches are necessary. Serotonin antagonists such as ondansetron have become mainstays. Benzodiazepines, glucocorticoids, and dopamine receptor antagonists are used frequently.

[Chapter 98](#)

PRIMARY SCLEROSING CHOLANGITIS

DEFINITION AND EPIDEMIOLOGY

Primary sclerosing cholangitis (PSC) is a probably autoimmune disease that causes multiple strictures of the extra- and intrahepatic bile ducts. The onset usually is in the fourth or fifth decade of life, and there is a 2:1 male predominance. Between 50% and 70% of patients with PSC also have inflammatory bowel disease, predominantly ulcerative colitis.

PATHOGENESIS

The pathogenesis is unclear, although an association with certain HLA patterns suggests an autoimmune basis. PSC is characterized by progressive, irreversible fibrosis of the bile ducts. Eventually the small intrahepatic ducts become obliterated and the large ducts strictured and narrowed. There is an approximately 10% lifetime risk of cholangiocarcinoma.

CLINICAL PRESENTATION

Symptoms, when present, include fatigue, right upper quadrant pain, and pruritus. Episodes of fever and chills suggest the presence of complicating bacterial cholangitis. Osteoporosis is frequent. The clinical course tends to be one of either recurrent episodes of cholangitis or of slow, silent progression of cholestasis and liver fibrosis with eventual cirrhosis and liver failure. Portal hypertension occurs early in the disease and may be present before the onset of cirrhosis.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

Results of liver biochemical tests generally reflect cholestasis (increased alkaline phosphatase and bilirubin levels). There are no biochemical or serologic tests specific for PSC. Until recently, the diagnostic standard was endoscopic retrograde cholangiopancreatography, but magnetic resonance cholangiography is now equally reliable. Liver biopsy is not helpful in diagnosis but is used to determine whether cirrhosis is present. A complete blood cell count may reveal leukocytosis among patients with cholangitis.

MANAGEMENT

Progression of the disease is slow. The 10-year survival rate is 85% among patients without symptoms and 65% among those with symptoms. Trials have shown that ursodeoxycholic acid, a bile acid, improves biochemical values without improving survival. The only cure is liver transplantation. Though the disease can recur, the survival rate after transplantation is higher than that for any other chronic liver disease. Other measures include pharmacologic prophylaxis of variceal bleeding for patients with esophageal varices, therapy for osteoporosis, and the use of cholestyramine to control pruritus.

[Chapter 125](#)

VIRAL GASTROENTERITIS

DEFINITION AND EPIDEMIOLOGY

Viral gastroenteritis is a common cause of acute infectious diarrhea. The usual pathogens are the rotaviruses (the most important cause of serious diarrhea among children worldwide) and the calciviruses (including the Norwalk agent). In the United States, rotavirus infection is most common in the winter. Although person-to-person spread can occur, the Norwalk agent usually is transmitted through ingestion of contaminated water or foods such as shellfish and salads.

CLINICAL FEATURES

The typical illness is characterized by fever, nausea, vomiting, cramps, and watery diarrhea. The diarrhea is not inflammatory; leukocytes and blood are only infrequently present in the stool. Bloody diarrhea should direct attention instead to bacterial or protozoan pathogens. There usually are no long-term sequelae.

DIAGNOSIS

Presumptive diagnosis of either infection can be confirmed with an increase in serum antibody titer or detection of viral antigens in stool.

MANAGEMENT

Treatment is limited to adequate fluid replacement and supportive care.

[Chapter 113](#)

VIRAL HEPATITIS

INTRODUCTION AND GENERAL CLINICAL FINDINGS

Viral hepatitis is a major cause of acute and chronic liver disease in the United States and worldwide. Five viruses (hepatitis viruses A, B, C, D, and E) are known chiefly to affect hepatic tissue. A hepatitis G virus has been described but has not yet been shown to cause clinical hepatitis. All five viruses cause acute hepatitis. The viruses associated with hepatitis B (HBV), hepatitis C (HCV), and hepatitis D (HDV) also cause chronic inflammation. HDV can infect only in the presence of HBV infection. It tends to worsen the acute hepatitis associated with HBV and to increase the risk of severe chronic disease. Hepatitis E virus is transmitted through the fecal–oral route. Endemic areas include India, Bangladesh, and Central and South America. The case–fatality rate is 1% to 3% overall, but 15% to 25% among pregnant women. Therapy is supportive.

The clinical presentation of acute viral hepatitis is the same regardless of the specific infecting virus. Many cases are subclinical or manifest with a flulike illness that may not be recognized as viral hepatitis unless liver chemistry blood tests are performed. Serum transaminase levels often are more than 20 times the normal limit. Some patients have the classic pattern of a viral prodrome followed by the development of overt jaundice.

EPIDEMIOLOGY, ETIOLOGY, AND PATHOGENESIS

Hepatitis A: Hepatitis A has a worldwide distribution and is transmitted almost exclusively through the fecal–oral route. Outbreaks may be caused by fecal contamination of food or drinking water. HAV contains RNA and is not cytopathic; the mechanisms by which it leads to cellular injury remain unclear. The incubation period ranges from 15 to 45 days.

Hepatitis B: The prevalence of HBV infection varies greatly throughout the world and is particularly high in certain parts of Africa, Asia, and the Mediterranean basin. The virus is transmitted mainly by means of percutaneous exposure or inapparent skin or mucosal exposure. The incubation period ranges from a few weeks to 6 months. Sexual and perinatal transmission rates are high. The likelihood of chronic infection declines with advancing age, such that fewer than 5% of healthy adults have chronic hepatitis after infection. HBV is a DNA-containing virus that is generally not cytopathic. The damaging effects of infection are thought to be caused by the immune response of the host to virally encoded proteins. Portions of the HBV genome may integrate into the genome of the host.

Hepatitis C: Hepatitis C has a high prevalence throughout the world. It is transmitted chiefly through the percutaneous route. Risk factors include blood transfusion before 1992, intravenous drug use, tattooing, hemodialysis, and occupational exposure to blood products. Sexual transmission is rare. Maternal–fetal transmission occurs occasionally at the time of birth. Alcohol use appears to increase HCV replication, and there is a high prevalence of hepatitis C infection among alcoholic patients with liver disease. HCV is an RNA-containing virus of the Flaviviridae family and has at least six distinct genotypes worldwide. The incubation period ranges from 2 weeks to 2 months.

CLINICAL FINDINGS

Hepatitis A: The infection is most often a subclinical disorder among children, but adults usually have symptoms. Unlike infection with the other hepatitis viruses, hepatitis A may cause serious cholestasis. Most cases are self-limited. In rare instances, fulminant hepatitis occurs and leads to death. Persons with underlying chronic liver disease are at increased risk of severe hepatitis A infection.

Hepatitis B: Most patients have no symptoms or have mild, flulike symptoms. Jaundice occurs among fewer than one-third of patients. A prodrome of fever, arthralgia, and rash occurs in 10% to 20% of cases of acute infection and is caused by circulating antigen–antibody complexes that activate complement after becoming deposited in synovium and cutaneous blood vessels.

Hepatitis C: Most acute and chronic HCV infections are asymptomatic. If symptoms occur as a result of acute infection, they generally last 2 to 12 weeks. A small number of persons with chronic HCV infection have signs and symptoms of liver disease, such as fatigue, mild right upper quadrant discomfort, nausea, anorexia, myalgia, or arthralgia. Extrahepatic manifestations develop among 1% to 2% of patients with chronic infection. The most important are essential mixed cryoglobulinemia, membranoproliferative glomerulonephritis, and porphyria cutanea tarda. Cirrhosis develops among at least 20% of patients older than 10 to 20 years.

DIAGNOSTIC EVALUATION

Hepatitis A: An anti-HAV IgM antibody response occurs with acute infection. It occurs early and usually lasts 3 to 6 months after the onset of clinical disease. As IgM antibody titer decreases, IgG anti-HAV emerges and persists for life.

Hepatitis B: Detection of HBV surface antigen (HBsAg) in serum establishes the diagnosis of HBV infection. HBsAg appears in the blood about 6 weeks after infection and usually is cleared within 3 months among patients with transient disease. Persistence beyond 6 months implies chronic infection. Antibody to HBV surface antigen (anti-HBs) generally can be detected 3 months after infection and implies recovery and immunity. Absence of anti-HBs suggests chronic infection. HbsAg usually can no longer be detected by the time anti-HBs appears. In some patients, however, both can be detected simultaneously. The presence of IgM antibody to HBV core antigen (anti-HBc IgM) signifies the presence of acute or reactivated chronic infection. Assessment of HBV DNA is a sensitive measure of viral replication and infectivity, as is detection of HBe antigen (HBeAg) in the bloodstream. Among patients with chronic infection, liver biopsy can assist in assessment of the degree of scar and inflammation and in the detection of viral antigens.

Hepatitis C: Serum alanine aminotransferase (ALT) level usually is less than five times the upper limit of normal. As many as 25% of carriers may have normal levels. Prothrombin time and levels of alkaline phosphatase, albumin, and serum bilirubin are normal until advanced liver disease develops. Iron and ferritin levels may be slightly elevated. The diagnosis is based on results of serologic tests to detect anti-HCV antibody and molecular tests to identify the presence of viral RNA. The initial serologic test usually is an immunoassay. Because of a risk of false-positive results, positive test results require confirmation with a second-generation recombinant immunoblot assay (RIBA-2). Anti-HCV antibody titers are present in almost all patients within 1 month after the onset of acute infection but may never become detectable among persons with compromised immune systems. Anti-HCV antibody is not neutralizing and does not confer immunity. Testing for the presence of HCV in serum or liver tissue is the standard for the diagnosis of active HCV infection. Liver biopsy is not necessary for diagnosis but assists in determining the degree of inflammation and scarring and in excluding other causes of liver disease. In general, there is a poor correlation between serum ALT level and liver disease activity.

determined at histologic examination.

PREVENTION AND OPTIMAL MANAGEMENT

Hepatitis A: HAV vaccine is effective for pre-exposure prophylaxis and is recommended for persons travelling to endemic areas, day care workers, sewage workers, homosexual men, and residents of communities experiencing hepatitis A outbreaks. Immune globulin is effective as postexposure prophylaxis if given to household and sexual contacts within 2 weeks of exposure. Treatment is supportive. Liver transplantation may be indicated for the rare patient with fulminant hepatic failure.

Hepatitis B: Transmission of HBV can be prevented by means of pre-exposure prophylaxis with HBV vaccine or, after exposure, with a combination of vaccination and HBV immune globulin. Pre-exposure vaccination is recommended for all infants at birth, children 11 to 12 years of age if not previously vaccinated, and persons of any age who are at high risk, including health care workers.

[Table 119.5](#) lists indications for treatment. Interferon alfa-2B, given at a dose of 5 million units subcutaneously daily or 10 million units subcutaneously 3 times a week for 4 to 6 months, clears HBV DNA and brings about disease remission for approximately one-third of treated persons. Patients with normal serum aminotransferase levels and those with decompensated cirrhosis are generally not candidates for interferon therapy. Lamivudine, a reverse transcriptase inhibitor, is approved for the management of chronic hepatitis B associated with viral replication and active inflammation. Orthotopic liver transplantation with HBV immunoglobulin given to block graft infection is accepted therapy for end-stage liver disease due to chronic hepatitis B.

Hepatitis C: There is no effective vaccine. Postexposure prophylaxis with immunoglobulin is not effective. Indications for treatment are listed in [Table 119.5](#). Patients with normal serum aminotransferase levels and those with decompensated cirrhosis are generally not candidates for therapy. Long-term response, defined as persistently normal serum HCV RNA levels for at least 6 months after completion of treatment, occurs among only 10% to 15% of patients treated with interferon-alfa monotherapy for 6 to 12 months. Side effects of treatment include acute flulike symptoms and chronic malaise and depression. The addition of ribavirin to interferon therapy produces a higher rate of sustained response (30% to 40%) but can cause hemolytic anemia. Liver transplantation is accepted therapy for end-stage liver disease due to hepatitis C.

[Chapter 119](#)

WILSON'S DISEASE

DEFINITION, EPIDEMIOLOGY, AND PATHOGENESIS

Wilson's disease is an uncommon autosomal recessive inherited disorder that affects 1 in 30,000 persons. In Wilson's disease, a defect in biliary copper excretion causes accumulation of copper in the liver and brain in excess of normal metabolic needs.

CLINICAL FEATURES

Wilson's disease can manifest in childhood or early adulthood with abnormal liver enzyme levels, complications of chronic liver disease, hemolytic anemia, or a variety of neurologic and neuropsychiatric disturbances. A small number of patients have fulminant hepatic failure. Copper deposition in Descemet's membrane in the periphery of the cornea produces characteristic Kayser–Fleisher rings.

LABORATORY FINDINGS AND DIAGNOSTIC EVALUATION

The diagnosis is established with a combination of clinical and biochemical findings. Laboratory studies show increased urinary copper excretion, and a low level of serum ceruloplasmin occurs among approximately 85% of patients. Liver enzyme levels are typically elevated and there may be laboratory evidence of chronic liver disease, such as hypoalbuminemia, thrombocytopenia, and elevated prothrombin time. Liver biopsy shows an increase in hepatic copper level and is necessary for definitive diagnosis. The gene for Wilson's disease has been identified, but routine genetic testing is impractical because more than 60 different mutations have been identified.

MANAGEMENT

Treatment usually is initiated with the copper chelator, D-penicillamine. Patients with side effects of this medication can be treated with trientine, another copper-chelating agent. Zinc supplementation can impair absorption of copper and can induce the synthesis of metallothionein, which binds copper in the intestine. If Wilson's disease is diagnosed before hepatic and neurologic complications have developed, the prognosis is excellent with lifelong copper chelation therapy. Hepatic transplantation has been used successfully to treat patients with fulminant or severe Wilson's disease. All first-degree relatives should be screened for the disorder.

APPROACH TO THE PATIENT WITH ACIDEMIA

DEFINITION

Arterial pH is determined by serum bicarbonate levels and arterial carbon dioxide tension ($P_a\text{CO}_2$). Acidemia is a systemic arterial pH less than 7.35.

PATHOPHYSIOLOGY

Respiratory acidosis is an increase in respiratory acid measured with $P_a\text{CO}_2$ and caused by a reduction in alveolar ventilation. The basis may be severe pulmonary disease, a respiratory muscle disorder or fatigue, or depression of ventilatory control.

Metabolic acidosis is characterized by a decline in bicarbonate level. It is caused by a marked increase in endogenous production of acid, such as lactic acid and ketoacids, loss of bicarbonate stores (diarrhea or renal tubular acidosis [RTA]), or progressive accumulation of endogenous acids in renal insufficiency. The three main types of RTA reflect different defects in urine acidification. The hallmark finding in distal RTA (type I) is inability of the distal tubule to acidify the urine appropriately. Acid retention then decreases bicarbonate level. Although inherited forms of RTA exist, most patients with distal RTA have a systemic illness, such as an autoimmune disorder, hyperthyroidism, hypercalciuria, pyelonephritis, or obstructive uropathy, or a side-effect of a drug such as amphotericin B or lithium.

In proximal RTA (type II), the tubule fails to reabsorb the normal amount of filtered bicarbonate. Metabolic acidosis often occurs in association with Fanconi syndrome, which is generalized dysfunction of the proximal tubule manifested by glycosuria, aminoaciduria, and phosphaturia. Associated systemic conditions include multiple myeloma and Wilson's disease. In both proximal and distal RTA, renal potassium excretion increases, and hypokalemia develops. Type IV RTA, which occurs among patients with diabetes mellitus and tubulointerstitial disease, is caused by a failure of the distal nephron to excrete normal amounts of acid and potassium. The cause usually is hypoaldosteronism or reduction in sensitivity to aldosterone. Unlike proximal and distal RTA, type IV RTA causes hyperkalemia.

Each form of acidosis provokes a compensatory response that tends to offset the change in pH. If the degree of compensation is either more or less than predicted ([Table 149.2](#)), an additional acid–base disturbance is present. In acute respiratory acidosis, an immediate compensatory increase in serum bicarbonate levels is caused by cellular buffering mechanisms. After 24 hours, an increase in renal bicarbonate reabsorption accomplishes an even greater increase in bicarbonate level. In metabolic acidosis, stimulation of medullary chemoreceptors increases ventilation and decreases $P_a\text{CO}_2$ so that acidosis is partially ameliorated.

CLINICAL CONSEQUENCES

Respiratory acidosis: A rapid increase in $P_a\text{CO}_2$ can cause a state of anxiety, dyspnea, confusion, psychosis, and hallucinations that can progress to coma. Lesser degrees of dysfunction in chronic hypercapnia include headaches, sleep disturbances, loss of memory, daytime somnolence, and personality changes.

Metabolic acidosis: Respiratory compensation triggers hyperventilation, which often is perceived by patients as dyspnea. Cardiac effects include reduced contractility and ventricular arrhythmia. Lethargy and coma may occur. RTA can cause symptoms and signs of intravascular volume loss and potassium imbalance. In distal RTA, chronic positive acid balance leads to calcium mobilization from bone, metabolic bone disease, hypercalciuria, urinary stone formation, and nephrocalcinosis. Proximal RTA is not associated with bone disease or nephrolithiasis, but acquired forms may have features of Fanconi syndrome.

DIFFERENTIAL DIAGNOSIS, LABORATORY STUDIES, AND DIAGNOSTIC TESTS

Respiratory acidosis: The differential diagnosis includes central causes (sedating drugs, stroke, central nervous system infection), airway obstruction (foreign body, bronchospasm), parenchymal disease (emphysema, chronic bronchitis, pneumoconiosis, adult respiratory distress syndrome), obesity, and neuromuscular disorders (muscular dystrophy, myositis, cord injuries, myasthenia gravis). Patients stimulated to hyperventilate by metabolic acidosis may experience respiratory fatigue if the metabolic abnormality is not controlled promptly. Pulmonary function testing, including measurement of lung volume and diffusing capacity, arterial oxygen levels, and neuromuscular studies, including electromyography, all may be useful.

Metabolic acidosis: The serum anion gap is used to differentiate high anion gap acidosis from hyperchloremic acidosis. The anion gap, defined as sodium ion concentration plus potassium ion concentration minus bicarbonate ion concentration, represents unmeasured anions normally present in plasma. When acid anions such as acetoacetate and lactate accumulate, the anion gap increases to higher than the normal range of 10 to 12 mEq per liter.

Disorders associated with an elevated anion gap include advanced renal failure, toxin ingestion (ethylene glycol, methanol, salicylates, and paraldehyde), ketoacidosis (alcoholic, diabetic, and starvation), and lactic acidosis. Measurement of serum levels of lactate and acetoacetate can be helpful. Other clinical features associated with high anion gap acidosis are listed in [Table 2](#).

Acidosis	Retained Anions	Associated Findings
Ketosis	Acetoacetate, β -hydroxybutyrate	Hypoglycemia, history of diabetes, starvation or alcohol intake
Uremic	Phosphate, sulfate, organic	Elevated BUN and serum creatinine concentration
Salicylate	Mixed organic	Associated respiratory alkalosis
Methanol	Formate	Elevated serum gap, retinits
Lactic	Lactate	Presence of shock, hypoxia
Ethylene glycol	Oxalate, malate	Highly elevated serum gap, hypocalcemia, calcium oxalate crystals in urine, acute renal failure

TABLE 2. HIGH ANION GAP METABOLIC ACIDOSIS

Hyperchloremic (normal anion gap) disorders include gastrointestinal bicarbonate loss (diarrhea, ureterosigmoidostomy), RTA types I, II, and IV, early renal

insufficiency, rapid administration of saline solution, acid loads, and the posthypocapnic state. Laboratory evidence of distal RTA can be found by calculating the urinary net charge, $Cl^-_u - (Na^+ + K^+)_u$, which becomes abnormally negative owing to a decline in urinary ammonium excretion. Proximal RTA can be diagnosed from an increased urine bicarbonate concentration response to administration of bicarbonate. Hyperkalemia suggests the existence of type IV RTA.

MANAGEMENT

Respiratory acidosis: Treatment depends on severity and rate of onset. Acute respiratory acidosis can be life threatening and may necessitate mechanical ventilation if the underlying cause cannot be reversed quickly. Supplemental oxygen must be carefully titrated in the treatment of patients with severe chronic obstructive disease who retain carbon dioxide at baseline, because it may worsen the respiratory acidosis. Chronic respiratory acidosis often is difficult to control, but general measures, such as smoking cessation, use of bronchodilators, glucocorticoids, and diuretics, and physiotherapy, to manage underlying conditions may be helpful. Respiratory stimulants are used only in selected cases.

Metabolic acidosis: [Table 149.9](#) outlines the therapy for the various forms of metabolic acidosis. Mild-to-moderate acidemia (pH greater than 7.20) often requires no specific therapy, especially if the underlying cause can be controlled. Proximal RTA is difficult to manage, because administered bicarbonate is rapidly filtered and lost. High doses therefore are necessary when treatment is needed. High doses of potassium supplements also are needed because of the kaliuresis induced by the high rate of distal delivery of bicarbonate.

Chapter 149

APPROACH TO ACUTE RENAL FAILURE

DEFINITION

Acute renal failure (ARF) is a clinical syndrome characterized by an abrupt decline in renal function.

PATHOPHYSIOLOGY

ARF can have prerenal, intrarenal, and postrenal causes. Prerenal ARF is caused by a decrease in renal blood flow. Intrarenal ARF is caused by a sudden, severe renal parenchymal insult, which most often is due to acute tubular necrosis (ATN) from ischemia or exposure to a nephrotoxic agent. Postrenal ARF is caused by obstruction at a site along the urinary tract.

CLINICAL FEATURES, DIFFERENTIAL DIAGNOSIS, AND DIAGNOSTIC TESTS

Prerenal: The causes are outlined in [Table 140.1](#); myocardial failure and intravascular volume depletion are most common. Important historical features and physical examination findings are presented in [Table 140.4](#). The urinalysis is usually unremarkable, though the urine tends to be highly concentrated (more than 450 mOsm per kilogram) and low in sodium (fractional excretion of sodium [FENa] less than 1%). Reabsorption of blood urea nitrogen (BUN) with sodium raises the ratio of BUN to creatinine (often more than 20:1)

Intrarenal: The causes include ischemic ATN, nephrotoxic ATN (aminoglycosides, amphotericin B, heavy metals, cisplatin, radiocontrast agents, and endogenous toxins such as myoglobin, hemoglobin, and myeloma light chains), vascular processes (atheroembolic disease, renal artery occlusion, and vasculitis), acute glomerulonephritis, and acute tubulointerstitial nephritis. Distinguishing clinical features are presented in [Table 140.4](#) and also include the following: (a) Hypertension, proteinuria, and hematuria, especially red blood cell casts, suggest acute glomerulonephritis. The urine has low sodium, low FENa, and is isotonic. (b) Skin rash, fever, eosinophilia, and eosinophiluria suggest acute interstitial nephritis when there is a history of exposure to a causative drug. Only biopsy provides enough information for a definitive diagnosis. (c) Anuria (less than 100 mL per 24 hours) can be caused by urinary tract obstruction or bilateral renal cortical necrosis, vascular occlusion, or overwhelming acute glomerulonephritis. (d) Myoglobinuric rhabdomyolytic ARF is associated with a high plasma level of creatine kinase and a urine dipstick test result positive for blood in the absence of red blood cells in the spun urinary sediment. Serum creatinine concentration often rises rapidly. Thus the BUN to creatinine ratio is often less than 10:1. Hyperkalemia often is severe. (e) Hemoglobinuric ATN is suggested when a hemolytic event is followed by excretion of dark urine; often with chills and hypotension.

Postrenal: Urine flow can be obstructed either in the kidney, as in crystal formation, methotrexate precipitation, and uric acid nephropathy after therapy for leukemia or lymphoma, or outside the kidney, as in ureteral compression or blockage. Acute ureteral obstruction typically causes severe colicky pain in the back and flank. Chronic obstruction can cause vague aching or no discomfort. Good urine output can be maintained in partial obstruction. A postvoid residual urine volume of more than 100 mL suggests infravesical obstruction. Renal ultrasonography reveals hydronephrosis and can also show polycystic or scarred kidneys but is less useful in showing the exact location and cause of obstruction. Computed tomography is useful in detecting extrinsic compression of the urinary tract. Intravenous pyelography remains the radiologic procedure of choice in the care of patients with normal renal function.

[Figure 140.1](#) demonstrates the use of urinary indexes and findings in the diagnosis of ARF.

TREATMENT

Prerenal: If ARF is caused by volume depletion, treatment involves saline and volume expanders. For patients in hemodynamically unstable condition, Swan-Ganz monitoring provides better measurement of effective intravascular volume. In hepatorenal syndrome, improvement depends on improved liver function.

Intrarenal: The underlying disease should be controlled, and nephrotoxic drugs should be discontinued. In ATN, fluid and electrolyte balance and adequate nutrition must be maintained, and infection should be managed. In early oliguric ARF, a trial of 80 to 400 mg intravenous furosemide or 12.5 to 25 mg mannitol may reduce the need for dialysis. Diuretics should be discontinued if urine flow does not improve. There are no clinical data to support the efficacy of low-dose dopamine. Uremic symptoms, volume overload, intractable acidosis, hyperkalemia, or oliguria with steadily rising creatinine concentration to 8 to 10 mg per deciliter are indications for dialysis.

Postrenal: The goals are to (a) decompress the urinary tract and (b) establish long-term drainage. Decompression may be followed by a large diuresis, hence hydration status and electrolytes must be monitored carefully. Uric acid nephropathy may be minimized by increasing urine pH with sodium bicarbonate infusion and acetazolamide. Patients receiving chemotherapy for leukemia should be pretreated with allopurinol for 1 to 3 days.

CLINICAL COURSE AND OUTCOME

Possible clinical problems include volume overload, hyponatremia, hyperkalemia, hyperphosphatemia, hypocalcemia, acidemia, and uremia (pericarditis, lethargy, vomiting, infection). Nonoliguric ATN has a better prognosis. Renal failure from ATN usually lasts 7 to 21 days; renal function then may return to baseline. The mortality rate for ATN after surgery or trauma is more than 40%. For nephrotoxic ATN, it is less than 10%.

Chapter 140

APPROACH TO THE PATIENT WITH ALKALEMIA

DEFINITION

Arterial pH is determined by the serum bicarbonate levels and arterial carbon dioxide tension (P_aCO_2). Alkalemia is a systemic arterial pH greater than 7.45.

PATHOPHYSIOLOGY

Respiratory alkalosis is a decrease in respiratory acid reflected by a decreased serum $P_a\text{CO}_2$ level and caused by alveolar hyperventilation. *Metabolic alkalosis* is characterized by an increase in bicarbonate level; it is caused by bicarbonate administration, loss of acid from the upper gastrointestinal tract, or failure of the kidneys to eliminate bicarbonate in the usual manner. Accompanying hypovolemia may enhance reabsorption of bicarbonate in the proximal tubule. Each form of alkalosis provokes a compensatory response that tends to offset the change in pH. If the degree of compensation is either more or less than predicted ([Table 149.2](#)), an additional acid–base disturbance is present. In respiratory alkalosis, the kidney begins to respond within several hours by decreasing bicarbonate reabsorption and acid production. The consequent decline in bicarbonate levels tends to bring the pH toward normal. Full compensation may take several days and depends on normal volume status and renal function. In metabolic alkalosis, compensatory respiratory hypoventilation increases $P_a\text{CO}_2$ and lowers pH.

CLINICAL CONSEQUENCES

Respiratory alkalosis: Effects vary according to duration and severity but are generally those of the underlying condition. A rapid decline in $P_a\text{CO}_2$ can cause dizziness, confusion, and seizures as a consequence of reduced cerebral blood flow.

Metabolic alkalosis: Effects are generally those of the underlying condition.

DIFFERENTIAL DIAGNOSIS, LABORATORY STUDIES, AND DIAGNOSTIC TESTS

Respiratory alkalosis: The differential diagnosis includes various cardiopulmonary conditions, especially those associated with dyspnea, central nervous system lesions, pregnancy, endotoxemia, presence of salicylates, hepatic failure, hypoxemia, sepsis, anxiety, and pain.

Metabolic alkalosis: Diuretics and vomiting are the most common causes. [Figure 149.2](#) shows the differential diagnosis and an approach based on urinary levels of chloride and potassium.

MANAGEMENT

Respiratory alkalosis: Treatment is directed at alleviating the underlying disorder. Patients with hyperventilation syndrome may benefit from reassurance and paper bag rebreathing during attacks.

Metabolic alkalosis: Treatment is directed at removing the underlying stimulus for bicarbonate generation. Chloride-responsive alkalosis ([Fig. 149.2](#)) is associated with volume contraction and generally is corrected with administration of saline solution, which eliminates the hypovolemic stimulus for enhanced renal bicarbonate reabsorption. Management of underlying problems such as vomiting also is helpful. If the vomiting is refractory to therapy, proton-pump inhibitors can be used to decrease the gastric acid loss. Alkalosis unresponsive to chloride is managed by means of control of the underlying condition, such as an excess of mineralocorticoid. Ongoing diuretic use should be discontinued, if possible. Accelerated renal bicarbonate loss can be achieved with acetazolamide, a carbonic anhydrase inhibitor. Hemodialysis can be effective when renal function is impaired.

[Chapter 149](#)

BLADDER CANCER

EPIDEMIOLOGY, ETIOLOGY, AND PATHOGENESIS

Bladder cancer accounts for more than 90% of malignant tumors of the urinary tract. The incidence increases with age and peaks during the seventh decade of life. The male-to-female ratio is about 4:1. Cigarette smoking is by far the leading risk factor. Others include occupational exposure to carcinogenic compounds in dyes, rubber, and paint; chronic infection of the lower urinary tract; history of external beam radiation to the pelvis; and use of cyclophosphamide. In the United States, about 90% of bladder cancers are transitional cell carcinoma (TCC); squamous cell carcinoma accounts for about 7%. In the Mediterranean basin, schistosomiasis is the main causative agent and is associated with squamous cell carcinoma.

CLINICAL FINDINGS

Most bladder cancers manifest as painless, gross or microscopic hematuria, which can occur suddenly and intermittently. Urinary frequency and urgency can be caused by bladder wall irritation or volume loss. Invasive bladder cancer may extend into the prostate, rectum, uterus or vagina, and sacral vertebrae. It spreads through the lymphatic and blood vessels to distant lymph nodes, lungs, liver, and bones. About 5% to 20% of patients have symptoms caused by metastatic lesions. Constitutional symptoms can occur with disseminated disease, but paraneoplastic syndromes are rare.

DIAGNOSTIC STUDIES

Routine urinalysis almost invariably shows hematuria, the degree of which does not correlate with the extent of the lesion. Intravenous pyelography reveals an intravesical filling defect in 60% of cases. Ultrasonography sometimes is used to assess the bladder wall and to evaluate the kidneys and ureters. Urine cytologic examination has a sensitivity and specificity of 80% for grade III tumors but relatively low sensitivity for grade I and II tumors. Direct visualization and biopsy of the tumor usually are performed by means of cystoscopy. Staging should include a complete blood cell count, hepatic and renal chemical analysis, chest radiography, and abdominal and pelvic computed tomography.

PROGNOSIS AND MANAGEMENT

The most significant prognostic factor in transitional cell carcinoma is the depth of tumor invasion; tumor grade also is important. For superficial papillary bladder cancer, the initial treatment is endoscopic resection. Intravesicular administration of Bacille Calmette Guerin (BCG) vaccine is adjuvant treatment of patients at high risk of recurrence. Patients with invasive cancer confined to the bladder organ usually are treated with radical cystectomy, which results in a 60% to 75% 5-year survival rate for T2 disease and a 20% to 40% survival rate with more invasive (T3 or T4) disease. Continent reservoirs such as the Koch pouch have been used to improve patient self-image after radical cystectomy. Postoperative combination chemotherapy has shown some promise. For patients with localized invasive disease who are not surgical candidates, radiation is alternative therapy. The role of neoadjuvant (first-line) systemic chemotherapy is being investigated. For patients with metastatic disease, combination chemotherapy is the treatment of choice, although therapy with even the best agents is associated with a median survival period of only 12.5 months.

[Chapter 160](#)

APPROACH TO THE PATIENT WITH CHRONIC RENAL FAILURE

DEFINITION

Chronic renal failure (CRF) is a slowly progressive and irreversible reduction in glomerular filtration rate (GFR). *Chronic renal insufficiency* is a term used to describe a mild to moderate reduction in GFR, usually less than 25 to 30 mL per minute, that has not reached the point at which symptoms of uremia appear.

PATHOPHYSIOLOGY

A characteristic of most forms of CRF is progressive deterioration of renal function long after the initial insult. The pathogenesis has not been fully explained but likely involves mesangial cytokine production and the adverse effects of chronic proteinuria. The rate of loss of GFR varies with the type of renal disease but tends to be constant for any given patient. Two major mechanisms account for uremic syndrome—accumulation of ill-defined toxins normally eliminated by the kidney and defects

in the function of specific organs.

CLINICAL FEATURES

The manifestations of CRF depend on severity and on the rapidity with which the reduction in GFR develops. In general, uremic symptoms develop when GFR decreases to less than 10 to 15 mL per minute. The initial symptoms may be so insidious that the patient is aware of them only in retrospect, after effective management has been implemented.

History: Uremia usually develops as the blood urea nitrogen (BUN) level exceeds 90 mg per deciliter. Generalized manifestations include fatigue and malaise. Gastrointestinal symptoms are common, including anorexia, nausea, vomiting, and hiccups. Cardiovascular symptoms consist of dyspnea, orthopnea, edema, and pericardial chest pain. Neuromuscular manifestations include impaired mentation and concentration, insomnia, irritability, headache, muscle cramps, restless legs, and twitching. Severe encephalopathy may develop and progress to confusion, stupor, seizures, and coma. Peripheral neuropathy may manifest initially as paresthesia with subsequent disturbances of motor function, including muscle weakness and atrophy. Autonomic neuropathy, especially among diabetic patients, may impair bowel and bladder function. Skin manifestations include itching and bruising. Genitourinary symptoms include nocturia, amenorrhea, and loss of libido.

Physical examination: The signs usually do not appear until late in the course. The patient may appear chronically ill with weight loss and muscle wasting. Dermal manifestations include pallor, yellow-brown discoloration, hyperpigmentation, ecchymosis, and petechiae. Inspection of the head may reveal hypertensive retinopathy or epistaxis. Cardiovascular findings include hypertension, cardiomegaly, edema, and in the preterminal stages, a pericardial friction rub. Kussmaul's respirations reflect the severity of the underlying metabolic acidosis. Mental status findings include confusion, drowsiness, stupor, or coma. Myoclonic twitches and asterixis are typical of advanced uremia. Sensory abnormalities may include loss of vibratory and position sense. Loss of deep tendon reflexes and foot drop may occur. Severe renal osteodystrophy may give rise to bone tenderness and fractures.

LABORATORY DATA

The diagnosis is established with documentation of an elevation in BUN and creatinine levels, typically in a ratio of 10:1 to 15:1. The BUN level is disproportionately elevated with urinary obstruction, cardiac decompensation, high protein intake, gastrointestinal bleeding, and catabolism associated with sepsis or glucocorticoid therapy. The creatinine level is disproportionately elevated with liver disease or malnutrition. When the GFR falls to less than 25 to 30 mL per minute, other laboratory abnormalities may occur, including normocytic anemia, metabolic acidosis, hyperphosphatemia, hypocalcemia, and hyperuricemia. Hyperkalemia is a late manifestation.

PATIENT EVALUATION

A primary question in the evaluation of renal failure is whether it is acute or chronic. Chronic failure implies stability and thus presents a less immediate threat. The best evidence that renal failure is chronic is a prior documented elevation in BUN and creatinine levels. Also valuable are findings of long-standing renal failure, such as renal osteodystrophy or small kidneys at ultrasonography (although normal or even large kidneys may be associated with CRF caused by polycystic kidney disease, myeloma, amyloidosis, and diabetic nephropathy). Anemia, hyperphosphatemia, hypocalcemia, and acidosis are relatively poor indicators that renal failure is chronic; the presence of these disorders often correlates better with the severity of renal failure.

A second question is whether potentially reversible factors contribute to or aggravate the renal failure, such as hypovolemia, hypertension, reflux nephropathy, congestive heart failure, nephrotoxins, sepsis, hypercalcemia, pericarditis, or pericardial tamponade. Definitive diagnosis should then be attempted in which specific diseases that might be remediable are considered, such as malignant hypertension, renal artery stenosis, Wegener's granulomatosis, systemic lupus erythematosus, multiple myeloma, obstruction, reflux, hypercalcemic nephropathy, interstitial nephritis, cholesterol emboli, and lead nephropathy.

DIFFERENTIAL DIAGNOSIS

CRF can have numerous causes ([Table 141.1](#)). The history and examination may reflect abnormalities of the underlying cause. The results of urinalysis typically are abnormal in most stages of renal failure and may show variable degrees of proteinuria, hematuria, pyuria, and casts. However, in many forms of CRF, such as hypertensive nephrosclerosis, obstructive uropathy, and polycystic kidney disease, urinalysis shows few abnormalities. Broad and waxy casts occur with CRF of almost any cause. The presence of heavy proteinuria or red blood cell casts suggests glomerulonephritis. Abnormal findings at serum and urine electrophoresis may occur with multiple myeloma. Serum and urine culture results may be positive in the presence of endocarditis or renal tuberculosis. Depressed serum complement levels and positive test results for antinuclear and anti-DNA antibodies are important clues to the presence of lupus nephritis. Antibodies for glomerular basement membrane are present in Goodpasture's syndrome or anti-glomerular basement membrane nephritis. The presence of antineutrophil cytoplasmic antibodies is helpful in the diagnosis of Wegener's granulomatosis and other systemic types of vasculitis.

Renal ultrasonography provides valuable data about cystic disease, renal calculi, or a dilated pelvicalyceal system. Unfortunately, renal biopsy is of limited value in establishing the cause of renal failure, because the histologic findings may be too unspecific to disclose the cause of the original insult. Nevertheless, in some forms of renal failure associated with normal-sized kidneys, renal biopsy may be useful.

CONSERVATIVE MANAGEMENT

Even after causes of renal failure that can be treated are ruled out, many factors may still require intervention. Control of blood pressure (systolic less than 125 to 130 mm Hg, diastolic less than 80 mm Hg) is essential to limit progression of CRF and development of atherosclerosis. Another therapeutic goal is to maintain near-normal values of serum calcium, phosphate, and parathyroid hormone. This is accomplished by means of restricting phosphate intake (less than 0.8 g per day), prescribing phosphate binders such as calcium carbonate (long-term administration of aluminum hydroxide has detrimental side effects) when the serum phosphate level exceeds 5.0 to 5.5 mg per deciliter, and adding calcium and calcitriol supplements if the serum calcium level is less than 8.5 mg per deciliter despite normal phosphate levels.

Patient without symptoms should be instructed to follow a diet that contains 4 to 6 g per day of sodium; this should be reduced to 2 to 3 g per day in the presence of edema or hypertension and expanded if hypotension or an acute decline in GFR ensues. If hyperkalemia is present, patients should follow a low-potassium diet and avoid medications that increase serum potassium level, such as angiotensin-converting enzyme inhibitors and spironolactone. The potassium binder sodium polystyrene sulfonate (Kayexalate) may be necessary in refractory cases. Sodium bicarbonate or citrate may be given when the serum bicarbonate level falls to less than 18 to 20 mEq per liter. The dosages of medications that are excreted by the kidney, including digoxin, insulin, and many antibiotics, must be adjusted. Magnesium-containing compounds, nonsteroidal antiinflammatory drugs, and radiographic contrast materials are particularly dangerous and should be avoided altogether. A low-protein diet can reduce symptoms and retard progression of CRF, but care must be taken to avoid malnutrition. Recombinant erythropoietin and iron supplements are used to control anemia.

INDICATIONS FOR DIALYSIS

Objective findings that indicate the need for renal replacement therapy include progressive peripheral neuropathy, pericarditis, inadequate nutrition, congestive heart failure, severe hypertension, extreme and refractory hyperkalemia, metabolic acidosis, and general malaise and weakness that interfere with the ability to work. Long-term dialysis ideally should be started when there is an expectation that uremic symptoms soon will develop. A creatinine clearance of less than 10 mL per minute often is used as a guideline. Long-term options include hemodialysis, peritoneal dialysis, and renal transplantation.

[Chapter 141](#)

APPROACH TO THE PATIENT WITH EDEMA

DEFINITION AND PATHOPHYSIOLOGY

Edema is the excessive accumulation of fluid within the interstitial space. Edema is caused by four primary abnormalities—increased mean capillary hydrostatic

pressure, decreased capillary oncotic pressure, increased capillary permeability to protein, or obstruction of lymphatic flow. Most disorders associated with edema are initiated by an alteration in oncotic or hydrostatic forces and are perpetuated by renal sodium retention.

DIFFERENTIAL DIAGNOSIS

Common disorders associated with either generalized or localized edema are categorized according to primary pathophysiologic mechanism ([Table 143.1](#)). Some conditions, including primary aldosteronism, acute glomerulonephritis, and estrogen administration, appear to produce edema by causing inappropriate retention of sodium by the kidney independent of a primary alteration in Starling forces.

CLINICAL FEATURES

Sodium retention that causes a generalized edematous state may be associated with pulmonary edema, peripheral edema, or ascites. Patients with pulmonary edema often report dyspnea and orthopnea. Physical examination shows tachypnea and pulmonary crackles. The chest radiograph shows interstitial edema or alveolar fluid accumulation. Peripheral edema is associated with swollen legs or presacral accumulation of fluid in a patient at bed rest. Pitting edema is the persistence of a depression in the skin after 10 seconds of pressure applied with the fingers and usually occurs when at least 10 lb (4.5 kg) of fluid has accumulated. Patients with ascites have increased abdominal girth. The demonstration of shifting dullness or a fluid wave at physical examination suggests the presence of ascites. Ascites can be confirmed with abdominal ultrasonography.

MANAGEMENT

Diuretics: Several classes are available. There are two groups of sulfonamide diuretics—the thiazides, such as hydrochlorothiazide, and the nonthiazides, such as chlorthalidone and metolazone. These agents act primarily at the distal tubule to inhibit the transport of sodium and chloride. Loop diuretics, such as furosemide, bumetanide, and ethacrynic acid, act at the thick ascending limb of the loop of Henle to inhibit the Na–K–2Cl transporter. These potent agents may increase urinary sodium excretion to more than 20% of the filtered sodium load. Potassium-sparing diuretics, such as spironolactone, triamterene, and amiloride, act in the distal tubule to induce natriuresis and to inhibit potassium excretion. If mild diuresis is needed, sulfonamide diuretics often are the agents of choice. They have poor efficacy in the setting of renal insufficiency. If more potent diuresis is needed, a loop diuretic is chosen. Loop diuretics bind to plasma proteins, and the effectiveness of these agents depends on the concentration of unbound drug. Therefore a single dose is more likely to be effective than the same amount administered in divided doses. Secondary hyperaldosteronism is common with cirrhosis. The diuretic of choice therefore is spironolactone, a competitive antagonist of aldosterone.

Diuretics alone often cannot eliminate generalized edema because of secondary physiologic changes that they induce. They may cause intravascular volume depletion, cardiovascular compromise, and untoward metabolic effects such as hypokalemia (except for potassium-sparing agents), hyponatremia, and hyperglycemia.

Adjunctive therapy: Restriction of dietary sodium and water intake is important. In general, this restriction limits the development of additional edema but has little effect on the resolution of existing edema. Bed rest or elevation of the lower extremities often improves the response to diuretics by increasing renal perfusion and blood return to the heart. The use of elastic stockings over edematous areas helps mobilize interstitial fluid and often promotes natriuresis and diuresis.

Disease-specific treatments: Among patients with cirrhosis, the use of high-volume paracentesis to manage ascites has become popular. Because this procedure can decrease effective arterial blood volume, concomitant colloid expansion, usually with albumin, is indicated. In the care of patients with congestive heart failure, the goal is to lower intravascular volume to the lowest level compatible with optimal cardiac output. This may necessitate monitoring of cardiac filling pressures in an intensive care unit. In the outpatient setting, the physician must rely on measurements of central venous pressure, assessed by measurement of jugular venous distention or hepatojugular reflux. For patients receiving an optimal drug regimen, daily weight is perhaps the best indicator of volume status. Increasing cardiac output with inotropic agents or vasodilators augments diuresis.

[Chapter 143](#)

APPROACH TO THE PATIENT WITH HEMATURIA

DEFINITION

Hematuria is the presence of excessive numbers of red blood cells (RBCs) in the urine and can be gross or microscopic. Finding more than 3 to 5 RBCs per high-power field is considered abnormal. A urine dipstick test result positive for blood in the absence of microscopic hematuria suggests the presence of hemoglobin or myoglobin in the urine.

DIFFERENTIAL DIAGNOSIS

Some causes of hematuria are listed in [Table 134.2](#). Among adults, infection is most common, followed by renal calculi, cancer, and prostatic hypertrophy.

HISTORY AND PHYSICAL EXAMINATION

Urothelial tumors are rare before the age of 40 years. Hematuria coincident with menses suggests endometriosis. Clots occur more often with nonglomerular lesions. Frequency, urgency, or dysuria suggests bladder or urethral involvement. Flank pain occurs with stones, acute obstruction, and IgA nephropathy. Systemic symptoms suggest lupus erythematosus or vasculitis. Use of oral contraceptives has been associated with loin pain–hematuria syndrome. Examination may reveal findings of a specific systemic illness.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

Initial studies include urinalysis, which confirms the presence of hematuria and may show RBC casts and proteinuria (glomerulonephritis) or pyuria and bacteria (infection). Marked proteinuria suggests intrinsic renal disease. Helpful blood studies include complete blood cell count, coagulation times, and serum measurement of blood urea nitrogen and creatinine. Other tests are outlined in [Fig. 134.1](#).

MANAGEMENT

Management is directed at the identified cause.

[Chapter 134](#)

HEMOLYTIC-UREMIC SYNDROME

DEFINITION

Hemolytic-uremic syndrome (HUS), a disease closely related to thrombotic thrombocytopenic purpura, is characterized by renal failure, thrombocytopenia, and microangiopathic hemolytic anemia.

ETIOLOGY, PATHOGENESIS, AND CLINICAL FEATURES

HUS may occur after infection with verocytotoxin-producing *Escherichia coli* strains or other bacteria, such as *Shigella* species, *Salmonella typhi*, *Campylobacter* species, *Yersinia* species, *Streptococcus pneumoniae*, or *Legionella* species. It also occurs among patients using oral contraceptives and among postpartum women. There is an association with some collagen vascular diseases, such as lupus erythematosus and scleroderma. The pathogenesis is thought to involve vascular

endothelial cell damage, but thrombocytopenia, enhanced platelet aggregation, and an abnormal factor VIII level also contribute. HUS among adults has a varied presentation. Renal function may decline subacutely in association with minimal hemolysis and thrombocytopenia. There also is an acute presentation with rapidly developing renal insufficiency and severe hemolysis and thrombocytopenia. A blood smear shows fragmented red blood cells. Renal biopsy shows widespread capillary wall thickening and capillary thrombi. Adults can have arteriolar necrosis and interlobular arterial thrombosis.

MANAGEMENT

Supportive therapy is critical. It includes vigorous control of blood pressure, fluids and electrolytes, and hemorrhage. Dialysis may be necessary. Therapy with exchange transfusions, plasmapheresis, and glucocorticoids has been associated with remission of the disease, although there have been no large, prospective trials of therapy.

Chapter 152

APPROACH TO THE PATIENT WITH HYPERKALEMIA

DEFINITION

Hyperkalemia is a serum potassium value greater than 5.0 mEq per liter.

PATHOPHYSIOLOGY

Hyperkalemia can be caused by a spurious laboratory value, redistribution from the intracellular to the extracellular compartment, or potassium retention. Chronic hyperkalemia is always the result of a defect in renal potassium excretion.

CLINICAL CONSEQUENCES

Depolarization of cell membranes leads to dysfunction of cardiac and skeletal muscle. An early manifestation is peaking of T waves on an electrocardiogram (ECG) that is most prominent with a potassium concentration greater than 6 mEq per liter. More severe cases cause widening of the QRS complex. Ventricular fibrillation and cardiac arrest may follow. Neurologic effects such as tingling, weakness, and even flaccid paralysis can occur when potassium concentration is greater than 8 mEq per liter. Respiratory muscles are spared.

DIFFERENTIAL DIAGNOSIS, LABORATORY STUDIES, AND DIAGNOSTIC TESTS

[Figure 147.1](#) outlines the differential diagnosis and the diagnostic approach to hyperkalemia.

MANAGEMENT

Acute hyperkalemia is a life-threatening abnormality. The higher the plasma level and more severe the ECG alterations, the more urgent is the need for treatment. [Table 147.1](#) lists therapies for hyperkalemia. The goals are to stabilize the myocardial membranes with calcium and to lower serum potassium level by means of redistribution and either gastrointestinal or renal potassium excretion.

Chapter 147

APPROACH TO THE PATIENT WITH HYPERNATREMIA

DEFINITION

Hypernatremia is a serum sodium concentration greater than 145 mEq per liter. Because body fluid tonicity is tightly regulated in healthy persons, hypernatremia is generally a disorder of the very old, very young, or very ill.

PATHOPHYSIOLOGY AND DIFFERENTIAL DIAGNOSIS

Sodium is the major extracellular cation, accounting for almost all of the osmolarity of this body fluid compartment. Therefore, hypernatremia always implies hypertonicity and a shift of water from the intracellular to the extracellular compartment. This cell shrinkage, especially that in the brain, is responsible for the clinical manifestations. Hypernatremia can be caused by a gain of solute in excess of water or by loss of water in excess of solute. Because hypertonicity is a potent stimulus to thirst, sustained hypernatremia always implies inadequate water intake. [Figure 145.2](#) outlines the differential diagnosis and the diagnostic approach to hypernatremia.

CLINICAL CONSEQUENCES

Because adaptive responses exist, the clinical manifestations depend on the rapidity of the increase in serum sodium level as well as the absolute level attained. When symptomatic, hypernatremia typically manifests as altered sensorium. Symptoms can range from agitation, restlessness, confusion, and lethargy to seizures, stupor, and coma. Reductions in brain volume can lead to intracranial hemorrhage from rupture of cerebral blood vessels. Changes in extracellular fluid volume may dominate the clinical findings. For example, hypernatremia due to excess salt often is associated with symptoms of volume overload such as edema, whereas hypernatremia caused by loss of hypotonic fluids is associated with signs of volume depletion. A patient with a pure water deficit generally appears clinically euvolemic, because only one-twelfth of a pure water deficit is derived from the intravascular compartment.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

The important laboratory studies are presented in [Figure 145.2](#). In addition, elevations in levels of blood urea nitrogen, creatinine, and uric acid support volume depletion and therefore suggest hypotonic fluid losses.

MANAGEMENT

Initial therapy should be directed at normalizing intravascular volume. When volume depletion is evident, isotonic (0.9%) saline solution should be infused. When pulmonary edema is present, initial therapy must include removal of the excess sodium with potent diuretics. Once intravascular volume is corrected, attention can be turned to the management of hypernatremia itself. Because of the danger that accompanies rapid correction of chronic hypertonicity (cerebral edema), aggressive therapy should never be used unless the hypertonicity can be ascertained to be acute in origin. Chronic hypernatremia always should be corrected over a period of several days.

Estimation of water deficit: The magnitude of an isolated free water deficit can be estimated as follows because total body solute has not changed from baseline in this situation. Current total body water (TBW) multiplied by serum sodium level equals normal TBW (roughly 60% of mass in kilograms) multiplied by normal serum sodium level. Therefore, for a 60 kg patient with a sodium level of 160 mEq per liter, the current TBW is $(0.6 \times 60) \times 140/160 = 31.5$ L, and the water deficit is 36 L – 31.5 L, or 4.5 L. The same calculation can be used to estimate the water deficit of patients with hypernatremia caused by loss of hypotonic fluids. The calculation, however, underestimates true water deficit if performed before the total body sodium deficit has been corrected with intravenous saline solution.

Correction of acute hypernatremia: No more than half of the estimated water deficit should be replaced during the first 24 hours. Neurologic status and serum sodium levels should be monitored carefully. The rest can be replaced over the ensuing 24 to 48 hours. The oral route is always preferable, if the patient is alert.

Otherwise, 5% dextrose in water should be administered intravenously.

[Chapter 145](#)

APPROACH TO THE PATIENT WITH HYPOKALEMIA

DEFINITION

Hypokalemia is a serum potassium value less than 3.5 mEq per liter.

PATHOPHYSIOLOGY

Most total body potassium exists within cells. Hypokalemia results either from (a) a shift of extracellular potassium to the intracellular compartment, usually associated with metabolic alkalosis and use of insulin or sympathomimetic agents, (b) renal or gastrointestinal loss of potassium, or (c) inadequate potassium intake.

CLINICAL CONSEQUENCES

The most important effects of hypokalemia, usually at values less than 3 mEq per liter, are on the myocardium. Severe hypokalemia may lead to prolongation of the PR interval and widening of the QRS complex. Atrioventricular block and supraventricular tachycardia can occur, and the risk of digitalis toxicity increases. Symptoms include malaise, muscular weakness, and muscle cramps. Constipation and ileus can occur. Hyperglycemia can be caused by defective insulin secretion, polyuria by impaired renal concentrating ability.

DIFFERENTIAL DIAGNOSIS, LABORATORY STUDIES, AND DIAGNOSTIC TESTS

[Figure 146.2](#) and [Figure 146.3](#) outline the differential diagnosis and the diagnostic approach to hypokalemia. Gastrointestinal fluid loss through diarrhea or vomiting and diuretic use are particularly common. Little potassium is lost in vomitus itself, but the loss of hydrochloric acid causes metabolic alkalosis and increases renal potassium excretion.

MANAGEMENT

The magnitude of potassium depletion can be inferred from the plasma level—300 mEq per 70 kg body weight leads to a reduction in plasma potassium of 1 mEq per liter. Severe weakness or serious cardiac dysrhythmia necessitates rapid correction. Otherwise, slow intravenous or oral therapy is preferable to lower the risk of hyperkalemia. Potassium chloride is available as a liquid and as a slow-release tablet.

[Chapter 146](#)

APPROACH TO THE PATIENT WITH HYPONATREMIA

DEFINITION

Hyponatremia is a serum sodium concentration less than 135 mEq per liter. It is one of the most common electrolyte disorders.

PATHOPHYSIOLOGY AND DIFFERENTIAL DIAGNOSIS

Sodium is the main extracellular cation, accounting, along with its companion anions, for almost all of the osmolarity of this body fluid compartment. Therefore, hypotonicity always implies hyponatremia. In contrast, hyponatremia can coexist with low, normal, or high levels of plasma tonicity. Hypotonic hyponatremia always reflects inability of the kidney to excrete enough electrolyte-free water to match water intake. Isotonic hyponatremia is a laboratory artifact caused by hypertriglyceridemia or paraproteinemia. Hypertonic hyponatremia is caused by the presence in extracellular fluid of abnormal amounts of osmotically active solutes other than sodium, such as glucose. These solutes draw water from the intra- to the extracellular compartment, causing cellular dehydration and hyponatremia. [Figure 144.1](#) shows the differential diagnosis and diagnostic approach to hyponatremia. The syndrome of inappropriate secretion of antidiuretic hormone (SIADH) deserves special mention. It is characterized by persistently elevated levels of antidiuretic hormone in the absence of physiologically appropriate stimuli such as intravascular volume depletion. It is associated with numerous medications and various intrathoracic and intracranial processes.

CLINICAL CONSEQUENCES

Clinical manifestations occur chiefly with hypotonic types of hyponatremia, because these disorders are associated with cellular edema. This intracellular volume expansion is of greatest importance in the brain, where it is translated into increased intracranial pressure. Because adaptive mechanisms exist, morbidity and mortality are related not only to magnitude of hypotonicity but also to rate of development. (For example, patients with a very gradual decline in serum sodium level to 120 mEq per liter may have no symptoms at all.) Elderly patients, persons with alcoholism, and premenopausal women have more severe neurologic consequences for any given degree of hypotonicity. The symptoms usually do not occur until serum sodium level falls to less than 125 mEq per liter, at which time the patient may have anorexia, nausea, and malaise. Between 120 and 110 mEq per liter, headache, lethargy, confusion, agitation, and obtundation may occur. Seizures and coma may occur as levels decrease to less than 110 mEq per liter. Focal neurologic findings are unusual but do occur.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

The laboratory evaluation is detailed in [Figure 144.1](#). Once isotonic and hypertonic disorders are excluded, urine osmolarity is the discriminating factor between excessive water intake and impaired renal diluting ability. For patients with the latter problem, measurement of urine sodium and physical examination can categorize patients according to extracellular volume status (hypovolemic, euvolemic, and hypervolemic). SIADH can be diagnosed when the urine is not maximally dilute (tonicity is greater than 100 mOsm per kilogram), there is no evidence of extracellular volume depletion, hypothyroidism and glucocorticoid insufficiency have been excluded, and the urine sodium level is greater than 20 mEq per liter. Decreased serum uric acid levels are common in SIADH. A water load test may be used in challenging cases but must be avoided in the care of patients with severe hyponatremia because of the risk of precipitating neurologic symptoms.

MANAGEMENT

Only hypotonic hyponatremia requires therapy directed at the sodium level. Therapy is directed at raising extracellular fluid tonicity to shift water out of the intracellular space and reduce cerebral edema. The rate of correction must be carefully regulated, however. Overly rapid correction can produce the irreversible neurologic deficits of central pontine myelinolysis. In most circumstances, the sodium level should be raised by no more than 10 mEq per liter in the first 24 hours and no more than 18 mEq per liter in the first 48 hours. Severe, symptomatic hypotonicity should be managed with 3% saline solution along with a loop diuretic to prevent complications of excessive extracellular volume. The management of chronic, asymptomatic hypotonicity should be directed at the underlying cause. Hypovolemic hyponatremia is managed by means of restoration of intravascular volume and correction of the cause of hypovolemia. Because euvolemic hyponatremia represents pure water excess, treatment depends on restricting water intake to less than daily water output. If the cause of SIADH cannot be corrected and water restriction is ineffective or poorly tolerated, demeclocycline can be used to inhibit vasopressin-mediated renal water reabsorption. Management of hypervolemic hyponatremia is difficult. Salt and water restriction is the mainstay of therapy. Diuretics help reduce the volume excess but may trigger vasopressin secretion and further water retention.

[Chapter 144](#)

IMMUNE-MEDIATED GLOMERULOPATHIES

PRESENTATION

Two broad categories of immune-mediated glomerulopathy are recognized. Acute nephritic syndrome includes some or all of the following: hematuria with red blood cell casts, oliguria; azotemia, hypertension, mild-to-moderate proteinuria (1 to 3 g per day), and moderate edema. The underlying glomerular disease usually is inflammatory in nature. A subgroup of patients with rapidly progressive glomerulonephritis have a course that leads to end-stage renal disease in weeks to months unless it is halted with treatment.

Nephrotic syndrome is defined by heavy proteinuria (more than 3 g per day), severe edema, and hypoalbuminemia, often accompanied by hyperlipidemia and hypercoagulability. Hematuria may be present but is not a major feature, and there is frequently only minimal impairment of glomerular filtration rate (GFR) at initial presentation. The underlying glomerular abnormality usually is not inflammatory.

PATHOLOGY

Immune-mediated glomerulopathy comprises a disparate group of diseases in which glomerular injury is thought to be caused directly by immunologic mechanisms. The decrease in glomerular filtration rate may lead to renal failure with accumulation of metabolic waste products (azotemia) and derangement in fluid and electrolyte balance. An alteration in permeability also leads to egress of cells or protein into the urine. The term *diffuse* implies that all or most glomeruli are affected more or less uniformly; *focal* and *segmental* mean that some glomeruli are only partly abnormal. *Proliferative lesion* refers to a hypercellular inflammatory process involving infiltrating leukocytes and proliferation of intrinsic glomerular cells. *Sclerosis* describes a degenerative process in which an increase in extracellular matrix accompanies the loss of glomerular cells and collapse of capillary loops.

DIFFERENTIAL DIAGNOSIS

[Table 150.1](#) lists clinical syndromes and histologic lesions caused by immunologic glomerular diseases. The immunopathologic classification of necrotizing and crescentic glomerulonephritis is outlined in [Fig. 150.3](#). IgA nephropathy is the most common form of primary glomerulonephritis. Certain nonimmune glomerulopathies may manifest as clinical syndromes indistinguishable from immune-mediated diseases, including diabetic nephropathy, hemolytic-uremia syndrome, amyloidosis, the paraproteinemia, and hereditary nephritis.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

The presence of various types of glomerulopathy often is suggested by historical data (e.g., recent pharyngitis with post-streptococcal glomerulonephritis, hemoptysis in Wegener's disease or Goodpasture syndrome, or the various systemic manifestations of systemic lupus erythematosus). [Table 150.2](#) outlines the serum complement profiles and serologic results associated with glomerular diseases. The specific diagnosis and therapy often are guided by the results of renal biopsy including immunofluorescence microscopic examination, which gives diagnostic information and an indication of the relative amounts of inflammation and fibrosis.

MANAGEMENT

The various conditions are managed different ways, although patients with nephrotic syndrome of any cause generally benefit from therapy with angiotensin-converting enzyme inhibitors, reduction of hyperlipidemia, and control of edema with sodium restriction and diuretics. For post-streptococcal glomerulonephritis, spontaneous resolution is the norm, and management is predominantly supportive. Other types of postinfectious glomerulonephritis are managed with appropriate antibiotics. Rapidly progressive glomerulonephritis generally requires immunosuppressive medications with or without plasma exchange (for anti-glomerular basement membrane disease). Patients with IgA nephropathy need to treatment as long as they have normal renal function and no hypertension or proteinuria. Those with more serious disease may respond to glucocorticoids, immunosuppressive agents, or omega-3 fatty acid products. Glucocorticoids are particularly effective in the management of minimal change disease, in which the overall prognosis is excellent.

The management of idiopathic membranous nephropathy with immunosuppressive medication is controversial. A reasonable approach is to reserve cytotoxic agents, in combination with glucocorticoids, for patients at high risk with progressive renal dysfunction or a debilitating nephrotic syndrome unresponsive to conservative therapy. The cornerstone of therapy for secondary membranous nephropathy is management of the associated disease or discontinuation of the offending drug. Primary focal segmental glomerulosclerosis (FSGS) is managed with prednisone or cytotoxic agents; cyclosporin A effectively reduces proteinuria. Secondary FSGS is best managed by removing the cause, if possible, and by lowering intraglomerular pressure with angiotensin-converting enzyme inhibitors.

Secondary causes of membranoproliferative glomerulonephritis (MPGN) type I should be diligently sought and controlled if possible. Idiopathic MPGN and MPGN type II are managed with a prolonged course of prednisone if either nephrotic syndrome or renal insufficiency is present. Because the World Health Organization classification recognizes six histologic classes of lupus nephritis, treatment decisions are based largely on the result of renal biopsy. Glucocorticoids with or without immunosuppressive agents such as cyclophosphamide or azathioprine are indicated for most patients.

[Chapter 150](#)

APPROACH TO THE PATIENT WITH NEPHROLITHIASIS

EPIDEMIOLOGY AND PRESENTATION

The lifetime risk of development of stone disease in industrial nations approaches 20% among men, a rate 3 to 5 times greater than among women. The peak age at onset for both groups is the twenties. The typical patient has severe pain that generally originates in the flank and radiates anteriorly toward the groin as the stone moves along the ureter to the bladder. Dysuria, gross hematuria, urgency, and frequency may be present. Passage of the stone confers almost instant relief. Associated urinary tract infection or obstruction contributes to morbidity, but death is rare. Stones in the renal pelvis may be asymptomatic or cause hematuria alone.

ETIOLOGY AND PATHOPHYSIOLOGY

Stones develop from urine that is oversaturated with respect to the ionic components of the stone. This may happen because of low urine volume, excessive excretion of the components, or other factors that determine solubility (such as urine pH and the presence of inhibitors of crystallization such as citrate). About 70% of all stones contain calcium (about 25% calcium oxalate, 5% calcium phosphate, and 40% both). Magnesium ammonium phosphate (struvite) stones account for approximately 15%, uric acid stones for 5%, and cystine for 2%.

Calcium stones: Calcium oxalate stones may be associated with hypercalciuria or hyperoxaluria. Hypercalciuria is associated with use of loop diuretics, distal renal tubular acidosis, and disorders that cause hypercalcemia. Hyperoxaluria is associated with fat malabsorption and high oxalate intake (see later). Calcium phosphate stones tend to occur in the setting of a high urinary pH, often in association with distal renal tubular acidosis.

Uric acid stones: The three cardinal features of uric acid nephrolithiasis are low urine volume, low urinary pH, and elevated urinary uric acid level. Disorders associated with increased serum and urine uric acid levels include leukemia and lymphoma, (especially after chemotherapy), gout, and renal failure. Patients with chronic diarrhea are particularly at risk, because they tend to have both low urine output (because of dehydration) and acidic urine (to compensate for the metabolic acidosis of diarrhea).

Struvite stones: These form only when the urinary tract is infected with urea-splitting bacteria such as *Proteus* and *Providentia* species. The stones grow rapidly and can fill the renal collecting system, resulting in a staghorn calculus.

Cystine stones: These result from a rare hereditary disorder in which a tubular defect enhances excretion of dibasic amino acids, including cystine. They are more likely to form in acidic urine.

HISTORY AND PHYSICAL EXAMINATION

All patients, even those with stones for the first time, should undergo a thorough interview and physical examination. There may be evidence of one or more of the disorders that predispose to stone formation. A history of frequent urinary tract infections suggests the possibility of struvite stones. Medications may be implicated: acetazolamide raises urinary pH and predisposes to calcium phosphate stone precipitation. Calcium-containing antacids, excessive vitamin D ingestion, and loop diuretics can increase calcium excretion. Excessive ingestion of vitamin C may cause hyperoxaluria. Information about a patient's fluid intake and diet is essential. Meats and other purine-containing foods augment uric acid excretion; foods rich in oxalate include spinach, kale, mustard greens, tea, chocolate, and nuts. The physical examination findings for patients who do not have renal colic usually are normal.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

Analysis of stone composition allows therapy to focus on measures that can decrease the urinary levels of the constituents. Elevated urinary pH (greater than 7) is associated with struvite and calcium phosphate stones; uric acid stones tend to form in acidic urine (pH less than 6). Microscopic urinalysis may show bacteria and leukocytes (the presence of which suggest infection), characteristic crystals, or hematuria that connotes active stone disease. For all patients, even those with a single stone, the following laboratory evaluation is warranted: serum electrolytes, creatinine, calcium, phosphorus, and uric acid levels. If serum calcium is high, parathyroid hormone level should be measured. Qualitative cystine screening of the urine should be performed in each case. For patients with a second stone or a growing stone, a 24-hour urine specimen collected while the patient continues eating his or her usual diet should be analyzed for volume, pH, calcium, phosphate, sodium, uric acid, oxalate, citrate, and creatinine. Radiologic studies are important in diagnosis and management. If the stones are radiopaque (those containing calcium and cystine), size, location, and number can be ascertained with radiography of the kidneys, ureter, and bladder. Intravenous urography can provide additional information, such as the presence of radiolucent stones (those containing uric acid), anatomic abnormalities, medullary sponge kidney, and obstruction. Ultrasonography may miss ureteral calculi.

DIFFERENTIAL DIAGNOSIS

Acute renal colic must be differentiated from other conditions that cause severe pain in either the costovertebral angle (CVA) or the upper and lower quadrants of the abdomen. Pain due to appendicitis often occurs in the right lower quadrant, but it usually originates in the periumbilical area rather than the CVA. Musculoskeletal pain or pain due to disc disease generally does not cause pain as severe as that due to renal colic and is not associated with dysuria or urgency. The presence of hematuria, crystalluria, or radiologic evidence of calculus further assists in making the correct diagnosis. Patients with stone disease may have hematuria even when not experiencing acute renal colic. If no urinary crystals are present, one must exclude other causes of painless hematuria, such as a malignant tumor, infection, or glomerulonephritis.

MANAGEMENT

Most stones less than 5 mm in diameter pass spontaneously. Larger stones, however, rarely pass through the narrow ureters without urologic intervention. The specific intervention, such as extracorporeal shock wave lithotripsy (ESWL), endoscopic removal, percutaneous nephrostomy, or open surgical removal, is selected on the basis of size, number, and location of the stone or stones. Medical management is used to prevent further stone occurrence or growth. Nonspecific therapies include an increase in fluid intake to more than 2 L per day and dietary adjustments. A low-sodium diet decreases both sodium and calcium excretion, and a reduction in dietary protein decreases calcium excretion and increases citrate excretion. Specific therapy is guided by stone analysis or is based on a strong diagnostic suspicion afforded by the serum and urine test results.

Calcium stones: Any underlying disease should be controlled. For patients with hypercalciuria (more than 300 mg per day for men and more than 250 mg per day for women), thiazide diuretics with potassium supplements decrease calcium excretion. A low-calcium diet is not recommended. It leads to negative calcium balance and bone demineralization and may enhance oxalate absorption and excretion. Citrate tablets may be useful to patients with hypocitraturia. Patients with excessive oxalate excretion (more than 100 mg per day) due to malabsorption should consume a low-fat diet and supplemental calcium with meals to bind oxalate. Cholestyramine chelates bile salts, fatty acids, and oxalate. Excessive urinary urate (more than 800 mg per day for men and more than 750 mg per day for women) can provide nuclei for calcium oxalate aggregation. Purine restriction or allopurinol may be needed to decrease urinary excretion of uric acid.

Uric acid stones: Therapy includes oral hydration to increase urine volume to more than 3 L per day and alkalinization of the urine (with oral bicarbonate, potassium citrate, or acetazolamide) to a pH of 6.5 (a higher pH can cause calcium phosphate precipitation). With a urine pH of 6.5, even uric acid levels as high as 1,000 mg per day may be soluble. Higher levels of excretion require dietary purine restriction or the use of allopurinol.

Struvite stones: After appropriate antibiotic therapy is instituted, ESWL or percutaneous nephrolithotomy usually is needed, because the stones are large and frequently form staghorns. Long-term use of suppressive antibiotics may be needed.

Cystine stones: Therapy consists of sufficient water intake to lower the urinary cystine concentration to less than 300 mg per day. Large volumes (more than 4 L per day) may be needed, however, and may be poorly tolerated. Urinary pH should be higher than 7.5. Medications such as D-penicillamine and tiopronin form soluble complexes with cysteine and decrease excretion of cystine. Cystine stones do not crush well with ESWL and when large have to be removed by means of percutaneous nephrolithotomy.

[Chapter 139](#)

APPROACH TO THE PATIENT WITH PROTEINURIA AND NEPHROTIC SYNDROME

DEFINITION

Proteinuria often is the first evidence of renal disease and usually is discovered at routine screening urinalysis. The incidence in population-based studies ranges from 0.6% to 10.7%. The quantity of urine protein has diagnostic and prognostic significance. Nephrotic proteinuria (more than 3.5 g per 24 hours) usually is caused by glomerular disease and is a risk factor for progression of underlying renal disease. Most patients, however, have non-nephrotic proteinuria (less than 3.5 g per 24 hours and usually less than 1 g per 24 hours), which is more typically associated with tubulointerstitial or glomerular diseases that have a more benign clinical course. Abnormally increased albumin excretion that cannot be detected with standard reagent strips is defined as *microalbuminuria*. It is common among patients with diabetes or hypertension, appears to be a marker of cardiovascular risk, and is predictive of development of diabetic nephropathy.

PATHOPHYSIOLOGY

Protein filtration is normally restrained by ionic charge and molecular size. The proximal tubule reabsorbs and catabolizes almost all filtered protein, so less than 150 mg per day is excreted. Glomerular damage eliminates charge or size selectivity. Leakage of protein then overwhelms the tubular reabsorptive capacity. Loss of glomerular basement membrane charge selectivity alone, usually in minimal change nephropathy, results in albuminuria and little loss of larger proteins such as globulins. Tubular disorders reduce reabsorptive capacity and can cause secretion of uroepithelial mucoproteins and IgA in response to inflammation. Immunoglobulin light chains (Bence Jones protein) are freely filtered by the normal kidney. Patients with excessive production have increased proteinuria but no albuminuria and hence a negative result of a urine dipstick test for protein.

HISTORY AND PHYSICAL EXAMINATION

Symptoms and signs of systemic diseases that cause proteinuria ([Table 135.1](#)) may be evident. The use of medications and street drugs should be documented. Hypertension is common in focal segmental glomerulosclerosis and proliferative glomerulonephritis but is uncommon with minimal change disease or membranous nephropathy. Signs of intravascular volume depletion or edema suggest hypoalbuminemia from nephrotic syndrome.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

Initial evaluation is limited to dipstick and microscopic urinalysis and measurement of urinary protein and serum blood urea nitrogen and creatinine. Fasting blood sugar or antinuclear antibody (ANA) titers may be obtained to screen for undiagnosed diabetes or systemic lupus erythematosus. Other diagnostic tests should be performed selectively on the basis of clinical suspicion. For patients with nephrotic range proteinuria, serum protein, albumin, triglycerides, cholesterol, calcium, and phosphate can be measured to assess for associated metabolic abnormalities (see later).

Measurement of urinary protein: Urine dipstick results are reliable in the detection of albuminuria that exceeds 20 to 30 mg per deciliter but are insensitive for detection of other proteins, such as Bence Jones protein. These proteins can be measured with protein precipitation techniques. In concentrated urine, dipstick protein may be falsely elevated. When the dipstick test is twice positive, urine protein should be quantified with 24-hour collection or the protein to creatinine ratio of an early morning specimen, which approximates the daily protein excretion rate in grams per 24 hours.

Microscopic urinalysis: The presence of red blood cell (RBC) casts indicates glomerulonephritis. Oval fat bodies and fatty casts accompany nephrotic glomerular proteinuria. Mild proteinuria with white blood cells but no hematuria is characteristic of tubulointerstitial disease.

Biopsy: Renal biopsy is indicated for unexplained nephrotic syndrome. Biopsy should be strongly considered in the care of a patient with non-nephrotic proteinuria who has azotemia, whose urine sediment contains RBCs or RBC casts, or who has a systemic disease that has eluded diagnosis.

DIFFERENTIAL DIAGNOSIS

Non-nephrotic proteinuria: Patients are more likely to have a normal glomerular filtration rate (GFR), normal results of urinalysis, and no associated systemic disease, although some systemic diseases such as vasculitis or incipient diabetes mellitus manifest as non-nephrotic proteinuria. Patients without serious systemic disease may have transient proteinuria that resolves without sequelae (associated with strenuous exercise, fever, acute illness, and congestive heart failure but may be idiopathic) or orthostatic proteinuria that occurs only when the patient is in the upright position (diagnosed by means of quantifying both daytime and nighttime protein excretion) and resolves spontaneously in 80% of cases. About 90% of young men with proteinuria have this condition. Persistent proteinuria occurs with either glomerular or tubulointerstitial disease. If no other abnormalities are found at urinalysis, the course often is indolent, although renal failure and hypertension may develop.

Nephrotic syndrome: This is caused by primary glomerulopathy or occurs as a manifestation of a systemic disorder ([Table 135.1](#)). Fifty percent to 70% of adults have an associated systemic illness, most commonly diabetes mellitus, systemic lupus erythematosus and other collagen vascular diseases, and amyloidosis. Chronic hepatitis C may be the most common infectious cause. Carcinoma can be associated with the histologic changes of membranous glomerulopathy, leukemia and lymphoma with those of minimal change disease. Between 30% and 50% of adult patients have idiopathic nephrotic syndrome without a systemic disorder. Biopsy usually reveals one of four pathologic entities—membranous glomerulopathy (30% to 40% of cases), focal segmental glomerulosclerosis (20% to 30%), minimal change disease (10% to 20%), or membranoproliferative glomerulonephritis (10% to 20%). Minimal change disease accounts for more than 80% of cases of nephrotic syndrome among children.

CLINICAL MANIFESTATIONS OF NEPHROTIC SYNDROME

Hypoalbuminemia is caused by a failure of hepatic synthesis to compensate for increased urinary losses. Some patients have edema because of reduced plasma oncotic pressure, but for others the cause may be increased blood volume from enhanced renal sodium reabsorption. Transudative pleural effusions and ascites may occur, but pulmonary edema is unusual in the absence of concomitant heart or renal failure. Hypoalbuminemia leads to increased hepatic synthesis of apolipoprotein B and hyperlipidemia (low-density lipoprotein cholesterol and triglyceride levels). Lipiduria is caused by increased glomerular permeability to low-molecular-weight proteins. Both arterial and venous thrombosis may occur, especially renal vein thrombosis. Urinary loss of antithrombin III may play a role, but numerous other potential mechanisms have been identified. Loss of vitamin D-binding globulin in the urine may lead to hypocalcemia, osteomalacia, and secondary hyperparathyroidism. Loss of immunoglobulins may contribute to the increased rate of infection among patients with nephrotic syndrome.

MANAGEMENT

There are specific therapies for particular glomerular and tubulointerstitial diseases. Supportive treatment of patients with proteinuria includes vigorous control of hypertension, which reduces the rate of decline in GFR. Angiotensin-converting enzyme inhibitors slow progression of renal disease independent of their antihypertensive effect, probably by means of reducing proteinuria and the toxic effects of filtered protein on the tubule cells. Aggressive blood glucose control among patients with diabetes has been shown to delay progression of nephropathy. Adequate protein intake is necessary to offset urinary losses. Restriction of dietary protein to delay progression of renal disease is controversial. Edema is treated with dietary sodium restriction (2 to 3 g per day) and judicious use of diuretics with or without low-dose dopamine. Overzealous diuresis of patients with edema who have intravascular volume depletion can precipitate acute renal failure. HMG-CoA reductase inhibitors are the most effective therapy for hypercholesterolemia. Thrombotic complications are managed with anticoagulants, although the risk to benefit ratio of long-term anticoagulation has not been established. Finally, doses of all drugs tightly bound to albumin may have to be reduced to avoid toxicity.

Chapter 135

RENAL CELL CARCINOMA

PATHOGENESIS, EPIDEMIOLOGY, AND ETIOLOGY

Renal cell carcinoma (RCC) originates from the proximal convoluted tubular cells. It usually manifests during the fifth to seventh decades of life. The median age at diagnosis is 60 years. Men are affected twice as frequently as women, but there is no racial predilection. About 2% of cases occur as part of autosomal dominant von Hippel-Lindau syndrome. Risk factors include smoking among men, obesity, and hypertension but not polycystic kidney disease.

CLINICAL FINDINGS

About 20% to 30% of lesions are found incidentally as small tumors in a clinically asymptomatic stage. The classic triad of hematuria, flank pain, and palpable mass occurs in fewer than 10% of patients. However, presentation with one or two of these symptoms is common. The tumor may extend and invade into surrounding structures, such as the inferior vena cava, ureter, adrenal gland, spleen, liver, or pancreas. Only 40% of patients have disease confined to the kidney at diagnosis; 20% have symptoms of metastatic lesions. The common sites of distant metastasis include the lungs, lymph nodes, liver, bone, and brain. Tumor secretion of parathyroid hormone-like protein, erythropoietin, antidiuretic hormone, or corticotropin may cause hypercalcemia, erythrocytosis, hyponatremia, or Cushing's syndrome, respectively.

DIAGNOSTIC STUDIES

For a patient believed to have RCC, initial characterization of a mass lesion may be achieved with intravenous pyelography or ultrasonography. Computed tomography (CT) is the technique of choice for diagnosis and staging. Magnetic resonance imaging (MRI) may have additional benefit in detecting tumors less than 2 cm in diameter and in delineating local anatomy more clearly. Angiography should be used only for tumors in a solitary kidney, for vascular mapping before surgery, and for instances in which tumor angioinfarction is planned. Additional staging procedures include basic laboratory test, chest radiography, and a bone scan. Patients with neurologic symptoms or signs should undergo CT or MRI of the brain. If the tumor appears to be confined to the kidney, the patient probably should undergo surgical resection without biopsy; a normal biopsy result would not prove conclusively the absence of cancer. In contrast, if there is extrarenal tumor involvement, CT-guided biopsy of the primary lesion may be indicated.

PROGNOSIS AND MANAGEMENT

The pathologic stage of RCC is the most important prognostic factor. Stage I (tumor confined within the capsule) has a 5-year survival rate of 65% to 85%; stage II (tumor invading through the capsule but confined within Gerota's fascia), 45% to 80%; stage III (tumor invading the renal vein, inferior vena cava, or regional lymph node), 15% to 35%; and stage IV (distant metastases), zero to 10%. For stages I to III, standard treatment is surgical resection. For some patients, partial

nephrectomy may replace conventional radical nephrectomy. Radiation therapy does not add any benefit. The outcome among patients with stage IV disease is very poor, because RCC is resistant to chemotherapy in general. The role of immunomodulators such as interleukin-2 and interferon- α is being defined. For patients with stage IV disease, nephrectomy should be considered only for palliation of local symptoms such as pain and hematuria. Radiation therapy may improve symptoms of metastasis to bone or brain.

[Chapter 160](#)

URINARY TRACT INFECTIONS

DEFINITIONS

Urinary tract infection (UTI) is one of the most common forms of infection. *Bacteriuria* is the presence of bacteria in the urine. The term *significant bacteriuria* was introduced to differentiate contaminated from infected urine. The criterion has been more than 10^5 colony-forming units per milliliter of urine, although urine from patients with symptomatic UTI may have lower colony counts. *Acute cystitis* is bacterial infection of the bladder epithelium or urethra. *Acute pyelonephritis* is a clinical syndrome of flank pain, fever, and chills due to bacterial invasion of the renal parenchyma. *Asymptomatic bacteriuria* is the presence of significant bacteriuria in the absence of any symptoms of infection. *Complicated UTI* is that which occurs among patients with functionally or anatomically abnormal urinary tracts and is more difficult to manage than other types of UTI. Recurrent infections are categorized as relapse or reinfection. *Relapse* is the recurrence of bacteriuria with the original infecting organism within 2 weeks of cessation of therapy. *Reinfectior* is recurrence of bacteriuria with a new organism.

EPIDEMIOLOGY

Among women, the prevalence of bacteriuria is 3% to 7% but rises to 10% to 25% among women older than 60 years. Among men, the prevalence is much lower but increases in later years. Risk factors for women include sexual intercourse, diabetes mellitus, and the use of spermicides for contraception. Risk factors for men include lack of circumcision and homosexual intercourse. Risk factors for both sexes include interruption of normal urine flow, renal calculi, bladder catheterization, and vesicoureteral reflux.

PATHOPHYSIOLOGY AND MICROBIOLOGY

Although infection by the hematogenous route (usually due to *Candida albicans* or *Staphylococcus aureus*) can occur, the ascending route is the most important. Migration of pathogens from the fecal-perineal reservoir causes colonization of the distal urethra, and the infection ascends to the proximal urethra and bladder or through the ureter to the kidney. The interaction between host defenses, including normal urine flow, and the organism determines whether infection occurs.

Urine is normally sterile. About 80% of community-acquired infections are caused by *Escherichia coli*; another 10% can be attributed to other gram-negative organisms, including *Klebsiella* species, *Proteus mirabilis*, and *Enterobacter* species. *P. mirabilis* is of particular importance because it predisposes to the formation of struvite calculi. *Staphylococcus saprophyticus* is the second most common cause of acute cystitis among young, sexually active women. *Enterococcus faecalis* is an important pathogen among the elderly and among patients who have undergone urinary tract instrumentation. *S. aureus* bacteriuria is less common and is frequently caused by bacteremic seeding of the kidneys during hematogenous infection. Nosocomial infection is more often caused by less susceptible strains of Enterobacteriaceae, *Pseudomonas aeruginosa*, yeast, and *E. faecalis*.

CLINICAL FEATURES AND DIFFERENTIAL DIAGNOSIS

Patients with acute cystitis have dysuria, urgency, and frequency sometimes accompanied by suprapubic discomfort or gross hematuria. Fever rarely exceeds 38°C (100.4°F) if infection is confined to the lower tract. The presentation of acute pyelonephritis consists of fever—usually greater than 38.5°C (101.2°F)—chills, and flank pain. Radiation of the pain to the groin suggests ureteral obstruction. Constitutional symptoms include malaise, anorexia, nausea, vomiting, diarrhea, myalgia, and headache. Fewer than 30% of patients have concomitant lower-tract symptoms. Physical examination findings may be normal, but there is often percussion tenderness in the costovertebral angle. Among the elderly, flank tenderness is less common and confusion is more common. The presentation of acute pyelonephritis can be confused with that of conditions such as bacterial pneumonia, myocardial infarction, acute hepatitis, cholecystitis, and acute pelvic inflammatory disease. Early varicella-zoster infection also can mimic renal pain.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

Diagnosis requires positive urine culture results, as defined earlier. The best criterion for infection with gram-negative aerobes among women with symptoms is 10^2 or more bacteria per milliliter with pyuria. Pyuria is the presence of more than 5 white blood cells per high-power field in centrifuged urine sediment. The leukocyte esterase dipstick test is less sensitive than is microscopic examination but is an acceptable, simple alternative. Pretherapy culture do not improve outcomes among healthy women with acute cystitis and may be unnecessary. Urine Gram stain is useful in predicting the presence of bacteriuria and may narrow the etiologic spectrum. Blood culture results are positive among 20% of patients with acute pyelonephritis; urine white blood cell casts are present among two-thirds of such patients.

Differentiation of upper- from lower-tract UTI may be clinically difficult. The absence of upper-tract signs is unreliable in excluding renal infection. As many as 30% of patients with "cystitis" have subclinical pyelonephritis as documented with localization studies. Despite its low sensitivity in the diagnosis of renal infection (30% to 70%), failure to respond to short-course antibiotic therapy may be the more practical way to diagnose upper UTI among women with only lower-tract symptoms.

Because anatomic abnormalities are present in about 25% of men with UTI, imaging studies such as helical computed tomography, renal ultrasonography, or intravenous pyelography usually are recommended. For women, these studies are necessary only with renal infections that relapse after a 2-week course of therapy. Radiographic and cystoscopic examination of women with reinfection who have no evidence of upper-tract involvement rarely helps identify important abnormalities.

MANAGEMENT

Lower-tract infection: The mainstay of treatment is antimicrobial therapy. Supporting measures such as hydration and urinary analgesia play only a minor role. Conventional therapy is a 7 to 14 day course of trimethoprim-sulfamethoxazole (TMP-SMX), amoxicillin, cephalexin, or a fluoroquinolone. For young, healthy women, several single-dose or 3-day treatment regimens cure 90% of lower-tract infections, a rate equivalent to that of longer conventional regimens. Therapy with TMP-SMX or ciprofloxacin is preferred for this purpose because of an increased incidence of amoxicillin resistance of community-acquired *E. coli* infection.

Upper-tract infection: All men and women with symptoms suggestive of upper-tract involvement should be treated with at least 14 days of antibiotics. Patients who are only moderately ill may be treated initially with oral antibiotics such as TMP-SMX or a fluoroquinolone. For sicker patients, the standard approach has been to start intravenous ampicillin plus an aminoglycoside while awaiting urine and blood culture data. Monotherapy with various agents, including cefotaxime, ceftazidime, piperacillin-tazobactam, ciprofloxacin, and TMP-SMX, has also been shown to be effective. Most patients are afebrile with minimal flank tenderness after 48 hours of therapy. If a patient is slow to respond, investigations are needed to exclude obstruction or abscess. Once the patient is afebrile for 24 hours, therapy can be switched to oral medication.

Asymptomatic UTI: Treatment may be indicated among certain subgroups at risk of increased morbidity, including patients undergoing urinary tract manipulation, those with diabetes mellitus, those who are pregnant, and those who have suppressed immune systems. Elderly patients and those who must stay in bed should not be treated because of the futility of maintaining sterile urine and because of the emergence of resistant organisms with therapy.

Recurrent infection: Relapses usually can be managed effectively with longer courses of the original antibiotic. For recurrent infection, prevention with single daily doses of TMP-SMX or fluoroquinolones is cost-effective among women who have more than two infections per year. An alternative strategy is prophylaxis only after intercourse. Women with sporadic infections may choose to self-diagnose and manage the infection themselves. Among postmenopausal women, intravaginal administration of estrogen alters the vaginal flora and reduces the rate of recurrent UTI.

BACTERIAL ARTHRITIS

DEFINITION

Bacterial arthritis can be classified as gonococcal, nongonococcal, or mycobacterial.

EPIDEMIOLOGY, ETIOLOGY, AND PATHOPHYSIOLOGY

Gonococcal arthritis: *Neisseria gonorrhoeae* is the most common organism causing bacterial arthritis, accounting for almost 75% of infections among healthy, sexually active adults. Disseminated gonococcal infection follows spread of infection from mucosal surfaces and is more common among women, especially during pregnancy, the immediately postpartum period, and within 1 week of menses. Also at risk are those with deficiencies of terminal complement components.

Nongonococcal infections: Most patients have one of the following risk factors: extremes of age, recent manipulation of or injury to a joint, chronic debilitating disease, a disease that alters joint integrity, immunosuppression, intravenous drug use, or prosthetic joints. Most organisms reach the joint through hematogenous spread, although extension from local soft tissue or bone can occur. Gram-positive cocci predominate in healthy adults, the elderly, and those with suppressed immune systems. Polyarticular infection usually is caused by *Staphylococcus aureus* and occurs most often with rheumatoid arthritis, hemophilia, and immunocompromising states. Gram-negative bacilli are present in patients with neutropenia and those who use intravenous drugs. *Staphylococcus epidermidis* is present in early postoperative prosthetic joint infection. Patients with sickle cell disease often are infected with *Salmonella* organisms.

CLINICAL FEATURES

Gonococcal infection: Two forms have been described. The bacteremic form, resembling serum sickness, occurs in about two-thirds of patients and consists of polyarthralgia, tenosynovitis, and dermatitis. It begins with migratory polyarthralgia, fever, chills, and constitutional symptoms. Tendonitis or tenosynovitis may affect the wrists, fingers, ankles, or toes. The skin lesions are papular or pustular, usually on the torso and extremities. Genitourinary symptoms usually are absent. The second form is nonerosive, suppurative arthritis that usually is monoarticular and affects the knees, feet, and ankles. The patient may have a fever, but rash and tenosynovitis usually are absent. Synovial fluid is inflammatory (white blood cell [WBC] count 30,000 to 100,000 cells per microliter). Either form can be associated with mild leukocytosis and a mild to moderate increase in erythrocyte sedimentation rate (ESR). The diagnosis is made through demonstration of the organism on a culture of mucosal surfaces (urethra, endocervix, rectum, or pharynx); blood, and synovial fluid. Blood culture results are positive in as many as 30% of cases in the bacteremic phase. Synovial fluid culture results are positive in about 50% of cases of purulent arthritis. The yield is higher on urogenital cultures, especially cervical cultures (80% to 90%).

Nongonococcal infection: Patients have an acute decrease in range of motion in a painful, warm, swollen joint. Signs of inflammation may be less impressive among patients with chronic disease. Most infections are monoarticular and involve the knees (42%), hips (13%), and ankles and shoulders (10% to 12%). Fibrocartilaginous joints of the axial skeleton are involved in intravenous drug users. Signs of systemic infection are common but may be absent among persons with diabetes, the elderly, and persons with compromised immune systems. Infection should be suspected in rheumatoid arthritis when one or two joints are more inflamed than the other joints. The peripheral WBC count is normal in 40% to 50% of cases, but C-reactive protein level and ESR usually are strikingly elevated. Radiographs usually are normal but should be obtained to rule out underlying osteomyelitis. Blood culture results are positive in 30% to 50% of cases. All suspect joints should be aspirated before antibiotics are started. The synovial WBC count typically is more than 50,000 per microliter with more than 90% neutrophils. A Gram stain is positive in about 50% of cases, bacterial cultures in as many as 95%.

MANAGEMENT

Gonococcal infection: Patients improve dramatically within 48 hours of beginning treatment with antibiotics. Therapy is initiated with intravenous antibiotics until the fever has resolved and the symptoms are controlled (typically 3 to 4 days in the bacteremic form and 7 to 10 days in the suppurative form) followed by a week of oral antibiotics. Because of increasing antibiotic resistance, intravenous therapy with ceftriaxone (1 g per day) is recommended initially, with a switch to penicillin if the strain is susceptible. Oral therapy consists of cefuroxime or ciprofloxacin (500 mg twice a day), and should be accompanied by doxycycline (100 mg twice a day), because genitourinary coinfection with *Chlamydia trachomatis* occurs in as many as 40% of cases. Daily aspiration may be needed for the first few days to ensure adequate response to therapy.

Nongonococcal infection: Treatment consists of parenteral antibiotics and drainage of the affected joint. Initial antibiotic therapy is directed at the most likely organism and may be modified when culture results are available. Intravenous therapy for 2 to 4 weeks is recommended to be followed by 2 to 4 weeks of oral therapy. Drainage is accomplished by means of daily joint aspiration, although immediate surgical intervention is needed for infection of the hip and shoulder and for unresponsive organisms in a damaged joint. The mortality rate is 5% to 10%; complete function is recovered by 50% to 70% of patients. Rheumatoid arthritis is associated with a worse prognosis.

[Chapter 182](#)

CHRONIC FATIGUE SYNDROME

DEFINITION

Chronic fatigue syndrome (CFS) is characterized by debilitating fatigue and a variety of other systemic symptoms.

EPIDEMIOLOGY, PATHOGENESIS, AND PATHOPHYSIOLOGY

CFS predominantly affects young women. The reported prevalence of chronic fatigue in the general population is 1% to 3%. Because CFS often follows a viral illness and shows some laboratory evidence of immune system activation, some investigators consider it to be a host response to triggering or persistent viral infection. However, studies of viruses, including Epstein–Barr virus, have been disappointing. Another view is that CFS and fibromyalgia are clinical correlates of a shared sleep disturbance.

CLINICAL FINDINGS

The onset of CFS is abrupt, often in the aftermath of a viral illness. Profound fatigue, sore throat, tender adenopathy found through the history rather than documented at examination, headache, and an array of neurologic symptoms, such as mild memory impairment or sensory disturbances, characterize the condition. Unrefreshing sleep, depression, and fibromyalgic tender points often are present. The diagnostic criteria for CFS are shown in [Table 185.2](#).

DIFFERENTIAL DIAGNOSIS AND LABORATORY FINDINGS

Medical conditions to be ruled out include anemia, chronic infection, including HIV infection, liver disease, hypothyroidism, chronic adrenal insufficiency, and systemic lupus erythematosus. Laboratory investigation should include a complete blood cell count, erythrocyte sedimentation rate, liver enzyme levels, thyroid-stimulating antibody, antinuclear antibody, and a chest radiograph. For selected patients, HIV screening and cortisol levels before and after adrenal stimulation are indicated. In CFS, all results should be normal.

PROGNOSIS AND MANAGEMENT

Therapy for CFS is similar to that for fibromyalgia---reassurance, physical exercise, aerobic conditioning, and tricyclic antidepressants. Acyclovir is ineffective.

[Chapter 185](#)

CHURG–STRAUSS SYNDROME (ALLERGIC ANGIITIS AND GRANULOMATOSIS)

DEFINITION, EPIDEMIOLOGY, AND PATHOPHYSIOLOGY

Churg–Strauss syndrome (CSS) is a rare hypereosinophilic, granulomatous disorder that affects small and medium-sized vessels. It has a predilection for smaller arteries, arterioles, capillaries, and venules. There is no clear sex preference, and persons of any age may be affected. Pathologic studies reveal intra- or extravascular granulomas and inflammatory lesions rich in eosinophils.

CLINICAL FEATURES

Systemic vasculitis occurs in the setting of asthma or allergic rhinitis. Asthma usually precedes the features of vasculitis by months to years, but both processes may begin simultaneously. Apart from asthma and eosinophilia, CSS is similar to Wegener's granulomatosis (WG) in that it can affect the upper and lower airways and kidneys. However, the allergic nasal and sinus disease of CSS generally is not destructive, and the pulmonary manifestations are more likely to be fleeting infiltrates and less likely to be nodules. The degree of blood and tissue eosinophilia in CSS usually is more marked than in WG, and the renal involvement usually is milder. Coronary arteritis, myocarditis, and gastrointestinal involvement are more frequent in CSS than in WG.

DIAGNOSTIC EVALUATION

There are no specific serologic tests. Erythrocyte sedimentation rate often is elevated. Diagnosis is best achieved with a combination of clinical findings and biopsy of symptomatic or abnormal structures.

MANAGEMENT

The response to high doses of prednisone (about 1 mg per kilogram per day) often is prompt. Cytotoxic agents such as cyclophosphamide should be reserved for patients with severe or progressive disease.

[Chapter 374](#)

FIBROMYALGIA

DEFINITION

Fibromyalgia is a clinical syndrome characterized by fatigue and widespread musculoskeletal pain and stiffness in the setting of normal laboratory and radiologic findings.

EPIDEMIOLOGY, PATHOGENESIS, AND PATHOPHYSIOLOGY

Fibromyalgia predominantly affects women. It is believed to be a self-maintained neuropsychiatric disturbance in which environmental or endogenous stress affects nonrapid eye movement during sleep. This disturbance in sleep causes pain amplification, depression, and fatigue. It may be associated with a variety of systemic illnesses, such as systemic lupus erythematosus, hypothyroidism, and Lyme disease.

CLINICAL FINDINGS

A typical patient reports fatigue, widespread pain, and stiffness. Sleep disturbance involves repeated awakening and greater fatigue on rising in the morning than on retiring at night. The patient may have symptoms of associated conditions, such as depression, migraine, irritable bowel syndrome, orthostatic intolerance, and temporomandibular joint pain. The examination reveals multiple, symmetric tender points ([Table 185.1](#)). In contrast to normal tenderness, the tenderness of fibromyalgia is characterized by an exaggerated emotional response, withdrawal of the tender part, and worsening of pain after examination. Examination often reveals the presence of previously unknown tender areas.

LABORATORY FINDINGS

Laboratory and radiographic findings are normal unless an associated disease causes an abnormality.

PROGNOSIS AND MANAGEMENT

Low doses of amitriptyline (25 mg at night) tend to improve the sleep pattern and diminish the pain. To decrease the pain further and restore endurance, a structured exercise program, particularly involving swimming or rhythmic dance, is recommended. Sympathetic support is helpful; patients need to understand that the condition is not crippling. Tender points often persist despite symptomatic improvement.

[Chapter 185](#)

GIANT CELL ARTERITIS

DEFINITION, EPIDEMIOLOGY, AND PATHOPHYSIOLOGY

Giant cell arteritis (GCA) is sterile granulomatous inflammation of large and medium-sized arteries. It is diagnosed among persons older than 50 years; the mean age is 70 years in most series. Women are affected 2 to 3 times more than men. There is an association with polymyalgia rheumatica (PMR); between 30% and 50% of

patients with GCA also have features of PMR.

CLINICAL FEATURES

GCA most often involves the temporal artery. New onset of severe headaches, scalp or temporal artery tenderness, acute monocular visual loss, and claudication of the muscles of mastication are among the common features. Systemic symptoms, such as fever, also are common, as are manifestations of PMR (discomfort of the hip and shoulder girdles). Some patients have inflammatory arthritis of the peripheral joints.

DIAGNOSTIC EVALUATION

There are no specific serologic tests. The erythrocyte sedimentation rate (ESR) usually is markedly elevated. The combination of typical clinical findings and an elevated ESR allows a clinical diagnosis, even without temporal artery biopsy. However, because it generally does not cause considerable morbidity, biopsy often is performed when clinical features are not entirely classic. Positive biopsy results occur among only 50% to 80% of patients considered likely to have GCA, depending on the size of the biopsy specimen, the clinical features of the illness, and whether bilateral samples have been obtained. A biopsy specimen that provides enough information for a diagnosis can be obtained even after more than 1 week of glucocorticoid therapy. A clinical diagnosis should be questioned if dramatic improvement does not occur within 72 hours after the initiation of glucocorticoid therapy.

MANAGEMENT

Prednisone (0.7 to 1.0 mg per kilogram per day) reduces symptoms within 1 to 2 days and often eliminates symptoms within 1 week. After about 1 month, a slow taper usually can be initiated. Unfortunately, the ESR does not always normalize with disease control, so it should not be relied on as the only measure of disease activity. Patients with disease that responds incompletely to glucocorticoids or that relapses with glucocorticoid taper often are treated with cytotoxic or immunosuppressive agents, although the efficacy of this approach has not been demonstrated in controlled trials.

[Chapter 181](#)

GOUT

DEFINITION AND EPIDEMIOLOGY

Gout is a heterogeneous group of disorders characterized by hyperuricemia, recurrent acute arthritis, joint destruction, tophi (painless, firm masses of urate crystals in and around joints or in soft tissue), renal damage, and uric acid urolithiasis. Acute gouty arthritis primarily affects middle-aged and elderly men and less commonly affects elderly women.

ETIOLOGY AND PATHOPHYSIOLOGY

Only about 20% of patients with hyperuricemia (serum urate level greater than 7 mg per deciliter for men and greater than 6 mg per deciliter for women) ever have gout. Nevertheless, a high serum level of uric acid, the end product of purine metabolism, is a prerequisite for the development of gout. Increased urate production (responsible for less than 10% of cases of gout) can be primary (idiopathic, genetic), secondary to elevated degradation of adenosine triphosphate (ethanol intake, tissue hypoxia, exercise, glycogen storage disease), secondary to increased nucleic acid turnover (blood dyscrasia, malignant tumor, psoriasis), or secondary to excessive purine intake. Decreased renal excretion (responsible for about 90% of cases of gout) can be caused by increased tubular reabsorption (diabetes insipidus, dehydration, diuretics) or decreased tubular secretion (inherited defect, acute ethanol intoxication, ketoacidosis, starvation, lead toxicity, and drugs such as salicylates, diuretics, ethambutol, and cyclosporine). Hyperuricemia leads to crystal deposition in joints and eventually (e.g., after 20 to 30 years of sustained hyperuricemia) may incite acute local inflammation. Local trauma and sudden increases or decreases in serum urate levels are known precipitating factors.

CLINICAL FEATURES

Acute and chronic gout: The basic pattern is one of acute attacks of exquisitely painful arthritis. At first, such attacks typically are monoarticular and associated with few constitutional symptoms. Later the attacks may be polyarticular and associated with fever. Attacks eventually recur at shorter intervals and resolve incompletely. In at least one-half of initial attacks, the first metatarsophalangeal joint is affected (podagra); 90% of persons with gout have acute attacks in the great toe at some time. Next in order of frequency as sites of initial involvement are the insteps, ankles, heels, wrists, finger, and elbows. The first attack commonly begins at night. Within a few hours, the affected joint becomes hot, dusky red, and extremely tender, and the symptoms may progress to resemble those of bacterial cellulitis. Symptoms usually peak within 24 hours.

Between attacks, there—typically is complete remission of symptoms. About 75% of patients have a second attack within 2 years. When the patient has no symptoms, the diagnosis can be uncertain. After many years, a stage of chronic gout develops. Deposits of monosodium urate around the joints increase and cause erosive changes, chronic swelling, and pain. Visible tophi occur after an average of 12 years of gout and may be located in the helix of the ear; on the ulnar surface of the forearm; in the fingers, hands, knees, and feet; or in the olecranon bursa. Eventually there may be severe joint destruction and deformation.

Renal diseases: Urate nephropathy is attributed to the deposition of monosodium urate crystals in the interstitium of the medulla and is associated with chronic hyperuricemia. It is rarely associated with clinically significant renal disease. Acute uric acid nephropathy is acute renal failure related to the formation of uric acid crystals in the collecting tubules, pelvis, or ureter. It is associated with markedly elevated urinary uric acid levels, most commonly in conditions of high cell turnover, such as leukemia, lymphoma, or the tumor lysis syndrome that sometimes accompanies chemotherapy. Uric acid calculi account for about 10% of all stones and occur in 10% to 25% of all patients with gout.

LABORATORY FINDINGS

During episodes of acute gout, serum urate levels may be spuriously normal or low and are unreliable for diagnosis. The condition is best diagnosed by means of examination of synovial fluid from the acutely inflamed joint under a polarizing microscope for negatively birefringent monosodium urate crystals in neutrophils. The crystals appear as needles with blunted ends. The synovial fluid leukocyte count ranges from 5,000 per microliter to 100,000 per microliter. With chronic disease tophi accumulate and produce soft-tissue densities on radiographs. Bony erosions typically consist of a round or oval shape, a sclerotic border, a punched-out appearance, and an overhanging edge of bone. Urinary uric acid excretion more than 800 to 1,000 mg per day while a normal diet is being consumed clearly shows that uric acid overproduction is the cause of hyperuricemia.

MANAGEMENT

Acute gout can be controlled with indomethacin or another nonsteroidal antiinflammatory agent (NSAID), although these agents should be avoided by patients with renal failure. Oral colchicine also is effective but commonly causes diarrhea, abdominal pain; and vomiting. Intra-articular or oral glucocorticoids are used to manage polyarticular attacks. With treatment, attacks may last 2 to 7 days; uncontrolled attacks may last several weeks. Therapy for hyperuricemia (to lower urate level to less than 6.8 mg per deciliter) is beneficial in preventing recurrent attacks, chronic gout, and renal complications. However, because such treatment can aggravate acute attacks, it is prudent to wait 4 to 6 weeks after an attack to initiate therapy and to use NSAIDs or daily colchicine concurrently for a few weeks. A uricosuric drug such as probenecid or a xanthine oxidase inhibitor such as allopurinol provides good long-term control. Allopurinol is preferred for patients known to overproduce urate, for those who undergo unsuccessful treatment with uricosuric agents, for those with a creatinine clearance of less than 60 mL per minute, and for those with uric acid nephrolithiasis or tophi. Asymptomatic hyperuricemia less than 13 mg per deciliter does not require therapy, although prophylaxis with allopurinol is indicated before chemotherapy among patients at risk for acute uric acid nephropathy due to tumor lysis syndrome.

[Chapter 177](#)

HENOCH–SCHÖNLEIN PURPURA

DEFINITION, EPIDEMIOLOGY, AND PATHOPHYSIOLOGY

Henoch–Schönlein purpura is a type of systemic, small-vessel vasculitis that predominantly affects postcapillary venules. Children of any age can be affected; adults are affected less often. There is no sex preference. IgA is the predominant immunoglobulin in circulating and tissue-deposited immune complexes.

CLINICAL FEATURES

In almost 70% of cases among children, upper respiratory infection precedes Henoch–Schönlein purpura by 1 to 3 weeks. Among adults, there usually is no association. The syndrome is characterized by an urticarial or purpuric rash that is most striking in gravity-dependent areas. Other common features include fever (75%), gastrointestinal pain or bleeding (70%), musculoskeletal symptoms (68%), and glomerulonephritis (45%). Gastrointestinal manifestations are less common among adults.

DIAGNOSTIC EVALUATION

There are no specific serologic tests. The diagnosis usually can be made on the basis of signs and symptoms, although skin or renal biopsy sometimes is necessary. IgA and complement deposition is characteristic.

MANAGEMENT

Most patients do well without glucocorticoid or immunosuppressive treatment. These agents should be used, however, if a patient has severe abdominal pain, peritoneal inflammation, gastrointestinal bleeding, or aggressive glomerulonephritis.

[Chapter 150](#)

INFLAMMATORY MYOPATHIES

DEFINITIONS

Idiopathic inflammatory myopathy is a group of conditions characterized by symmetric proximal muscle weakness and evidence of nonsuppurative inflammation in skeletal muscle. The group includes polymyositis, dermatomyositis, myositis with associated connective tissue disease, myositis with associated malignant disease, inclusion body myositis, and focal myositis.

ETIOLOGY AND PATHOGENESIS

The cause is unknown, but these disorders are believed to develop in genetically susceptible persons as a result of immune-mediated processes that might be triggered by environmental factors such as viral infections.

PREVALENCE AND EPIDEMIOLOGY

These are uncommon diseases. The age at onset for the group as a whole has a bimodal distribution, with a peak at 10 to 15 years of age and another at about 50 years of age. Myositis associated with malignant disease and inclusion body myositis are more common after 50 years of age. Blacks are affected more than whites, and women twice as often as men (in inclusion body myositis, however, the ratio is reversed).

CLINICAL FEATURES

Symmetric proximal muscle weakness is the dominant feature. It can be accompanied by myalgia and tenderness. Atrophy may develop over time. Systemic symptoms include malaise, fatigue, morning stiffness, arthralgia, anorexia, weight loss, and low-grade fever.

Polymyositis: The onset usually is insidious. Involvement of the proximal shoulder and pelvic girdles is most common; the neck flexors and pharyngeal muscles also may be involved. Facial and bulbar muscle weakness is rare, and ocular muscle involvement does not occur. Cardiac involvement is uncommon, but heart block, supraventricular arrhythmia, or cardiomyopathy may develop and cause palpitations, syncope, or heart failure. Interstitial pulmonary fibrosis, arthralgia, and Raynaud's phenomenon are more common among patients with a myositis-specific autoantibody.

Dermatomyositis: Patients have all the features of polymyositis and also have cutaneous features, which may predate the onset of weakness by as much as 4 years. The classic changes are Gottron's papules (violaceous scaly areas over the knuckles, elbows, and knees) and heliotrope discoloration of the eyelids or periorbital regions. Other rashes also occur. Among some patients, the rash and muscle weakness tend to remit and flare up together; among others, there is no apparent connection.

Myositis with other connective tissue diseases: Muscle weakness may accompany systemic lupus erythematosus, scleroderma, mixed connective tissue disease, Wegener's granulomatosis, polyarteritis nodosa, and giant cell arteritis. The myopathic features may be indistinguishable from those of polymyositis.

Myositis with malignant disease: The association is somewhat controversial but seems more likely with dermatomyositis than with polymyositis. With the exception of ovarian cancer among women with dermatomyositis, the sites and types of tumors are the same as those among other patients of the same age and sex.

Inclusion body myositis: Lower extremity weakness tends to predominate; the distinctive clinical feature is involvement of distal muscles. Myalgia and muscle tenderness are uncommon. Dysphagia occurs among about one-third of patients.

DIFFERENTIAL DIAGNOSIS

Conditions that can mimic idiopathic inflammatory myopathy include neurologic disorders (muscular dystrophy, myasthenia gravis, amyotrophic lateral sclerosis, Eaton–Lambert syndrome), infectious disease (toxoplasmosis, viral infection, trichinosis), electrolyte disorders (hyponatremia, hypocalcemia, hypokalemia, hypophosphatemia, hypomagnesemia), exposure to toxins and medications, inborn errors of metabolism (mitochondrial myopathy, carnitine deficiency, glycogen storage diseases), sarcoidosis, and chronic fatigue syndrome.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

Serum levels of muscle enzymes (creatine kinase, aldolase) are elevated and can be used to gauge disease activity and the response to therapy. The erythrocyte sedimentation rate is mildly increased in about 50% of patients. Anemia is uncommon. Most patients have circulating autoantibodies such as Jo-1 and SRP. Electromyographic changes suggestive of inflammatory myopathy include the triad of increased insertional activity, fibrillations, and sharp positive waves. Patients with inclusion body myositis also may have neuropathic features. In 10% of cases, the electromyogram is normal. Magnetic resonance imaging can be used to establish the extent of disease and to localize sites for biopsy. The characteristic changes at biopsy include degenerating and regenerating fibers, fibrosis, and an endomysial inflammatory infiltrate with lymphocytes surrounding and invading nonnecrotic fibers. Inclusion body myositis also shows lined vacuoles on histologic examination and filamentous inclusions at electron microscopic examination.

PROGNOSIS AND MANAGEMENT

Treatment involves physical therapy, glucocorticoids, and early detection of pulmonary fibrosis and swallowing abnormalities. Prednisone is given in a single morning dose of about 1 mg per kilogram (2 mg per kilogram in severe cases). It is continued until strength improves, usually over weeks to months. The medication is then

tapered gradually over many months. Glucocorticoids produce a response among 90% of patients and complete remission among 50% to 75%. If there has been no remission after 6 to 12 weeks, a second agent such as azathioprine or methotrexate should be added. The cutaneous manifestations of dermatomyositis may respond to hydroxychloroquine. Myositis associated with malignant disease or connective tissue disease generally responds to therapy for the associated condition. Inclusion body myositis can be refractory to therapy.

[Chapter 180](#)

LYME DISEASE

DEFINITION AND EPIDEMIOLOGY

Lyme disease (LD) is a multisystem inflammatory condition caused by spirochetes known collectively as *Borrelia burgdorferi* and spread by *Ixodes* ticks. About 90% of cases in the United States occur in the following states: Massachusetts, Connecticut, Rhode Island, New York, New Jersey, Pennsylvania, Minnesota, Wisconsin, and California. Most cases occur during the late spring, summer, and early fall. It takes 48 hours or more after tick attachment for LD to be spread; even in areas where 40% of adult *Ixodes* ticks carry *B. burgdorferi*, LD develops among only about 1% of people who are bitten. Only about 30% of patients recall being bitten by a tick.

CLINICAL FEATURES

Early, localized disease: Erythema migrans occurs among 50% to 80% of patients, usually less than 1 month after the tick bite. It expands over a few days, often with central clearing, and is most often found in or near the axilla or groin. Half of all patients have multiple lesions caused by spirochetemia. Patients also may have fatigue, malaise, headache, myalgia, arthralgia, and lymphadenopathy.

Early, disseminated disease: This stage occurs days to months after the tick bite and can occur with no antecedent erythema migrans or documented tick bite. Musculoskeletal symptoms are common and include migratory polyarthritides or arthralgia and fibromyalgia. Neurologic findings, which occur among 10% of untreated patients, include lymphocytic meningitis, cranial nerve palsy (especially of the seventh cranial nerve), and radiculoneuritis. About 8% of untreated patients have carditis, including mild myopericarditis and any degree of heart block, which usually begins to resolve during or even before the initiation of therapy.

Chronic or late disease: Late disease occurs months to years after infection and may not be preceded by other features of LD. About 80% of untreated patients have musculoskeletal symptoms, including arthralgia, intermittent arthritis, and chronic monoarthritis, usually in the knee. The other feature is tertiary neuroborreliosis, which is characterized by encephalopathy, cognitive dysfunction, and peripheral neuropathy. Acrodermatitis chronica atrophicans may occur.

DIAGNOSIS

Enzyme-linked immunosorbent assay (ELISA) and Western blot techniques are used to detect antibodies to *B. burgdorferi*. The results suggest exposure but alone do not provide enough information for a diagnosis. The diagnosis is made on clinical grounds, and the test results are used only for confirmation. False-positive ELISA results can occur with other spirochetal diseases (e.g., syphilis), rheumatologic diseases (e.g., rheumatoid arthritis), and other infections (e.g., endocarditis, Epstein-Barr disease). Positive and equivocal ELISA results therefore necessitate corroboration with Western blot results. The ELISA result may not become positive for 6 to 8 weeks and may never become positive if the patient receives antibiotic therapy early in the course. Antibody levels may stay elevated for years after successful treatment.

MANAGEMENT

Timely antibiotic therapy prevents progression to later stages of disease, although it may not decrease the duration or severity of many of the features of early LD. Early, localized disease can be controlled with 3 to 4 weeks of oral doxycycline or amoxicillin. The later stages require intravenous therapy for 2 to 4 weeks; third-generation cephalosporins, penicillin G, and chloramphenicol can be used. There is no evidence that prolonged therapy or oral therapy after intravenous therapy is helpful. Fewer than 10% of patients with early LD have a Jarisch-Herxheimer reaction within the first days of therapy (a worsening of many of the signs and symptoms). This usually lasts for less than a day and is never fatal. Because studies suggest that the risk of contracting LD from a known tick bite is small, prophylactic therapy is not recommended.

[Chapter 183](#)

OSTEOARTHRITIS

DEFINITION AND EPIDEMIOLOGY

Osteoarthritis (OA) is a joint disease characterized by progressive loss of articular cartilage and reactive changes in the underlying bone. OA is the most common form of arthritis. Risk factors include increasing age, female sex, African-American race, obesity, trauma, abnormal joint biomechanics, prior inflammatory joint disease, and metabolic disorders such as hemochromatosis and acromegaly.

PATHOPHYSIOLOGY

OA is thought to be primarily a disease of the articular cartilage and subchondral bone with mild secondary inflammation in the synovial membrane. Proliferation of cartilage at the margins of the joint and subsequent endochondral ossification lead to formation of the osteophytes, the radiologic hallmark of OA.

CLINICAL FEATURES

History: The typical patient with OA is middle-aged or elderly and has a gradual onset of pain and stiffness accompanied by loss of function. The joints most commonly involved include the distal and proximal interphalangeal joints of the hands, first carpometacarpal, cervical or lumbar intervertebral joints, first metatarsophalangeal, knees, and hips. The pain usually is mild, is worsened by use of the involved joints, and improves or is relieved with rest. Pain at rest and nocturnal pain are features of severe disease or of local inflammation. Morning stiffness is common, but the duration is considerably shorter (often less than 30 minutes) than in active rheumatoid arthritis. Gel phenomenon, stiffness after inactivity, is common and resolves within several minutes. In many instances, pain and stiffness are modified by weather changes, generally worsening with damp, cool, rainy weather.

Physical examination: Bony enlargement with tenderness at the joint margins and periarticular tendons is common. Limitation of motion of the affected joint usually is related to osteophyte formation or severe cartilage loss. Heberden's and Bouchard's nodes are bony enlargements of the distal and proximal interphalangeal joints, respectively. Mild signs of local inflammation may be present, but a hot, erythematous, markedly swollen joint suggests superimposed crystalline or infectious arthritis. Crepitus, present among more than 90% of patients with OA of the knee, is caused by irregularity of the opposing cartilage surfaces.

LABORATORY FINDINGS

The diagnosis usually is confirmed with radiographs. The classic finding is marginal osteophyte formation. With disease progression, radiographs show subchondral sclerosis of the bone and asymmetric joint space narrowing caused by loss of articular cartilage. Bone demineralization and marginal erosions do not occur. The presence of these findings strongly suggests inflammatory arthritis. The complete blood cell count and erythrocyte sedimentation rate usually are normal. Because as many as 20% of elderly patients have a low titer of rheumatoid factor, the presence of this factor does not exclude a diagnosis of OA. Synovial fluid analysis usually reveals noninflammatory fluid. The leukocyte count rarely exceeds 2,000 per microliter.

MANAGEMENT

Nonpharmacologic approaches include patient education, physical and occupational therapy, range of motion and strengthening exercises, aerobic conditioning, and weight loss. The main indication for drug therapy is pain relief. Simple analgesics, such as acetaminophen, are the drugs of choice. Several studies have

demonstrated that the short-term efficacy of acetaminophen is comparable with that of nonsteroidal anti-inflammatory drugs (NSAIDs). Patients who do not respond to acetaminophen should be treated with an NSAID. The various NSAIDs are approximately equal in efficacy, although cyclooxygenase-2-specific inhibitors have the lowest incidence of adverse upper gastrointestinal side effects. Although there is no indication for systemic glucocorticoid therapy, intra-articular glucocorticoid injections have a role in the care of patients with effusion in the joints and signs of local inflammation. The frequency of injections should be limited to fewer than 4 per year. Topical analgesic creams, such as capsaicin, sometimes are useful. Patients are candidates for reconstructive joint surgery if the symptoms are not adequately controlled with medical therapy and if they have moderate to severe pain and functional impairment.

[Chapter 175](#)

OSTEOPOROSIS IN OLDER ADULTS

DEFINITION

Osteoporosis is a disease characterized by low bone mass, microarchitectural deterioration of bone tissue, enhanced bone fragility, and an increase in the risk of fractures.

EPIDEMIOLOGY, ETIOLOGY, AND PATHOPHYSIOLOGY

Each year in the United States, approximately 1 million persons sustain fragility fractures. Among women, the incidence of vertebral fractures begins to increase near the time of menopause; the incidence of hip fracture accelerates approximately 10 years later. Older women have an incidence of hip fracture twice that of older men; the female to male ratio for vertebral fractures is 8:1. The pathogenesis is multifactorial and may involve increased bone resorption (due to hypogonadism and secondary hyperparathyroidism from calcium deficiency) and diminished osteoblast activity.

RISK FACTORS

Primary osteoporosis: Risk factors for primary osteoporotic fracture that can be modified include cigarette smoking, low body weight, estrogen deficiency, lifelong low calcium intake, alcoholism, impaired eyesight, recurrent falls, inadequate physical activity, and poor health. Risk factors that cannot be modified include a personal history of fracture, advanced age, female sex, dementia, and having a first-degree relative with a history of fracture.

Secondary causes: Osteoporosis can be associated with primary hyperparathyroidism (detected with an increased level of ionized calcium), multiple myeloma (serum and urine electrophoresis), Paget's disease (increased alkaline phosphatase level), osteomalacia (increased alkaline phosphatase and decreased vitamin D levels), hyperthyroidism (decreased level of thyroid-stimulating hormone, increased level of thyronine), and hypogonadism among men (decreased free testosterone level). Implicated medications include glucocorticoids, excess thyroid supplementation, anticonvulsants, methotrexate, cyclosporine, and heparin.

DIAGNOSIS

The diagnosis is made by means of bone mineral density (BMD) measurement before fracture or with the occurrence of a fracture. According to World Health Organization criteria, BMD is evaluated in relation to that of young adult women who are at the age of peak bone mass. For each standard deviation below peak bone mass (called a 1 unit decrease in t score), a woman's risk of fracture approximately doubles. Osteopenia is defined as a t score between (-1) and (-2.5) , osteoporosis as a t score of -2.5 or less. The use of biochemical markers of bone density, such as urinary deoxypyridinoline cross links and serum or urine N telopeptides of type I collagen, is under study; they may be useful in monitoring response to treatment.

Measurement of BMD (best obtained with dual-energy x-ray absorptiometry) should be considered for: (a) all postmenopausal women younger than 65 years with one or more additional risk factors; (b) all women older than 65 years; (c) all postmenopausal women with fractures; (d) women considering therapy for osteoporosis, if BMD testing would facilitate the decision; and (e) women who have been using hormone replacement therapy (HRT) for a long time. BMD determination also can be used to establish the diagnosis and severity of osteoporosis among men.

PREVENTION AND MANAGEMENT

Prevention begins with risk factor modification and calcium (1,500 mg per day) and vitamin D (400 to 800 IU per day) supplements. If HRT is contraindicated or unacceptable to the patient, raloxifene (60 mg per day) or alendronate (5 mg per day) should be considered. BMD measurement should be repeated every 2 to 3 years. If more than 4% of BMD has been lost, one should consider combination therapy (e.g., HRT plus alendronate or alendronate plus raloxifene).

An algorithm for the treatment of postmenopausal women with osteoporosis is presented in [Fig. 465.4](#).

[Chapter 465](#)

POLYARTERITIS NODOSA

DEFINITION, EPIDEMIOLOGY, AND PATHOPHYSIOLOGY

Polyarteritis nodosa is an inflammatory disease of medium-sized or small arteries. It affects patients of any age with no sex preference.

CLINICAL FEATURES

Patients may have fever, musculoskeletal symptoms, neurologic symptoms (peripheral more than central), cardiac disease, gastrointestinal vasculitis, and a variety of skin lesions, including livedo, nodules, ulcers, and gangrene but not palpable purpura. The peripheral neuropathy often is mononeuritis multiplex but may be symmetric polyneuropathy. Glomerulonephritis is not a feature, but patients may have renal failure or hypertension due to involvement of the renal arteries.

DIAGNOSTIC EVALUATION

There are no specific serologic tests. The erythrocyte sedimentation rate often is elevated. Diagnosis is best achieved by means of biopsy of symptomatic or abnormal structures. If this approach is impossible or unrevealing and visceral or systemic symptoms are present, angiography should be considered. To maximize the diagnostic yield, a complete study should include the celiac artery and its principal branches, the superior and inferior mesenteric arteries, and the renal arteries.

MANAGEMENT

Uncontrolled polyarteritis nodosa has a 5-year mortality rate higher than 85%. Treatment with high-dose glucocorticoids may improve this rate to 48%, and the combination of glucocorticoids and an immunosuppressive agent, usually cyclophosphamide, may further reduce it to approximately 20%.

[Chapter 181](#)

RHEUMATOID ARTHRITIS

DEFINITION AND EPIDEMIOLOGY

Rheumatoid arthritis (RA) is chronic, symmetric polyarthritis of the small joints of the hands and feet and of the larger appendicular joints. It is the most common form of inflammatory arthritis, affecting 1% of the population. Women are affected 2 to 3 times more often than men. The disease can begin at any age, but the peak onset

is in the fifth decade of life.

ETIOLOGY AND PATHOGENESIS

Susceptibility to RA has a genetic component. There is some evidence of both infectious and autoimmune causes, but a definite connection has yet to be proved. In RA, the synovium is transformed into a hyperplastic, chronically inflamed tissue. The change is caused by local proliferation of fibroblast-like cells, an increase in the number of macrophage-like synoviocytes, and a prominent mononuclear cell infiltrate comprising mainly T cells, B cells, and macrophages.

CLINICAL FEATURES

Articular manifestations: Although many patterns occur, RA typically begins insidiously with symmetric polyarticular arthritis involving the small joints of the hands and feet. In some cases, there is an abrupt onset of polyarthritis associated with constitutional signs such as fever and weight loss. Morning stiffness lasting greater than 30 minutes is particularly prominent and can persist for several hours. A similar gel phenomenon occurs when patients remain in a single position for a prolonged period. The proximal interphalangeal (PIP) and metacarpophalangeal (MCP) joints usually are tender and swollen. Prominent distal interphalangeal joint involvement is more characteristic of psoriatic arthritis or osteoarthritis. Wrist disease is common. Deformities of the hand include radial deviation at the MCP joints. Swan neck and boutonniere deformities of the hands and feet are common later in the course. Larger proximal joints such as the elbows, shoulders, knees, and hips may be affected. Cervical spine disease is another frequent complication. In long-standing disease, the odontoid process can become severely eroded, predisposing the patient to subluxation of the atlantoaxial joint and resultant myelopathy. Rheumatoid joints are at high risk of bacterial infection.

Extra-articular manifestations: Rheumatoid nodules are present in about 20% of patients (almost all of whom have rheumatoid factor that can be detected) and are caused by the formulation of extra-articular granulation tissue. They can appear anywhere but are most common on bony prominences and tendon sheaths. They tend to wax and wane over time. Pleuropulmonary manifestations include asymptomatic effusions, interstitial lung disease, and parenchymal rheumatoid nodules. Other complications include pericardial effusion, carpal tunnel syndrome, popliteal (Baker's) cysts, episcleritis or scleritis, amyloidosis, and sicca syndrome. A vasculitic syndrome similar to idiopathic polyarteritis nodosa can occur among patients with rheumatoid factor and cause complications such as mononeuritis multiplex and palpable purpura. Felty's syndrome is RA with splenomegaly and hypersplenism.

LABORATORY STUDIES

Characteristic findings include mild normocytic, normochromic anemia, a normal leukocyte count, and an elevated erythrocyte sedimentation rate. Rheumatoid factors are antibodies, usually IgM, that bind to the Fc portion of immunoglobulin. About 85% of patients with RA have positive serologic results for rheumatoid factor and are prone to having more aggressive disease. Despite its name, the test is relatively nonspecific. A positive result occurs among 1% to 5% of healthy persons and among patients with endocarditis, tuberculosis, other connective tissue diseases, sarcoidosis, and hepatic cirrhosis. The white blood cell count in the synovial fluid usually is moderately elevated (2,000 to 20,000 cells per microliter) with about 50% to 75% neutrophils. Synovial biopsy provides little useful information. Bone radiographs can help with the diagnosis and can be used to follow response to therapy. The first changes in the hand usually are periarticular osteopenia and soft-tissue swelling, especially of the PIP and MCP joints. With progression of the disease, cartilage loss causes joint-space narrowing, and bone erosions appear in the recesses of joints where bone is not protected from synovial fluid by cartilage. In advanced disease, the erosions and joint-space narrowing become more prominent, intra-osseous cysts can occur, and a variety of deformities can be visualized.

DIAGNOSIS

There are no specific diagnostic tests. The American College of Rheumatology revised 1987 criteria require four or more of the following for at least 6 weeks: morning stiffness (more than 1 hour before maximal improvement), arthritis of three or more joint areas observed by a physician (e.g., MCP joints, wrists, knees), arthritis of the hands, symmetric arthritis, rheumatoid nodules, serum rheumatoid factor, or radiographic changes typical of RA (e.g., marginal erosions, periarticular osteopenia).

MANAGEMENT

A typical paradigm for treating patients is shown in [Fig. 174.2](#).

[Chapter 174](#)

SCLERODERMA AND RAYNAUD'S PHENOMENON

DEFINITIONS

Systemic sclerosis (scleroderma) is characterized by thickening and fibrosis of the skin (scleroderma) and by distinctive forms of involvement of the internal organs. Scleroderma can be grouped into two principal syndromes of prognostic and therapeutic importance. Patients with diffuse or generalized scleroderma are at risk of rapidly progressive and widespread skin involvement and the early development of the full complement of abnormalities of the internal organs. A nearly equal number have slowly progressive skin changes that usually are restricted to the fingers, hands, and face and may have an extended course before the development of visceral abnormalities. This group has limited scleroderma, historically termed the *CREST syndrome* variant (subcutaneous calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, telangiectasia). Raynaud's phenomenon (RP) is the clinical syndrome of episodic color changes of the digits in response to cold or, for some patients, emotional stress. The typical sequence is pallor (arterial constriction) followed by cyanosis (venospasm and oxygen desaturation) followed by reactive hyperemia.

ETIOLOGY AND PATHOGENESIS

Early tissue lesions feature inflammatory cells such as T lymphocytes, monocytes, and mast cells. Fibroblast stimulation leads to excessive production of collagen. A complex array of cells and signal factors leads to accumulation of extracellular matrix in addition to the collagen, including glycoaminoglycan, fibronectin, adherence molecules, and tissue water. RP may be caused by one of three following mechanisms: vasospasm (associated with primary or idiopathic RP, migraine, pheochromocytoma, and use of b-blockers or ergots), narrowing of digital arteries caused by intimal accumulation of ground substance and collagen (connective tissue diseases, vibration syndrome, arteriosclerosis, thromboangiitis obliterans), or increased blood viscosity (cryoglobulinemia, paraproteinemia, polycythemia).

INCIDENCE AND EPIDEMIOLOGY

The annual incidence of scleroderma is 1 to 2 cases per 100,000 persons. The onset is highest in the fourth and fifth decades of life and is four times more common among women. There is no consistent link to race or geographic region. The link between silicone gel breast implants and scleroderma that has been described in case reports has not been supported in formal studies. RP occurs among as many as 10% of premenopausal women. Primary RP typically begins in the teens to early twenties; secondary forms begin later in life. Among men RP usually is a secondary form.

CLINICAL FEATURES

Raynaud's phenomenon and skin involvement: The typical sequence in all forms of scleroderma is RP, followed by finger and hand edema, which typically is painless, followed by tightening and thickening of the skin. In limited scleroderma, unlike the diffuse variant, patients may have RP alone for years before other manifestations develop.

Musculoskeletal features: As skin thickening worsens, underlying joints become tethered and restricted. Symptoms of arthritis are common. Weakness and atrophy may occur. Skin tightening on the face may restrict the ability to open the mouth and may impair adequate oral hygiene.

Gastrointestinal involvement: Atrophy of the muscularis and submucosal fibrosis occur in all forms of scleroderma. Weakness of the lower esophageal sphincter causes chronic reflux esophagitis. Hypomotility of the lower esophagus causes dysphagia for solid foods. Small-bowel involvement manifests as intermittent abdominal cramping and diarrhea. Bacterial overgrowth and malabsorption from intraluminal stagnation may occur. Colonic involvement manifests as constipation.

Hepatic disease is uncommon, although patients with limited scleroderma may have primary biliary cirrhosis.

Cardiac involvement: Patchy fibrosis, of the myocardium occurs among as many as 80% of patients. Supraventricular and ventricular arrhythmias occur among 60% to 70% of patients. Involvement of the conduction system is less frequent.

Pulmonary involvement: Lung disease combining interstitial inflammation, fibrosis, and vascular injury is a major cause of morbidity and mortality. Patients with diffuse scleroderma are more likely to have interstitial lung disease (basilar rales, abnormal findings on chest radiographs, loss of lung volume), whereas those with limited scleroderma are at risk of progressive pulmonary hypertension and a disproportionate loss of diffusing capacity.

Renal involvement: Scleroderma renal crisis is the sudden onset of accelerated to malignant hypertension and progressive renal insufficiency. It usually is accompanied by microangiopathic hemolytic anemia. It is caused by obliterative vasculopathy and occurs most often in the first 2 to 3 years after the diagnosis of the diffuse form of scleroderma.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

Nonspecific serologic abnormalities are common, including antinuclear antibodies (usually nucleolar in pattern) in 90% of patients and rheumatoid factor in 30%. Many have a moderate elevation in erythrocyte sedimentation rate. Anticentromere antibody is found in 50% to 60% of patients with limited scleroderma but rarely in those with diffuse disease. Antibodies to DNA topoisomerase I and RNA polymerases I and III have low sensitivity but excellent specificity.

PROGNOSIS AND MANAGEMENT

Raynaud's phenomenon: Cessation of cigarette smoking is a necessity. Warm mittens and footwear are helpful. Medications that may be useful include calcium channel blockers, such as nifedipine and amlodipine, and sympatholytic agents, such as prazosin. When digits are compromised by ischemia, which is more common in secondary forms of RP, angiographic localization of the occlusion and prompt therapy are needed.

Scleroderma: Morbidity and mortality are related chiefly to visceral involvement. The early accrual of visceral disease in diffuse scleroderma is responsible for a 5-year survival rate of 60%. There are no proven, effective therapies for the basic fibrotic features of scleroderma and none that can be described as disease-modifying. Prolonged therapy with D-penicillamine has been used because this agent inhibits cross linking of collagen. However, a multicenter dosage comparison of 1 g per day and 125 mg every other day did not demonstrate an effect on survival rate, skin thickening, or internal organ status. Numerous studies of immunosuppressants have proved their lack of benefit.

Visceral involvement: Nonsteroidal anti-inflammatory drugs and physical therapy are useful for musculoskeletal disorders. Symptoms of gastroesophageal reflux and esophagitis respond to gastric acid suppression and changes in lifestyle. Patients with diarrhea and cramping often are treated with antibiotics for presumed bacterial overgrowth. Little is known about effective therapy for cardiac and pulmonary disease. Pulmonary hypertension may respond to prostacyclin preparations. Early management of renal crisis with angiotensin-converting enzyme inhibitors can arrest the progressive renal insufficiency and ameliorate the hypertension.

Chapter 179

SMALL-VESSEL VASCULITIS (HYPERSENSITIVITY VASCULITIS)

DEFINITION AND PATHOPHYSIOLOGY

Vasculitis that exclusively involves arterioles and predominantly postcapillary venules can occur as a limited cutaneous disease or be part of a more severe systemic vasculitic process. Limited cutaneous vasculitis has been called *hypersensitivity vasculitis* even though a triggering antigen usually cannot be identified. Biopsy of the skin usually demonstrates leukocytoclastic angiitis with or without immune complex deposition.

CLINICAL FEATURES AND DIFFERENTIAL DIAGNOSIS

Cutaneous vasculitis most often manifests as palpable purpura. Urticarial lesions are less common. Cutaneous vasculitides can occur in association with infection (endocarditis, hepatitis B and C, or caused by *Neisseria*, *Rickettsia*, cytomegalovirus, or HIV), malignant disease (predominantly myelo- or lymphoproliferative diseases but also solid-tissue carcinoma), allergic reactions to drugs, cryoglobulinemia, and systemic autoimmune disorders, such as rheumatoid arthritis, lupus erythematosus, or Sjögren's syndrome. Nonvasculitic causes of purpura include Kaposi's sarcoma, bacterial and fungal emboli, steroid therapy, amyloidosis, senile purpura, warfarin necrosis, calciphylaxis, and trauma.

DIAGNOSTIC EVALUATION

Clinical examination often is sufficient to make the diagnosis, although biopsy may be necessary in some contexts to differentiate vasculitis from nonvasculitic causes of purpura.

MANAGEMENT

If cutaneous vasculitis is mild and of recent onset without compromise of skin integrity, and a controllable etiologic factor is not identified, only careful observation may be necessary. However, progression or visceral involvement necessitates treatment. Therapy with nonsteroidal anti-inflammatory drugs, colchicine, dapsone, or pentoxifylline may be tried, although these agents are inconsistently helpful. Glucocorticoids should be used sparingly, and cytotoxic therapy for non-necrotizing, isolated cutaneous disease should be avoided. If extremely high levels of cryoglobulins are present, apheresis may be of benefit, although results of controlled studies are not available.

Chapter 181

SPONDYLARTHROPATHIES

DEFINITIONS

Spondylarthropathy encompasses a family of chronic inflammatory disorders primarily affecting peripheral and axial joints. Members of this family include ankylosing spondylitis, a predominantly axial form of arthritis usually beginning in the sacroiliac joints and slowly progressing to spinal fusion; Reiter's syndrome, or reactive arthritis, an acute peripheral type of arthritis associated with nongonococcal urethritis, conjunctivitis, or other mucocutaneous features, which typically occurs after enteric or genitourinary infection; psoriatic arthritis, a slowly progressive peripheral type of arthritis, with or without axial disease, that occurs in the setting of cutaneous psoriasis; and enteropathic arthritis, a peripheral or axial arthropathy accompanying ulcerative colitis and Crohn's disease.

ETIOLOGY AND EPIDEMIOLOGY

An atypical immune response to certain bacteria, mediated by HLA-B27 and other class I major histocompatibility complex genes, is believed to underlie most forms of spondyloarthropathy. The prevalence of these disorders, especially ankylosing spondylitis and reactive arthritis, generally parallels the frequency of HLA-B27 in different populations. American and European whites are affected more often than other racial groups.

CLINICAL FEATURES

Unifying features of the forms of spondylarthropathy include (a) a tendency for involvement of sacroiliac and other spinal joints (sacroiliitis and spondylitis); (b) peripheral arthritis, typically asymmetric and oligoarticular; (c) inflammatory lesions of tendon and fascial insertions (enthesopathy) at peripheral and axial sites; (d)

extra-articular complications affecting the eye (anterior uveitis) or heart (aortitis and conduction disturbance); (e) disease onset among young adults, especially men; (f) absence of rheumatoid factor and other autoantibodies; and (g) strong associations with class I histocompatibility antigens, especially HLA-B27. Despite these common characteristics, each of the disorders manifests unique clinical features.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

Laboratory abnormalities are few. Mild normocytic, normochromic anemia and elevation in erythrocyte sedimentation rate can occur in all types. Modest leukocytosis and thrombocytosis are most common in acute Reiter's syndrome and enteropathic arthritis. Serum rheumatoid factor and antinuclear antibody tests results are uniformly negative. Synovial fluid findings include leukocyte counts ranging from 5,000 to 50,000 per microliter (the highest counts occurring in Reiter's syndrome), elevated protein levels, normal glucose levels, and an absence of organisms on Gram stain and culture. Radiologic abnormalities occur in all forms of spondylarthropathy, depending on the involved joints.

PROGNOSIS AND MANAGEMENT

Death occurs in fewer than 5% of cases and is caused primarily by vertebral fractures, especially of the cervical vertebrae, cardiac complications, and amyloidosis. Therapy involves pharmacologic suppression of joint inflammation in conjunction with physical therapy to preserve axial and peripheral joint function and to prevent deformity. Unlike rheumatoid arthritis, this type of arthritis usually does not respond to salicylates, propionic acids, glucocorticoids, or long-acting drugs such as gold salts, D-penicillamine, or hydroxychloroquine. Instead, the nonsteroidal anti-inflammatory drugs indomethacin, tolmetin, piroxicam, and others are more effective in suppressing symptoms of pain and stiffness and signs of inflammation. Sulfasalazine (2 to 3 g per day) has been shown to be effective in relieving joint symptoms and signs in all of these conditions.

For all patients with reactive arthritis, an attempt should be made to identify the causative microorganism so that appropriate antibiotics can be prescribed. Immunosuppressants such as methotrexate or azathioprine sometimes are needed, but they should be used sparingly by patients with reactive arthritis in view of the possibility of promoting bacterial persistence. The presence of peripheral arthritis among patients with inflammatory bowel disease indicates active bowel inflammation. Treatment of the bowel with glucocorticoids or other medications, or colectomy for ulcerative colitis, results in resolution of the peripheral, but not the axial, joint disease.

[Chapter 176](#)

SYSTEMIC LUPUS ERYTHEMATOSUS

DEFINITION AND EPIDEMIOLOGY

Systemic lupus erythematosus (SLE) is a chronic, multisystem disease of unknown causation. The estimated prevalence in the United States is 0.05% to 0.1% of the population; African-Americans and other minorities appear to be at higher risk. Disease onset is most common in the second and third decades of life; women of childbearing age are affected disproportionately.

ETIOLOGY AND PATHOGENESIS

Although the cause is unknown, genetic (e.g., inherited complement deficiencies and some HLA haplotypes), environmental (e.g., ultraviolet light, aromatic amines, and certain medications), and hormonal (high estrogen to androgen ratio) factors have been implicated. The pathologic features are those of an inflammatory disorder with evidence of autoimmunity, immune complex deposition, complement activation, and chronic lymphocytic inflammation. Thromboembolic phenomena can result from the binding of antibodies to coagulation factors or cofactors, platelets, or endothelium.

CLINICAL FEATURES

The American College of Rheumatism (ACR) classification criteria are listed in [Table 178.1](#); other manifestations are included in [Table 178.2](#). Most patients have mild to moderate disease with chronic, smoldering symptoms punctuated by gradual or sudden increases in disease activity (flare-ups). Drug-induced SLE (most strongly associated with hydralazine and procainamide) tends to cause skin manifestations, arthralgia, and serositis and to spare the kidneys and central nervous system (CNS).

LABORATORY STUDIES AND DIAGNOSTIC TESTS

Common laboratory abnormalities are listed in [Table 178.1](#). The erythrocyte sedimentation rate may be markedly elevated but can be normal even in active disease. The antinuclear antibody (ANA) test result almost always is positive but is not specific for SLE. Demonstration of antibodies against double-stranded DNA is the most helpful confirmatory test; unlike the ANA test, anti-DNA titers may reflect disease activity and even be predictive of impending flare-ups. Anti-Smith antibodies also are very specific for SLE but are found infrequently. Anti-ribosomal P and anti-neuronal antibodies support a diagnosis of CNS lupus. Anti-histone antibodies are present in almost all cases of drug-induced SLE. Anti-Ro (SSA) and anti-La (SSB) antibodies are found in as many as half of patients and indicate a greater likelihood of cutaneous manifestations, photosensitivity, and neonatal lupus among the offspring of female patients. Low complement levels (particularly of C3, C4, and total hemolytic complement) are important both in diagnosis in monitoring disease activity. Various tests can indicate a thrombotic tendency, including anti-cardiolipin antibodies and the so-called lupus anticoagulant.

Ancillary studies for selected patients include radiographs of affected joints, echocardiography for patients with myocardial or pericardial disease, high-resolution computed tomography of the lungs to define parenchymal lung disease, and magnetic resonance imaging of the CNS to evaluate patients for suspected CNS lupus. Biopsy is invaluable in the evaluation of skin and kidney disease. The results of renal biopsy can be classified into World Health Organization classes I through VI, higher classes reflecting more serious disease.

DIAGNOSIS

There is no single diagnostic test. The diagnosis should be considered only when clinical suspicion is aroused by an appropriate set of symptoms. For such patients, a positive ANA test result can further strengthen the suspicion. A negative test result generally directs the evaluation elsewhere. A positive ANA result also opens up the possibility of finding more SLE-specific autoantibodies, such as anti-DNA. Although the ACR criteria provide a useful frame of reference, the diagnosis for an individual patient does not depend on meeting these criteria but on a consistent diagnostic impression by a qualified clinician. A large number of symptoms and signs not included in the ACR criteria may be present or absent in patients under evaluation.

MANAGEMENT

Although the mainstay of therapy for active SLE is glucocorticoids, the medications chosen must be tailored to the organs involved and the activity of the disease in these organs ([Table 178.2](#)). Antimalarial agents, such as 200 to 400 mg hydroxychloroquine every day, are very useful in long-term management, particularly the prevention of flare-ups.

[Chapter 178](#)

TAKAYASU'S ARTERITIS

DEFINITION, EPIDEMIOLOGY, AND PATHOPHYSIOLOGY

Takayasu's arteritis is large-vessel vasculitis that involves the aorta and its main branches. It chiefly affects young women. The cause is unknown. Stenotic lesions are characteristic, but aneurysms can form, particularly in the aortic root.

CLINICAL FEATURES

Morbidity is caused by organ ischemia. Common syndromes include extremity claudication, cerebral ischemia, renal artery hypertension, coronary syndromes, and mesenteric vascular insufficiency. In about 20% of patients, aortic root involvement may cause valvular insufficiency and congestive heart failure. Fever may be present, but skin lesions, pulmonary infiltrates, and glomerulonephritis are unusual. Examination may disclose vascular bruits, particularly of the upper extremities, and asymmetric peripheral pulses or blood pressures.

DIAGNOSTIC EVALUATION

There are no specific serologic tests. The erythrocyte sedimentation rate often is elevated. Angiography can establish the initial diagnosis and can be repeated to assess the degree of disease progression. The utility of other imaging techniques, such as ultrasonography and magnetic resonance imaging, is under investigation.

MANAGEMENT

Approximately 60% of patients achieve remission with glucocorticoid therapy (e.g., 1 mg prednisone per kilogram per day). Patients with disease that is resistant or relapses on tapering of drug therapy can be treated with low doses of cyclophosphamide or weekly doses of methotrexate. Whenever feasible, anatomic correction of clinically significant lesions should be considered, especially in the setting of renal artery stenosis and hypertension. Adequate blood pressure control is critical. When peripheral blood pressures does not accurately reflect aortic root pressure because of extensive arterial stenosis, intravascular pressure recordings can be obtained during angiography.

[Chapter 181](#)

WEGENER'S GRANULOMATOSIS

DEFINITION, EPIDEMIOLOGY, AND PATHOPHYSIOLOGY

Wegener's granulomatosis (WG) is a multisystem necrotizing vasculitis. It is an uncommon disease, equally frequent in men and women, with a mean age at diagnosis of about 40–45 years. Disease manifestations are caused by aseptic inflammation with necrosis, granuloma formation, and vasculitis of the upper and lower respiratory tract, ears, eyes, kidneys, skin, or nervous system. Biopsy shows geographic necrosis with giant cells and vessel necrosis.

CLINICAL FEATURES

Most patients first seek medical attention because of upper or lower airway disease. The finding of recurrent epistaxis, mucosal ulceration, nasal septal perforation, nasal deformity, or hearing loss suggests WG. About 80% of patients do not have renal involvement at the time of diagnosis, and about 50% do not have overt lung disease. Over the course of the illness, however, more than 80% have pulmonary or renal disease. Pulmonary involvement may cause coughing hemoptysis, dyspnea, or pleuritis. Computed tomography of the chest is more sensitive than radiography of the chest in demonstrating nodules and infiltrates. Renal involvement manifests as glomerulonephritis associated with hematuria, red blood cell casts, azotemia, or uremia. Musculoskeletal features are common, but joint deformity or destruction are rare. About 25% of patients have peripheral or central nervous system disease.

DIAGNOSTIC EVALUATION

Approximately 90% of patients with active disease have an immunofluorescence test result positive for antineutrophil cytoplasmic antibodies (ANCA), usually in a cytoplasmic (C-ANCA) rather than a perinuclear pattern (P-ANCA). Antibody titers correlate loosely with disease activity. A positive ANCA test result is not entirely specific for WG, however. A suspected diagnosis of WG ideally should be confirmed by means of biopsy. Open lung biopsy is the most likely to yield an unequivocal diagnosis. Tranbronchial specimens often are inadequate but are useful in excluding infection. Nasal biopsy may not provide enough information for a diagnosis. Renal biopsy usually shows a glomerulonephritis with little evidence of immune complex deposition.

MANAGEMENT

Management of severe, generalized WG should include initial glucocorticoid therapy in conjunction with cyclophosphamide. After substantial improvement has occurred, usually within 1 month, high-doses of glucocorticoids can be tapered over several months. Cytotoxic therapy should be continued for at least 1 year after the induction of remission. For patients with less severe disease, weekly doses of methotrexate can be used in place of cyclophosphamide. Daily treatment with trimethoprim-sulfamethoxazole has been shown to decrease the frequency of upper airway flare-ups in WG without influencing the course of renal or pulmonary disease.

ACUTE LEUKEMIA

DEFINITIONS AND PATHOPHYSIOLOGY

Acute leukemia is caused by uncontrolled proliferation of a malignant clone of hematopoietic cells that does not differentiate and mature normally. Leukemic cells are introduced into the blood from the bone marrow. They may divide in the blood or infiltrate an organ, such as the spleen, liver, or lymph nodes, where they may also divide and then reenter the blood. In acute lymphocytic leukemia (ALL), the abnormal clone has characteristics of lymphoid cells. All other types of acute leukemia are classified as acute myeloid leukemia (AML). AML is subdivided according to cell type—myelocytic, promyelocytic, myelomonocytic, monocytic, erythroleukemic, and megakaryocytic.

EPIDEMIOLOGY

Acute lymphocytic leukemia: Most patients are younger than 15 years. The median age of adult patients is 42 years. Men are affected more often than women.

Acute myeloid leukemia: The average patient is older than 55 years at diagnosis. The incidence increases with age. Ionizing radiation and some chemotherapeutic agents, especially alkylating agents, are associated with an increased incidence of AML.

CLINICAL FINDINGS

Acute lymphocytic leukemia: Adults usually have the subacute onset of fatigue, lethargy, and anorexia. Petechiae or easy bruising may be found. An expanding bone marrow mass can cause bone pain. Most patients have palpable lymphadenopathy; the spleen is palpable in 50% of patients. About 15% of patients have a fever, which may be caused by occult infection. Signs of increased intracranial pressure or cranial nerve dysfunction caused by leukemic infiltration of the central nervous system may be evident. Anemia, granulocytopenia, and thrombocytopenia are almost always present at the time of diagnosis. For 85% of patients, the blood smear reveals lymphoblasts. The bone marrow biopsy specimen almost always is hypercellular with lymphoblastic predominance and a reduction in normal elements. Cerebrospinal fluid should be examined for leukemic cells. Serum lactate dehydrogenase and uric acid levels usually are elevated.

Acute myeloid leukemia: The features vary somewhat among the different subtypes. Adults usually have a vague history of progressive lethargy. However, as many as one-third of patients may come to medical attention with an acute illness due to infection. The patients usually have petechiae. Lymphadenopathy, splenomegaly, and hepatomegaly are unusual. The white blood cell (WBC) count is normal, elevated, or depressed with equal frequencies at diagnosis, although granulocytopenia is essentially universal. Anemia and thrombocytopenia usually are present. Blast cells are initially absent from the peripheral blood in about 15% of cases. The bone marrow usually is markedly hypercellular and has at least 50% to 75% leukemic cells. Uric acid levels generally are elevated.

DIAGNOSTIC EVALUATION

Morphologic examination, histochemical reaction, cytogenetic and enzymologic studies and cell surface antigen identification are the principal laboratory tools for differentiating ALL from AML and for identifying clinically important subtypes of both.

PROGNOSIS AND MANAGEMENT

Acute lymphocytic leukemia: Prognosis is influenced adversely by advanced age, B-cell phenotype, greatly elevated WBC count at diagnosis, and a complex, abnormal karyotype. Most adults respond well to initial therapy, but unlike children with ALL, most adults ultimately die of the disease. Before chemotherapy is started, active infection must be controlled with antibiotics, and hyperuricemia with hydration and allopurinol. The standard induction regimens include drugs such as vincristine, prednisone, daunorubicin, and L-asparaginase. After the patient has achieved a complete remission and recovered from induction therapy, intensive postremission therapy with drugs not used during induction or with bone marrow transplantation is necessary to maximize the duration of the response. The median duration is 1 to 2 years; most relapses occur within 3 years. About 30% to 40% of patients live disease free for 5 years after treatment. Central nervous system involvement can be managed effectively with intrathecal methotrexate.

Acute myeloid leukemia: Remission therapy usually consists of only two drugs, cytarabine and daunorubicin or idarubicin. Almost all patients need prophylactic platelet transfusions and at least 90% need empiric broad-spectrum antibiotic therapy for fever while granulocytopenic. Complete remission is obtained among 70% or more of adults. All-*trans* retinoic acid induces remission of acute promyelocytic leukemia through induction of maturation and differentiation rather than by means of cytotoxicity. Intensive postremission therapy prolongs remission to a mean of 12 to 24 months. About 30% to 50% of patients with a complete response live disease free for at least 5 years after treatment. Late relapses occur but are rare.

[Chapter 227](#)

AMYLOIDOSIS

DEFINITION

Amyloidosis refers to a group of protein deposition diseases. Amyloid is a substance that consists of protein fibrils. Stained with Congo red and viewed with polarized light, it produces an apple-green birefringence.

EPIDEMIOLOGY AND ETIOLOGY

Approximately 2,500 cases occur annually in the United States; only 1% of patients are younger than 40 years. In primary amyloidosis, the fibrils consist of monoclonal κ or λ light chains. The condition is closely related to multiple myeloma. Secondary amyloidosis is associated with inflammatory processes such as rheumatoid arthritis and Crohn's disease. The fibrils consist of protein A. Other varieties include familial amyloidosis, senile amyloidosis, and a β_2 microglobulin amyloidosis associated with renal dialysis.

CLINICAL FINDINGS

Primary amyloidosis: Weakness, fatigue, and weight loss are common, as are light-headedness, syncope, change in voice or tongue, dyspnea, and edema. Nephrotic syndrome, hepatomegaly, macroglossia, congestive heart failure, carpal tunnel syndrome, peripheral neuropathy, and orthostatic hypotension occur in 10% to 30% of cases.

Secondary amyloidosis: At diagnosis, more than 90% of patients have renal insufficiency or nephrotic syndrome. Gastrointestinal involvement often manifests as a malabsorption syndrome. Unlike primary amyloidosis, secondary amyloidosis rarely involves the heart and peripheral nerves.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

Primary amyloidosis: Findings are those suggested by pattern of organ involvement. They may include azotemia and an echocardiogram that demonstrates increased ventricular wall thickness and an abnormal myocardial texture. Monoclonal protein is found in the serum and the urine of more than 70% of patients. The diagnosis depends on the demonstration of amyloid deposits. Findings at examination of an abdominal fat aspirate or rectal biopsy are abnormal more than 90% of the time.

Secondary amyloidosis: Most patients have azotemia and proteinuria. The diagnosis is made by means of biopsy of an affected organ.

PROGNOSIS AND MANAGEMENT

Primary amyloidosis: The median survival period ranges from 1 to 2 years. Therapy is unsatisfactory, but melphalan and prednisone prolong survival several months.

Secondary amyloidosis: The median survival time is approximately 2 years. Treatment depends on the underlying disease. Renal transplantation is helpful.

[Chapter 235](#)

APPROACH TO THE PATIENT WITH ANEMIA

DEFINITION

Anemia represents a reduction in the normal red blood cell (RBC) mass within the body as measured with peripheral blood hemoglobin level and hematocrit. The hematocrit of healthy men is $47\% \pm 7\%$; that of healthy women is $42\% \pm 5\%$.

PATHOPHYSIOLOGY

The normal cycle of erythropoiesis requires coordination of erythropoietin stimulation with the necessary precursor cells and building blocks in a conducive microenvironment. RBC structure and extramedullary circumstances then determine the life span of the erythrocyte. Lesions in any component of this cycle can cause anemia.

DIFFERENTIAL DIAGNOSIS

Hyporegenerative versus hyperregenerative anemia: If shortened RBC survival causes anemia, as in bleeding or hemolysis, an erythropoietin surge leads to the release of increased numbers of reticulocytes (immature RBC precursors). An elevated reticulocyte count (more than 100,000 per microliter) thus indicates that the marrow is attempting to compensate for an extramedullary abnormality. A lower reticulocyte count suggests an abnormality within the marrow.

Categorization of anemia according to size of red blood cells: Anemia can be classified as microcytic, normocytic, or macrocytic ([Table 211.2](#)). Microcytic anemia originates in an iron or hemoglobin deficiency. Most cases of macrocytic anemia are caused by folate and vitamin B₁₂ deficiencies. Normocytic anemia is a more heterogeneous group that includes most hemolytic disorders ([Table 211.3](#)).

HISTORY AND PHYSICAL EXAMINATION

Anemia often is asymptomatic unless it is severe, develops rapidly, or occurs in a patient with an underlying cardiopulmonary disorder. The symptoms include dyspnea on exertion, angina, and fatigue. Physical examination may reveal conjunctival and palmar pallor, tachycardia, and a systolic flow murmur.

Microcytic anemia: Patients with an iron deficiency may have overt hemorrhage or symptoms that suggest a source of occult bleeding. Result of stool tests for occult blood may be positive. Family history and ethnic background are useful in the diagnosis of thalassemia. History or examination findings of chronic inflammatory disease such as osteomyelitis or rheumatoid arthritis suggest anemia of chronic disease.

Normocytic hyporegenerative anemia: Findings of chronic inflammation suggest anemia of chronic disease. The symptoms of uremia may be elicited. Pancytopenia is suggested by a history of easy bruising or frequent infection. Hematologic malignant disease may be associated with fever, weight loss, lymphadenopathy, or splenomegaly.

Normocytic hyperregenerative anemia: The history may suggest hemolytic anemia (e.g., malaria among travelers or autoimmune hemolysis among patients with other symptoms of systemic lupus erythematosus). The history and physical examination may suggest a source of hemorrhage. However, hemorrhage causes a hyperproliferative anemia only if it has not caused a concomitant iron deficiency.

Macrocytic anemia: Hypothyroidism, alcoholism, and chronic liver disease may be apparent. Patients with vitamin B₁₂ deficiency, but not those with folate deficiency, often have a loss of vibratory and positional sense in the lower extremities.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

In addition to reticulocyte count and cell size determination, the initial approach includes examination of a peripheral blood smear, white blood cell and platelet counts, and measurement of RBC distribution width (RDW), an indicator of the range of RBC sizes. An overall approach is outlined in [Fig. 211.1](#).

Microcytic anemia: Iron deficiency is suggested by low serum levels of ferritin, a storage form of iron. The absence of bone marrow iron stores is considered the diagnostic gold standard, but a trial of iron therapy can be useful. In thalassemia, the RBCs are particularly microcytic for the degree of anemia; hemoglobin electrophoresis may help establish a diagnosis. Sideroblastic anemia shows iron accumulation in the mitochondria of developing RBCs within the marrow (ringed sideroblasts).

Normocytic hyporegenerative anemia: Results of bone marrow biopsy often are definitive. The anemia of renal failure has low erythropoietin levels; blood urea nitrogen and creatinine levels are elevated. Aplastic or hypoplastic processes affect the WBC and platelet counts. Marrow infiltration produces myelophthisis, in which the peripheral blood smear shows nucleated and teardrop-shaped RBCs and immature WBCs that have been extruded from the marrow.

Normocytic hyperregenerative anemia: Hemolysis may be associated with hyperbilirubinemia, low haptoglobin levels, and production of RBC autoantibodies. The peripheral blood smear may provide many diagnostic clues (e.g., schistocytes in microangiopathic processes that fragment RBCs and spherocytes in immune-mediated processes or hereditary spherocytosis).

Macrocytic anemia: Megaloblastic anemia is associated with exaggerated macrocytosis (mean corpuscular volume [MCV] more than 115 fL), a reduction in platelet and WBC counts, high levels of lactate dehydrogenase (LDH), and hypersegmentation of polymorphonuclear leukocytes on the peripheral blood smear. Serum

vitamin B₁₂ and RBC folate tests help identify the specific deficiency. The coexistence of iron deficiency anemia and megaloblastic anemias may yield a normal MCV but an elevated RDW. Nonmegaloblastic macrocytic anemia does not cause pancytopenia.

MANAGEMENT

Anemia frequently is not the primary concern but is instead a clue to the presence of an underlying disorder that must be identified and treated (e.g., iron deficiency as a first manifestation of colon cancer). Management of the underlying disorder improves or resolves the anemia. If the degree of improvement is insufficient or there are acute symptoms of anemia, RBC transfusions can be performed.

[Chapter 211](#)

APLASTIC ANEMIA

DEFINITION, EPIDEMIOLOGY, AND ETIOLOGY

Aplastic anemia is a syndrome of bone marrow failure characterized by pancytopenia of the peripheral blood and hypocellularity of the bone marrow. Patients of all ages and both sexes are affected. It is caused by various pathophysiologic processes that affect the pluripotent stem cells. Most cases appear to be acquired, but approximately 50% have no identifiable cause and are called *idiopathic*. Recognized causes are listed in [Table 230.1](#).

CLINICAL FEATURES

Two types of presentation are possible depending on the severity of pancytopenia. Some patients have a gradual onset of signs and symptoms of anemia, including fatigue, dyspnea, and pallor. Laboratory evaluation reveals variable but often mild pancytopenia and hypoplastic bone marrow. Other patients have signs and symptoms of thrombocytopenia and leukopenia in addition to those of anemia. They may have a sudden onset of high-spiking fevers and spontaneous petechiae and ecchymosis. In more severe cases, patients may have retinal hemorrhage, epistaxis, or oral mucosal bleeding. Except for evidence of bleeding, the physical examination findings generally are unremarkable. Lymphadenopathy and splenomegaly are not seen. In the absence of granulocytes, the findings associated with infection, such as pneumonia, may be minimal.

LABORATORY STUDIES

Laboratory evaluation should include studies that attempt to identify the cause of the aplasia, including tests for paroxysmal nocturnal hemoglobinuria, systemic lupus erythematosus, hepatitis, infectious mononucleosis, and pregnancy. Deficiency of vitamin B₁₂ or folate should be excluded. Cytogenetic analysis may be helpful in identifying myelodysplastic syndromes and those with underlying chromosomal fragility states, such as Fanconi's anemia.

PROGNOSIS AND MANAGEMENT

General supportive management: Drugs that interfere with platelet function should be avoided. Women of childbearing age should undergo menstrual suppression. Because of the need for frequent phlebotomy and transfusions, indwelling vascular catheters may be necessary. Fever and potential infection should be managed promptly and aggressively with cultures and antibiotics. Transfusions should be used judiciously. Active bleeding should be controlled with platelet transfusion if the platelet count is less than 20,000 per microliter. Prophylactic platelet transfusions need not be given until the platelet count is less than 5,000 to 10,000 per microliter. Transfusions should be leukocyte depleted, and family-derived transfusions should be avoided if bone marrow transplantation is being considered. Cytomegalovirus (CMV) antibody-negative patients should receive transfusions only from CMV antibody-negative donors.

Definitive treatment: Any possible offending exposures should be discontinued. Specific therapies include marrow stimulation (androgens, cytokines), immunosuppression (antithymocyte globulin, glucocorticoids, cyclophosphamide, cyclosporine), and bone marrow transplantation. The last should be considered primary treatment of patients younger than 40 to 45 years.

[Chapter 230](#)

BREAST CANCER

EPIDEMIOLOGY AND ETIOLOGY

The term *breast cancer* usually refers to adenocarcinoma, the most common malignant neoplasm of mammary tissue and, with lung cancer, one of the two most common cancers of women in the developed world. Risk factors include advanced age, history of breast cancer in a first-degree relative (especially if the lesions are bilateral or the relative is premenopausal), early onset of menarche (12 years of age or earlier), nulliparity or first pregnancy after 35 years of age, alcohol consumption, and prior radiation exposure. Current evidence suggests that use of oral contraceptives or postmenopausal estrogen replacement is associated with a slight increase in risk. Use of newer estrogens such as raloxifene may actually reduce risk. Germ-line mutations of the genes *BRCA1* and *BRCA2* are associated with a higher risk of both breast and ovarian cancer. Benign lesions such as cysts, mastitis, and most fibroadenomas are not predisposing conditions. The incidence of breast cancer among men is about 1% of the incidence among women.

PATHOPHYSIOLOGY, CLASSIFICATION, AND STAGING

Most adenocarcinomas of the breast are thought to arise from ductal epithelial cells. These cancers may be in situ or infiltrating (also called *invasive*). The in situ carcinomas are further classified as lobular carcinoma in situ (LCIS) or ductal carcinoma in situ (DCIS). LCIS and DCIS do not invade the parenchyma or stroma and have a very low potential for generating metastasis. DCIS lesions are usually regarded as a unilateral, very early, preinvasive form of true breast cancer. LCIS, in contrast, often is considered a marker of carcinogenic potential (equally shared with the uninvolved breast) rather than true cancer. Invasive adenocarcinoma, which does infiltrate into surrounding normal tissue, also has ductal and lobular types, the ductal types predominating. The most common sites of metastasis are the axillary lymph nodes. The number of nodes containing cancer is a good indicator of the propensity of the tumor to metastasize to more distant anatomic sites such as bone, lung, liver, and brain. About 15% of breast cancers have special histopathologic patterns, including mucinous and papillary types. Inflammatory breast cancer is an especially aggressive form of the disease characterized by diffuse breast swelling, erythema and warmth of the skin, breast pain, and peau d'orange edema of the skin.

Breast cancer is staged through assessment of tumor size (T), nodal involvement (N), and the presence or absence of distant metastases (M) and subsequent classification of the stage as 0, I, IIA, IIB, IIIA, IIIB, or IV. Proper staging requires pathologic examination of the breast tissue and axillary nodes, physical examination, chest radiography, and measurement of serum markers such as liver transaminases and alkaline phosphatase. Physical examination is not a reliable way of assessing axillary nodal involvement. With sentinel lymph node mapping, a radioactive tracer or a dye is introduced into the breast at tumor resection, and only the nodes that first take up the substance are dissected. If these nodes are free of cancer, it is extremely likely that the other axillary nodes will be free as well.

CLINICAL FINDINGS

A review of breast symptoms is essential. The rest of the history should focus on indications of possible metastasis, such as bone pain and respiratory difficulties. The physical examination should include special emphasis on the breast, axilla, and supraclavicular areas. The presence of a supraclavicular node is an indication of metastatic disease and therefore alters prognosis and treatment.

LABORATORY EVALUATION

A preoperative mammogram is useful in evaluating the rest of the abnormal breast and the contralateral breast for masses or calcifications before definitive surgery. A normal mammogram does not exclude the presence of a malignant lesion, however. A biopsy must be performed on a persistent mass regardless of the

mammographic findings. Bone and liver scans are not performed routinely if laboratory values are normal. A complete blood cell count (CBC) and chemistry panel are recommended. After surgical treatment, a yearly mammogram is obligatory, and many oncologists obtain CBCs, hepatic enzymes, and alkaline phosphatase levels on a routine basis.

PROGNOSIS AND MANAGEMENT

DCIS and LCIS: DCIS can manifest as a mass, but it is more commonly found by means of biopsy of abnormal calcifications detected with a mammogram. Optimal management is not yet established. Most patients undergo radiation therapy after local excision. Although there is no established role for systemic chemotherapy because of the very small likelihood of metastasis, tamoxifen may decrease the risk of invasive breast cancer among patients treated with lumpectomy and radiation. Because LCIS usually is not palpable and is invisible at mammography, the diagnosis is commonly incidental to breast biopsy performed for another reason. Because the presence of LCIS is an indicator of a propensity for development of breast cancer and because both breasts are at equal risk, treatment options include observation alone or bilateral simple, prophylactic mastectomy. There is no role for radiation therapy. Recent data have demonstrated a 50% reduction in the risk of infiltrating breast cancer among patients with a history of LCIS who are treated with tamoxifen.

Infiltrating tumors: Adverse prognostic factors include a greater number of positive axillary nodes, larger tumor size, poorly differentiated histologic features, and the absence of receptors for estrogen and progesterone in the cancer cells. Most patients with stage I cancers, many with stage II cancers, and some with stage III cancers can be cured with local therapy. Patients with more advanced stage III cancers and with stage IV disease cannot be cured with surgery alone and need systemic therapy. Local therapy consists of surgery (now often breast sparing rather than mastectomy or radical mastectomy), axillary dissection, and radiation therapy. Adverse effects include disfigurement (breast reconstruction can be performed) and lymphedema (which may occur less often when sentinel lymph node–mapping techniques are used). Systemic drug therapy is used in the following three settings: (a) as an adjunct to local therapy to limit micrometastatic disease, (b) in the management of overt metastatic disease, and (c) as primary therapy for locally advanced breast cancer to render the local disease amenable to surgical and radiotherapeutic approaches. Cyclophosphamide, methotrexate, 5-fluorouracil, paclitaxel, and docetaxel are the chemotherapeutic drugs used most commonly. The first three often are combined into the CMF regimen. The drug most commonly used in hormonal therapy for breast cancer is tamoxifen (usually 20 mg by mouth per day), which acts as an antiestrogen in breast tissue. Tumor estrogen receptors are required. The most common toxicities are hot flashes, irregular menses, and depressed mood. Increased risk of uterine cancer has also been found.

Metastatic disease: In addition to systemic treatment, some metastatic processes may necessitate special therapy. For example, bony metastases leading to intractable pain or to skeletal instability may necessitate radiation therapy or even surgery. Malignant pleural effusions may necessitate repeated thoracentesis or pleurodesis with a sclerosing agent. Morbidity from central nervous system metastasis can be minimized by use of glucocorticoids and radiation therapy. Hypercalcemia generally responds to immediate intravenous hydration followed by the administration of a biphosphonate such as pamidronate.

Chapter 220

CHRONIC LEUKEMIA

DEFINITIONS

Chronic leukemia is a group of heterogeneous proliferative disorders involving lymphoid or myeloid cells that retain some capability of differentiation and maturation. The group includes chronic lymphocytic leukemia (CLL), chronic myelocytic leukemia (CML), and hairy cell leukemia (HCL).

EPIDEMIOLOGY AND PATHOPHYSIOLOGY

Chronic lymphocytic leukemia: CLL is caused by malignant expansion of a clone of lymphocytes. Most patients in the United States have the B-cell subtype. T-cell CLL is more common in Japan. CLL occurs primarily among older persons and is equally distributed between men and women.

Chronic myelocytic leukemia: CML is a myeloproliferative disorder of the stem cells common to bone marrow cells and B lymphocytes. Abnormalities of red blood cell (RBC), and platelet production accompany the increase in granulocytes. All of the cells have the Philadelphia (Ph) chromosome, which reflects reciprocal translocation of material between chromosomes 9 and 22. The key event is translocation of the *ABL* gene. CML usually is diagnosed in midlife or later.

CLINICAL FINDINGS AND DIAGNOSIS

Chronic lymphocytic leukemia: About half of patients come to medical attention with lymphadenopathy in addition to lymphocytosis (usually more than 15,000 cells per microliter). Splenomegaly also may be present. Anemia and thrombocytopenia usually are late features unless an autoimmune process has supervened. Fever and painful lymphadenopathy are uncommon and suggest infection. The bone marrow usually is diffusely displaced by small, mature lymphocytes. A few patients have abdominal tumors with the histologic features of large cell lymphoma (Richter's syndrome). Associated autoimmune phenomena, such as hemolytic anemia, can develop at any time and do not influence prognosis. Death usually is related to infection. The T-cell variety tends to involve the skin and to respond less well to therapy.

Chronic myelocytic leukemia: Initially, patients are asymptomatic, though complaints related to splenomegaly may be offered. The WBC count usually is 2 to 4 times the upper limit of normal, and the blood smear discloses the immaturity of the granulocyte series (myelocytes, metamyelocytes). The platelet count is normal or elevated, and anemia does not occur early in the course. Leukocyte alkaline phosphatase activity is low or absent and helps to differentiate CML from other causes of granulocytosis, such as infection and polycythemia vera. The bone marrow is hypercellular, primarily because the granulocyte compartment is expanded and immature (but not blastic). There often is an accelerated phase or blastic phase within 3 to 4 years of presentation.

PROGNOSIS AND MANAGEMENT

Chronic lymphocytic leukemia: CLL usually is an indolent disease with a median survival period of 3 to 10 years, depending on presenting stage. Therapy is palliative and does not influence survival. No therapy is needed for asymptomatic lymphocytosis with minimal lymphadenopathy and normal RBC and platelet counts. In time, progressive lymphadenopathy or hepatosplenomegaly may necessitate therapy with an alkylating agent such as chlorambucil with or without prednisone. Splenectomy or splenic irradiation may benefit patients with hypersplenism. Lymphomatous transformation necessitates parenteral combination chemotherapy.

Chronic myelocytic leukemia: An adverse prognosis is associated with higher degrees of leukocytosis, the presence of blasts in the peripheral blood, and greater splenomegaly and thrombocytosis. Oral hydroxyurea is used to treat the chronic form of the disease. Recombinant interferon- α also is effective. These treatments are palliative, and it is uncertain that they delay the blastic phase, which may necessitate intensive antileukemic chemotherapy. Allogeneic bone marrow transplantation in the chronic phase can cure about half of patients.

Chapter 228

HODGKIN'S DISEASE

DEFINITION AND PATHOPHYSIOLOGY

Hodgkin's disease is a B-cell lymphoid neoplasm. The diagnosis is based on the recognition of Reed–Sternberg cells interspersed among a reactive mixed-cell population of lymphocytes, eosinophils, histiocytes, plasma cells, and neutrophils.

EPIDEMIOLOGY AND ETIOLOGY

The incidence of Hodgkin's disease is higher among men than women and higher among blacks than whites. The rate increases through early life, peaks in the third decade, declines until 45 years of age, and steadily increases thereafter. There is evidence of both an infectious cause (Epstein–Barr viral genomes are found in 18%

to 50% of persons with Hodgkin's disease) and a genetic susceptibility. The disease also is associated with a variety of defects in cellular immunity.

CLASSIFICATION

Four histologic types have been described, based on the appearance and relative proportions of Reed–Sternberg cells and the histologic background—lymphocyte predominance, nodular sclerosis, mixed cellularity, and lymphocyte depletion. The nodular sclerosis type is most common among young adults. The mixed cellularity type predominates among children and the elderly.

CLINICAL FINDINGS

The most common presentation is an unexplained mass or swelling in the superficial lymph nodes, especially in the neck. The nodes are characteristically nontender and have a rubbery consistency. About two-thirds of patients have intrathoracic disease at diagnosis. Mediastinal lymphadenopathy and splenic involvement are common. Constitutional symptoms, called *B symptoms*, include fever in excess of 38°C, drenching night sweats, and weight loss exceeding 10%. The presence of the rare Pel–Ebstein fever (a cyclic pattern of high fevers for 1 to 2 weeks alternating with afebrile periods of similar lengths) almost confirms the diagnosis of Hodgkin's disease. Unexplained, generalized pruritus may occur. Pain in involved lymph nodes immediately after the ingestion of alcohol is almost pathognomonic for Hodgkin's disease.

LABORATORY STUDIES, DIAGNOSTIC TESTS, AND STAGING

The diagnosis of Hodgkin's disease is made by means of biopsy. Baseline studies should include a complete blood cell count, liver and renal chemical analysis, and measurement of calcium. Cytopenia may occur as a result of marrow involvement, hypersplenism, or autoimmune destruction. An elevated erythrocyte sedimentation rate correlates with advanced disease and a worse prognosis. The evaluation also includes computed tomography of the chest, abdomen, and pelvis. Bone marrow biopsy is not a routine procedure. The use of staging laparotomy and splenectomy has become increasingly selective. The anatomic distribution of Hodgkin's disease in contiguous lymphatic structures is predictable and nonrandom. These patterns form the basis for the Ann Arbor staging classification ([Table 3](#)), which has been shown to correlate well with prognosis.

Stage	Description
I	Involvement of a single lymph node region or localized involvement of a single extranodal organ or site (IE)
II	Involvement of more than one lymph node region on the same side of the diaphragm or of one or more lymph node regions and localized involvement of an extralymphatic organ or site (IIE) on the same side of the diaphragm
III	Involvement of lymph node regions on both sides of the diaphragm, which may be accompanied by involvement of the spleen (IIIS) or by localized involvement of an extralymphatic organ or site (IIIE) or both (IIISE)
IV	Diffuse or disseminated involvement of one or more extralymphatic organs or sites with or without lymph node involvement
A	Asymptomatic
B	Fever, sweats, unexplained weight loss of more than 10% of body weight

TABLE 3. ANN ARBOR STAGING CLASSIFICATION FOR HODGKIN'S DISEASE

PROGNOSIS AND MANAGEMENT

Hodgkin's disease is one of the most highly curable malignant diseases. About 80% of patients with newly diagnosed disease are cured, and fewer than 10% will die directly of the disease. Tumor burden and older age are adverse prognostic factors. Additional prognostic variables include histologic type, sex, the presence of B symptoms, the number of disease sites, and the presence of bone marrow involvement.

Primary therapy: Stage I or II supradiaphragmatic disease is controlled with extended-field radiation therapy, chemotherapy, or both. Cure rates greater than 90% have been reported with combination therapy, such as radiation therapy and chemotherapy with doxorubicin, bleomycin, vinblastine, and dacarbazine. For extensive mediastinal disease, a combination of radiation therapy and chemotherapy can cure 70% to 80% of patients. Sixty-five percent to 70% of patients with stage III or IV disease treated with chemotherapy regimens containing doxorubicin hydrochloride (Adriamycin) are free of disease after 5 years.

Relapse: Relapse after radiation therapy responds very well to chemotherapy. Relapse after primary chemotherapy or combination therapy has a less favorable outcome. The initial remission duration after primary chemotherapy greatly affects response to subsequent treatment. High-dose therapy with stem cell rescue is the favored treatment when primary induction fails or when there is a brief initial remission.

Complications of therapy: Acute effects such as nausea can be managed effectively. Of greater concern are later effects, including second malignant diseases (acute leukemia, non-Hodgkin's lymphoma, and solid tumors such as breast cancer), and sterility. Mediastinal and neck irradiation are associated with cardiac disease and hypothyroidism, respectively.

Chapter 232

INHERITED DISORDERS OF BLOOD COAGULATION

EPIDEMIOLOGY, ETIOLOGY, AND PATHOPHYSIOLOGY

Hemophilia is the most frequent cause of a clinically severe hemorrhagic diathesis. Deficiency in factor VIII causes hemophilia A (classic hemophilia, 80% to 90% of cases) and deficiency of factor IX causes hemophilia B. The genes for both factors are located on the X chromosome, accounting for the X-linked inheritance of the disorders. The specific genetic defect can be either a point mutation or a deletion. The severity of bleeding is directly correlated with the level of residual clotting factor activity; most patients have undetectable levels. Von Willebrand's disease (VWD) is the most common inherited (autosomal dominant pattern) bleeding disorder. It is caused by a deficiency of von Willebrand's factor (VWF), a large plasma glycoprotein that serves as a carrier of factor VIII and as an adhesive bridge between platelets and the vessel wall. There are three subtypes of VWD. Type I and type III are produced by mutations that completely disrupt the function of VWF. The type II variants are usually caused by single amino acid substitutions that cause mildly decreased or altered function, particularly loss of the largest and most functionally active VWF multimers. Type IIB is accompanied by thrombocytopenia.

CLINICAL FEATURES

Hemophilia: The presentations of the two forms of hemophilia are essentially indistinguishable. The diagnosis should be suspected for any man or boy with a severe congenital bleeding disorder and for older men with mild bleeding. The bleeding is primarily localized to soft tissues or joints. The most serious complication is central nervous system hemorrhage, which can follow even minor trauma. Mildly affected patients may show only easy bruising and excessive bleeding after trauma or surgery. The bleeding manifestations have been overshadowed by the profound infectious complications (HIV infection and hepatitis) that have developed among patients who received blood products before 1984.

Von Willebrand's disease: Unlike that in hemophilia, bleeding in VWD is immediate and most prominent from mucosal surfaces. Symptoms usually are mild, except in type III disease. Nosebleeds are a common presentation, as are easy bruising, gastrointestinal bleeding, and excessive menstrual bleeding. Bleeding into joints or deep tissue usually does not occur except in type III VWD, in which severe VWF deficiency engenders a critical deficiency of factor VIII.

LABORATORY FINDINGS

Hemophilia: Bleeding time and prothrombin time (PT) are normal. The activated partial thromboplastin time (aPTT) is at least mildly prolonged. The critical diagnostic tests are specific assays for factor VIII and factor IX procoagulation activity. Levels in excess of 25% generally are associated with normal hemostasis.

Von Willebrand's disease: The PT and aPTT generally are normal, except among patients with type III disease, in whom a marked reduction in factor VIII can lead to a prolongation of the aPTT. The bleeding time typically is prolonged. The standard VWD evaluation consists of three laboratory tests—VWF activity (based on platelet aggregation induced by the antibody ristocetin in the presence of VWF), factor VIII coagulation activity, and VWF antigen level. In typical type I VWD, levels of all substances are similarly decreased to the range of 20% to 50% of normal.

MANAGEMENT

Hemophilia: The foundation is replacement of the missing clotting factor. Because the available products are rapidly changing, consultation with a hemophilia specialist may be helpful. Most patients with newly diagnosed hemophilia are treated with recombinant factor VIII or factor IX, although high cost and limited availability restrict use to short-term management of profuse hemorrhage or prophylactic treatment before a surgical procedure. Unfortunately, inhibitory factor VIII antibodies develop in 10% to 20% of patients. Mild-to-moderate hemophilia A sometimes can be successfully managed with desmopressin (DDAVP), which can produce a two- to fivefold increase in factor VIII that lasts for several hours. The fibrinolytic inhibitor *e*-aminocaproic acid can be effective in the control of dental or superficial bleeding.

Von Willebrand's disease: Desmopressin can produce a two- to threefold increase in plasma levels of VWF and factor VIII that can last for 4 to 12 hours. It can be administered intravenously or in a nasal spray. Use of this agent is relatively contraindicated in type IIB VWD, because it can exacerbate thrombocytopenia. Patients with severe type III VWD often need treatment with factor replacement. Because a recombinant VWF product is not currently available, treatment is limited to selected factor VIII concentrates prepared from pooled plasma that contain large amounts of VWF. Patients also can be treated with fresh frozen plasma or cryoprecipitate, although use of these products carries risk of infection. *e*-Aminocaproic acid can be effective in the control of dental or mucosal bleeding. Estrogen and oral contraceptives increase VWF levels and are particularly useful in managing menorrhagia.

[Chapter 237](#)

APPROACH TO THE PATIENT WITH LEUKOCYTOSIS

DEFINITIONS

Leukocytosis is elevation of the white blood cell (WBC) count above the normal range. An elevated total WBC count can be attributed to an elevation in one or more of the individual classes of leukocytes: neutrophils (more than approximately 8,000 cells per microliter), eosinophils (more than 450 cells per microliter), basophils (more than 100 cells per microliter), monocytes (more than 1,000 cells per microliter), and lymphocytes (more than 6,000 cells per microliter). Each of these cell types makes an important contribution to host defense and repair. The degree of elevation is important; normal ranges are really the mean and two units of standard deviation in a large population sampling. The higher the WBC count, the less likely it is that it is a normal gaussian variation.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of leukocytosis depends on the class of leukocyte affected and the duration of the elevation, if that can be determined. The causes of neutrophilia and eosinophilia are listed in [Table 216.1](#) and [Table 216.2](#). Basophilia is rare and should prompt consideration of the existence of myeloproliferative disease, such as chronic myelogenous leukemia (CML) or polycythemia vera, and many of the disorders associated with eosinophilia. Monocytosis is most often a sign of acute bacterial, viral, protozoan, or rickettsial infection. Monocytosis without neutrophilia occurs especially with tuberculosis, syphilis, brucellosis, and typhoid fever. Lymphocytosis most commonly occurs with acute viral infection. However, persistent lymphocytosis is more commonly a sign of clonal lymphoproliferative disease, especially chronic lymphocytic lymphoma (CLL), than of infection.

HISTORY AND PHYSICAL EXAMINATION

Leukocytosis itself usually is asymptomatic, and the clinical presentation is determined instead by the underlying etiologic factors. Signs and symptoms of infection, inflammatory disease, and hematologic malignant disease are particularly relevant.

DIAGNOSTIC EVALUATION

The findings depend on the condition underlying the leukocytosis. The leukocyte alkaline phosphatase score is useful in evaluating persistent neutrophilia. The result is near zero in CML but is normal to elevated in reactive, secondary neutrophilia and polycythemia vera. If the result is low, examination of a bone marrow aspirate may detect the t(9:22) translocation associated with CML. Unexplained, persistent basophilia or monocytosis should prompt bone marrow aspiration for morphologic and karyotyping studies. The blood smear of a patient with persistent lymphocytosis may reveal smudge cells, a sign of B-cell CLL, or large lymphocytes with fine granules, a sign of T-cell CLL. Flow cytometric analysis of the blood may show patterns of lymphocyte cell surface proteins diagnostic of either form of CLL.

MANAGEMENT

The underlying disease should be managed, if possible.

[Chapter 216](#)

APPROACH TO THE PATIENT WITH LYMPHADENOPATHY

PATHOPHYSIOLOGY

Lymph node enlargement may be caused by infiltration of inflammatory cells into the lymph node (infection), malignant transformation and proliferation of cells indigenous to the node (lymphoma), infiltration of the node by metastatic malignant cells (leukemia and cancer of epithelial and sarcomatous origin), or accumulation of benign cells or substances in the node parenchyma (lipid-storage disease and amyloidosis).

HISTORY AND PHYSICAL EXAMINATION

Age: Among persons younger than 30 years, most cases are benign and caused by infection. Among patients older than 50 years, only 40% of cases are benign, so malignancy must be excluded.

Other symptoms and signs: Fever is common with infection and malignant disease. Symptoms and signs of localized infection may be present. Night sweats or weight loss suggest lymphoma, HIV infection, or tuberculosis.

Characteristics of nodes: In acute infection, the nodes may be tender, assymmetric, or matted. In chronic infection, they may be less tender and more symmetric. In lymphoma, they often are large, rubbery, and nontender. Metastatic carcinoma produces hard, fixed, asymmetric nodes.

Location of nodes: See [Table 201.1](#).

Examination of spleen: Tender enlargement occurs in mononucleosis. Lymphoma, leukemia, lipid storage disease, and amyloidosis also may cause splenomegaly.

DIAGNOSTIC TESTS

There is no routine battery of laboratory tests. Complete blood cell count and blood smear may be helpful when infection or malignant disease is suspected. Monospot, throat culture, serologic testing for HIV, and autoimmune antibody testing are used in appropriate settings. Serologic titers for cytomegalovirus or toxoplasmosis may be helpful. Radiographs often are unnecessary in the presence of superficial lymphadenopathy. Chest radiographs and computed tomography of the chest, abdomen, and pelvis reveal deeper nodes and are especially useful if lymphoma is suspected. Aspiration is particularly useful in diagnosing metastatic carcinoma or infectious lymphadenitis but does not provide tissue for the histopathologic review critical in classification of lymphoma. Biopsy is appropriate for (a) persistent, unexplained, localized or generalized lymphadenopathy, especially if the node is firm, rubbery, or fixed; (b) lymphadenopathy accompanied by fevers, night sweats, and weight loss but no clear infectious source; or (c) staging for patients with known malignant disease. The largest accessible node should be selected. Biopsy provides enough information for diagnosis in only about 50% of cases. When biopsy does not provide enough diagnostic information, the patient must be observed closely with repeated biopsy to find persistent lymphadenopathy and repeated examination to find constitutional symptoms.

DIFFERENTIAL DIAGNOSIS

See [Table 201.3](#).

MANAGEMENT

If a specific infection is suspected, a period of observation or trial of antimicrobial therapy may be instituted. Empiric use of antibiotics or glucocorticoids should be avoided. HIV testing should be considered for those with persistent generalized lymphadenopathy. If nodes have characteristics that suggest malignancy or if unexplained lymphadenopathy persists, biopsy should be performed. However, biopsy should be avoided in the evaluation of patients who may have infectious mononucleosis, because the pathologic findings may mimic those of malignant lymphoma.

[Chapter 201](#)

MULTIPLE MYELOMA

DEFINITION

Multiple myeloma (MM) is a malignant disease of plasma cells. It is associated with the production of monoclonal immunoglobulin (M protein).

EPIDEMIOLOGY

The annual incidence of MM in the United States is 3 to 4 cases per 100,000 persons. The median age at diagnosis is 75 years. Blacks have twice the risk of whites and men twice the risk of women. The cause is unknown.

CLINICAL FINDINGS

Most patients have anemia, and many have pallor, fatigue, and dyspnea. Most also have lytic, punched-out bone lesions and pain. In most instances the pain ceases when the patient is at rest. Bone tenderness or pathologic fractures may occur, especially in the vertebrae, ribs, and sternum. About 5% of patients have spinal cord compression during the course of disease. Symptoms and signs include unremitting back pain, especially radicular pain, unilateral or bilateral numbness of the lower extremities, paresis or paralysis, urinary or bowel incontinence, hyperreflexia, and pathologic reflexes. Hypercalcemia may cause anorexia, somnolence, nausea, vomiting, constipation, or dehydration. Recurrent infection with encapsulated organisms occurs among about 10% of patients, owing to decreased production of polyclonal antibody. Infection with gram-negative pathogens is common if there is neutropenia. Hypercalcemia and the production of nephrotoxic light chains (Bence Jones proteinuria) often lead to renal impairment. Bleeding generally occurs late in the disease and is caused by thrombocytopenia and interference of the M protein with clotting factors. Amyloidosis, usually asymptomatic, complicates as many as 10% of cases.

LABORATORY STUDIES

Serum and urine immunoelectrophoresis always is performed. A monoclonal protein is present in the serum of 85% of patients and in the urine of 75%. About 1% to 2% have neither and therefore have nonsecretory disease. A skeletal radiographic survey shows characteristic lytic lesions in almost 70% of patients (bone scintigraphy is less reliable). Magnetic resonance imaging or computed tomography of suspected areas may be needed to demonstrate bone lesions. Hypercalcemia and renal insufficiency occur among 10% to 15% of patients. One-half have an elevated b₂-microglobulin level.

DIAGNOSIS AND STAGING

Many disorders are associated with monoclonal gammopathy, including MM, monoclonal gammopathy of undetermined significance (MGUS), primary amyloidosis, and cryoglobulinemia. For a patient with no symptoms and less than 2 g per deciliter of monoclonal protein, the most likely diagnosis is MGUS. The diagnostic criteria for MM are (a) M protein in the serum or urine, (b) more than 10% plasma cells in the marrow aspirate, and (c) demonstration of bone lesions, anemia, hypercalcemia, or renal failure. Stage is based on hemoglobin concentration, calcium level, the presence or absence of bone lesions or renal insufficiency, and the quantities of monoclonal immunoglobulin in the blood and urine. The level of b₂-microglobulin also is predictive of outcome.

PROGNOSIS AND MANAGEMENT

The typical course lasts 3 to 4 years, but there is a wide variation in survival periods. The cause of death usually is infection or bleeding. The goal of therapy is control, not cure. Therapy with melphalan and prednisone produces a response for about 50% of patients. Combination chemotherapy may be advantageous for rapidly lowering tumor burden but has not been shown to increase survival time. Interferon can prolong the plateau phase after discontinuation of chemotherapy but also fails to improve survival time. Peripheral stem cell transplantation is gaining prominence, especially for younger, healthier patients. Radiation therapy is used for bone lesions that pose a threat to life or that may cause long-term disability. Antibiotic prophylaxis with trimethoprim-sulfamethoxazole or ciprofloxacin may improve outcome. Renal function may be preserved by means of minimizing risk of infection, dehydration, and exposure to contrast dyes and nephrotoxic antibiotics. Hypercalcemia should be controlled.

[Chapter 234](#)

NON-HODGKIN'S LYMPHOMA

DEFINITION AND PATHOPHYSIOLOGY

Non-Hodgkin's lymphoma (NHL) is a heterogeneous group of malignant tumors that begin as a clonal malignant expansion of B or T lymphocytes. NHL is caused by transformation of normal lymphoid cells at various stages of differentiation. Numerous chromosomal translocations have been found.

EPIDEMIOLOGY AND ETIOLOGY

NHL is the fifth most common cause of cancer death in the United States. The incidence increases with age, although Burkitt's and lymphoblastic lymphoma are more common among children. There is an association with HIV infection, chronic immunosuppressive therapy, certain autoimmune diseases (such as Hashimoto's

thyroiditis and Sjögren's syndrome), and infection with HTLV-1, Epstein-Barr virus, and *Helicobacter pylori*. Most cases have no identifiable etiologic factor.

CLASSIFICATION

The Working Formulation ([Table 233.1](#)) classifies NHL into three prognostic grades based on the appearance of the disease within the node (follicular versus diffuse) and on the principal size of the lymphoma cells (small, cleaved cells versus large, noncleaved cells versus mixed populations). A Revised European-American Classification is gaining favor. Follicular lymphoma (low grade) accounts for 30% to 40% of cases.

CLINICAL FINDINGS

NHL generally manifests as progressive lymphadenopathy. Patients may have constitutional symptoms (fever, night sweats, unexplained weight loss), fatigue, early satiety due to splenomegaly, or regional pain from enlarging tumor masses. Bone marrow involvement may produce anemia, thrombocytopenia, or predisposition to atypical or recurrent infection. Intermediate- and high-grade NHL more often is associated with rapidly progressive (weeks or months) lymphadenopathy, constitutional symptoms, and central nervous system (CNS) involvement.

LABORATORY STUDIES, DIAGNOSTIC TESTS, AND STAGING

The diagnosis is made by means of biopsy. Clinicians who suspect lymphoma should inform the pathologist so that special studies can be added to routine histologic examination. Histologic subtype determines the type and speed of staging procedures. Baseline studies should include a complete blood cell count, liver and renal chemical analysis, and measurement of calcium, lactate dehydrogenase (LDH), and b_2 microglobulin. The evaluation also usually includes bone marrow biopsy and computed tomography of the chest, abdomen, and pelvis. Patients with high-grade lymphoma or CNS symptoms should undergo diagnostic lumbar puncture. The Ann Arbor staging system is used (see [Table 3](#)). Spread is hematogenous and unpredictable.

PROGNOSIS AND MANAGEMENT

Adverse outcome is associated with advanced age, the presence of systemic symptoms, CNS or marrow involvement, elevated LDH and b_2 microglobulin levels, and certain cytogenetic markers. Histologic type and stage also are important. The International Prognostic Index was devised to stratify patients by risk and to guide choice of therapy.

Low grade: Although the course is generally indolent, transformation to higher-grade illness occurs at a rate of about 6% per year. Localized disease is managed with radiation therapy; about 50% of patients are disease-free at 10 years. Stage III or IV disease is incurable with standard therapy; watchful waiting and single-agent or combination chemotherapeutic regimens can be used. Autologous stem cell transplantation and monoclonal antibodies have been used for refractory or relapse cases.

Intermediate grade: Combination chemotherapy (most commonly CHOP) can be curative. Radiation therapy can be added for localized disease. Localized disease has 70% to 80% long-term disease-free survival rate. Advanced-stage disease has a 5-year survival rate of 30% to 50%.

High grade: Intensive combination regimens produce the best results. Complete responses occur among 20% to 30% of patients, but less than 5% of patients survive long term. CNS prophylaxis (intrathecal chemotherapy and craniospinal irradiation) is routine. If the prognostic score is poor, autologous stem cell transplantation can be used as consolidation therapy.

Chapter 233

POLYCYTHEMIA VERA

DEFINITIONS AND EPIDEMIOLOGY

Polycythemia vera (PV), a myeloproliferative disorder, is autonomous clonal proliferation of multipotential stem cells that results in generalized hyperplasia of the bone marrow, increased production of red blood cells (RBCs), and an absolute increase in the number of circulating RBCs. PV is most often diagnosed among persons between 50 and 70 years of age. There is a slight male predominance.

CLINICAL FEATURES AND COURSE OF DISEASE

The preerythrocytotic phase of PV often is unrecognized. RBC mass is normal, and the only abnormalities may be pruritus after bathing or splenomegaly. This phase lasts for a few months to 1 to 2 years. The erythrocytotic phase often is first recognized when the patient sustains an occlusive arterial or venous lesion, such as cerebral or myocardial infarction or ischemia, portal venous obstruction, or peripheral venous thrombosis. The expanded RBC mass produces symptoms of hyperviscosity such as headaches, dizziness, and visual disturbances. Plethora and conjunctival or oral mucosal suffusion are common. Some patients have epistaxis, ecchymosis, or gastrointestinal or genitourinary hemorrhage. Gastrointestinal symptoms and peptic ulcer disease are frequent. Episodes of acute gout associated with overproduction of urate occur among about 5% of patients. The most common physical finding is splenomegaly, which occurs among almost 90% of these patients. Hepatomegaly occurs among about half. The erythrocytotic phase may last 5 to 10 years if treatment is given.

A proliferative phase follows and usually is characterized by thrombocytosis, leukocytosis, and increasing splenomegaly. It usually lasts a few years. Evolution into the postpolycythemic myeloid metaplasia phase is gradual and occurs among 20% of patients. Asthenia is the most common symptom. Weight loss, generalized wasting, myelofibrosis, and cytopenia develop. Most patients with disease in this phase have a shortened survival period, dying either of complications or of evolution to acute nonlymphocytic leukemia.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

PV usually is recognized by an increase in RBC count, hemoglobin concentration, and hematocrit. Early in the disease, the RBCs are of normal size. Because mucosal bleeding is common, iron deficiency may develop and lead to microcytosis and normalization of the RBC count. Thrombocytosis and increased numbers of granulocytes and basophils are common. There is an increase in leukocyte alkaline phosphatase activity and in serum levels of vitamin B₁₂ (from augmented production of cobalamin-binding proteins). The bone marrow is diffusely hypercellular, with an increase in all hematopoietic elements but without pathognomonic histologic changes. In later phases, marrow fibrosis and pancytopenia develop. Diagnostic criteria are presented in [Table 231.1](#).

PROGNOSIS AND MANAGEMENT

The median survival rate improves with therapy from 18 months to 9 to 14 years. In the preerythrocytotic phase, therapy with H₁ and H₂ blockers may ameliorate pruritus. During the erythrocytotic phase, phlebotomy is the treatment of choice. Because the likelihood of thrombotic events increases during the first 2 to 3 years of phlebotomy treatment, treatment with hydroxyurea or recombinant interferon- α (rIFN- α) often is added. Low-dose aspirin may be beneficial. Myelosuppressive therapy is indicated for young patients requiring phlebotomy of more than 6 units per year or for anyone with features of the proliferative phase, such as thrombocytosis or splenomegaly. Hydroxyurea is the drug of choice, and rIFN- α is emerging as an alternative. Anagrelide is particularly effective in improving thrombocytosis. Therapy during the postpolycythemic myeloid metaplasia phase is supportive. Erythropoietin has reduced transfusion requirements. Recurrent painful splenic infarctions or symptomatic congestive splenomegaly may necessitate splenectomy. Transition to leukemia is associated with a poor response to therapy.

Chapter 231

PROSTATE CANCER

DEFINITION

Prostate cancer generally refers to adenocarcinoma of the prostate, which accounts for more than 98% of all cases of prostate cancer.

INCIDENCE AND EPIDEMIOLOGY

Prostate cancer is the most common cancer among men and the second leading cause of cancer-related deaths of men. In 1998, an estimated 184,500 new cases were diagnosed. Prevalence increases with age.

ETIOLOGY

A hereditary risk has been demonstrated; incidence varies with race and ethnic background (highest for African Americans). Vasectomy, smoking, infection, and level of sexual activity are not considered risk factors. Prostate cancer is an androgen-sensitive disease.

PATHOGENESIS AND PATHOPHYSIOLOGY

The prostate is situated at the base of the bladder. Most tumors originate in the peripheral zone. The prominent grading system is that of Gleason (scores from 2 to 10). It reflects aberrations in glandular architecture. Patients with higher Gleason scores have shorter survival periods. Staging paradigms include the American (ABCD) and tumor–node–metastasis (TNM) systems; the latter is more accurate. The most common site of distant metastasis is bone. The spine is most commonly affected, and the metastases generally are osteoblastic.

CLINICAL FINDINGS

Localized prostate cancer is asymptomatic. Urinary symptoms, such as frequency, dysuria, or decreased force, can occur but are much more common with benign prostatic hyperplasia. Microscopic or gross hematuria is more representative of a urinary tract infection, urinary tract stones, or a tumor of the bladder or kidney. Metastatic disease can cause bone pain, weight loss, or fatigue. Approximately 75% of patients have clinically localized disease at diagnosis, mainly owing to the use of measurement of prostate-specific antigen (PSA) as a screening tool. There are few physical findings. Digital rectal examination is not a sufficiently sensitive or specific test for detection.

LABORATORY FINDINGS

Levels of prostate-specific antigen: PSA determination has taken a central role in the diagnosis of prostate cancer. PSA is not specific to prostate cancer, however. Elevations can occur with benign prostatic hyperplasia and in infected normal tissue. A normal value of 4.0 ng per milliliter has been established, but a level from 4 to 10 ng per milliliter has only a 20% chance of being associated with prostate cancer. Conversely, 20% to 35% of clinically detectable prostate cancers are associated with a PSA level less than 4.0 ng per milliliter. A number of techniques for improving the test characteristics of PSA measurement have been proposed, including age-specific normal ranges, determination of the PSA level per unit volume of prostatic tissue, and measurement of the rate of change in PSA levels over time. Once prostate cancer is diagnosed, PSA measurements are an excellent way to monitor response to therapy and detect treatment failure.

Other studies: The diagnosis is almost always made by means of transrectal ultrasound (TRUS)–guided needle biopsy. A bone scan is the most sensitive method to detect osseous metastasis, but abnormal findings may reflect injury or arthritis. Computed tomography (CT) of the pelvis depicts regional lymphadenopathy. For patients with a PSA level less than 10 ng per milliliter, the diagnostic yield of an evaluation for metastasis, which includes CT and a bone scan, is very low.

PROGNOSIS AND MANAGEMENT

Localized disease: Without treatment, the average survival period for stage A and B disease is 8 to 10 years. Radical prostatectomy is considered a standard of care for men younger than 70 years who have an expected survival time of more than 10 years. The principal morbidities are urinary incontinence (less than 5%) and erectile dysfunction (more than 50%). Patients with localized disease have a 5-year disease-free survival rate of 95%. External beam radiation is considered an equivalent treatment and is the preferred therapy for clinical stage C or T3 disease. Patients older than 70 years are commonly referred for radiation therapy. Complications include erectile dysfunction (20% to 80%), rectal bleeding or diarrhea (less than 5%), and urinary incontinence (less than 1%). Active observation, with androgen ablation reserved for palliative use at the time of progression, is a reasonable option for patients with a low-grade tumor or less than a 10-year expected survival period.

Metastatic disease: Patients with disease in the lymph nodes but no osseous disease are generally treated with some form of androgen ablation. Pelvic irradiation often is used to treat younger patients. The 5-year overall survival rate is 70% to 85%. Patients with distant metastatic disease usually are treated with androgen deprivation, which results in tumor regression in more than 80% of cases. It is accomplished either through surgical castration or the administration of luteinizing hormone–releasing hormone agonists (such as leuprolide or goserelin), with or without an anti-androgen such as flutamide. Chemotherapy has previously been unsuccessful in the management of hormone-refractory prostate cancer, although recent results are encouraging.

Chapter 223

SICKLE CELL DISEASE

DEFINITIONS AND ETIOLOGY

Sickle cell disease (SCD) is a hereditary hemoglobin disorder in which sickling of red blood cells (RBCs) causes chronic hemolytic anemia, vascular occlusion, and progressive organ damage. In SCD, both of the β -globin chains have a substitution of valine for glutamic acid in the sixth position. Sickle cell trait occurs when there is one normal gene and one sickle cell gene. Hybrid types of hemoglobinopathy exist that combines one sickle cell gene with either a hemoglobin C gene (SC disease) or a gene for β -thalassemia (sickle β -thalassemia).

EPIDEMIOLOGY

The estimated frequency among newborn African Americans is 1 in 600. Because persons with sickle cell trait have a greater chance of surviving severe malaria, the distribution of the sickle cell gene throughout the world parallels that of *Plasmodium falciparum*.

PATHOPHYSIOLOGY

The mutation in the β -globin chain causes deoxygenated hemoglobin to polymerize, making it relatively insoluble and rigid. The kidney, spleen, retina, and bone marrow often are affected because conditions are sufficiently hypoxic and acidotic to induce sickling.

CLINICAL FEATURES

The clinical manifestations are those of anemia and vaso-occlusion. The anemia includes chronic hemolysis, aplastic crisis, and splenic sequestration. The vaso-occlusive complications (called *crises*) include pain and organ impairment, such as splenic infarction, stroke, aseptic necrosis of the hip, and acute chest syndrome. Almost every organ system can be affected ([Table 245.1](#)).

LABORATORY TESTS AND DIAGNOSTIC STUDIES

Laboratory evaluation for SCD includes examination of the peripheral blood smear, which demonstrates sickle cells. The presence of nuclear remnants (Howell–Jolly

bodies) within the red cell indicates functional asplenia. The mean corpuscular volume is high because of the presence of young red blood cells. The numbers of granulocytes and platelets increases. Definitive diagnosis can be made with hemoglobin electrophoresis and a solubility test (which confirms that a hemoglobin migrating in the S position on electrophoresis is S and not D or G).

PROGNOSIS AND MANAGEMENT

Among patients receiving care in designated SCD programs, 50% are alive at 45 years of age. Therapy should first be directed at the elimination of hypertonicity, dehydration, acidosis, and hypoxemia. RBC transfusions are indicated for cardiac decompensation, severe acute anemia, erythroid hypoplasia with a hemoglobin concentration less than 5.0 g per deciliter, stroke and transient ischemic attacks, multiorgan failure syndrome, acute chest syndrome, and preoperative preparation for surgery. Transfusions should not be used in the management of chronic steady-state anemia, acute painful episodes, or infection. Hydroxyurea can increase fetal hemoglobin level and decrease the frequency of painful crises. Bone marrow transplantation and gene therapy are under investigation.

Painful crises should be managed with adequate analgesia once surgical causes have been excluded. Severe pain necessitates parenteral administration of morphine, preferably with patient-controlled methods. With improvement, the dose and route of administration can be modified. Because of the frequency and consequences of bacteremia, unexplained fever should be considered an emergency. Prompt antibiotic therapy is required while the diagnostic evaluation is undertaken. The presence of encapsulated organisms must be considered strongly if a patient has functional asplenia.

[Chapter 245](#)

APPROACH TO THE PATIENT WITH SPLENOMEGALY

PATHOPHYSIOLOGY

The spleen is the largest lymphoid organ in the body. It consists of a fibrous capsule and radiating fibrous trabeculae that enclose the white and red pulp. Splenomegaly can be caused by infiltration of the organ by reactive lymphoid cells or proliferating macrophages (infection or inflammation), neoplastic cells (hematologic malignant disease), or abnormal material (amyloidosis, Gaucher's disease). Vascular congestion or space-occupying lesions also can cause splenomegaly. Splenomegaly often is associated with hypersplenism, a pathologic increase in the normal splenic sequestration and destruction of circulating blood elements.

DIFFERENTIAL DIAGNOSIS

Systemic infections such as mononucleosis are the most common cause of moderate and transient splenomegaly. Massive splenomegaly usually is caused by lymphoma or a myeloproliferative disorder ([Table 202.1](#)).

HISTORY AND PHYSICAL EXAMINATION

The presentation depends on the underlying disease. The most common symptom directly related to the spleen is pain in the left upper quadrant from capsular stretching or splenic infarction. The patient also may have early satiety. The interview should be focused on symptoms and predispositions that suggest infectious or hematologic malignant disease. If a patient has a long history of splenomegaly, a neoplastic process often is implicated; infectious splenomegaly more commonly develops over days. A history of alcoholism or previous liver disease suggests portal hypertension from hepatic cirrhosis. The examination reveals evidence of splenomegaly. The larger the spleen, the greater is the likelihood of a serious underlying medical problem. As the organ enlarges, dullness may be detected at percussion of the ninth intercostal space in the left anterior axillary line. Palpation of the spleen during inspiration usually signifies enlargement. However, patient can have marked splenomegaly in the absence of a palpable spleen. The enlarged spleen generally is not tender in infiltrative and malignant diseases. It may be tender in the presence of acute infection. Examination for lymphadenopathy and chronic liver disease is particularly important.

DIAGNOSTIC TESTS

A palpable spleen in an adult always necessitates evaluation. Testing of the spleen itself often is unnecessary, but computed tomography, magnetic resonance imaging, ultrasonography, and radioisotope scanning all have a place in determining shape, size, and the presence of parenchymal abnormalities. The most valuable laboratory tests are the complete blood cell count (hypersplenism causes cytopenia), blood smear, and measurement of liver enzymes. For patients with fever, blood cultures and specific viral serologic tests often are useful. Bone marrow aspiration and biopsy are often useful in the diagnosis of malignant disease, lipid storage disorders, and disseminated fungal and mycobacterial infection. Biopsy of enlarged lymph nodes often discloses the diagnosis.

MANAGEMENT

Medical indications for splenectomy include two broad categories—diagnostic splenectomy and splenectomy to alleviate the consequences of splenomegaly, chiefly cytopenia. The main complication is the risk of serious infection, particularly by encapsulated bacterial organisms such as *Streptococcus pneumoniae*, *Neisseria meningitidis*, and *Haemophilus influenzae*. All patients undergoing splenectomy should receive vaccinations against these organisms at least 10 days before the procedure, if possible.

[Chapter 203](#)

APPROACH TO THE PATIENT WITH THROMBOCYTOPENIA

DEFINITIONS

Thrombocytopenia is a reduction in the number of circulating platelets. Automated blood counting has allowed frequent detection of mild to moderate thrombocytopenia.

PATHOPHYSIOLOGY AND DIFFERENTIAL DIAGNOSIS

Thrombocytopenia develops when there is a profound dysequilibrium between platelet production, distribution, and destruction. Impairment of production usually is part of a multilineage process and may be congenital or acquired ([Table 213.1](#)). Any disorder that causes splenomegaly increases splenic sequestration of platelets. Some of these processes also accelerate splenic destruction of platelets. Platelet destruction has an immunologic or a nonimmunologic basis ([Table 213.2](#)). The differential diagnosis of simultaneous thrombosis and thrombocytopenia includes heparin-induced thrombocytopenia, thrombotic thrombocytopenic purpura (TTP), hemolytic-uremic syndrome (HUS), systemic lupus erythematosus, and disseminated intravascular coagulation.

HISTORY AND PHYSICAL EXAMINATION

Spontaneous bleeding is rare at platelet counts more than 30,000 per microliter. As counts decrease to less than 20,000 per microliter, patients may have easy bruisability, gingival bleeding after brushing, menorrhagia, and epistaxis. As counts decrease to less than 5,000 per microliter, persistent gastrointestinal bleeding and spontaneous intracranial hemorrhage may occur. Evidence of chronicity may be obtained from prior platelet counts or a history of excessive bleeding. Attention should be given to medications, alcohol use, recent infections, and family history. Symptoms and signs of a multisystem disorder may be elicited. Examination should include a through eye examination, stool testing for occult blood, and special attention to the liver, spleen, and lymphatic tissue.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

No single paradigm fits all cases. A complete blood cell count and peripheral blood smear should be routinely performed, however. Platelet clumping can cause underestimation of the actual count and can be caused by EDTA, the anticoagulant in which blood is routinely collected. Examination of the blood smear shows the clumps. The smear also may provide clues such as schistocytes (in HUS and TTP), hypersegmented neutrophils (megaloblastic anemia), and leukemic cells. Mean

platelet volume commonly is increased in processes that accelerate peripheral destruction of platelets. The utility of testing for antibodies to platelet glycoproteins is not well established. Bone marrow aspiration and biopsy may be indicated when the cause remains uncertain.

MANAGEMENT

If possible, the underlying disease should be managed. The risk of bleeding may be reduced by avoidance of trauma, control of medical problems that predispose to bleeding (hypertension, peptic ulcer disease), and avoidance of medications that interfere with platelet function (such as aspirin). For patients with active bleeding, platelet transfusion to achieve a level of at least 20,000 cells per microliter is indicated. Counts of 50,000 cells per microliter to 100,000 cells per microliter generally are required for surgical procedures. For patients in clinically stable condition who do not need an invasive procedure, there is no absolute level of thrombocytopenia at which a platelet transfusion is mandatory. Platelet transfusion is associated with a higher risk of allergic, pyogenic, and infectious complications than is red blood cell transfusion; moreover, in about 40% of patients alloantibodies develop that ultimately render transfusions (even of HLA-matched platelets) futile. Platelet transfusions are contraindicated in TTP and HUS in the absence of severe hemorrhage, because they can worsen the thrombosis.

Chapter 217

APPROACH TO THE PATIENT WITH THROMBOSIS AND PULMONARY EMBOLISM

PRESENTATION AND ETIOLOGY

Thrombosis is among the most common problems encountered by physicians. Arterial thrombosis is principally a complication of arteriosclerosis and most often presents with coronary ischemia and as cerebrovascular and peripheral vascular disease. Other conditions associated with arterial thrombosis include homozygous and heterozygous homocysteinemia, arteritis, myeloproliferative disorders, thrombotic thrombocytopenic purpura (TTP), heparin-induced thrombocytopenia, and the antiphospholipid antibody syndrome. Venous thrombosis occurs most often in the veins of the lower extremities, where it presents with pain and swelling. Venous thrombi may also dislodge and cause pulmonary embolism (PE). Inherited disorders predisposing to venous thrombosis include deficiencies of antithrombin III, protein C, protein S, and plasminogen; factor V Leiden; prothrombin G20210A; homocysteinemia; and dysfibrinogenemia. Acquired disorders that increase the risk of venous thrombosis include malignancy, immobilization, pregnancy, oral contraceptive and estrogen use, nephrotic syndrome, antiphospholipid antibody syndrome, and paroxysmal nocturnal hemoglobinuria.

Pathophysiology:

Arterial thrombi are composed primarily of aggregated platelets (white thrombi) and form when the endothelial lining of the artery is breached, allowing platelets to interact with subendothelial connective tissue. Thrombi may form on the surface of an atherosclerotic plaque when its surface is denuded or disrupted and platelets are exposed to thrombogenic material in the plaque interior. Venous thrombi are composed primarily of fibrin and trapped RBCs (red thrombi). Venous thrombi can form in regions of venous stasis, especially when coagulability is enhanced by conditions such as those listed earlier.

History and Physical Examination:

Arterial thrombi: When arterial thrombosis complicates a myeloproliferative disorder such as polycythemia rubra vera or essential thrombocytosis, it is likely to occur in arteries involved by atherosclerosis and thus lead to acute MI or stroke. In contrast; the hyaline thrombi characteristic of TTP obstruct normal arterioles.

Venous thrombi: The symptoms result from obstruction of venous outflow and from accompanying local inflammation. Most often, symptomatic deep venous thrombosis (DVT) presents as calf discomfort or tenderness or as unexplained leg edema. Larger thrombi rarely lyse completely and may instead organize and recanalize. The resultant venous obstruction and venous valve destruction can produce the post-phlebotic syndrome of chronic calf pain associated with brawny edema, hyperpigmentation, induration, and ulceration of the lower leg. Less commonly, significant thrombosis can also involve the axillary, mesenteric, hepatic, renal, and cerebral veins. Hepatic vein thrombosis (Budd-Chiari syndrome) is a feature of the myeloproliferative disorders and paroxysmal nocturnal hemoglobinuria. Acute and chronic renal vein thrombosis occurs in the nephrotic syndrome, especially that associated with membranous glomerulonephritis.

Pulmonary embolism: Venous thrombi that lead to PE are almost invariably located in the proximal veins of the legs, but may begin as calf vein thrombi that extend proximally. Patients with PE most often complain of dyspnea, pleuritic chest pain, or hemoptysis; the examination most commonly reveals tachypnea or tachycardia. Of note, asymptomatic DVT has been found in 70% of patients with confirmed PE and asymptomatic PE has been detected in about 50% of patients with proximal DVT.

Differential Diagnosis:

Conditions confused with DVT of the legs include muscle strains and tears, swelling related to paralysis, lymphatic obstruction, Baker's cyst, cellulitis, internal derangements of the knee, and the postphlebotic syndrome. The symptoms of PE are nonspecific; the differential diagnosis includes panic attacks and a broad range of cardiopulmonary conditions.

Diagnostic Evaluation:

Venous thrombi: A diagnosis of DVT is difficult on clinical grounds alone and should be based on objective tests. The standard is venogram, but it is invasive and associated with a 2%-3% incidence of chemical phlebitis. Real-time B-mode ultrasonography is reported to be 97% sensitive and specific for proximal DVT in symptomatic patients. The most sensitive finding is failure of a vein to collapse under gentle pressure. The test is not as sensitive for calf vein or pelvic vein thrombi or for thrombi in asymptomatic patients. Nevertheless, most recent studies suggest that it is safe to withhold anticoagulant therapy in the face of normal serial real-time-B-mode ultrasound examinations. Impedance plethysmography (IPG) measures changes in electrical impedance in the calf following deflation of a pressure cuff around the thigh; it detects impairment in venous outflow from the leg. It is far less sensitive than previously thought and cannot be recommended as a test to rule out DVT. The roles of plasma D-dimer levels, CT, and magnetic resonance venography remain to be determined.

Pulmonary embolism: Unless contraindicated, anticoagulation should be initiated while the results of the diagnostic evaluation are pending. The CXR may show non-specific findings of hemidiaphragmatic elevation, small pleural effusions, or ill-defined parenchymal infiltrates. The ABG usually reveals widening of the alveolar-to-arterial oxygen gradient, often with a low PO_2 . The ECG most often shows tachycardia with nonspecific ST segment and T-wave changes. The most commonly used initial diagnostic test for PE is ventilation and perfusion lung scanning (V/Q scans). PE is highly unlikely if the scans are entirely normal. In contrast, PE is very likely if the scans show a normal ventilation pattern with two or more large perfusion defects (>25% of an anatomic lung segment). Unfortunately, most patients with suspected PE have abnormal but non-diagnostic scans and require further testing. [Figure 378.2](#) shows a stepwise initial diagnostic approach that incorporates clinical probability, V/Q scans, and lower extremity ultrasound studies. Pulmonary arteriography is considered the diagnostic gold standard, but is expensive, invasive, and not always available. Recently, spiral CT scanning has shown promise in the diagnosis of PE, particularly emboli that lodge in segmental or larger pulmonary vessels.

Evaluation for Hypercoagulability:

Arterial thrombi: Because most cases of arterial thrombosis result from atherosclerosis, and not from abnormalities of platelet function or blood coagulation, studies should focus on the extent of the atherosclerosis and on factors that might contribute to its progression. When arterial thrombosis occurs in the absence of significant atherosclerosis, hemostatic abnormalities should be sought.

Venous thromboembolism: Because tests to detect specific causes of thrombosis are expensive and are unlikely to change the management of patients following the first episode of thrombosis, such testing should be restricted to patients with recurrent thrombosis, unless the patient has a family history strongly suggestive of a hereditary disorder. It is important to remember that measurement of proteins associated with familial thrombosis (antithrombin III, proteins C and S) may not be reliable until several weeks after an acute thrombotic episode and may be affected by warfarin therapy (proteins C and S are vitamin K-dependent). On occasion, venous thrombosis is a presenting symptom of malignancy, particularly when patients have mucin-producing carcinomas (Trousseau's syndrome). Malignancy has been found in 3%-10% of patients presenting with venous thrombosis and in 7%-11% of patients during the subsequent 6-24 months. It is found most often in patients

without an obvious cause for venous thrombosis, in those with recurrent idiopathic thrombosis, and in those older than 60 years. However, there is no evidence that an extensive workup to detect malignancy is beneficial. A reasonable approach is to supplement routine studies with multiple fecal samples for occult blood, PSA measurements in men, and mammography in women.

Prevention:

Arterial thrombi: Drugs that inhibit platelet function (e.g. aspirin, ticlopidine, and clopidogrel) have been shown to be beneficial in preventing thrombosis in patients with atherosclerotic vascular disease.

Venous thromboembolism: Prophylactic heparin given at a dose of 5,000 units every 12 hours decreases the incidence of DVT and PE in general surgical patients. It is less effective for prophylaxis following orthopedic surgery or trauma, however. In these circumstances, more effective approaches include subcutaneous heparin adjusted to maintain a top normal PTT or the use of low molecular weight heparin (LMWH) or moderate-dose warfarin therapy.

Treatment:

Arterial thrombi: Except for specific circumstances such as unstable angina, early acute MI, and selected cases of peripheral arterial thrombosis, the goal for patients with arterial thrombi is prevention of recurrence with anti-platelet agents.

Venous thromboembolism: The treatment of choice for venous thromboembolism (including symptomatic calf vein thrombi and PE) is heparin (either intravenous or subcutaneous) at a dose sufficient to prolong the PTT to 1.5-2.5 times the mean of the control PTT. Achieving this dose within the first 24 hours of treatment has been found to minimize treatment failure and recurrence. Generally, an initial intravenous bolus of 5,000 units followed by >30,000 units/24 hours is required. LMWH preferentially catalyzes the inhibition of factor Xa over the inhibition of thrombin. When given at a fixed dosage subcutaneously once or twice daily and without laboratory monitoring, LMWH has been found to be at least as effective as standard heparin. It is particularly advantageous in the outpatient setting, where its higher cost is outweighed by the saved costs of hospitalization. Current practice is to treat with heparin for at least 5 days, starting warfarin on day #1. Once the warfarin effect is adequate (INR = 2.0-3.0), an overlap of 2 days is recommended to insure that patients are adequately anticoagulated when the heparin is stopped and to prevent the rare occurrence of warfarin-induced skin necrosis. The duration of warfarin therapy depends on the inciting cause of the DVT. In patients with reversible risk factors such as recent surgery, 6-12 weeks may be sufficient. However, in patients with idiopathic thrombosis, a longer course of therapy is necessary. Although the optimal duration of therapy remains to be established, a recent study revealed a recurrence rate of 27%/patient-year in a group treated for 3 months compared to 1.3%/patient-year in those treated for an average of 12 months, suggesting that treatment for only 3 months is inadequate. Patients with ongoing risk factors or recurrent venous thromboembolism should be treated indefinitely. When there are contraindications to the use of anticoagulant drugs (such as active bleeding) or if thrombosis recurs despite adequate anticoagulation, vena caval interruption may be indicated to reduce the risk of PE. Surgical thrombectomy and thrombolytic agents such as streptokinase and tissue plasminogen activator are usually reserved for patients with life-threatening pulmonary embolism or massive iliofemoral thrombosis where compromise of the adjacent arterial circulation seems imminent.

BACTERIAL MENINGITIS

DEFINITION, EPIDEMIOLOGY AND ETIOLOGY

Meningitis develops when the cerebrospinal fluid (CSF) in the subarachnoid space becomes infected, usually because of hematogenous spread. Community-acquired meningitis is particularly common among children, young adults, and the elderly. Among children and young adults, the most common pathogens are *Streptococcus pneumoniae*, *Neisseria meningitidis*, and *Haemophilus influenzae* type B, although the incidence of *H. influenzae* infection has decreased dramatically because of the wide use of vaccine. Elderly patients are infected most often by gram-negative bacilli, *S. pneumoniae*, and *Listeria monocytogenes*. Patients who have undergone splenectomy or who have sickle cell disease are particularly susceptible to *S. pneumoniae* and *H. influenzae* infection. Bacterial meningitis due to head trauma, craniotomy, CSF leak, or congenital defects such as spina bifida is most frequently caused by *Staphylococcus aureus* and *S. pneumoniae* and less frequently by *Pseudomonas aeruginosa* or other Enterobacteriaceae. Patients undergoing cancer chemotherapy and those with underlying immunodeficiency are prone to infection with a variety of pathogens, including *L. monocytogenes*, Enterobacteriaceae, mycobacteria, and fungi. An increasing proportion of cases are nosocomially acquired, and approximately one-third of such cases are caused by gram-negative bacteria other than *H. influenzae*.

CLINICAL FEATURES

The cardinal features are fever, headache, and nuchal rigidity. Other signs of cerebral dysfunction vary depending on the onset and clinical course of the illness. They include confusion, cranial nerve palsy, and seizures. In acute purulent meningitis caused by *S. pneumoniae*, *N. meningitidis*, and *H. influenzae* type B, progression from confusion and lethargy to coma can occur within 24 hours. Other common symptoms include weakness, anorexia, shaking chills, profuse sweats, photophobia, vomiting, and myalgia of the lower extremities. At examination, neck stiffness may be subtle or marked. Kernig's and Brudzinski's signs suggest meningeal inflammation. Cranial nerve palsy, principally of the third, fourth, sixth, and seventh nerves, occurs among 10% to 20% of patients. Focal neurologic findings such as hemiparesis, visual field defects, papilledema, and dysphasia suggest the coexistence of a brain abscess, subdural empyema, or septic thrombophlebitis.

DIFFERENTIAL DIAGNOSIS AND DIAGNOSTIC TESTS

The typical CSF profiles in bacterial and nonbacterial meningitis are shown in [Table 431.3](#). Partially controlled bacterial meningitis typically is associated with lymphocytic predominance in the CSF. Patients with viral meningitis have polymorphonuclear pleocytosis in the CSF early in the course of disease. In bacterial meningitis, the yield of both Gram stain and culture is reduced by prior administration of antimicrobial agents. There are several techniques for the rapid detection of specific microbial antigens in the CSF. Blood culture results are positive in at least 50% of cases.

MANAGEMENT

[Table 431.4](#) lists choices for initial empiric antimicrobial therapy in various age groups. The final antibiotic selection should be guided by culture results and susceptibility data. Penicillin G remains the drug of choice for meningococcal meningitis. A third-generation cephalosporin such as ceftriaxone or cefotaxime is best for *H. influenzae* type B and penicillin-resistant *S. pneumoniae*, though vancomycin should be used if there is high-level penicillin resistance and an elevated minimum inhibitory concentration to third-generation cephalosporins. Newer quinolones such as trovafloxacin are effective against high-level penicillin-resistant pneumococcal meningitis in experimental models, but clinical experience is limited. Meningitis caused by *P. aeruginosa* should be managed with the combination of an antipseudomonal β -lactam plus a fluoroquinolone or an aminoglycoside. Ampicillin or penicillin G plus an aminoglycoside should be used to control *L. monocytogenes* infection.

There is no consensus regarding the use of glucocorticoids as adjunctive therapy for acute bacterial meningitis among adults. It is also unclear whether therapy with monoclonal antibodies or other agents directed at blocking the effect of inflammatory cytokines in the CSF can prevent hearing loss, seizure disorders, or other chronic neurologic sequelae.

[Chapter 279](#)

CANDIDAL INFECTIONS

EPIDEMIOLOGY AND PATHOGENESIS

Candida organisms are ubiquitous and are normal commensal organisms of humans and certain animals. *Candida albicans* is the most prominent of the eight species that infect humans with frequency. Most species exist in three forms—yeast (which may bud), hyphae, and pseudohyphae. Severe infections usually are iatrogenic. The two most important predisposing factors are neutropenia and exposure to broad-spectrum antibiotics. *Candida* organisms are the third most common pathogen in blood cultures of hospitalized patients.

CLINICAL FEATURES

Skin and mucous membranes: Intertrigo on the warm, moist areas of the skin occurs among obese and diabetic patients. Chronic mucocutaneous candidiasis is a long-standing, severe disease associated with lymphocyte-mediated immuno-deficiency. Thrush is manifest by white plaques in the oral cavity. It occurs among patients who have taken antibiotics or used inhaled steroids and among those who are severely debilitated or immunocompromised, such as patients with AIDS. Candidal esophagitis causes odynophagia and white plaques on the esophageal mucosa. It occurs frequently among patients receiving cytotoxic chemotherapy and among patients with AIDS.

Genitourinary system: Although *Candida* species are found in the urine of 8% of healthy men and 12% of healthy women, candiduria may signify cystitis, pyelonephritis, papillary necrosis, or perinephric abscess. A common problem is prolonged colonization of the bladders of patients with indwelling Foley catheters.

Intravascular infection: About 2% of cases of endocarditis are caused by *Candida* organisms, and 50% of these are complications of cardiac surgery. The hallmarks of candidal endocarditis are large vegetations and occlusion of large vessels. Infection at sites of peripheral indwelling intravascular catheters is another common cause of persistent candidemia.

Disseminated Candidiasis: Widespread disseminated candidiasis occurs most frequently among patients with neutropenia and those experiencing prolonged, complicated postoperative courses of disease. Other predisposing factors include use of antibiotics, neutropenia, the presence of an indwelling intravascular catheter,

and exposure to hyperalimentation fluid and steroids.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

Intravascular infection is associated with positive results of blood cultures. Mucosal membrane infections can be diagnosed on the basis of the clinical appearance of the lesions and recovery of the organism from scrapings of the infected area. The diagnosis of candidal infection of deep organs requires biopsy evidence of the organism invading the tissue. There are no reliable serologic tests for invasive candidiasis.

MANAGEMENT

Mucocutaneous infection is successfully controlled with azole antifungal agent such as fluconazole, itraconazole, and ketoconazole. For most patients, candiduria is self-limited, but some may need an amphotericin B bladder washout or treatment with oral fluconazole. All patients with candidemia should be treated with an antifungal agent. Removal of an infected intravenous catheter is necessary but not sufficient. Fluconazole has been demonstrated to be as effective as amphotericin B in the management of candidemia among patients with and without neutropenia. Until further studies are completed, therapy for life-threatening candidal infections is amphotericin B.

[Chapter 203](#)

CELLULITIS

DEFINITIONS

Cellulitis is a spreading acute infection of the skin and subcutaneous tissues characterized by erythema, warmth, swelling, and tenderness. It may be classified as mild and uncomplicated, severe, high risk, or necrotizing.

ETIOLOGY AND CLINICAL FEATURES

Most cases of cellulitis are mild and uncomplicated. They are caused by group A streptococci or *Staphylococcus aureus*. Diffuse erythema, swelling, and tenderness develop over 2 to 4 days. In an extremity, a red line along the course of lymphatic vessels indicates accompanying lymphangitis. Enlargement and tenderness of regional lymph nodes are common. Fever, malaise, and chills often are present.

Orbital cellulitis is a rare complication of sinusitis and carries a risk of blindness, brain abscess, and meningitis. Erysipelas usually follows a streptococcal sore throat and usually affects the young and the elderly. The infection involves the dermis and the lymphatic vessels and manifests as pain and bright-red peau d'orange lesions with advancing red borders that are sharply demarcated from normal skin. Erysipeloid is a form of cellulitis that occurs among workers who handle fish, meat, and poultry. It is caused by the gram-positive bacillus *Erysipelothrix rhusiopathiae*. About 1 week after a minor injury to the hand, a violaceous painful area appears. As the central area clears, the lesion spreads outward with distinct raised borders. Animal and human bites of the hands are potentially dangerous because of tissue damage and secondary infection. *Pasteurella multocida* often infects dog and cat bites, and *Eikenella corrodens* often is implicated in human bites. Deep infections such as tenosynovitis are particularly common after human bites. Necrotizing cellulitis is a serious gangrenous soft-tissue infection often associated with the presence of anaerobic bacteria, tissue toxins, and bacterial synergy. It should be suspected when a patient has edema out of proportion to erythema, skin vesicles, crepitus on palpation or air in the tissues on a radiograph, local anesthesia, or patchy gangrene of the skin.

MANAGEMENT

Most cases of cellulitis can be managed simply on an outpatient basis. Severe, complicated, or high-risk infections necessitate aggressive inpatient antibiotic therapy and often surgery. Patients with necrotizing infections must be treated surgically. Uncomplicated mild cellulitis, commonly caused by *Streptococcus pyogenes* or *S. aureus*, responds well to oral cloxacillin or cephalexin (500 mg every 6 hours for 7 to 10 days). For patients allergic to penicillin, erythromycin (500 mg every 6 hours for 7 to 10 days) is an alternative. Local therapy includes cleansing the area and resting the extremity. In severe cellulitis, treatment should start with intravenous cloxacillin (1 g every 6 hours). Intravenous vancomycin (500 mg every 8 hours if renal function is normal) and teicoplanin (1 g daily) are alternatives for patients allergic to penicillin. An aminoglycoside may be added when the clinical setting suggests that gram-negative bacilli may play a role (e.g., perianal cellulitis, neutropenia, glucocorticoid therapy, and diabetes mellitus), although monotherapy with second- or third-generation cephalosporins is an alternative in these situations.

Erysipelas usually responds to intravenous penicillin G (1 million units every 6 hours). Orbital cellulitis is managed with broad-spectrum antibiotics. Computed tomographic evidence of an abscess or intracranial involvement and failure to respond to antibiotics within 48 hours are indications for prompt exploration and decompression of the orbit. Erysipeloid responds to amoxicillin-clavulanate or erythromycin. Animal and human bites necessitate therapy with oral amoxicillin-clavulanate and local debridement.

[Chapter 263](#)

INFECTIONS CAUSED BY DIMORPHIC FUNGI

DEFINITION

The dimorphic fungi are soil-growing organisms that exist in a mycelian form in the environment but grow as yeast at body temperature. Infections caused by these fungi include histoplasmosis, coccidioidomycosis, blastomycosis, and sporotrichosis. The clinical manifestations depend on the immune status of the host; normal hosts may have minimal symptoms, but those with immunocompromise may develop overwhelming, disseminated infection.

EPIDEMIOLOGY, CLINICAL FEATURES, AND DIAGNOSIS

Histoplasmosis: *Histoplasma capsulatum* is the etiologic agent of histoplasmosis, a disease endemic to the Ohio River and Mississippi River valleys. The organism is found in soil contaminated with droppings from fowl. The clinical manifestations depend on underlying host defense, intensity of exposure, and previous immunity. The acute self-limited illness is characterized by flulike symptoms of fever, chills, headache, myalgia, anorexia, nonproductive cough, and chest pain. A chest radiograph may show enlarged hilar and mediastinal lymph nodes with patchy infiltrates. After heavy inoculation, more extensive pulmonary disease may develop. Inflammatory complications such as arthritis and erythema nodosum occur among about 10% of patients with symptomatic infection. Dissemination is most likely among patients with advanced AIDS, organ transplant recipients, and patients receiving steroids or chemotherapy. The manifestations include fever, weight loss, gastrointestinal lesions, skin lesions, oropharyngeal ulceration, adrenal insufficiency, meningitis, endocarditis, hepatomegaly, lymphadenopathy, and pancytopenia from bone marrow involvement. The diagnosis is established by means of culture, histopathologic examination, or serologic testing. Skin tests are not useful because most persons in endemic zones have reactive skin tests, and cross reactions with other fungi are common.

Coccidioidomycosis: Coccidioidomycosis is caused by *Coccidioides immitis*, a soil organism endemic to the southwestern United States, Mexico, and South America. Infection is asymptomatic for 60% of infected persons and is indicated by a positive skin test result. For the remaining 40%, a self-limited, flulike illness develops 1 to 3 weeks after exposure. It is characterized by a dry cough, pleuritic chest pain, myalgia, arthralgia, fever, sweats, anorexia, and weakness. Immune complex complications can include an erythematous macular rash, erythema multiforme, and erythema nodosum. Acute infection usually resolves without therapy. Approximately 5% of persons with the infection have pulmonary residua, which include nodules and cavities. Chronic progressive pulmonary infection is characterized, particularly among immunocompromised patients, by the development of extensive thin-walled cavities that may be complicated by cavity rupture, bronchopleural fistula, and empyema. Extrapulmonary disease develops in 1 in 200 patients and typically involves the skin and soft tissues, bones, and meninges. The diagnosis can be established by means of identification of spherules in histopathologic specimens or by means of culture. Serologic tests can be performed, although skin tests are of limited utility.

Blastomycosis: Most cases of blastomycosis, which is caused by *Blastomyces dermatitidis*, occur in the midwestern and southeastern United States and the

Canadian provinces of Ontario, Quebec, and Alberta. About 50% of infected persons have symptoms such as fever, chills, cough, myalgia, and arthralgia. A chest radiograph may show lobar or segmental consolidation, although a nodular pattern may be seen with chronic infection. The acute pulmonary symptoms usually resolve, but patients may have progressive pulmonary disease or disseminated infection. The skin is the most frequent site of dissemination; the verrucous or ulcerative lesions may be mistaken for squamous cell carcinoma. Other extrapulmonary sites include subcutaneous tissue, bones, the genitourinary tract (prostate and epididymis), and the central nervous system. The diagnosis is established by means of demonstration of the organism on wet preparations or histopathologic study. The organism can be cultured, but the presence of the mycelian form before conversion to a yeast does not confirm the diagnosis. Serologic studies are less reliable.

Sporotrichosis: Sporotrichosis is caused by the soil fungus *Sporothrix schenckii*, usually by means of direct inoculation from contaminated soil or plants, especially thorny plants such as roses. After an incubation period of 1 to 10 weeks, reddish-purple, nodular, cutaneous lesions appear that follow the lymphatic vessels and frequently ulcerate. Direct spread to bone or joints sometimes occurs. Pulmonary infection and disseminated infection are uncommon.

MANAGEMENT

Guidelines for selection of an antifungal agent are given in [Table 336.1](#). In general, amphotericin B is preferred as initial treatment of profoundly ill patients. Side effects include fever, chills, and hypotension during initiation of therapy; malaise; anemia; azotemia, renal tubular acidosis; hypokalemia; and hypomagnesemia. Lipid-associated formulations cause less nephrotoxicity but are very expensive. They are most appropriate for patients who are intolerant of therapy with standard amphotericin B. The azoles (ketoconazole, itraconazole, and fluconazole) are used as primary treatment of less acutely ill patients and as long-term therapy after a brief course of amphotericin B. All have oral formulations and have a potential for pharmacokinetic interaction with many other agents. The chief side effect is hepatotoxicity.

Chapter 302

INFECTIVE ENDOCARDITIS

DEFINITIONS AND PATHOGENESIS

Infective endocarditis (IE) is microbial invasion of the endocardium, usually involving valvular surfaces. Disruption of the endocardial surface exposes collagen and promotes adherence of platelets and fibrin. IE occurs when circulating microorganisms colonize the injured endocardial surface. Bacteria invade the blood through local barriers, such as skin and mucous membranes, or are directly inoculated into capillaries and venules, as in dental surgery.

EPIDEMIOLOGY AND MICROBIOLOGY

The epidemiologic pattern of IE is a function of the frequency of bloodstream invasion by pathogens and the prevalence of predisposing endocardial disease. The mean age of patients with IE has increased and is now about 55 years. Risk factors include valvular heart disease (including mitral valve prolapse), intravenous drug abuse (IVDA), and use of intravascular or intracardiac devices.

Streptococci are the most commonly reported cause of native valve endocarditis (NVE), *Streptococcus viridans* species predominating (about 35% of all cases). About 80% of patients have underlying cardiac disease and are infected when the bacteria, which are normal oral flora, gain access to the bloodstream. Enterococcal IE accounts for about 10% of all cases. About 40% of patients have no known underlying heart disease. Older men undergoing urologic procedures, women undergoing gynecologic procedures, and parenteral drug users are at particular risk. *Streptococcus bovis* IE is associated with bowel lesions, including colon cancer. Staphylococci cause 25% of cases of NVE; 90% are caused by *Staphylococcus aureus*. No prior valve abnormality is recognized in one-third of these patients. Aerobic gram-negative bacteria cause 5% to 10% of cases; risk factors include IVDA and the presence of prosthetic valves. For another 5% to 10% of patients with presumed IE, no etiologic microorganism is isolated from the blood, most commonly because of prior antibiotic use. Coagulase-negative staphylococci are the most common cause of prosthetic valve endocarditis (PVE).

CLINICAL FEATURES

History: There may be known underlying heart disease and a preceding bacteremic event such as dental work, IVDA, or instrumentation of the gastrointestinal or genitourinary tracts. Fever is present in more than 90% of cases. Most patients with subacute IE have nonspecific symptoms such as malaise, arthralgia, myalgia, and fatigue. Symptoms of congestive heart failure are present among about 50% of those with NVE. Emboli to the lungs or abdominal organs can cause chest or abdominal pain.

Physical examination: Most patients with left-sided valvular disease have murmurs at some point but may not initially. Classic peripheral signs include petechiae, Roth's spots (oval retinal hemorrhages), splenomegaly, clubbing, Osler's nodes (painful, purple to red nodules on the pads of the fingers or toes), linear splinter hemorrhages beneath the fingernails or toenails, and red, macular Janeway lesions on the palms or soles.

Special situations: IE associated with IVDA most commonly involves *S. aureus* infection of the tricuspid valve. Such patients typically have an acute onset of fever, pleuritic chest pain, dyspnea, and cough. A murmur of tricuspid regurgitation usually is heard. The initial chest radiograph is abnormal in most cases and may show nodular opacities, abscesses with cavitation, patchy pneumonitis, or pleural effusions. Gram-negative infections are frequent. Infection with *Pseudomonas aeruginosa* is associated with high mortality.

Prosthetic valve IE occurs among about 2% of patients after valve replacement, one-third of these cases occurring within 2 months of surgery. Infection by staphylococci (both *S. aureus* and coagulase-negative species) is the most common cause, but gram-negative bacilli and fungi are more common than in NVE. Patients come to medical attention in much the same manner as those with NVE, although a higher frequency of a new or changed murmur reflects a higher rate of local suppurative complications, such as valve ring abscess.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

The blood culture is the most important laboratory test. Bacteremia is typically low grade and constant. One of the first two sets yields the etiologic bacteria in 90% of cases. At least three sets should be obtained within the first 24 hours for patients with suspected IE. Nonspecific laboratory abnormalities include anemia and an elevated erythrocyte sedimentation rate. Leukocytosis is unusual in subacute IE but is more likely in acute IE caused by staphylococci, pneumococci, or gonococci. Hematuria, proteinuria, and detectable rheumatoid factor are present in about one-half of cases. Echocardiography is the most useful imaging study. Transthoracic echocardiography reveals vegetations in about 50% to 60% of patients. Transesophageal echocardiography is more accurate and has a sensitivity approaching 90%. Echocardiography is useful for defining the severity of valvular destruction, detecting complications such as abscess or aortic mycotic aneurysm, and assessing the hemodynamic effects of IE. The Duke criteria for IE are listed in [Table 270.2](#).

COMPLICATIONS

Cardiac: Valvular dysfunction, usually insufficiency, is the most important complication. Extension of a paravalvular abscess in the conduction system may cause varying degrees of atrioventricular block and bundle branch block. This is most common in aortic valve IE. Pericarditis is especially frequent with staphylococcal disease. Heart failure is the most common cause of death. Valvular dysfunction is the usual basis, but embolic myocardial infarction, myocarditis, and conduction disturbances can contribute.

Noncardiac: Emboli, which occur among about one-third of patients, may be bland (uninfected) or septic and are most common with *S. aureus* and fungal IE. In left-sided IE, the spleen, kidney, brain, and heart are most commonly affected. Mycotic aneurysms complicate 15% to 25% of cases; they occur most frequently in the central nervous system and abdominal aorta. The main risk is rupture with bleeding, sometimes months to years after the infection has resolved. Renal failure from immune-complex glomerulonephritis occurs among 10% of patients.

MANAGEMENT

Antibiotics: Therapy must include bactericidal drugs given parenterally for a prolonged time (2 to 6 weeks, depending on the clinical circumstances). Antimicrobial therapy should be started without delay in the following four situations: when the clinical diagnosis seems certain, although blood culture results are not yet available; when the diagnosis seems likely and the patient is seriously ill; when antimicrobial therapy for another condition is necessary; and when the patient may have IE, and blood culture results are positive. Empiric therapy must include agents likely to be effective against enterococci. Antistaphylococcal agents should be considered in the treatment of patients with PVE; those with a rapidly progressive illness that suggests acute IE; those with aortic valve involvement but without prior valvular abnormality; those with IVDA; those with a previously infected intravenous catheter; and those undergoing long-term hemodialysis. Once the infecting pathogen is identified, a more specific antibiotic regimen is administered.

Surgery: Indications include severe or refractory heart failure, valvular obstruction, fungal endocarditis, ineffective antimicrobial therapy, and instability of a prosthetic valve. Relative indications in NVE include nonstreptococcal IE, recurrent IE, intracardiac extension of infection, the presence of two or more emboli, and echocardiographic detection of vegetations or mitral valve preclosure. Relative indications in PVE include early infection, nonstreptococcal late PVE, and periprosthetic leak. Tricuspid valve IE is generally well tolerated hemodynamically; persistent infection with resistant bacteria or fungi is the most common surgical indication.

PROPHYLAXIS

Although the use of prophylactic antibiotics to prevent IE is recommended in certain situations, no randomized, controlled trials addressing this issue have been performed, and most cases of IE do not occur in association with an invasive procedure. The risk of bacteremia is highest for some dental and oral procedures, intermediate for urologic procedures, and lowest for most gastrointestinal procedures (with the exception of esophageal dilation and variceal sclerotherapy), including those that involve biopsy. According to the American Heart Association, high-risk cardiac conditions include the presence of prosthetic valves, prior IE, complex cyanotic congenital defects, and the presence of surgically constructed systemic-pulmonary shunts. Rheumatic heart disease and mitral valve prolapse with valvular regurgitation are classified as moderate risk. Antibiotic selection is directed against *S. viridans* for dental, oral, respiratory, and esophageal procedures (2 g amoxicillin before the procedure is the preferred antibiotic) and against enterococci for other gastrointestinal and urologic procedures (amoxicillin or ampicillin with or without gentamicin, depending on risk).

Chapter 270

EPSTEIN–BARR VIRUS INFECTION AND INFECTIOUS MONONUCLEOSIS

DEFINITION

Epstein–Barr virus (EBV) is a DNA human herpesvirus associated with infectious mononucleosis (IM) and a number of malignant diseases, such as Hodgkin's disease, Burkitt's lymphoma in Africa, and nasopharyngeal carcinoma in China. It is also the causative agent of hairy leukoplakia of the tongue among immunocompromised patients.

EPIDEMIOLOGY AND PATHOPHYSIOLOGY

EBV occurs worldwide and spreads from person to person by close contact and exchange of oral secretions. IM typically occurs in adolescence and the early third decade of life. The incubation period is 4 to 6 weeks. The virus infects lymphocytes and the oropharyngeal epithelium. Like other herpesviruses, EBV causes infections with three phases—primary, latent, and reactivated. Reactivation is associated with the malignant conditions.

CLINICAL FEATURES

Primary EBV infection causes about 90% of cases of IM. The onset is insidious, and acute pharyngitis often is the primary symptom. The classic findings are fever lasting up to 3 weeks or more, lymphadenopathy, splenomegaly, and florid atypical lymphocytosis, with malaise that may be slow to resolve. Coupled with a positive heterophil antibody reaction or Monospot test, these findings are sufficient for diagnosis in most cases. The diagnosis is made definite by the finding of EBV antibodies. Complications include acute hepatitis that usually is mild and transient, neurologic syndromes such as encephalitis, neuritis, transverse myelitis, and Guillain–Barré syndrome, and hematologic abnormalities such as agranulocytosis, aplastic anemia, and thrombocytopenia. These usually resolve without therapy. A rare complication is splenic rupture. Acute IM sometimes seems to lapse into a chronic phase that lasts as long as a year or more and is marked by persistent fatigue, low-grade fevers, malaise, and a labile emotional state. IM caused by cytomegalovirus mimics that caused by EBV, although sore throat and atypical lymphocytosis may not be as prominent.

LABORATORY FINDINGS

For IM, the diagnosis is confirmed by finding antibodies to EBV viral capsid antigen (VCA) (both IgG and IgM in primary infection) and, ideally, EBV early antigen (EA-D) but not EBV nuclear antigen (EBNA) antibodies. Antibodies to EA-D are transient and indicate recent or reactivated infection, whereas antibodies to EBNA often cannot be detected in primary infection, and appear only months later. The characteristic pattern of past infection would be a moderate titer of IgG VCA antibodies and a low titer of EBNA antibodies, both persistent for life.

PROGNOSIS AND MANAGEMENT

Most cases are mild and resolve within 2 to 3 weeks. Treatment is supportive. Controlled trials of acyclovir for IM have disclosed marginal benefit, in part because many of the symptoms are caused by secondary immunopathologic processes unaffected by antiviral therapy. There is also no evidence that so-called chronic mononucleosis responds to antiviral drugs.

Chapter 314

APPROACH TO THE PATIENT WITH FEVER OF UNKNOWN ORIGIN

DEFINITION

Fever is a complex physiologic process characterized clinically by a body temperature higher than 37.7°C (100°F). The temperatures of the rectum, mouth, and tympanic membrane all can be used to estimate core temperature. On average, rectal readings exceed oral readings by 0.4°C (0.7°F) and exceed tympanic membrane readings by 0.8°C (1.4°F).

PATHOPHYSIOLOGY AND CLINICAL MANIFESTATIONS

Fever is a process in which the thermoregulatory set point is altered by the action of various cytokines on the anterior hypothalamus. Hyperthermia, in contrast, is an increase in body temperature not mediated by such cytokines. Hyperthermia is not regulated, is not defended by physiologic mechanisms, and does not respond to standard antipyretic agents. Disorders associated with hyperthermia include malignant hyperthermia, neuroleptic malignant syndrome, pheochromocytoma, and thyrotoxicosis, all of which increase heat production, and dehydration and heatstroke, which decrease heat loss. Experiments with animals have shown that fever enhances survival during some infections. However, when fever is extreme, the beneficial effect is reversed, and febrile convulsions can occur.

DIFFERENTIAL DIAGNOSIS

Most fevers either resolve spontaneously or are diagnosed quickly, usually in association with an infection. Fevers that persist for 2 to 3 weeks and defy intensive diagnostic scrutiny (fevers of unknown origin) occur more often with common diseases that have unusual manifestations than they do with exotic disorders. The three most common causes of the syndrome are infection, malignant neoplasia, and connective tissue disorders ([Table 266.4](#)). Familial Mediterranean fever is a hereditary disorder characterized by recurrent episodes of unexplained fever, frequently accompanied by peritonitis, pleuritis, or monarticular arthritis. Long-term colchicine

therapy reportedly decreases the incidence of attacks and complications. Many medications have been reported to cause drug fever. Quinidine, α -methyldopa, and penicillins have been implicated most frequently. The various medications differ in the average duration of therapy that precedes the fever. For antibiotics, the median time lag between initiation of therapy and the onset of drug fever is 6 days. The fever generally abates within 48 to 72 hours of discontinuation of the offending agent.

HISTORY AND PHYSICAL EXAMINATION

A detailed history and careful examination are crucial. Important historical features include occupation, recent travel, exposure to a pet, and food consumption. When performing the physical examination, one should not overlook the fundoscopic examination, the less prominent chains of lymph nodes, and the prostate, epididymis, and testicles.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

Initial studies should include a complete blood cell count, urinalysis, biochemical tests, serologic tests for fungal infection and connective tissue disorders, examination of the stool for occult blood, and bacterial cultures of urine, sputum, and blood. Chest radiography, electrocardiography, lumbar puncture, tuberculin skin test, and thyroid function tests also are performed. Abnormalities detected with one of these studies should be pursued with more specific investigations. If the initial studies are not revealing, more specialized studies are ordered, such as computed tomography of the brain, chest, and abdomen, oral cholecystography, gallium scintigraphy, intravenous pyelography, and gastrointestinal endoscopy. Biopsies of the liver, bone marrow, and skin may follow.

MANAGEMENT

Antipyretic therapy: In most clinical settings, antipyretics alone are sufficient to reduce fever. Studies comparing the efficacy of acetaminophen and aspirin have not found substantial differences. The two are equally effective in relieving the malaise, headache, and myalgia that often accompany fever. Salicylates should be avoided by those with peptic ulcer disease and bleeding disorders, and acetaminophen by patients with underlying liver disease. During extreme pyrexia, physical methods such as sponging and application of cooling blankets are combined with use of antipyretic agents to lower temperature. In hyperthermia, such measures may be the only effective antipyretic therapy.

Specific therapy: If an etiologic factor is identified, therapy for that disorder is initiated. If all of the diagnostic studies listed earlier fail to yield a diagnosis, the physician has three options, as follows: (a) repeat the entire evaluation in the hope that abnormalities may have developed in a previously normal test result; (b) direct a therapeutic trial against a probable but unproven diagnosis such as occult tuberculosis; (c) observe the patient for new signs or symptoms that merit further investigation and plan for a systematic reevaluation in 6 to 8 weeks.

[Chapter 266](#)

GONOCOCCAL INFECTIONS

DEFINITION AND EPIDEMIOLOGY

Infection with the gram-negative diplococcal bacteria *Neisseria gonorrhoeae*, is transmitted by means of sexual contact. In the United States, the incidence of infection is highest among adolescents and young adults, particularly the urban poor and minority ethnic groups. Coexistent chlamydial infection is common. The most common infection among men is urethritis. Among women, endocervicitis is most common, but the complication of pelvic inflammatory disease (PID) is most important. Because most infected women have no symptoms, uncontrolled endocervical infection is an important bacterial reservoir. A man's likelihood of infection after a single exposure to an infected woman is about 25%. The incubation period is 3 to 4 days.

CLINICAL FEATURES

Infection among women: Urethritis may cause dysuria and a urethral discharge. Symptoms of endocervical infection are recognized by only about 25% of women. Patients typically have an unusual or purulent vaginal discharge and may have irregular or abnormal menstrual periods. For about 20% of women with endocervical gonorrhea, the infection spreads to involve the endometrium, fallopian tubes, and peritoneum, causing PID. The symptoms and signs of PID include fever, pelvic pain, adnexal masses, and pain with cervical motion. Perihepatitis (Fitz-Hugh and Curtis syndrome) often manifests as right upper quadrant pain and elevated liver enzyme levels and may occur after retrograde spread of infection.

Infections among men: Between 60% and 95% of men with urethritis have symptoms, typically urethral discharge and dysuria. *N. gonorrhoeae*, along with *Chlamydia trachomatis*, is also a common cause of epididymitis among men younger than 35 years.

Infections among women and men: Conjunctivitis can occur among adults whose fingers are contaminated with infected genital secretions. Pharyngeal infection is acquired through oral-genital sex; transmission by means of kissing or through oral secretions is rare. Isolation of the organism from the anal canal is common among women who have endocervical infection. Anorectal infection among men occurs in those who engage in receptive anal intercourse with an infected partner. Symptoms (most often absent) include pruritus, tenesmus, purulent discharge, and bloody diarrhea. Disseminated gonococcal infection (DGI) occurs in less than 1% of genital infections, usually among menstruating women. The symptoms variably include fever, skin rash, joint or tendon pain, and migratory polyarthritides. Gonococcal infection is the most common cause of septic arthritis among young adults.

LABORATORY FINDINGS

Among men with symptomatic urethritis, the diagnosis can be made when a Gram stain of the urethral discharge reveals gram-negative diplococci within neutrophils. The sensitivity is more than 90%, and the specificity is 98% to 99%. Therefore, cultures are not indicated if the stain result is positive. The diagnosis of gonococcal infection among women and at all anatomic sites in men except the urethra is best made by means of culture. In DGI, blood culture results are positive in only 25% of cases and joint fluid cultures in only 10%. A presumptive diagnosis can be made when a young adult with typical clinical findings has *N. gonorrhoeae* isolated from a mucosal surface and responds rapidly to antibiotic therapy directed at the gonococci. An enzyme immunoassay can be performed to diagnose genital infection for men and women. However, it offers no advantage over Gram stain for men and is less sensitive and specific than culture for women.

PROGNOSIS AND MANAGEMENT

Effective antibiotic therapy eradicates gonococcal infection. Resolution of symptoms indicates cure; follow-up cultures are unnecessary. Controlled gonococcal arthritis usually has no sequelae, but gonococcal salpingitis may lead to infertility, ectopic pregnancy, or recurrent PID. Guidelines for management of gonococcal infection reflect the emergence of antibiotic resistance, the frequency of coexisting chlamydial infections, and the potentially serious complications.

Uncomplicated infection: Options for infection of the urethra, cervix, and rectum include cefixime (400 mg by mouth in a single dose), ceftriaxone (125 mg intramuscularly [IM] in a single dose), ciprofloxacin (500 mg by mouth in a single dose), or ofloxacin (400 mg by mouth in a single dose). Patients also receive a regimen effective against possible coinfection with *C. trachomatis*, such as azithromycin (1 g by mouth in a single dose) or doxycycline (100 mg by mouth twice a day for 7 days).

Complicated infection: Therapy for PID includes agents active against *N. gonorrhoeae*, *C. trachomatis*, gram-negative facultative bacteria, streptococci, and anaerobic bacteria. One approach includes either cefotetan (2 g intravenously [IV] every 12 hours) or cefoxitin (2 g IV every 6 hours) plus doxycycline (100 mg IV or by mouth every 12 hours) until 24 hours after the patient improves clinically followed by doxycycline (same dose) to complete 14 days of therapy. An alternative is clindamycin (900 mg IV every 8 hours) plus gentamicin (2 mg per kilogram IV or IM followed by 1.5 mg per kilogram every 8 hours) until clinical improvement occurs, at which time therapy is changed to clindamycin (450 mg by mouth four times a day) or doxycycline (100 mg by mouth twice a day) to complete a total of 14 days of therapy. Patients with DGI should receive ceftriaxone (1 g IM or IV every 24 hours) or cefotaxime (1 g IV every 8 hours) for 1 week. For persons allergic to β -lactam drugs, alternatives include ciprofloxacin (500 mg IV every 12 hours) or ofloxacin (400 mg IV every 12 hours). Reliable patients with uncomplicated cases can be discharged 24 to 48 hours after improvement and may complete therapy with an oral regimen of cefixime (400 mg twice a day), ciprofloxacin (500 mg twice a day), or

ofloxacin (400 mg twice a day).

Chapter 280

HIV INFECTION AND AIDS

DEFINITION AND EPIDEMIOLOGY

Acquired immunodeficiency syndrome (AIDS) is a condition of decreased cellular immunity caused by the human immunodeficiency virus (HIV). An estimated 40 million persons worldwide have the infection. HIV is chiefly transmitted through sexual contact, although it also can be transmitted through blood exposure. Increased transmission has been associated with the presence of genital ulcers or other sexually transmitted diseases. The mean time from infection to clinical expression of AIDS is 8 to 10 years. Persons at high risk include homosexual and bisexual men, users of injected drugs, persons with hemophilia, recipients of blood products, and the sexual partners of these persons. The probability of transmission from an infected pregnant woman to her infant is about 25%.

PATHOPHYSIOLOGY

HIV is a retrovirus composed of single-stranded RNA surrounded by a protein envelope. It primarily infects cells with a CD4 + cell-membrane glycoprotein. Once the virus enters cells, uncoating occurs, and a reverse transcriptase enzyme transcribes viral RNA into double-stranded DNA, which is then inserted into the host genome. When the cell is activated by antigenic or viral stimulation, DNA transcription occurs, and new viral particles are assembled at the cell surface. The infected cell then dies. After the initial infection of monocytes, macrophages, and dendritic cells, the virus disseminates to the germinal center of lymph nodes.

CLINICAL DEFINITION OF HIV INFECTION

Depending on the stage, HIV infection can be asymptomatic or cause severe opportunistic infections or cancer. A revised Centers for Disease Control and Prevention (CDC) classification identifies three clinical categories.

Category A: Patients have asymptomatic HIV infection, persistent generalized lymphadenopathy, or acute (primary) HIV illness.

Category B: Patients have symptoms but do not have the conditions in categories A or C. Associated conditions include bacillary angiomatosis, vulvovaginal or oropharyngeal candidiasis, cervical dysplasia or carcinoma in situ, unexplained fever, and diarrhea lasting longer than 1 month.

Category C: Patients have symptoms and a combination of any of the following: candidiasis (esophageal, tracheal, bronchial); extrapulmonary coccidioidomycosis; extrapulmonary cryptococcosis; invasive cervical cancer; chronic intestinal cryptosporidiosis; cytomegalovirus (CMV) retinitis or CMV infection in organs other than liver, spleen, or nodes; HIV encephalopathy; herpes simplex with chronic mucocutaneous ulcer, bronchitis, or pneumonia; disseminated histoplasmosis; chronic isosporiasis; Kaposi's sarcoma; Burkitt's lymphoma; extrapulmonary *Mycobacterium avium* or *Mycobacterium kansasii* infection; pulmonary or extrapulmonary *Mycobacterium tuberculosis* infection; *Pneumocystis carini* pneumonia (PCP); recurrent pneumonia; progressive multifocal leukoencephalopathy (PML); recurrent *Salmonella* bacteremia; cerebral toxoplasmosis; or HIV wasting syndrome.

CD4 + cell count Because progression of HIV infection yields a decline in CD4 + cell population that predisposes patients to infection, the CDC classification scheme includes CD4 + cell count as a marker of disease progression, as follows: category 1, 500 or more cells per microliter; category 2, 200 to 499 cells per microliter; and category 3, fewer than 200 cells per microliter. Categories A3, B3, and C are AIDS. No CDC definitions currently include HIV RNA levels.

CLINICAL PRESENTATION

There is a typical relation between clinical manifestations of HIV infection and CD4 + cell count ([Fig. 341.1](#)).

Acute HIV infection: Approximately 20% of patients have acute seroconversion syndrome, typically a mononucleosis-like illness of sudden onset. Fever, lethargy, headaches, lymphadenopathy, sore throat, and macular rash are the most common symptoms and signs.

Fever: The most common symptom among persons with HIV infection is fever. Common etiologic factors include PCP, *M. avium-intracellulare* (MAC) infection, bacterial pneumonia, sinusitis, lymphoma, catheter infection, drug allergy, and occasionally CMV infection.

Lymphadenopathy: Diffuse lymphadenopathy involving the axillary, inguinal, and cervical areas is common. Generalized lymphadenopathy can occur with acute HIV infection, mycobacterial or fungal infection, lymphoma, Kaposi's sarcoma, syphilis, toxoplasmosis, and infection with Epstein–Barr virus (EBV) or CMV.

Cutaneous manifestations: The most commonly reported maculopapular rashes include molluscum contagiosum, secondary syphilis, cryptococcosis, histoplasmosis, candidiasis, atypical mycobacteria, and warts. The most common causes of nodular lesions include bacillary angiomatosis, MAC infection, and Kaposi's sarcoma. Vesicopustular lesions are typical of herpes simplex and varicella-zoster infection. The most common noninfectious skin disorder is seborrheic dermatitis.

Nervous system manifestations: AIDS dementia complex is diagnosed among one-third of adult patients. Other causes of declining mental activity include depression and the early stages of PML. Cognitive impairment with altered consciousness most commonly is caused by advanced AIDS dementia complex, cryptococcal meningitis, *Toxoplasma* encephalitis, CMV encephalitis, tuberculous meningitis, and herpes simplex encephalitis. Drugs, hypoxemia, and metabolic abnormalities also can depress consciousness. Focal neurologic signs developing over several days suggest *Toxoplasma* encephalitis, primary CNS lymphoma, tuberculosis, or cryptococcoma. PML is caused by a papovavirus (the JC virus), manifests slowly among patients with AIDS and CD4 + counts of 100 or more cells per microliter, and causes altered mentation with or without limb weakness, visual defects, or seizures.

Visual loss: Acute loss of vision is most commonly caused by CMV papillitis, varicella-zoster virus retinitis, secondary syphilis, cryptococcal meningitis, and bacterial or fungal endophthalmitis.

Gastrointestinal signs and symptoms: The most common cause of oral and pharyngeal lesions is candidiasis (thrush). Oral ulcers may be caused by herpes simplex virus or CMV. Oral hairy leukoplakia is a painless Epstein–Barr infection of the epithelium of the tongue. The most common cause of dysphagia and odynophagia is candidiasis. CMV esophagitis usually manifests as odynophagia with little dysphagia. Chronic watery diarrhea and enteritis are common with infection by *Cryptosporidium*, *Cyclospora*, *Giardia*, *Isospora belli*, *Microsporida*, and MAC organisms. Weight loss is a common manifestation of AIDS.

Respiratory tract signs and symptoms: Bacterial sinusitis is common. The causes of cough and fever vary in different settings. If the CD4 + count is 200 or more cells per microliter and the chest radiograph is clear, acute sinusitis and bronchitis are likely. If the CD4 + count is less than 200 cells per microliter and the chest radiograph is clear, one must also consider PCP, tuberculosis, cryptococcosis, and MAC infection. If infiltrates are found on the chest radiograph, the differential diagnosis expands to include infection with the bacteria associated with community-acquired pneumonia. The most common cause of dyspnea is PCP, although bacterial pneumonia and infection with fungi and mycobacteria also can cause this symptom. Noninfectious causes include pulmonary lymphoma, Kaposi's sarcoma of the lung, primary pulmonary hypertension, and cardiomyopathy.

Musculoskeletal signs and symptoms: Although of low incidence, septic arthritis is the most common infection of the musculoskeletal system. *Staphylococcus aureus* is the most commonly isolated organism. Reiter's syndrome is more prevalent among patients with HIV infection. Other musculoskeletal infections include osteomyelitis, pyomyositis, and septic bursitis.

LABORATORY ABNORMALITIES

Results of routine laboratory tests often are abnormal among patients with HIV infection ([Table 346.4](#)). The CD4 + lymphocyte count reflects the degree of immunocompromise and is predictive of susceptibility to particular infections ([Fig. 341.1](#)). The level of plasma HIV RNA correlates to total viral burden and is the best

prognostic indicator of HIV infection. Higher levels, especially those greater than 30,000 to 55,000 copies per milliliter, are associated with more rapid disease progression, more rapid CD4 + lymphocyte depletion, and higher risk for AIDS or death.

MANAGEMENT

Anti-retroviral medications: Currently available agents can be divided into two categories: inhibitors of HIV protease (such as saquinavir, zidovudine, didanosine, zalcitabine, stavudine, lamivudine, and abacavir), or non-nucleoside (such as nevirapine, delavirdine, and efavirenz).

Initial therapy: Anti-retroviral therapy should be initiated for any patient with symptoms, regardless of CD4 + lymphocyte count and plasma HIV RNA level, and for those with either a CD4 + lymphocyte count less than 500 cells per microliter or a plasma HIV RNA level greater than 5,000 copies per milliliter. Current guidelines suggest only two initial approaches to anti-retroviral therapy—two nucleosides with a protease inhibitor (or the zidovudine–zalcitabine combination) or two nucleosides with efavirenz (preferred) or nevirapine or delavirdine (alternatives). Other regimens may be selected, however, on the basis of factors such as medication side effects and patient compliance. Within 3 to 6 weeks of the initiation of effective therapy, a three- to tenfold decrease in the HIV RNA level should occur. The assay is repeated on a regular basis to confirm continued efficacy. The most durable responses occur among persons in whom the viral load has declined to less than the limit of detection (fewer than 400 to 500 copies per milliliter in standard testing and fewer than 50 copies per milliliter in highly sensitive assays).

Changing Therapy: If the toxicity of a particular drug is intolerable, that drug can be replaced with an alternative without changing the other components of the regimen. If treatment fails, however, a single drug should never be switched or added. Instead, the entire treatment history should be investigated, and an effort should be made to avoid new drugs with potential for cross resistance. It is not clear how helpful some resistance tests may be. Because information about optimal combinations and sequences is rapidly changing, patients who do not have good results with an initial regimen should be treated by practitioners highly experienced in the care of patients with HIV infection.

APPROACH TO INFECTION IN THE IMMUNOCOMPROMISED HOST

SPECIFIC IMMUNOLOGICAL DEFICITS

Immunocompromised patients pose special challenges because of the wide spectrum of infections encountered, the difficulties in establishing a diagnosis, and the limited efficacy of therapeutic regimens. Management strategies differ with the underlying immunologic deficit. Among patients with severe neutropenia and among those with asplenia, the risk of fulminant infection is so great that empiric antibiotic therapy must be administered promptly. In contrast, among patients with impaired cellular immunity (lymphoma, AIDS), the spectrum of potential pathogens is so great that establishing a specific diagnosis is of paramount importance. [Table 267.1](#) lists many of the important kinds of immunocompromise, examples of diseases associated with them, and the infections frequently associated with them. Although neutropenia is defined as an absolute neutrophil count (ANC) less than 1,000 per microliter, most severe infections occur when the ANC is less than 100 per microliter.

MANAGEMENT OF FEVER IN AN IMMUNOCOMPROMISED HOST

Neutropenia: Fever (101°F or higher) in a neutropenic patient should be considered indicative of infection unless there is another, obvious cause. Patients with neutropenia cannot mount an adequate inflammatory response and can have extensive infection without characteristic symptoms and signs. The physician should obtain appropriate culture specimens and perform a careful examination. If the patient is acutely ill or has signs of infection when the fever is first detected, broad-spectrum antibiotic therapy should be initiated immediately. Otherwise, antibiotic therapy can be delayed until the fever has persisted for at least 2 hours. Current antibiotic regimens of choice include combinations of broad-spectrum b-lactams plus aminoglycosides (with or without vancomycin for the possibility of resistant gram-positive infection) and certain broad-spectrum agents, such as cefepime, imipenem, meropenem, used alone. Alternatives to aminoglycosides include quinolones and trimethoprim–sulfamethoxazole.

If the patient responds to initial therapy and never has signs of local infection, oral therapy can be substituted and the patient discharged. As long as the patient continues to have neutropenia, therapy should be continued for 1 week or for 4 days after the patient becomes afebrile, whichever is longer. If the patient has signs of localized infection, the duration of therapy depends on the clinical response. If patients remain febrile despite therapy with broad-spectrum antibiotics, one must consider drug or transfusion fever, tumor fever, and infection caused by antibiotic-resistant bacteria, viruses, mycobacteria, protozoa, or fungi. Of these, the most common is fungal infection. Because culture specimens often do not provide enough information to confirm a diagnosis, a therapeutic trial of antifungal therapy is appropriate.

Other causes of immunosuppression: Infection among patients with impaired lymphocyte and monocyte function is diverse in causation and usually is indolent. For these reasons, empiric therapy should be deferred in favor of vigorous attempts at diagnosis. Careful history taking is critical, and special attention should be given to possible exposures. Biopsy of infected tissue is the most rapid and reliable diagnostic procedure, although special stains and culture procedures may be needed. Serologic profiles and skin tests may be necessary. Lists of site-specific infections are helpful. [Table 267.4](#) lists some causes of pneumonitis among persons with compromised immune systems.

[Chapter 267](#)

INFLUENZA

DEFINITION AND EPIDEMIOLOGY

Influenza viruses are pleomorphic members of the Orthomyxoviridae. Of the three types, only influenza A and B are important causes of morbidity and mortality. Epidemics occur annually in temperate climates during the cold weather months. Minor antigenic changes in the hemagglutinin or neuraminidase lead to decreased reactivity with antibody acquired from previous infection. Influenza is spread through contact with virus-containing respiratory secretions. The incubation period ranges from 1 to 5 days. School-aged children usually are affected disproportionately at the start of an epidemic.

CLINICAL FEATURES

Illness is typically characterized by systemic symptoms such as fever, headache, myalgia, and malaise in association with respiratory symptoms that include sore throat and dry cough. However, 30% of persons with the infection have upper respiratory symptoms without fever and another 20% have no symptoms. With febrile influenza, the systemic symptoms often are more prominent at the onset of illness and subside as the respiratory symptoms worsen. Fever and systemic symptoms usually last 3 to 5 days; the cough may last several weeks. The two principal pulmonary complications are primary viral pneumonia and secondary bacterial pneumonia. Exacerbations of asthma also occur. Nonpulmonary complications include myositis, myocarditis, pericarditis, and neurologic diseases such as transverse myelitis and Guillain–Barré syndrome. Reye syndrome is a severe complication among children.

LABORATORY STUDIES AND DIAGNOSIS TESTS

A presumptive diagnosis can be made for patients with typical clinical features of febrile influenza when influenza is documented to be in the community. The diagnosis is confirmed by means of detection of the virus in respiratory secretions or a serologic response to the virus. Rapid virus detection tests have good specificity (more than 90%) but low sensitivity (less than 60% among adults).

MANAGEMENT

Antipyretics and analgesics are used for symptom relief, although salicylates should be avoided in the treatment of children because of an association with Reye syndrome. For influenza A infections only, amantadine and rimantadine are effective in reducing the duration of symptoms and viral shedding when administered

within 48 hours after the onset of illness. Rimantadine has fewer side effects, such as insomnia, light-headedness, and irritability.

PREVENTION

Inactivated influenza vaccines have been shown to prevent hospitalization and death in high-risk populations. Vaccines should be offered to persons older than 65 years, those with chronic medical illnesses or cardiopulmonary disease, and residents of chronic care facilities and persons who can transmit the virus to them, such as health care workers and household members. Administration of the vaccine to members of the general population who are not at high risk also is acceptable. The composition of the vaccine changes from year to year to reflect the antigenic changes seen in circulating influenza A and B viral isolates. Persons with egg allergies should not be given the vaccine. Amantadine and rimantadine are approved for the prophylaxis of influenza A virus infection and should be considered in the care of persons at high risk who are vaccinated after influenza A virus activity has begun (for up to 2 weeks after vaccination), those with immunodeficiency, and persons for whom the vaccine is contraindicated.

[Chapter 310](#)

MALARIA

DEFINITION, EPIDEMIOLOGY, AND PATHOPHYSIOLOGY

Malaria is the sequela of infection with one of four species of plasmodia: *Plasmodium falciparum*, *P. vivax*, *P. ovale*, and *P. malariae*. Malaria is endemic in most of the developing tropical world. Transmission depends on the bite of an infected *Anopheles* mosquito, which introduces sporozoites into the human circulation. Within hepatocytes, the parasite matures to a merozoite stage. The merozoites invade red blood cells (RBCs) and mature further through a series of erythrocytic stages. After 48 to 72 hours, the host RBC is lysed, freeing merozoites that can then invade additional RBCs and perpetuate the cycle. *P. vivax* and *P. ovale* have persistent liver stages that may remain dormant in the liver for 6 to 12 months or more.

P. falciparum malaria is the most serious infection, partly because this species, unlike the others, can invade RBCs of any age and can therefore cause greater degrees of parasitemia. In addition, RBCs containing mature *P. falciparum* parasites adhere to the microvascular endothelium and can cause ischemia, hypoglycemia, and acidosis in affected tissues. Pulmonary edema may be caused by capillary leak syndrome.

CLINICAL FEATURES

The cardinal clinical features of malaria are recurring fevers and chills (associated with lysis of RBCs) in the absence of localizing signs. The periodicity of the fevers is typically 48 hours with *P. vivax* or *P. ovale* and 72 hours with *P. malariae*. In contrast, irregular fevers occur with *P. falciparum* infection. In severe *P. falciparum* infection, acute complications include coma, pulmonary edema, acute renal failure, thrombocytopenia, and gastroenteritis. Chronic infection may produce splenomegaly.

DIAGNOSIS

Malaria is diagnosed by means of identification of parasites on a Giemsa-stained blood film. Experienced observers can determine both the degree of the parasitemia and the infecting species of plasmodium. Antigen detection and DNA probes can be useful but are not used routinely.

MANAGEMENT

The Centers for Disease Control and Prevention (CDC) maintains a 24-hour telephone line to help physicians in the treatment of patients with severe and complicated malaria: (888) 232-3228. Similar information is available on the Internet at the CDC site: <http://www.cdc.gov>. Infection of a nonimmune patient with *P. falciparum* is considered a medical emergency and generally requires hospitalization. Chloroquine should be used if the patient has come from an area where there is no evidence of chloroquine resistance. [Table 322.2](#) lists alternatives available in the United States for the treatment of patients who may have been exposed to chloroquine-resistant species.

PREVENTION

Although efforts are underway, no safe and effective malaria vaccine exists. Chemoprophylaxis is the most important preventive measure. Chloroquine (500 mg weekly beginning 1 week before exposure and continuing until 4 weeks after exposure) is the agent of choice for persons traveling to areas without chloroquine resistance. Alternatives for travel to areas with documented resistance to chloroquine include mefloquine (250 mg weekly during exposure and for 4 weeks after exposure) and doxycycline (100 mg per day beginning 1 day before exposure and continuing until 4 weeks after exposure). It also is important to reduce vector exposure as much as possible with mosquito netting and mosquito repellents (DEET). A 2-week course of primaquine (15-mg per day) given after the traveler leaves the malaria-endemic area effectively prevents late relapse caused by the hepatic stages of *P. vivax* or *P. ovale*.

[Chapter 322](#)

OSTEOMYELITIS

DEFINITIONS

Osteomyelitis is defined as inflammation involving the bone marrow, the surrounding cortical bone, and the periosteum. *Acute osteomyelitis* is defined as the first clinical episode, complete with the signs, symptoms, and diagnostic confirmation of bone infection. *Chronic osteomyelitis* is the diagnostic term for bone infections not controlled with one or more treatment attempts.

PATHOPHYSIOLOGY

Pathogens gain access to bone in three ways—hematogenous dissemination, direct inoculation, or extension from contiguous sites. Bone infection among children and intravenous drug users usually is hematogenous. In contrast, direct inoculation at the site of fracture or injury is common among adults. Osteomyelitis extending from contiguous infected sites often occurs among patients with diabetes who have foot infections or among patients with decubitus ulcers. Regardless of the route of entry, the initial bone infection causes inflammation, vascular compromise, local hypoxia, and eventually the death of bone tissue. Infection may result in formation of avascular tissue, or bone sequestrum, which forms a nidus for persistent infection.

ETIOLOGY

Staphylococcus aureus is the most common pathogen among adults, accounting for 50% to 70% of cases. The number of infections with gram-negative bacilli, either as a single infectious agent or as a part of a polymicrobial infection, has increased recently. These organisms have been cultured in as many as 50% of infections in some studies. These bacteria are more likely to cause osteomyelitis among patients with open fractures and prolonged hospitalization, patients who have undergone multiple hospital procedures, and those who have an extended stay in intensive care units. Infection with *Staphylococcus epidermidis* is common after implantation of an orthopedic prosthesis and in poststernotomy osteomyelitis. The presence of anaerobic bacteria should be considered when infection follows a human bite or is contiguous to a dental, intraabdominal, foot, or ear-nose-throat infection. Polymicrobial aerobic and anaerobic infections are common among patients with diabetes and those with decubitus ulcers.

CLINICAL FEATURES

Adults often have localized pain unresponsive to nonsteroidal anti-inflammatory drugs, heat, or rest. Swelling or redness may be present. Patients with vertebral osteomyelitis may have back pain; however, patients with infections of the larger cortical bones or patients with peripheral neuropathy might not have pain. The extremity should be examined for signs of venous stasis, acrocyanosis, edema, draining sinus tracts, erythema, induration, tenderness, and impaired range of motion

or sensory perception. The history should include questions regarding previous illnesses and any conditions that might have contributed to local or systemic host immune deficiencies.

DIAGNOSIS

Diagnosis involves a combination of clinical suspicion, appropriate laboratory tests, and radiographic and radionuclide scanning studies. It should be confirmed by means of histologic examination and microbiologic culture of bone specimens obtained at surgery or percutaneous needle biopsy.

Laboratory tests: The white blood cell count usually is elevated only in the early stages of infection. The erythrocyte sedimentation rate often is elevated.

Radiographs: In the early stages of osteomyelitis, specific signs on conventional radiographs may be absent for as long as 2 weeks. Within 4 weeks, one or more of the following changes should be evident: periosteal elevation, lytic bone destruction, sclerosis, or the presence of sequestrum or an overlying soft-tissue mass. Computed tomography and magnetic resonance imaging (MRI) are useful adjuncts in evaluations of selected patients, particularly in the early stages, when conventional radiographs are normal. MRI has excellent specificity, especially in differentiation of bone tumor and infarction from osteomyelitis. It is the modality of choice for diagnosing and staging spinal infection and for staging the extent of infection in long cortical bones before definitive open debridement. Bone scanning with technetium Tc99m has excellent sensitivity for the diagnosis of osteomyelitis, especially within the first 2 weeks, but the specificity is relatively low. False-positive results occur among patients with tumors or infarction or patients with bone injury involving the periosteum.

Culture results: Blood cultures may be positive in the acute phase of the disease, but is rare among adults. Swab cultures of sinus tracts usually are not accurate. Therefore, microbiologic diagnosis almost always depends on aerobic and anaerobic culture of a bone biopsy specimen.

MANAGEMENT

Therapy for acute or chronic osteomyelitis requires prolonged antibiotic therapy (4 to 6 weeks) and complete surgical debridement of necrotic bone and soft tissue where there is evidence of residual sequestrum or foreign material. Parenteral administration is generally recommended, although quinolones have been effective given orally. Broader-spectrum agents frequently are necessary for chronic osteomyelitis because polymicrobial infection is more common in such cases. The most effective strategy is the institution of appropriate antimicrobial therapy based on culture and sensitivity results after complete surgical debridement. For *S. aureus*, therapy may include a β -lactamase-resistant penicillin such as nafcillin, a first-generation cephalosporin such as cefazolin, or a fluoroquinolone. Infection with *S. epidermidis* or methicillin-resistant strains of *S. aureus* necessitates use of vancomycin. Enterococcal infections can be managed with ampicillin plus gentamicin. Pseudomonal infections respond best to a combination of an aminoglycoside and a third-generation cephalosporin (such as ceftazidime), ciprofloxacin, or semisynthetic penicillin (such as piperacillin). Other gram-negative organisms can be controlled with ciprofloxacin or the combination of ticarcillin and clavulanic acid. The presence of anaerobic organisms may necessitate therapy with clindamycin or metronidazole.

Chapter 265

STREPTOCOCCAL PHARYNGITIS AND RHEUMATIC FEVER

DEFINITION, INCIDENCE, AND EPIDEMIOLOGY

Pharyngitis is the most common clinical manifestation of group A streptococcal infection. Most cases of pharyngitis, however, are caused by respiratory viruses. Most cases of streptococcal pharyngitis occur during winter and spring. Transmission occurs through large respiratory droplets from infected persons; thus the infection is common in crowded settings such as child care centers, schools, and military barracks.

CLINICAL FINDINGS

Characteristic symptoms include the acute onset of fever and sore throat. Headache, abdominal pain, vomiting, and malaise also can occur, especially among children. Physical examination typically reveals pharyngeal erythema and edema. Tonsils are enlarged and may have a grayish-white exudate. Tender anterior cervical lymphadenopathy frequently is present. Signs of upper respiratory infection such as rhinorrhea, cough, and hoarseness suggest a nonstreptococcal cause.

COMPLICATIONS

Suppurative complications: These include direct extension of infection and resultant peritonsillar or retropharyngeal abscess, sinusitis, otitis media, mastoiditis, or cervical lymphadenitis. Bacteremic spread may produce metastatic foci of infection.

Nonsuppurative sequelae: These include acute rheumatic fever and acute glomerulonephritis, although the later more often follows cutaneous streptococcal infection. In acute rheumatic fever, which usually occurs 2 to 3 weeks after the pharyngitis, antibodies to streptococcal M protein epitopes may cross react with myocardial proteins, antigens in the basal ganglia, and antigens in articular cartilage. Major manifestations include carditis, which may lead to mitral and aortic valve stenosis; arthritis, particularly of the ankles, knees, wrists, and elbows; chorea; subcutaneous nodules; and erythema marginatum, which is a serpiginous, erythematous rash on the torso or extremities. Minor manifestations include fever, arthralgia, first-degree heart block, and elevated levels of acute-phase reactants. That there has been preceding group A streptococcal infection can be ascertained with serologic tests and less commonly with culture.

DIAGNOSTIC EVALUATION

The accurate diagnosis of group A streptococcal pharyngitis cannot be made with consistency through clinical findings alone. Throat swab culture remains the standard for diagnosis. Rapid antigen detection tests offer excellent specificity but low sensitivity. For this reason, negative results of such tests should always be followed by a throat culture.

MANAGEMENT

Treatment reduces spread, prevents suppurative and nonsuppurative complications, and may shorten the duration of illness. Penicillin V (250 mg by mouth three times a day for 10 days) or intramuscular benzathine penicillin (600,000 U for patients who weigh less than 27 kg; 1,200,000 U for patients who weigh more than 27 kg) is the treatment of choice. Erythromycin is recommended for treatment of persons with penicillin allergy. Therapy can be initiated for up to 9 days after the onset of symptoms and still prevent the occurrence of rheumatic fever. Repeat throat culture to document cure after therapy is not recommended. Because recurrences of rheumatic fever may follow subsequent group A streptococcal infections, intramuscular benzathine penicillin given every 4 weeks is recommended for at least 5 years after an episode of rheumatic fever.

Chapter 275

SYPHILIS

DEFINITION AND EPIDEMIOLOGY

Syphilis is a chronic, systemic, sexually transmitted disease caused by the spirochete *Treponema pallidum* subspecies *pallidum*. Most cases are caused by sexual contact with mucocutaneous lesions that occur in the primary or secondary stages. Late syphilis is considered noninfectious. Throughout the 1990s, rates of primary and secondary syphilis declined 84% in the United States.

PATHOPHYSIOLOGY

Organisms rapidly penetrate intact mucous membranes and microscopically abraded skin and disseminate soon thereafter. Two histopathologic features characterize

the syphilitic lesions of all stages of disease—obliterative endarteritis, in which hyperplasia and swelling of endothelial cells completely occlude blood vessels, and a loose perivascular infiltrate consisting of lymphocytes, macrophages, and plasma cells. Granuloma formation is common with more advanced disease.

CLINICAL FINDINGS AND DIFFERENTIAL DIAGNOSIS

Primary syphilis: Although classic syphilis is divided into stages, there is considerable temporal, clinical, and histopathologic overlap among them. The chancre, the primary lesion of syphilis, appears at the incubation site after an incubation period of 10 to 90 days (average, 3 weeks). It begins as an erythematous papule that ulcerates before healing spontaneously within 2 to 4 weeks. The typical chancre is painless, solitary, rounded, and has a raised, discrete border with a rubbery consistency. Approximately 50% of patients with primary syphilis have painless, nonsuppurative, bilateral regional lymphadenopathy. Primary syphilis must be differentiated from other causes of genital ulceration, including venereal infection (e.g., chancroid, herpes genitalis, lymphogranuloma venereum, and granuloma inguinale), nonvenereal infection (e.g., cat-scratch fever and sporotrichosis), and noninfectious disorders (e.g., trauma and malignant disease).

Secondary syphilis: About 6 to 24 weeks after infection, usually when the chancre is either healing or has disappeared entirely, the secondary, or disseminated, stage of syphilis begins. The cutaneous lesions (syphilids) usually are described as macular or maculopapular and are generally symmetric and widespread, varying from several millimeters to several centimeters in diameter. Some patients have lesions characteristically confined to the distal extremities, especially the palms and the soles. Syphilids may resemble lesions of psoriasis, lichen planus, or pityriasis rosea. Other common mucocutaneous manifestations include patchy alopecia and thinning of the eyebrows and beard; diffuse redness of the tonsils and pharynx; and moist, papular excrescences in the intertriginous areas (condyloma lata) that are highly infectious. Generalized lymphadenopathy often is present, and splenomegaly may occur. Other organ systems that may be involved include the gastrointestinal tract (granulomatous hepatitis associated with a markedly elevated alkaline phosphatase level), the central nervous system (headache and meningism, less commonly basilar meningitis, acute hydrocephalus, optic neuritis, or cerebrovascular syndromes), the eyes (anterior uveitis), the kidneys (rare instances of immune complex glomerulonephritis), and the bones (mild osteitis with bone pain).

Latency: After the manifestations of secondary syphilis subside, untreated patients enter an asymptomatic stage, called *latency*. About 25% of patients experience one or more infectious relapses during the first 4 years of latency; after that, infectious relapses are rare. These relapses may be indistinguishable from the patient's previous secondary episode, but cutaneous lesions tend to be less prominent, and mucosal lesions may predominate. Isolated visceral relapses can occur.

Tertiary syphilis: Approximately 30% of untreated patients with late latent disease have one or more forms of tertiary syphilis years, even decades, after infection. Tertiary syphilis is traditionally divided into three categories—benign tertiary (gummatous), cardiovascular, and neurosyphilis. Gummatous disease is characterized by the development of one or more granulomatous lesions (gummas) 7 to 10 years after initial infection. They can occur anywhere but are most common on mucocutaneous surfaces and in bone. Cardiovascular syphilis is caused by obliterative endarteritis of the vasa vasorum of the large arteries, particularly the proximal ascending aorta, that leads to aneurysmal dilatation. Aortic regurgitation and congestive heart failure can occur. There are four categories of neurosyphilis—*asymptomatic* (cerebrospinal fluid [CSF] abnormalities only), *meningovascular* (manifesting as stroke), *gummatous* (central nervous system mass lesions), and *parenchymatous* (tabes dorsalis and generalized paresis). Tabes dorsalis is caused by demyelination of the posterior columns of the spinal cord, dorsal roots, and dorsal root ganglia. Patients experience lancinating pain, pupillary abnormalities, impotence, bladder incontinence, truncal ataxia, lower extremity areflexia, and a profound loss of position and vibratory sensation in the lower extremities that gives rise to chronic traumatic arthritis (Charcot joints). Generalized paresis is an insidious dementia that can include seizures, dramatic and bizarre changes in personality, and intellectual deterioration.

LABORATORY FINDINGS

Diagnosis requires either reactive serologic results or identification of the treponeme in clinical specimens. Serologic tests are the mainstay of diagnosis. Nontreponemal tests (e.g., VDRL and rapid plasma reagin) measure flocculating antibodies to a mixture of cardiolipin, cholesterol, and lecithin. These antibodies presumably arise from the interaction of treponemes with host tissues. Titers tend to be highest in secondary disease and decline gradually thereafter. Approximately 30% of patients with primary, late latent, and tertiary disease have nonreactive test results. Many conditions may give rise to falsely positive results, either acutely (various viral illnesses, malaria, *Mycoplasma pneumoniae* infection) or chronically (autoimmune disorders such as lupus erythematosus, narcotic addiction, leprosy, pregnancy, and normal aging).

Treponemal tests measure antibodies specific to the pathogenic treponemes and are necessary to confirm that reactive nontreponemal serologic results are caused by treponemal infection. The most commonly used are the fluorescent treponemal antibody absorption test (FTA-ABS) and the microhemagglutination assay—*Treponema pallidum* (MHA-Tp). These tests are almost perfectly sensitive for secondary, latent, and tertiary disease but are only about 85% sensitive for primary disease. False-positive results occur among as much as 2% of the general population owing to cross reaction with nonpathogenic treponemes.

The most rapid and direct means of identifying treponemes in clinical specimens is dark-field microscopic examination. Exudates from chancres and moist secondary lesions are most amenable to this procedure. Examination of specimens from mucosal surfaces is not recommended because they are colonized with nonpathogenic treponemes that may be confused with *T. pallidum*. Demonstration of treponemes in tissue may be accomplished by means of silver stain or anti-*T. pallidum* antibodies, the latter being more sensitive and specific.

To diagnose neurosyphilis, CSF examination should be performed on any patient with reactive serologic results and neurologic abnormalities. Active disease usually is accompanied by CSF pleocytosis, usually lymphocytic, and often by an elevated protein level. In the absence of a traumatic lumbar puncture, a reactive CSF-VDRL test result is almost 100% specific for neurosyphilis, although its sensitivity varies from about 60% (tabes dorsalis) to nearly 100% (meningovascular syphilis).

MANAGEMENT

Penicillin is the drug of choice for therapy for all stages of syphilis ([Table 297.2](#)). Several hours after receiving therapy, some patients experience a sudden onset of chills, fever, tachycardia, headache, flushing, and headache (Jarisch–Herxheimer reaction). Symptoms usually abate within 24 hours and can be managed with aspirin. When initially reactive, nontreponemal serologic results should be followed at regular intervals, ideally beginning 3 months after therapy, to confirm cure. On average, among successfully treated patients with primary or secondary syphilis, titers decrease fourfold at 6 months and eightfold at 12 months. Patients with early syphilis and nontreponemal test results that remain active at a low, stable titer also may be considered cured.

[Chapter 297](#)

TUBERCULOSIS

DEFINITION, INCIDENCE, AND EPIDEMIOLOGY

Tuberculosis (TB) is infection by *Mycobacterium tuberculosis*. Asia and Africa currently have more than 70% of reported cases. In the United States, infection rates have declined since 1953, except for a period from 1985 through 1992. Cases tend to cluster in urban areas, where the infection disproportionately affects persons with HIV disease, members of racial and ethnic minorities, and those who are foreign born. *M. tuberculosis* is transmitted through the air by droplet nuclei expelled from the cough of a person with pulmonary or laryngeal TB. The risk is greatest in spaces lacking air volume, fresh air, and natural or ultraviolet light. The best predictors of a patient's contagiousness are the number of bacilli in the pulmonary secretions and the presence and frequency of cough. Persons with latent infection (see later) are not contagious.

PATHOGENESIS

Once inspired, droplet nuclei may lodge in the pulmonary alveoli to establish infection. Among approximately 5% of those infected, bacilli multiply locally over weeks to months to cause primary tuberculosis—hilar or peritracheal lymphadenopathy, lobar pneumonia, usually in the middle or lower lobes, or pleuritis. Infection includes the invasion of alveolar macrophages, within which the mycobacteria can survive and disseminate throughout the body. In response, infected macrophages may combine to form swirls of multinucleated giant cells in a stroma of fibrous inflammatory tissue, the hallmark of tuberculous granuloma. Over a period of years, a granuloma may become relatively large and calcified.

Most persons with *M. tuberculosis* infection have no signs of infection other than development of delayed-type hypersensitivity to tuberculin proteins. In such cases, the infection generally becomes latent and may uncommonly evolve to active disease only after many years, particularly if the person sustains an

immunocompromising condition or reaches old age. Reactivation disease is much more common than primary disease. Although it can take place in any tissue, reactivation most often occurs in the apical regions of the lung. Large caseous foci may produce visible cavities in the lung parenchyma and destroy lung tissue over a period of years.

CLINICAL FINDINGS

Pulmonary TB constitutes 80% to 85% of active cases. The other cases are extrapulmonary. Concomitant pulmonary and extrapulmonary disease occurs among about 7% of patients, and miliary TB accounts for 0.2% of cases. The diagnosis of TB can be elusive, because the disease can masquerade as a variety of pulmonary illnesses, including bacterial or viral pneumonia, interstitial lung disease, and neoplasm. Moreover, among patients with compromised immune systems, such as those with AIDS, symptoms generally are subtle, and chest radiographic findings may be atypical.

Pulmonary disease: About 10% to 20% of persons with active TB have no symptoms, particularly those who are elderly or who have early disease. The most common symptoms include cough with or without sputum production and hemoptysis, fever, night sweats, and weight loss. Other symptoms include pleuritic chest pain, dyspnea, hemoptysis, fatigue, and anorexia. The physical findings are nonspecific and vary depending on the stage of the disease. In early disease, the examination findings may be normal. Later signs include rales, rhonchi, or signs of consolidation such as tubular breath sounds or enhanced tactile fremitus. In advanced disease, generalized wasting may occur.

Extrapulmonary disease: Extrapulmonary TB usually is a consequence of lymphohematogenous dissemination of *M. tuberculosis* organisms during primary infection and is more common among immunocompromised patients. In descending order of frequency, the most common forms are lymphatic (scrofula, usually involving the cervical and supraclavicular chains), pleural (usually unilateral), bone and joint (most often vertebral and also known as Pott's disease), genitourinary, meningeal, peritoneal, and pericardial. Symptoms of local disease generally are limited to the affected site. Symptoms in systemic (miliary) disease are nonspecific and may consist only of constitutional symptoms such as fever, anorexia, and weight loss.

DIAGNOSTIC EVALUATION

A thorough clinical evaluation is essential. It is especially important to obtain accurate information about past TB exposure and immunocompromising conditions or medications. Other important diagnostic elements include a Mantoux tuberculin skin test, which has a positive result among 85% to 90% of immunocompetent patients with pulmonary TB; chest radiography; and smears and cultures for acid-fast bacteria (AFB).

Pulmonary disease: TB may have various manifestations on chest radiographs, but the hallmark is an infiltrate with cavitation, usually in the apical region. Other findings include lymphadenopathy, lobar infiltrates, and interstitial infiltrates. Unless occult pulmonary disease is suspected, computed tomography of the chest is not usually helpful in the initial evaluation. Laboratory abnormalities may include leukocytosis or leukopenia and normocytic anemia.

Extrapulmonary disease: Chest radiography can demonstrate a pleural effusion or a form of cardiomegaly suggestive of pericardial effusion. Effusions from peritoneal, pleural, and pericardial spaces typically are lymphocytic exudates. Fluid glucose level usually is low but may be normal; protein level is elevated. Smears, cultures, and biopsy specimens from these sites are positive in about 65%, 75%, and 85% of cases, respectively. The diagnostic yield from a cerebrospinal fluid smear and culture is disappointingly low (15% and 50%, respectively), but polymerase chain reaction techniques improve rates of detection. In miliary disease, blood cultures can be useful and biopsy specimens from sites such as the liver, bone marrow, lymph nodes, and lung may be examined for evidence of granuloma formation and AFB.

Management when TB is suspected: The diagnosis of TB may be suggested by symptoms and signs or by a positive tuberculin skin test result. It is important to determine the patient's degree of possible contagiousness when making decisions regarding disposition and restrictions in activity. Patients believed to have TB can be hospitalized or be evaluated as outpatients, depending on the severity of illness and the living situation. If patients are hospitalized, prompt isolation in a negative pressure room is critical for preventing transmission. For all persons believed to have TB, sputum specimens should be obtained on three consecutive mornings and sent for AFB smear and culture. If the smear results are negative, the patient is considered noninfectious. All cases of suspected TB must be reported to the local health department.

MANAGEMENT

Pulmonary disease: Hospitalized patients with positive smear results should remain in isolation, and persons being treated as outpatients should remain at home until they have three consecutive negative smears and have demonstrated a clinical response to antituberculous therapy. The course of therapy is divided into two components—the initial intensive phase (usually 2 weeks to 2 months in duration) and the continuation phase (4 months or longer, aimed at killing the few bacilli harbored in intracellular compartments). The three guiding principles of therapy are as follows: (a) regimens must contain at least three drugs to which the organisms are susceptible; (b) the drugs must be taken regularly; and (c) drug therapy must be continued for a sufficient period of time. First-line drugs include isoniazid (INH), rifampin, pyrazinamide (PZA), ethambutol, and streptomycin. Many treatment approaches may be used; one common regimen consists of daily doses of INH (5 mg per kilogram, up to 300 mg), rifampin (10 mg per kilogram, up to 600 mg), and PZA (20 to 35 mg per kilogram, up to 2 g) for the first 2 months and followed by INH and rifampin at the same dosages for another 4 months.

Extrapulmonary disease: Therapy for extrapulmonary TB usually follows the same principles as for pulmonary TB. The same drug regimens are used for the same durations. The exceptions are miliary TB, TB of bone and joints, and TB meningitis, all of which necessitate 12 months of therapy. Management of TB pericarditis and meningitis also includes adjunctive use of glucocorticoids, to lessen the risk of constrictive pericarditis and permanent neurologic sequelae, respectively.

Therapy for drug-resistant TB: Multidrug-resistant TB (MDRTB) is suspected when the source of infection is known to have had drug-resistant disease and when a patient does not respond to adequate therapy. Drug susceptibility of a bacterial isolate can confirm the presence of MDRTB. When a patient is believed to have disease resistant to at least INH and rifampin, the initial regimen should contain at least three drugs to which susceptibility is considered likely and to which the patient is naive. Second-line antituberculous drugs include quinolones, capreomycin, cycloserine, kanamycin, ethionamide, and paraaminosalicylic acid. Medications should be administered under directly observed therapy. In the event of treatment failure, at least two drugs not previously taken by the patient should be added to the regimen simultaneously. Therapy for MDRTB should extend for at least 12 months after culture-negative status has been achieved.

SCREENING

Target groups and technique: Tuberculin skin testing is performed to ascertain who is at high risk of latent infection with *M. tuberculosis* and who would benefit from therapy to prevent reactivation. Current recommendations suggest that the following groups be screened: persons with HIV infection, close contacts of persons with infectious TB, persons with immunocompromising medical conditions, users of injected drugs, foreign-born persons from areas where TB is common, homeless persons, low-income populations, and residents or workers in congregate settings, such as correctional institutions, nursing homes, and mental institutions. The Mantoux tuberculin skin test with 5 units of purified protein derivative (PPD) is the standard method. The PPD is placed subcutaneously into the volar aspect of the forearm, and the result is interpreted 48 to 72 hours later. A positive reaction is determined by the size of the induration (not erythema) in millimeters and varies depending on risk category ([Table 294.3](#)). A two-step test, which consists of a second test 1 to 3 weeks after an initially negative test result, is more sensitive, because it may detect cases of latent infection in which the initial immune response is muted but becomes evident owing to a booster phenomenon.

Therapy for Latent infection: Persons with a positive tuberculin skin test result should undergo chest radiography and clinical evaluation to exclude active disease. If the findings are normal, latent infection is likely. The decision to treat patients for latent infection depends on the person's circumstances. Treatment is recommended, regardless of age, for the following groups: those who are known or are likely to have HIV infection, close contacts of a person with TB, persons who inject drugs, persons with skin test results that have recently (within 2 years) converted, persons with certain medical conditions (such as diabetes mellitus, chronic renal failure, an organ transplant, hematologic malignant disease, ongoing use of glucocorticoids, and prior gastrectomy), and those who have chest radiographic findings that suggest prior active TB but have not received adequate antituberculous therapy. The following groups should be treated only if younger than 35 years: foreign-born persons from areas where TB is common; medically underserved, low-income populations; and homeless persons. A 9-month course of daily INH therapy is now thought to be the most effective regimen for eradication of latent TB infection. For persons with conditions in which neuropathy is common, such as diabetes, uremia, alcoholism, and HIV infection, pyridoxine also should be administered.

VARICELLA-ZOSTER VIRUS INFECTION

DEFINITION, EPIDEMIOLOGY, AND ETIOLOGY

Varicella-zoster virus (VZV) is a member of the herpesvirus family that causes two diseases, varicella and zoster. Varicella (chickenpox), the primary infection, is mainly a highly contagious disease of young children, but about 5% of adults in the United States are susceptible. The infection tends to be more severe among adults. Zoster, the secondary infection, is caused by reactivation of VZV acquired during varicella that became latent within sensory ganglia. It is mainly a disease of adults with a steady rise in incidence after 50 years of age. Zoster also is more common among persons with compromised cellular immunity.

CLINICAL FINDINGS

Varicella: Varicella manifests as a generalized, pruritic rash after an incubation period ranging from 10 to 21 days. The rash, which is usually accompanied by fever, is most concentrated on the torso and head and consists progressively of maculopapules, vesicles, pustules, and crusts. There are often several crops of lesions, so all forms of the rash may be present on any one area of skin. All vesicles usually crust within 5 to 7 days, at which time the patient is no longer contagious to others. About 5% of adult patients have pulmonary involvement 1 to 6 days after the onset of the rash. Although usually self-limited and benign, varicella can be severe or fatal among pregnant women, those with immunodeficiency or hematologic malignant disease, and those treated with chemotherapeutic agents or high doses of glucocorticoids. Such patients may have hemorrhagic skin lesions, severe pneumonia, and disseminated intravascular coagulation.

Zoster: Zoster manifests as a unilateral rash in a dermatomal distribution; one to three dermatomes usually are involved. Fever may be present. Zoster occurs most commonly in the thoracic region, followed by the facial-cervical area, torso, and extremities. Pain occurs in the acute phase, and patients, particularly those older than 50 years, may have postherpetic neuralgia for many months after the rash has healed. Some patients have only dermatomal pain without a rash, a situation that may lead to considerable diagnostic confusion. Zoster of the face often involves the ophthalmic division of the trigeminal nerve. This commonly is associated with central nervous system involvement such as headache, aphasia, and seizures. Granulomatous angiitis of the cerebral blood vessels occurs occasionally among elderly patients.

DIAGNOSIS

Infections caused by VZV usually are distinctive, so laboratory confirmation often is unnecessary. However, about 10% of cases diagnosed clinically as zoster may actually be caused by herpes simplex virus (HSV). For example, HSV, rather than VZV, is almost always the cause of recurrent dermatomal rashes. A specific diagnosis of VZV infection is best made by means of culturing the skin scrapings of vesicular lesions. Serologic tests also can be performed. The Tzanck smear does not differentiate between VZV and HSV infection.

MANAGEMENT

Local measures, such as application of calamine lotion for varicella and Burow's solution for zoster, often are used.

Varicella: Aspirin should not be given to children and adolescents with varicella because of the risk of Reye syndrome. Acetaminophen can be used to control fever. Antihistamines may be given to reduce itching. Patients with severe or potentially severe infection, such as those with compromised immune systems, should be treated with intravenous acyclovir (30 mg per kilogram per day for adults), although the dosage should be reduced in the treatment of patients with renal insufficiency. In the care of patients with competent immune systems, oral acyclovir (4 g per day in 5 divided doses) started within 24 hours of onset of the rash shortens the course of varicella by about 1 day but does not prevent complications or transmission.

Zoster: Acyclovir is effective even if 3 days have elapsed since the onset of the rash, but the benefit is greater with earlier intervention. Because there is some indication that acyclovir therapy given for 7 days may decrease pain associated with zoster and the incidence of postherpetic neuralgia, it has become customary to treat elderly patients who have early zoster. Famciclovir and valacyclovir have been approved for oral therapy for zoster. Because these agents are administered only 3 times a day, patient compliance may be better with these agents than with acyclovir. The use of glucocorticoids is controversial; these agents have not been shown to improve healing or decrease postherpetic neuralgia, but they may improve quality of life.

PREVENTION AND CONTROL

Passive immunization against varicella may be achieved with varicella-zoster immune globulin (VZIG). It is indicated for prevention or modification of severe varicella among persons at high risk, including those with an underlying malignant disease or immunodeficiency and those receiving high doses of glucocorticoids. Recipients should have had intimate exposure to VZV within the preceding 5 days from a person with either varicella or zoster. A live attenuated varicella vaccine has been approved for use in the care of healthy varicella-susceptible children and adults. Adults should be given two doses 1 month apart.

APPROACH TO THE MANAGEMENT OF THE PATIENT WITH ACUTE RESPIRATORY DISTRESS SYNDROME

DEFINITION AND ETIOLOGY

Acute respiratory distress syndrome (ARDS, previously called adult respiratory distress syndrome) represents the abrupt onset of diffuse lung injury characterized by severe hypoxemia and generalized pulmonary infiltrates in the absence of cardiac failure. It has most often been associated with sepsis syndrome and bacterial or viral pneumonia. Other causes include major traumatic injury, aspiration of gastric contents, massive transfusion, inhalation injury, pancreatitis, near-drowning, fat embolism after long bone fractures, and drug overdose.

PATHOPHYSIOLOGY

Structural changes: Inflammatory cells, especially neutrophils, accumulate within the alveolar space and are believed to contribute to lung injury by releasing granular enzymes and oxidants. Type I alveolar epithelial cells undergo cytopathic changes, and the alveolar basement membrane is damaged. Changes in cellular permeability allow interstitial and alveolar edema; hyaline membranes are then produced by aggregation of fibrin and other proteins in the alveolar space. As the process continues, intravascular thrombosis, loss of pulmonary microvasculature, and fibrotic distortion of septal architecture occur.

Physiologic changes: ARDS is associated with impaired gas exchange, altered lung mechanics, and pulmonary vascular changes. Lung compliance and functional residual capacity decrease, and work of breathing increases. The loss of microvasculature in the later stages leads to pulmonary hypertension.

CLINICAL PRESENTATION AND DIAGNOSIS

ARDS develops rapidly, usually within 12 to 72 hours of the predisposing event. Respiratory distress, severe hypoxemia, and generalized pulmonary infiltrates all are necessary for the diagnosis. The most widely accepted definition of hypoxemia in this setting is a ratio of the arterial oxygen tension (P_{aO_2}) to the fraction of inspired oxygen (FIO_2) less than 200. Congestive heart failure as an alternative diagnosis can be excluded either clinically or by determining that the pulmonary artery occlusion pressure is less than 18 mm Hg. To date, no specific laboratory findings have been described.

PROGNOSIS AND MANAGEMENT

Therapy is primarily supportive. Well-controlled studies have failed to find a benefit for glucocorticoids in the management or prevention of ARDS. The selective pulmonary vasodilator nitric oxide has been shown to improve oxygenation and to reduce pulmonary artery pressures without affecting mortality. Mechanical ventilation is almost always needed, as is positive end-expiratory pressure (PEEP). The assist-control (A/C) ventilator mode is preferred by most experts. Lower ventilator tidal volumes (6 mL per kilogram rather than 10 to 15 mL per kilogram) have been proved to decrease ventilator-associated lung injury, such as barotrauma-induced pneumothorax, and to reduce mortality. Survival rates in the most recent studies have been 60% to 70%. The course is variable, lasting from a few days to several weeks. The average duration of mechanical ventilation is approximately 10 to 12 days. One-third of the deaths of patients with ARDS are related to the underlying disease or injury.

ASTHMA

DEFINITION, EPIDEMIOLOGY, AND ETIOLOGY

Asthma is defined as intermittent, reversible airway obstruction in association with increased nonspecific bronchial reactivity and airway inflammation. It is one of the most common and expensive chronic illnesses in the United States, affecting 5% to 10% of the population. The incidence follows a bimodal age distribution, with an early peak from 4 to 10 years of age and second peak after 40 years of age. African American and Hispanic populations, particularly those in inner city areas, have both higher incidences and higher mortality rates than other groups. The basis for asthma is poorly understood. Multifactorial genetic factors likely contribute to susceptibility, but environmental exposures also are important. Among children, potential triggers include maternal cigarette smoking, infection with respiratory syncytial virus, and exposure to indoor allergens such as house dust mites, cockroaches, cats, and molds. Among adults, occupational asthma is prevalent in the lumber, plastics, and paint industries and among hospital workers with a sensitivity to latex.

PATHOPHYSIOLOGY

For asthma to develop, a complex immunologic reaction involving inflammatory cells and cytokines must be initiated and maintained. Although many cell types may be involved, lymphocytes, eosinophils, and mast cells predominate. Tissue damage involves the epithelium and the submucosal space, and hyperplasia of the airway smooth muscle occurs. Reversible airflow limitation is present, demonstrated by a reduction in the ratio of forced expiratory volume in 1 second (FEV_1) to forced vital capacity (FVC) (less than 75% among adults) and an improvement in the FEV_1 'more than 12% to 15% after inhalation of a β -agonist. Other physiologic changes include hyperinflation (increased residual volume) and increased airway resistance. Airway hyperresponsiveness is demonstrated by methacholine, histamine, or exercise testing. A positive result of a methacholine challenge is defined as a reduction in FEV_1 of 20% or more with 8 mg per milliliter or less of methacholine. However, other diseases can be associated with airway hyperresponsiveness, such as chronic obstructive pulmonary disease (COPD), congestive heart failure (CHF), bronchiectasis, and seasonal allergic rhinitis.

CLINICAL FINDINGS AND DIAGNOSIS

The symptoms of asthma include cough, wheezing, chest tightness, and dyspnea. The diagnosis should be made through documentation of reversible airway obstruction (see earlier) in the setting of symptoms of the disease. Because of the intermittent nature of the disease, however, an occasional patient may have normal spirometric findings. If the history suggests asthma, the patient's peak flow can be monitored at home. Variation in peak flows more than 10% generally is considered diagnostic of asthma. If this sign is not present and the patient still has symptoms, a methacholine challenge may be performed (see earlier). The methacholine challenge is particularly helpful in the evaluation of patients with cough variant asthma, who often have normal spiograms and no symptoms other than cough.

DIFFERENTIAL DIAGNOSIS

Differentiation of COPD from asthma among cigarette smokers can be difficult. COPD usually decreases diffusion capacity, which does not occur in asthma. Vocal cord dysfunction involves involuntary closure of the vocal cords, usually during inspiration but occasionally during expiration as well. The diagnosis is made through laryngoscopic visualization of inappropriate closure of the cords during inspiration or flattening of the inspiratory limb of a flow-volume loop. Upper airway obstruction due to tumors or strictures causes flattening in both the inspiratory and expiratory phases of the flow-volume loops. CHF can cause wheezing known as *cardiac*

asthma.

MANAGEMENT

A thorough history should be obtained to determine possible triggers such as exposure to allergens, use of nonsteroidal anti-inflammatory drugs, and occupational exposure to antigens. If indoor allergens are suspected, allergy skin testing should be undertaken to guide avoidance therapy. Exacerbating factors such as sinus disease, gastroesophageal reflux, and stressful life situations should be sought. [Table 363.1](#) outlines the current definitions for asthma severity. [Table 363.2](#) presents the appropriate treatments for each level.

Chronic maintenance therapy: In general, inhalation of glucocorticoids is the cornerstone of the management of all but the most mild asthma. These agents are effective and safe and counter the underlying inflammatory basis of the disease. The side effect of oral thrush can be minimized with the use of a spacer device or by rinsing the mouth after use. Fluticasone, budesonide, and beclomethasone are likely more potent than flunisolide or triamcinolone. Cromones such as nedocromil and cromolyn sodium are considered second-line agents for long-term control among adults. Little is known about the mechanism of action. Although these agents do have mast cell-stabilizing properties, the clinical importance of this effect is unclear.

Theophyllines are nonspecific phosphodiesterase inhibitors with weak bronchodilating effects and some antiinflammatory properties. They are classified as second-line agents for long-term control among patients with mild or moderate persistent asthma. Disadvantages include numerous drug-drug interactions and a narrow therapeutic window that can lead to seizures and arrhythmias with higher serum drug levels. Long-acting inhaled β -agonists include salmeterol and formoterol. These agents provide effective bronchodilation for more than 12 hours and have been shown to prevent nocturnal symptoms and diurnal peak flow fluctuations. They are primarily recommended for use with inhaled glucocorticoids in moderate persistent asthma. Because the pharmacokinetic properties make these drugs poor therapy for acute exacerbations, patients should always have a short-acting inhaled β -agonist to use for acute symptoms.

Leukotriene modulators (zafirlukast, montelukast, zileuton) diminish the production of leukotrienes and have shown efficacy in control of asthma induced by allergens, exercise, or aspirin. The most recent guidelines suggest that these drugs be used to manage mild, persistent asthma as alternatives to inhaled glucocorticoids, theophylline, and cromones.

Quick relief medications: Patients may need quick relief if symptoms worsen acutely. However, because patients' perceptions of airflow limitation do not correlate well with the actual degree of obstruction, home peak flow monitoring should be used to guide therapy. More than a 20% decrease in peak flow should be an indication for attention and treatment by the patient, whereas a 50% decline from baseline always necessitates an aggressive approach by the treating physician. All patients should have an action plan to begin treatment at home. This can include increased use of short-acting inhaled β -agonists, such as albuterol, and initial oral glucocorticoid therapy if there is insufficient response to the β -agonists. Although systemic glucocorticoids are the most effective asthma medications, toxicity necessitates that ongoing use be as limited as possible. The initial daily dose of prednisone for patients with an acute, severe exacerbation is 60 to 120 mg. The dose can be tapered gradually on the basis of clinical response.

Chapter 363

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

DEFINITIONS

Chronic obstructive pulmonary disease (COPD) is a group of disorders that have in common the presence of persistent airflow obstruction. Chronic bronchitis is characterized clinically by chronic cough and sputum production for at least 3 months for 2 successive years without other known causes. Emphysema is a condition with abnormal permanent enlargement of airspaces distal to the terminal bronchioles accompanied by nonfibrotic destruction of walls. Asthma is characterized by reversible airway narrowing and increased responsiveness to various stimuli. Many patients have features of more than one of these diseases and are given the less specific diagnosis COPD.

INCIDENCE AND EPIDEMIOLOGY

The overall prevalence in the United States is 4% to 6% among men and 1% to 3% among women. COPD is recognized among 10% to 15% of adults older than 55 years. As of 1990, COPD was the fourth leading cause of death in the United States and accounted for more than 13% of all hospitalizations.

ETIOLOGY AND PATHOGENESIS

Cigarette smoking is the most important risk factor and accounts for nearly 90% of all cases of COPD. Current smokers have 10 times the relative risk of nonsmokers. There is, however, marked individual variation in susceptibility; only 10% to 15% of smokers experience COPD. It has not been clearly established that passive smoke exposure causes COPD. The mechanisms by which smoking leads to COPD are not well understood. In the case of emphysema, the disease seems to be caused by an imbalance between lung proteases and antiproteases that leads to increased lung destruction. An inherited deficiency of a α_1 protease inhibitor is associated with premature emphysema. In chronic bronchitis, pathologic changes in the airways include an inflammatory cell response, goblet cell proliferation, and an increase in smooth muscle.

CLINICAL FEATURES

COPD typically manifests later in life. The insidious development of dyspnea is the hallmark symptom. A cough is frequent and often is attributed to smoker's cough early in disease. The cough usually is productive of mucoid sputum. There may be a history of frequent respiratory infections. Some patients with COPD have abnormal gas exchange with hypoxemia or hypercapnea. Hypoxemia may be associated with cognitive or personality changes, polycythemia, and cyanosis. Chronic hypercapnea may cause headache.

During the physical examination, it is important to assess maximum expiratory flow for persons at high risk. This can be assessed easily with forced expiratory time (FET). Healthy persons can exhale completely within 4 seconds. An FET longer than 6 seconds signifies substantial obstruction. Other physical signs develop only when the disease is moderate to severe. Overinflation of the lungs can increase the anteroposterior diameter of the thorax, lower and flatten the diaphragm, and reduce respiratory excursion. The accessory breathing muscles (neck and intercostals) contribute more to ventilation. Wheezing with tidal respirations may be evident. With advanced emphysema, the breath sounds are diminished because of a reduction in flow and an increase in lung inflation. Signs of pulmonary hypertension and right-sided heart failure, such as peripheral edema and hepatic congestion, usually represent advanced disease.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

Pulmonary function tests: The central diagnostic feature is reduced expiratory airflow due to airway narrowing. Spirometry is the standard test and is useful for detecting obstruction, staging severity, and following the disease course. A reduction in forced expiratory volume in 1 second (FEV_1) in relation to the forced vital capacity (FVC)—the FEV_1/FVC ratio—is the standard indicator of obstruction. The FEV_1 is the best measure of severity; it correlates with exercise tolerance and survival. Measurements of lung volume reveal increased residual volume, functional residual capacity, and sometimes total lung capacity (TLC). Emphysema causes a greater increase in TLC than do other lung diseases and reduces carbon monoxide diffusing capacity because of the loss of alveolar-capillary surface area.

Radiologic studies: Chest radiography has limited usefulness in diagnosing or staging COPD. The main use of this modality is in detecting other parenchymal lung or cardiovascular diseases that manifest with similar symptoms. With advanced emphysema a chest radiograph may reveal hyperinflation of the lungs with a low, flat diaphragm and an increase in the retrosternal airspace on the lateral projection. The emphysematous lungs may appear radiolucent because of bullous changes. High-resolution computed tomography may document evidence of emphysema.

Arterial blood gas analysis: The analysis may reveal hypoxemia, particularly with exercise, and hypercapnea, particularly in advanced disease. The relation between gas exchange abnormalities and other measures of lung function is poor. Two characteristic patterns of disease can be defined with blood gas findings. Patients with severe dyspnea, mild hypoxemia, and normal-to-low arterial PCO_2 have been called *pink puffers* (type A COPD), reflecting their color and increased

breathing effort. Patients with severe hypoxemia, carbon dioxide retention, right-sided heart failure, but little dyspnea are called *blue bloaters* (type B COPD), reflecting their bloated, cyanotic appearance and low ventilation. These differences may reflect variations in ventilation–perfusion (\dot{V}/\dot{Q}) mismatching and central respiratory drive. Most patients, however, fall between these two extremes.

MANAGEMENT

Prevention: Primary and secondary prevention strategies include avoidance or discontinuation of cigarette smoking and a α_1 protease inhibitor replacement for persons with both proven genetic deficiency and abnormal lung function. Tertiary prevention to reduce complications of symptomatic disease include smoking cessation, influenza and pneumococcal vaccination, and pulmonary rehabilitation.

Oxygen therapy: Oxygen is the only therapy proven to prolong survival. Studies have justified the long-term use of oxygen therapy for severe resting hypoxemia (arterial P_{O_2} 55 mm Hg or less). For patients with an arterial P_{O_2} between 56 and 59 mm Hg, oxygen therapy is indicated if erythrocytosis (hematocrit 55% or more) or cor pulmonale is present. The decision for long-term therapy should be made only when the patient has been in stable condition with optimal therapy for at least 30 days.

Symptomatic treatment: Medical treatment is directed at the reversible component of airway obstruction and control of secretions. Bronchodilators used to improve symptoms and increase airway caliber include β_2 -agonists, anticholinergics, and methylxanthines such as theophylline. β_2 -Agonists are best administered by means of inhalation with an emphasis on proper technique. The most common side effects are tremor and tachycardia. Anticholinergics such as ipratropium bromide have recently gained prominence in the management of COPD. They, too, are best administered by means of inhalation. Oral theophylline improves bronchial tone, diaphragmatic function, respiratory drive, and mucociliary clearance. The target therapeutic level is typically 10 to 20 μg per milliliter. Side effects occur even within this range; they include tremor, insomnia, irritability, and gastrointestinal upset. More serious side effects, including vomiting, arrhythmias, hypotension, and seizures, generally develop at higher blood levels.

Glucocorticoids can be beneficial to some patients with stable symptoms. A limited trial is probably justified for patients who cannot be treated with standard bronchodilators alone. Treatment should be continued only for the minority who have marked improvement in pulmonary function. Inhaled steroids are safer, but their effectiveness has not been as well established. Oral or intravenous steroids are clearly indicated for patients experiencing acute flare-ups of COPD.

Control of secretions is important for patients with a chronic productive cough. These patients should be encouraged to drink several glasses of fluid each day, but excessive hydration is not warranted. The patients also should be taught the technique of controlled coughing, which involves deep inspiration, breath-holding for a few seconds, and then coughing two or three times. The use of mucolytic agents (iodinated glycerol, nebulized acetylcysteine, or recombinant DNase) to thin secretions and promote clearance is controversial. Because cough is an essential protective mechanism, cough suppression therapy is not recommended. For acute exacerbations, when sputum changes color and increases in volume, treatment with antibiotics for 7 to 10 days is indicated. Oral antibiotics such as trimethoprim–sulfamethoxazole, amoxicillin, amoxicillin–clavulanate, tetracycline, or erythromycin are commonly chosen to cover pathogens colonizing the respiratory tract, including *Haemophilus influenzae*, *Streptococcus pneumoniae*, and *Moraxella catarrhalis*.

Chapter 364

APPROACH TO THE PATIENT WITH COUGH

EPIDEMIOLOGY AND PATHOPHYSIOLOGY

Coughing is the fifth most common symptom among patients at outpatient clinics in the United States. The cough reflex is subserved by vagal afferent pathways arising from the trachea, intrapulmonary airways, and larynx. Although it is an important natural defense mechanism, excessive coughing generates considerable intrathoracic pressure and may be associated with complications such as pneumothorax, syncope, subconjunctival hemorrhage, cervical disc prolapse, urinary incontinence, and esophageal perforation.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis is extensive (Table 352.2). Acute cough usually is caused by viral or bacterial upper respiratory infection. It also, however, can be a manifestation of more serious conditions such as acute bacterial pneumonia, congestive heart failure, pulmonary embolism, asthma, or aspiration. These conditions usually are accompanied by other symptoms, such as dyspnea or fever. Chronic cough (cough that persists for more than 1 month) is most commonly caused by asthma, gastroesophageal reflux (GER), postnasal drip, chronic bronchitis, or bronchiectasis. Smoking is also a common cause of coughing.

DIAGNOSTIC APPROACH

The best approach is to exclude first the most common conditions associated with chronic dry coughing—postnasal drip, asthma, and GER. Often the history and physical examination are sufficient to suggest one of these diagnoses, and a therapeutic trial can then be undertaken. If further diagnostic evaluation for these conditions is necessary, the tests performed should be based on the initial suspicion, as follows: for possible postnasal drip, allergy tests and sinus computed tomography (CT); for suspected asthma, peak expiratory flow measurements at home and a bronchoprovocation test with histamine or methacholine; and for possible GER, 24-hour pH monitoring and perhaps endoscopic examination of the esophagus. A chest radiograph is recommended for most patients, unless a cause is quickly apparent and the cough improves with therapy. If the diagnosis remains elusive, studies such as full pulmonary function tests, lung CT, and fiberoptic bronchoscopy should be considered.

MANAGEMENT

Specific therapies: Many of the causes of chronic cough have specific therapies. The most straightforward is discontinuation of an offending medication, such as an angiotensin-converting enzyme (ACE) inhibitor, although it may take weeks for the cough to resolve. Postnasal drip is managed with glucocorticoid nasal sprays and an antihistamine with or without a short course of nasal decongestants; an antibiotic is used if purulent sinusitis is suspected. GER is managed with histamine 2 blockers or proton pump inhibitors, asthma with bronchodilators and inhaled glucocorticoids.

Nonspecific therapy: Opiates such as codeine are the most effective antitussive agents, but they cause physical dependence, respiratory depression, nausea and vomiting, and constipation. Non-narcotic antitussives include dextromethorphan, a synthetic morphine derivative with no analgesic or sedative properties. It is a constituent of many nonprescription cough remedies. Mucolytic agents such as acetylcysteine often are used to facilitate expectoration by reducing sputum viscosity in patients with chronic bronchitis, but there is little evidence that these agents are beneficial. Local anesthetics such as aerosolized lidocaine should be reserved for cases of severe, intractable cough, because they remove reflexes that protect the lungs from noxious substances.

Chapter 352

CYSTIC FIBROSIS

EPIDEMIOLOGY AND PATHOPHYSIOLOGY

Cystic fibrosis (CF) is an autosomal recessive disorder; it affects 1 in 3,000 U.S. whites, 1 in 15,000 African Americans, and 1 in 90,000 Asian Americans. The CF gene encodes for the CF transmembrane conductance regulator (CFTR). In CF, one of the chloride ion channels of epithelial cells is either absent or dysfunctional. This leads to decreased water content and increased viscosity of various secretions, including those in the lung and the pancreas. In addition, the high sodium concentrations in airway secretions may inactivate the antimicrobial peptides secreted by airway epithelial cells.

CLINICAL FINDINGS

Pulmonary and sinus disease: Symptoms generally begin in childhood. A self-perpetuating destructive inflammatory reaction is manifested by bronchitis, bronchiolitis, bronchiectasis, and a progressive decline in pulmonary function. Infection is predominantly caused by *Staphylococcus aureus*, *Haemophilus influenzae*, and *Pseudomonas aeruginosa* organisms. *P. aeruginosa* eventually becomes the dominant organism in more than 90% of patients; a mucoid strain eventually replaces other pathogens. Acute exacerbations consist of increased coughing, sputum production, and dyspnea. Hemoptysis and pneumothorax are complications of more advanced disease. Clubbing of the fingers and toes is a universal finding. Mechanical obstruction of the sinus ostia by viscous mucus can occur and is followed by bacterial infection. Nasal polyposis is common.

Pancreatic and gastrointestinal disease: Most patients have exocrine pancreatic insufficiency and malabsorption; acute pancreatitis occurs in 10% of cases. Diabetes mellitus occurs among 15% of patients. It is slow in onset and nonketotic. Episodes of complete or partial intestinal obstruction occur among 10% to 20% of adult patients. Other gastrointestinal complications include gastroesophageal reflux, peptic ulceration, Crohn's disease, cholelithiasis, and elevated levels of liver enzymes.

Other complications: Men with CF have obstructive azoospermia and are infertile. Women have normal fertility. Nondestructive, episodic arthritis, most commonly involving the lower limbs and fingers, occurs among some patients. Patients are susceptible to osteopenia and osteoporosis.

LABORATORY FINDINGS

The diagnosis is based on a positive result of a sweat chloride test (more than 60 mEq per liter) or results of genetic tests that demonstrate two CF alleles and symptoms compatible with CF. The sweat test is highly sensitive (96% in adults) and specific for CF, although false-positive results can occur if the patient has hypoadrenalism, hypothyroidism, or nephrogenic diabetes insipidus. Chest radiographs first show overinflation, peribronchial cuffing, and small infiltrates and then show bronchiectasis and diffuse fibrosis, which is most marked in the upper lobes. Almost all patients have panopacification of the paranasal sinuses. Malabsorption is characterized by elevated fecal fat levels and decreased serum levels of fat-soluble vitamins.

PROGNOSIS AND MANAGEMENT

In the United States in 1997, the median survival period was 30.6 years. Prognostic factors include genotype, pulmonary function, results of chest radiographs, and nutritional status. The forced expiratory volume in 1 second (FEV₁) is the single most sensitive predictor of mortality. An FEV₁ less than 30% of predictive is associated with a 45% 2-year mortality risk. About 95% of patients die of pulmonary complications.

Pulmonary and sinus disease: The mainstays of treatment are chest physical therapy and antibiotics, although the bacterial pathogens rarely are eradicated. For exacerbations, intravenous antibiotics are usually given for 2 weeks. The use of prophylactic antibiotics, including aerosolized forms, is controversial. Inhaled bronchodilators such as β_2 -agonists and ipratropium bromide are indicated for those who respond. Recombinant human DNase alters the rheologic qualities of the sputum by cutting the size of DNA molecules. Oral glucocorticoids slow the decline in pulmonary function but cause serious side effects. Inhalation of steroids has been less well studied but seems reasonable in the care of patients with an asthmatic component to the disease. Oxygen therapy is given to patients with hypoxemia. A final therapeutic option for a few patients is lung transplantation. Sinus disease is managed with antibiotics, nasal irrigation, nasal steroids, and, if necessary, surgical drainage.

Pancreatic and gastrointestinal disease: Malabsorption is managed with oral pancreatic enzymes. Diabetes necessitates dietary control and insulin; the use of oral hypoglycemic agents is controversial. Intestinal obstruction is treated with rehydration, nasogastric suction, and hyperosmolar enemas. Surgery rarely is needed.

Nutritional management: Nutritional deficiencies are caused by malabsorption, decreases in food intake, and an increase in metabolic requirements due to the disease. Malabsorption must be controlled. Most patients need vitamin A and E supplementation. Enteral feedings should be offered to patients who lose weight despite aggressive dietary measures.

Genetic counseling: Patients and their relatives should be offered nondirective counseling concerning carrier testing and the risks of having a CF-affected child.

Gene therapy: CFTR vectors have been given to CF patients, either to the nose or lungs or both. The efficacy and safety of this intervention are under study.

[Chapter 370](#)

APPROACH TO THE PATIENT WITH DYSPNEA

DEFINITIONS AND PATHOPHYSIOLOGY

The term *dyspnea* is used to describe a variety of perceptions of difficulty or distress relating to breathing. Several factors may be identified that help determine whether a given pathophysiologic condition is associated with dyspnea. There may be an increased ventilatory requirement or a reduced ventilatory capacity. Even if ventilatory requirements are within a person's capacity, the ventilatory effort may be increased by such factors as abnormal lung mechanics or respiratory muscle fatigue. Finally, for any condition to cause dyspnea, there must be sensory perceptions related to breathing and ventilatory stimuli.

DIFFERENTIAL DIAGNOSIS

Acute dyspnea: Dyspnea developing over minutes to days most often reflects an acute cardiac or pulmonary process. Cardiovascular causes include thromboembolism, pericardial disease, and pulmonary edema due to myocardial or valvular dysfunction. Pulmonary processes likely in this context include diffuse airway obstruction; pneumonia; upper airway obstruction; compression of the lung by chest wall trauma or diaphragmatic or pleural processes; rapidly progressive inflammatory disease; or diffuse lung injury with noncardiogenic pulmonary edema.

Chronic dyspnea: Longstanding dyspnea is more likely to present diagnostic difficulty. [Table 351.1](#) categorizes causes of chronic dyspnea according to pathophysiologic mechanism.

HISTORY AND PHYSICAL EXAMINATION

It is important to establish the acuity of the symptoms and to determine the patient's current and past activity levels. Patients may have unconsciously reduced their activity levels to avoid symptoms of breathlessness. One should identify environmental, temporal, and postural factors that worsen the symptoms and ask about associated symptoms such as chest pain, cough, or syncope. The physical examination has to be comprehensive. Although attention should be directed at cardiorespiratory findings, signs of systemic diseases such as collagen vascular disorders, thyroid disease, or neurologic syndromes also should be sought.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

Acute dyspnea: For acutely ill patients, chest radiography to evaluate for pulmonary infiltrates or edema and arterial blood gas analysis to assess the adequacy of gas exchange are almost always indicated. Peak expiratory flow rates provide an objective measure of the severity of airflow obstruction among patients with airway disease. Electrocardiography (ECG) is indicated whenever cardiac disease is known or suspected. Additional studies that might be indicated on the basis of the initial evaluation include perfusion lung scanning to evaluate for thromboembolism, echocardiography to assess valvular or ventricular dysfunction, and analysis of respiratory secretions or lung tissue to identify infectious agents or noninfectious inflammatory processes.

Chronic dyspnea: The cause often is evident from the results of history, examination, and basic screening tests such as hematocrit and blood chemistries. Additional tests should be selected with specific goals; no set sequence of diagnostic studies can be recommended. The most useful tests usually are measures of pulmonary function, including simple spirometry, lung volume, and diffusing capacity. Chest radiography usually is indicated to demonstrate focal or diffuse disease of the lung parenchyma and to assess cardiac size. Exercise testing may uncover dysfunction of a diseased organ system that had been adequately compensated at rest. A comprehensive exercise test includes measurement of respiratory gas exchange, ventilation, heart rate and blood pressure, ECG, pulse oximetry, and when appropriate, arterial blood gas analysis. The following studies are reserved for selected patients: spirometry with bronchoprovocation when asthma is suspected

despite normal results of pulmonary function tests, echocardiography chiefly for identifying valvular lesions and resting or exercise ventricular dysfunction, bronchoscopy for finding focal obstructing lesions of the airways, and computed tomography for confirming the presence of interstitial inflammatory diseases, which may require histologic examination for specific diagnosis.

MANAGEMENT

Treatment is directed at the underlying condition, if possible. For many disorders, however, particularly chronic obstructive pulmonary disease, interstitial lung disease, and pulmonary hypertension, treatment may not reverse the disease or relieve its symptoms fully. Nonspecific interventions include supplemental oxygen, which may relieve dyspnea even for some patients with normal arterial oxygen levels; narcotic analgesics; anxiolytics; and pulmonary rehabilitation.

Chapter 351

IDIOPATHIC PULMONARY FIBROSIS

DEFINITION, EPIDEMIOLOGY, AND PATHOPHYSIOLOGY

Idiopathic pulmonary fibrosis (IPF) is the prototypic interstitial lung disease and is characterized by progressive pulmonary parenchymal inflammation and fibrosis. Most patients receive the diagnosis in the fifth to seventh decades of life. Although no racial, seasonal, or geographic variations have been found, men appear to be at slightly greater risk than women. The true prevalence is unknown. The pathogenesis is highly complex and probably multifactorial; genetic, viral, environmental, and autoimmune factors have been implicated.

PATHOLOGY

The alveolar walls become progressively thickened by fibrosis. Alveolar spaces and vascular beds become obliterated, and the parenchymal architecture becomes distorted into multiple cystic structures surrounded by dense bands of fibrotic tissue. Fibroblasts are prominent, and the lymphocyte and plasma cell populations expand within the alveolar wall.

CLINICAL FEATURES

The symptoms are nonspecific. Most patients notice the insidious development of exertional dyspnea with or without a nonproductive cough. Constitutional symptoms such as fatigue, malaise, and weight loss are less common. With disease progression, patients may have dyspnea at rest and produce sputum. Exertional chest discomfort and peripheral edema are associated with the development of pulmonary hypertension and cor pulmonale. Although the physical findings can be normal in early stages of disease, chest auscultation usually reveals basilar inspiratory crackles. As the disease progresses, the crackles become coarser and more widespread, and digital clubbing and cyanosis may develop. The presence of a prominent P₂, palpable pulmonary arterial impulse, or right ventricular heave suggests pulmonary arterial hypertension. Jugular venous distention, hepatomegaly, and peripheral edema signal the development of cor pulmonale.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

Laboratory studies: Rheumatoid factor, antinuclear antibodies, and cryoglobulin may be present in low titer. The complete blood cell count usually is normal.

Chest imaging and pulmonary function tests: A chest radiograph typically shows bibasilar reticular opacities with reduced lung volume. As the disease progresses, the upper lung fields become involved, coarse polygonal markings (honeycombing) become evident, and pulmonary arterial enlargement and cardiomegaly may occur. High-resolution computed tomography is more sensitive than chest radiography in the detection of parenchymal abnormalities. Typical findings include reticular opacities, honeycombing, traction bronchiectasis, architectural distortion, and focal areas of ground-glass opacities. The distribution of these abnormalities usually is peripheral, subpleural, and basal. Static pulmonary function tests reveal the characteristic findings of restrictive lung disease, including reductions in forced expiratory volume at 1 second (FEV₁), forced vital capacity (FVC), and total lung volume with a normal or elevated ratio of FEV₁ to FVC. The diffusing capacity of the lung for carbon dioxide (D_{LCO}) is reduced, reflecting a loss of functional alveolar capillary gas exchange area. The resting arterial blood gas values may be normal but typically reveal some degree of hypoxemia and respiratory alkalosis. Carbon dioxide retention is a late finding. Cardiopulmonary exercise testing reveals diminished maximal oxygen consumption and exercise capacity, elevated physiologic dead space, and oxygen desaturation.

Bronchoalveolar lavage and biopsy: Bronchoalveolar lavage findings are highly variable and nondiagnostic. Transbronchial lung biopsy can help exclude the diagnosis if definitive diagnostic findings are recovered (e.g., infection, granulomatous inflammation, or malignant lesions); however, findings of nonspecific interstitial fibrosis must not be considered diagnostic of IPF because of the sampling error inherent to the technique. Surgical lung biopsy from multiple sites can better confirm the diagnosis and may be predictive of the response to therapy.

PROGNOSIS AND MANAGEMENT

The median survival period after the onset of symptoms is less than 5 years. Most patients experience steadily progressive deterioration. Patients with IPF have a 10% to 15% incidence of lung cancer.

For a few patients, treatment appears to stabilize or retard disease progression. Because patients rarely improve appreciably with glucocorticoid therapy alone, combination therapy with azathioprine or cyclophosphamide has been recommended as initial treatment. In the absence of complications or adverse effects of the medications, therapy should be continued for 6 months, at which time repeat studies should be performed to determine whether there has been objective improvement. Anecdotal reports suggest that methotrexate, D-penicillamine, antioxidants, colchicine, and cyclosporine occasionally are helpful, but there are no data to justify routine use of these agents. For patients who respond to therapy, treatment is continued indefinitely. Lung transplantation is a realistic option for many patients who do not respond to therapy.

Important adjuncts to therapy include smoking cessation, administration of supplemental oxygen to those with resting or exercise-induced hypoxemia, and judicious diuretic therapy for those with cor pulmonale. Pneumococcal and influenza vaccines should be administered to all patients.

Chapter 371

LUNG CANCER

DEFINITION, CLASSIFICATION, AND EPIDEMIOLOGY

The term *lung cancer* usually is applied to neoplasms arising from the respiratory epithelium (bronchogenic carcinoma). Bronchogenic carcinoma is divided into two major groups—small-cell lung cancer (SCLC) and non-small cell lung cancer (NSCLC). SCLC is part of the spectrum of neuroendocrine tumors. NSCLC includes adenocarcinoma, squamous cell carcinoma, large cell carcinoma, and their subtypes. In the United States, lung cancer is the second most common malignant tumor among both men and women. The diagnosis is made most typically between the ages of 55 and 74 years. The incidence among men has declined since peaking in 1984, whereas the incidence among women continues to climb. One-third of all cancer deaths are attributable to lung cancer.

ETIOLOGY AND PATHOGENESIS

Tobacco smoking is estimated to be responsible for 80% to 90% of cases of lung cancer. Exposure to environmental cigarette smoke and the smoking of pipes or cigars increase risk to a lesser degree. Indoor exposure to radon is thought to be responsible for 10% of cases of lung cancer in the United States. Other risk factors include asbestos exposure, chronic obstructive pulmonary disease (COPD), and diets lacking fresh fruits and vegetables. Lung cancer is thought to arise from

pluripotent respiratory epithelial stem cells that undergo neoplastic transformation as a result of the accumulation of numerous, carcinogen-induced genetic mutations.

CLINICAL FINDINGS

Local and regional effects: Coughing, or a change in a chronic cough, is the most common symptom and may be caused by bronchial mucosal invasion by tumor, postobstructive pneumonitis or atelectasis, tumor cavitation, or pleural effusion. Dyspnea and hemoptysis, usually blood-streaked sputum, each occur among about 50% of patients, and chest pain among about 40%. Pleural effusions occur among 10% of patients. The malignant effusions usually are exudative, lymphocytic, moderate to large in size, and ipsilateral to the main tumor. Extension of the cancer to the mediastinum can cause phrenic or recurrent laryngeal nerve palsy. Extension to the pericardium can produce effusions, tamponade, or dysrhythmia. Obstruction of venous return in the superior vena cava causes a syndrome of headache, facial fullness, jugular venous congestion, prominent collateral venous channels over the upper chest, and swelling of the face, neck, and upper extremities. Pancoast syndrome is invasion of the chest wall, brachial plexus, and sympathetic ganglion by a tumor in the superior sulcus. The symptoms are pain in the ipsilateral shoulder and scapula, pain in the ulnar nerve distribution, and Horner's syndrome (ptosis, miosis, and ipsilateral facial anhidrosis).

Metastatic effects: Common sites of metastatic spread are the adrenal glands, liver, central nervous system (CNS), and bone. Adrenal metastases usually are asymptomatic and detected as unilateral adrenal enlargement at staging computed tomography (CT) of the chest extended to the upper abdomen. Liver metastases are more common in SCLC (25%) than NSCLC (5%). Brain metastases occur most frequently with SCLC (10% at presentation) and adenocarcinoma, least often with squamous cell carcinoma. Skeletal metastases typically are osteolytic lesions of the vertebral bodies, ribs, and long bones of the extremities. SCLC has the highest propensity for bony metastases (25% of patients at initial staging).

Paraneoplastic effects: Approximately 10% to 20% of patients have paraneoplastic syndromes due to effects of lung cancer apart from the physical presence of the primary or metastatic lesions. Hypercalcemia, usually in association with squamous cell cancer, is the most common of these. It is caused primarily by tumor production of parathyroid hormone--related peptide. The syndrome of inappropriate secretion of antidiuretic hormone (SIADH) causes hyponatremia and inappropriately increased urine osmolality and is nearly always caused by SCLC. SCLC and pulmonary carcinoid tumors may cause Cushing's syndrome through ectopic production of corticotropin or corticotropin-releasing hormone. The Eaton--Lambert myasthenic syndrome occurs in 1% to 3% of cases of SCLC and is characterized by proximal muscle weakness, hyporeflexia, and autonomic dysfunction. Other autoimmune neurologic syndromes are less common. Cachexia is a common paraneoplastic syndrome of multifactorial causation. Clubbing of the fingers and toes may occur and often is accompanied by hypertrophic osteoarthropathy, painful periosteal inflammation of the lung bones of the arms and legs. Lung cancer can cause a hypercoagulability state and recurrent thrombophlebitis (Trousseau's syndrome).

DIAGNOSIS

The essential aspects of the evaluation are histologic differentiation of SCLC from NSCLC, accurate appraisal of the extent of the disease, and determination of the patient's performance status. Difficulty differentiating SCLC from NSCLC is unusual, but SCLC can be mistaken for carcinoid tumors or lymphoma. Differentiation of primary lung cancer from pulmonary metastatic lesions may necessitate special immunohistochemical tests.

Imaging studies: Chest radiography is 70% to 80% sensitive in detection. Squamous cell carcinoma often manifests as a perihilar mass that may cavitate, adenocarcinoma as a solitary peripheral nodule or mass, large cell carcinoma as a large peripheral mass, and SCLC as a rapidly enlarging central mass with early hilar and mediastinal spread. CT provides further definition of the appearance of the primary lesion; may depict concurrent lymphadenopathy, parenchymal disease, or pleural involvement; and guides diagnostic maneuvers.

Biopsy techniques: The sensitivity of sputum cytologic examination is highest for central squamous cell cancer but less than 20% for peripheral nodules. The yield of cells from thoracentesis of a malignant pleural effusion is 50% to 70%, depending on the number of samples submitted. Diagnostic techniques that can be used during flexible fiberoptic bronchoscopy include forceps biopsy, brushing, and washing. The diagnostic yield is high for central lesions, especially if the tumor is endoscopically visible. For peripheral lesions sampled with fluoroscopic guidance, the yield ranges from about 15% for lesions smaller than 2 cm in greatest dimension to 80% for lesions larger than 4 cm. Transbronchial needle aspiration of paratracheal, subcarinal, and hilar lymph nodes can be helpful in staging, although a negative result does not exclude lymph node metastases. Transthoracic needle aspiration may be used to sample peripheral lesions or those with extension to the mediastinum, pleura, or chest wall. The false-negative rate is 10% to 20%, however, so a negative result cannot be interpreted as a diagnostic end point unless a specific benign diagnosis can be made from the aspirate. The procedure is associated with a 15% to 30% incidence of pneumothorax. Thoracic surgical procedures may be used to exclude metastatic spread to mediastinal lymph nodes. This operation is necessary for any patient with NSCLC who has mediastinal nodes larger than 1 cm in greatest dimension and is considered a candidate for thoracotomy and surgical resection of the primary lesion.

STAGING

Non--small cell lung cancer: Staging is based on the TNM classification, in which *T* refers to the size and location of the primary tumor, *N* to the local lymph node involvement, and *M* to the presence of distant metastasis. There are eight stage groupings: 0, IA, IB, IIA, IIB, IIIA, IIIB, and IV. The 5-year survival rate ranges from 67% for stage IA (tumor smaller than 3 cm in greatest dimension without nodal or distant metastases) to 1% for stage IV (any case with distant metastasis). All patients with NSCLC should undergo a complete blood cell count, serum chemical profile (including liver enzymes), chest radiography, and chest CT to the level of the adrenal glands. If the findings are normal, no further testing is necessary. Liver imaging with contrast CT or ultrasonography is recommended if hepatomegaly is detected or liver test results are abnormal. Radionuclide bone scanning is warranted when the patient has hypercalcemia, focal bony abnormalities, or an increased bone alkaline phosphatase level.

If NSCLC is believed to be resectable, the clinician must determine whether there are medical contraindications to surgery and whether there is adequate pulmonary reserve for a curative lung resection. Between 80% and 90% of patients with lung cancer have COPD. Patients with a forced expiratory volume in 1 second (FEV₁) greater than 1.5 to 2 L (or 60% of predicted value) and a diffusing capacity of the lung for carbon dioxide (D LCO) greater than 60% of predicted value can proceed directly to thoracotomy. Patients with lower values need quantitative ventilation-perfusion lung scanning and arterial blood gas analysis. Either a Pco₂ greater than 45 mm Hg or a predicted postoperative FEV₁ less than 0.8 L (or less than 40% of predicted value) indicates high risk of postoperative problems.

Small-cell lung cancer: The TNM staging system usually is not applied to SCLC because of the limited role of surgery and because more than 90% of patients have locally advanced (stage III) or metastatic (stage IV) disease when they come to medical attention. Cases instead are classified as *limited* (tumor confined to one hemithorax and its regional lymph nodes) or *extensive* (everything else) disease. Pretreatment evaluation includes the tests for NSCLC described earlier. In addition, because two-thirds of patients have extensive disease when they come to medical attention, it is prudent to obtain a radionuclide bone scan and perform either CT or magnetic resonance imaging of the brain.

MANAGEMENT

Non--small cell lung cancer stages I and II: Surgical resection with curative intent is the treatment of choice for the 20% to 25% of patients with NSCLC that falls into these stages. The standard operation is thoracotomy with mediastinal lymph node sampling combined with lobectomy, bilobectomy, or pneumonectomy. Less extensive resection should be reserved for patients with a pulmonary status that does not allow lobectomy. Adjuvant chemotherapy has not been shown to improve survival, and postoperative radiation therapy actually worsens outcomes. A follow-up chest radiograph should be obtained every 3 to 4 months for the first 2 years and every 6 to 12 months thereafter.

Non--small cell lung cancer stages III and IV: Studies have suggested that preoperative chemotherapy (with or without radiation therapy) followed by surgery improves survival among patients with stage IIIA disease and carefully selected patients with stage IIIB disease. Thoracic radiation therapy combined with platinum-based chemotherapy is recommended for inoperable stage IIIA and IIIB disease. Palliative radiation therapy alone is an option for patients with limited medical reserve. For the 50% of patients with NSCLC who have metastatic disease (stage IV) when they come to medical attention, there are no curative options. The median survival time is only 5 to 7 months. Radiation therapy can be used for palliation of brain or bone metastasis or to relieve bronchial or superior vena caval obstruction. Chemotherapy provides a modest survival benefit (1.5 months) over supportive care.

Small--cell lung cancer: SCLC is highly responsive to current systemic therapy; the response rate is 80% to 90%. Current therapy for limited disease consists of four cycles of etoposide and either cisplatin or carboplatin, with thoracic radiation therapy administered concurrently with at least two of the cycles. Complete responses can be obtained by 50% of patients. The median survival time is 18 to 20 months, and the 5-year survival rate is 15% to 20%. Extensive disease is managed with the

same chemotherapy, but thoracic radiation therapy is not recommended. Complete responses are obtained in 25% of cases; the median survival time is 9 months, and there are almost no 5-year survivors. Prophylactic cranial irradiation is controversial and should not be considered unless the disease is in complete remission. This treatment decreases the rate of CNS relapse but may be associated with the late sequelae of cognitive dysfunction and ataxia.

Chapter 377

OBSTRUCTIVE SLEEP APNEA

DEFINITION, PATHOPHYSIOLOGY, AND EPIDEMIOLOGY

Obstructive sleep apnea (OSA) is characterized by the recurrent collapse of the pharyngeal airway during sleep. Most patients have anatomically small pharyngeal airways owing to obesity, small or posteriorly placed mandibles, or tonsillar hypertrophy. During sleep, a substantial decrement in the activity of the pharyngeal dilator muscles leads to the collapse of the airway. Progressive hypoxemia and hypercapnia then stimulate respiratory effort, which awakens the patient. The dilator muscles reactivate, and airway patency and ventilation are restored. When hypoxemia and hypercapnia are corrected, the patient returns to sleep, and the process begins again. Studies have suggested that 4% of men and 2% of women have at least mild OSA.

CLINICAL CONSEQUENCES

Sleep fragmentation causes neurocognitive effects. Patients are sleepy, perform less well at many tasks, and perceive their quality of life to be substantially diminished. The hypoxemia and hypercapnia appear to be linked to cardiovascular consequences, such as systemic hypertension and mild pulmonary hypertension. Cardiac arrhythmia also has been reported. A relation to stroke and myocardial infarction has not been proved.

DIAGNOSTIC APPROACH

Symptoms and signs suggestive of OSA include (a) loud snoring, (b) witnessed apnea or gasping during sleep, (c) neck or collar size more than 16.5 inches (42 cm) for men and more than 15.5 inches (39 cm) for women, and (d) occasional dozing or falling asleep during the day when not busy or active. Snoring alone, unless a social nuisance, rarely necessitates further testing or treatment. The most commonly used diagnostic study for OSA is the in-laboratory split night study. During the initial 2 to 3 hours of the study, polysomnographic monitoring is used to determine the combined number of episodes of apnea and hypopnea per hour of sleep (respiratory disturbance index; RDI). *Apnea* is defined as complete cessation of ventilation for longer than 10 seconds. *Hypopnea* as a decrement in ventilation (generally more than 50%) associated with oxygen desaturation or arousal. Patients with symptoms and an RDI greater than 5 probably need therapy.

MANAGEMENT

Treatment is tailored to the severity of OSA. For patients with mild disease, behavioral approaches such as weight loss, maximizing nasal patency, avoidance of alcohol or sedatives near bedtime, and avoidance of a supine sleeping posture may be beneficial. For severe disease, the main therapeutic options are nasal continuous positive airway pressure (CPAP), dental appliances, and upper airway surgery. Nasal CPAP applies positive pressure through the nose to the pharyngeal airway, pneumatically splinting the airway open. It can be started during the second portion of the in-laboratory split night study and titrated to the pressure that abolishes the disordered breathing. It is highly effective for most patients, but compliance is difficult. Should CPAP prove ineffective or intolerable, dental appliances can be considered. Most are fabricated by a dentist and are used to advance the mandible and pull the tongue apparatus off the posterior pharyngeal wall. Upper airway surgery is aimed at enlarging the pharyngeal airway so that sleep-induced decrements in muscle activity do not lead to airway collapse. Most procedures include removal of the uvula and portions of the soft palate with or without advancement of the tongue or mandible. The success rate varies from 30% to 90% for different procedures. There are no effective methods of determining which patients will respond.

Chapter 382

APPROACH TO THE PATIENT WITH PLEURAL DISEASE

DEFINITIONS AND PATHOPHYSIOLOGY

Pleurisy is inflammation of the pleura with or without pleural effusion, an accumulation of excess fluid in the pleural space. The parietal pleura, unlike the visceral pleura and lung, is a highly sensitive surface. Injury and inflammation therefore cause pain. The presence of pleural effusion signifies that there is a dysequilibrium in the formation and removal of pleural fluid. An effusion may form because of alterations in hydrostatic or oncotic forces that favor the transudation of fluid into the pleural space (transudative effusion) or because of capillary protein leak or decreased removal of protein from the pleural space (exudative effusion).

CLINICAL FEATURES

Pleurisy: The patient has pain on breathing that can be minimal or severe. It is worsened by deep breathing, coughing, and sneezing. It may be relieved by manual pressure against the chest wall. Dyspnea is common. It is partially caused by voluntary and involuntary restriction in respiration. A large associated pleural effusion often contributes as well. Other associated symptoms depend on the cause of pleurisy. Examination shows splinted respiratory movements and a pleural friction rub (best heard at or near the end of inspiration). There also may be evidence of associated pleural effusion.

Pleural effusion: The patient may have no symptoms, may report pleurisy, or may have painless dyspnea. Examination shows decreased breath sounds and dullness to percussion on the affected side. There may be consolidative findings, such as egophony, in the atelectatic lung adjacent to the effusion.

DIFFERENTIAL DIAGNOSIS

Pleurisy: Pleurisy can be caused by direct trauma to the chest wall but most commonly is caused by viral infection; by extension of localized disease of the lung (pneumonia, pulmonary embolism), mediastinum (esophageal rupture), pericardium (pericarditis, Dressler's syndrome), or abdomen (pancreatitis, subphrenic abscess); or by systemic disease such as systemic lupus erythematosus, rheumatoid arthritis, sarcoidosis, or uremia. The presence or absence of pleural fluid may help differentiate these possibilities: viral, rheumatoid, and sarcoid pleurisy often lack effusions; bacterial pneumonia, lupus erythematosus, and postcardiac injury syndrome usually are associated with accumulation of pleural fluid.

Pleural effusion: Causes of transudative and exudative effusions are listed in [Table 358.4](#) and [Table 358.5](#).

LABORATORY STUDIES AND DIAGNOSTIC TESTS

Chest radiographs may show a pleural effusion or evidence of a condition such as pneumonia or pneumothorax. Pleural fluid analysis is the most helpful diagnostic test in establishing the cause of pleurisy or a pleural effusion and should include measurements of cell counts, protein, lactate dehydrogenase (LDH), glucose and amylase concentrations, pH, and appropriate cultures. A definitive diagnosis, such as finding malignant cells or specific organisms, can be established in only 25% of cases, but a presumptive diagnosis based on the clinical impression can be substantiated in an additional 50%. The fluid is characterized as an exudate if it meets any of the following criteria: (a) ratio of pleural fluid protein to serum protein greater than 0.5; (b) ratio of pleural fluid LDH to serum LDH greater than 0.6; or (c) pleural fluid LDH greater than 0.45 multiplied by the upper limit of normal of the serum LDH; (d) ratio of pleural fluid cholesterol to serum cholesterol greater than 0.3; or (e) pleural fluid cholesterol greater than 45 mg per deciliter. Essentially all patients with pleurisy have exudative effusions.

Examination of the aspirate: Straw-colored fluid is typical of all transudates. A milky effusion suggests chylothorax. Bloody effusion in the absence of trauma suggests pulmonary embolism, pleural neoplasm, uremia, postcardiac injury syndrome, or asbestosis. The presence of pus confirms the diagnosis of empyema.

Cell counts: A fluid leukocyte count of more than 10,000 per milliliter with polymorphonuclear predominance suggests bacterial pneumonia, pancreatitis, and lupus pleuritis. A low leukocyte count (less than 5,000 per milliliter) with lymphocyte predominance usually is found with tuberculous pleurisy. Pleural fluid eosinophilia (more than 10% of pleural leukocytes) occurs with pneumothorax, hemothorax, asbestosis, pulmonary embolism, and parasitic and drug-induced disease. It is rarely

associated with carcinoma or tuberculosis.

Protein and amylase: When exudative criteria are met with LDH but not protein measurements, malignant disease and parapneumonic effusion should be considered. An increased pleural fluid amylase level is found with pancreatitis, malignant disease, or esophageal rupture.

Glucose and pH: Causes of pleural effusion with low pH (less than 7.30) and a glucose level less than 50 mg per deciliter include empyema, esophageal rupture, rheumatoid pleurisy, lupus pleuritis, malignant disease, and tuberculous pleurisy.

Cytology: Pleural fluid cytology has a positive diagnostic yield among 40% to 90% of patients with malignant pleural tumors (high with adenocarcinoma but low with Hodgkin's disease). Tumors can cause effusions owing to local effects without directly involving the pleural space.

Other tests: The presence of immunologic markers in pleural fluid, such as rheumatoid factor and antinuclear antibody, suggest the presence of the associated diseases but with the exception of lupus erythematosus cells is not enough information for diagnosis. If the cause is unclear after pleural fluid analysis, other studies may be necessary, including ventilation-perfusion lung scanning, abdominal or chest computed tomography, bronchoscopy or thoracoscopy, and pleural biopsy (frequently needed for the diagnosis of tuberculous or malignant pleurisy).

MANAGEMENT

Treatment varies with the underlying disease. Drainage of the pleural space is necessary to manage empyema, esophageal rupture, some cases of pneumothorax, and parapneumonic effusion. Subphrenic abscesses also necessitate drainage. Metastatic pleural disease may respond to chemotherapy, but chemical pleurodesis or pleuroperitoneal shunt may be necessary for palliation. Lupus pleuritis and postcardiac injury syndrome respond rapidly to glucocorticoid therapy, and most patients with pleurisy obtain relief with nonsteroidal anti-inflammatory drugs.

Chapter 358

SARCOIDOSIS

DEFINITION, INCIDENCE, AND EPIDEMIOLOGY

Sarcoidosis is a systemic granulomatous disorder of unknown causation that most commonly affects adults. It occurs worldwide but may be more common in Scandinavian countries, the United Kingdom, Ireland, Japan, and the United States. The estimated prevalence ranges from 1 to 40 per 100,000 population. Within the United States, blacks have three times the incidence of whites.

ETIOLOGY AND PATHOGENESIS

The cause remains unknown. The disease most likely represents a hypersensitivity response to one or many agents (bacteria, fungi, chemicals) by a person with either an inherited or acquired predisposition. However, no infective agent or single antigen has been consistently linked to sarcoidosis. The basic pathologic lesion is noncaseating granuloma made up of radially arranged epithelioid cells with pale nuclei, a few multinucleated giant cells, and lymphocytic infiltration.

CLINICAL FINDINGS

Sarcoidosis may involve one or multiple organ systems. Most patients have nonspecific systemic symptoms such as fatigue, weight loss, fever, anorexia, and, occasionally, chills and night sweats.

Respiratory tract: The respiratory system is involved in more than 90% of cases. Symptoms typically include dyspnea, retrosternal chest discomfort, and nonproductive cough. Hemoptysis is rare. In fewer than 20% of cases, interstitial involvement causes inspiratory crackles in association with restricted lung volume and abnormalities of gas exchange during pulmonary function testing. Bronchial involvement often results in airflow limitation and bronchial hyperreactivity. Sarcoidosis of the upper respiratory tract occurs in 2% to 18% of patients and may produce nasal obstruction, recurrent or persistent sinusitis, and hoarseness. Chest radiographic abnormalities are classified as follows: stage 0, no abnormality; stage I, bilateral hilar adenopathy without parenchymal infiltrates; stage II, hilar adenopathy with parenchymal infiltrates; stage III, parenchymal infiltrates without hilar adenopathy; and stage IV, fibrosis with honeycombing, hilar retraction, bullae, or emphysema. Radiographic evidence of disease does not necessarily progress through all stages.

Lymphatic and hematologic systems: Palpable peripheral lymphadenopathy occurs in 5% to 30% of cases, especially in the cervical, epitrochlear, axillary, and inguinal regions. The nodes are discrete, mobile, and nontender. Splenomegaly occurs in 10% of cases. Peripheral lymphopenia is the most common hematologic manifestation, although mild anemia and thrombocytopenia also can occur.

Cardiac system: Serious cardiac involvement occurs among 5% to 10% of patients. Symptoms may include chest pain, palpitations, and even sudden cardiac death. Half of patients with cardiac sarcoidosis have abnormalities of rhythm, conduction, or repolarization. Other manifestations include pericarditis, papillary muscle dysfunction, and infiltrative cardiomyopathy with congestive heart failure. Echocardiographic findings can suggest the diagnosis; the diagnostic yield of endomyocardial biopsy is low.

Other organ systems: Ocular lesions occur among about 25% of patients, granulomatous uveitis being the most common finding. The symptoms include blurred vision, photophobia, and excessive lacrimation. Approximately 25% of patients have dermal manifestations such as erythema nodosum (painful, 1 to 2 cm, red nodules over the shins), lupus pernio (a violaceous nodular or plaque-like lesion over the nose, cheeks, and ears), and purple-red, indurated annular lesions. Neurologic manifestations, affecting fewer than 10% of patients, may include cranial nerve palsy (particularly unilateral facial nerve palsy), peripheral neuropathy, myopathy, hypopituitarism, and central diabetes insipidus. Headache and confusion, accompanied by cerebrospinal fluid lymphocytosis, reflect leptomeningeal sarcoidosis. Nephrolithiasis is the most common renal manifestation; it stems from the overproduction of calcitriol and consequent hypercalciuria with or without hypercalcemia. Clinically significant hepatic dysfunction is uncommon even though liver biopsy reveals granulomatous involvement of the liver in most patients. Up to one-third of patients have hepatomegaly or a cholestatic pattern of liver enzyme elevations.

Special syndromes: Symmetric parotid swelling associated with uveitis, with or without facial nerve palsy, is called *Heerfordt's disease*. Lofgren's syndrome, characterized by fever, arthralgia, erythema nodosum, and bilateral hilar lymphadenopathy, generally has a good prognosis.

DIFFERENTIAL DIAGNOSIS

Mimics of sarcoidosis include (a) infections by organisms that commonly trigger a granulomatous host response, such as mycobacteria, fungi, bacteria, and parasites, (b) occupational or lung diseases such as hypersensitivity pneumonitis, chronic beryllium disease, and other metal-induced lung diseases, (c) drug-induced granulomatous vasculitis, and (d) autoimmune disorders associated with granulomatous lesions, such as Wegener's granulomatosis, primary biliary cirrhosis, and Churg–Strauss syndrome.

DIAGNOSTIC EVALUATION

Diagnosis depends on compatible clinical signs and symptoms, histologic findings of noncaseating granuloma in affected organs, and the exclusion of other granulomatous diseases. Transbronchial lung biopsy has a diagnostic yield approaching 90%; other potential biopsy sites in a given patient include the conjunctiva, skin, lip, peripheral lymph nodes, and enlarged mediastinal lymph nodes. The specimens should be carefully examined and cultured for infectious organisms capable of causing granulomatous disease. Serum angiotensin-converting enzyme level is elevated in more than one-half of patients, but this elevation is not specific to sarcoidosis. The recommended baseline evaluation includes a complete blood cell count, liver chemical analysis, renal function tests, measurement of serum calcium and 24-hour urine calcium excretion, chest radiography, pulmonary function tests (including gas exchange), electrocardiography, and a slit-lamp examination of the eyes to exclude subclinical uveitis.

PROGNOSIS AND MANAGEMENT

Without therapy, stage I disease remits in 60% to 80% of cases, stage II in 50% to 60%, and stage III in less than 30%. Factors associated with a poor prognosis include older age at onset, black race, symptoms lasting more than 6 months, splenomegaly, lupus pernio, multiorgan involvement, and extrathoracic disease. Pulmonary infiltration that persists for longer than 2 years is unlikely to remit without therapy.

Glucocorticoids are the mainstay of therapy. In most cases, a 3-month period of observation before treatment allows assessment of disease activity. If there is interval deterioration in lung function or gas exchange, oral glucocorticoids should be started (e.g., 40 mg prednisone daily for 6 to 12 weeks with a gradual taper to 5 to 10 mg daily for 6 to 12 months). If steroids are ineffective or associated with severe side effects, methotrexate can be used (7.5 to 15 orally each week), often in combination with a lower dose of prednisone. Lung transplantation is an option for some patients; however, patients with sarcoidosis may have an abnormally high rate of rejection, and the disease can develop in the pulmonary allograft. Hydroxychloroquine (200 mg by mouth twice a day) is efficacious for cutaneous sarcoidosis and for hypercalcemia. Management of cardiac sarcoidosis may involve antiarrhythmic agents, pacemakers, and implantable defibrillators.

[Chapter 373](#)

APPROACH TO THE PATIENT WITH A SOLITARY PULMONARY NODULE

DEFINITION

A solitary pulmonary nodule (SPN) is a single circumscribed nodular density within the lung parenchyma.

DIFFERENTIAL DIAGNOSIS

Infectious granuloma and primary bronchogenic carcinoma each account for between 30% and 60% of SPNs in most series. Hamartoma constitutes about 6%, bronchial adenoma 2%, and metastatic malignant lesions 3% to 5%. Miscellaneous conditions (such as intrapulmonary lymph nodes, pulmonary infarction, and arteriovenous malformations) account for fewer than 5% of SPNs.

FACTORS THAT PREDICT A BENIGN RATHER THAN A MALIGNANT NATURE

Clinical features: The probability that a lesion is malignant increases progressively with increasing age. SPNs in patients younger than 35 years are malignant in fewer than 2% of cases. In contrast, SPNs are malignant in 15% to 30% of patients between the ages of 35 and 45 years and in more than 50% of patients older than 50 years. The presence or absence of symptoms cannot differentiate benign from malignant lesions. Although smoking history has predictive value, the risk of malignancy among nonsmokers older than 35 years is sufficiently high to justify aggressive evaluation.

Radiographic appearance: Various radiologic criteria have been applied to differentiate benign from malignant SPNs, including the size and growth rate of the lesion and the presence or absence of calcification. The likelihood of malignancy increases with increasing size of the lesion. SPNs smaller than 1 cm in diameter are benign in more than 90% of cases. Seventy percent of SPNs exceeding 2 cm and more than 90% of those larger than 3 cm are malignant. Lesions stable in size for 2 or more years are so rarely malignant that they can be followed with radiographs at 6 and 12 months. This approach is helpful when prior radiographs, not only reports, can be obtained. However, obtaining serial radiographs prospectively to assess the rate of growth before confirming the nature of the lesion is not recommended. Calcification within the SPN markedly reduces the chance of malignancy but does not exclude it. The pattern of calcification is of great importance. Dense, central calcification, multiple punctate foci, and a laminated pattern all are reliable signs that a lesion is benign. Large clumps of calcification within the lesion (popcorn pattern) are essentially pathognomonic for hamartoma.

Although these various features are useful in estimating the probability that a lesion is benign or malignant, they can be misleading. The only radiographic criteria that reliably prove that a lesion is benign are distinctive central, laminated, popcorn diffuse calcification within the nodule and lack of growth for at least 2 years.

DIAGNOSTIC TESTS

Computed tomography of the chest: Computed tomography (CT), especially thin-section CT, is far more sensitive than plain chest radiography in detecting calcification and can provide information about the size of the lesion, distribution of calcification, and regularity of the margin. Quantitative determination of the amount of calcification is reported in Hounsfield units (HU). There is a high likelihood of malignancy for lesions larger than 2.5 cm or with an irregular edge. Thus only lesions meeting all of the following CT criteria should be categorized as benign: (a) diffuse calcification (attenuation value more than 164 HU) occupying at least 10% of the cross-sectional area, (b) a smooth margin with no irregularity or spiculation, and (c) diameter less than 2.5 cm.

Other diagnostic studies: Positron emission tomography has been shown to discriminate accurately between benign and malignant lesions more than 2 cm in diameter but is not widely available. Flexible fiberoptic bronchoscopy (FFB) or percutaneous needle aspiration can be helpful, because thoracotomy may be avoided if a specific benign tumor can be established with either technique. Thoracotomy is needed, however, if the biopsy findings are nonspecific or normal. FFB helps establish the diagnosis of 40% to 80% of malignant SPNs but only 5% to 20% of benign SPNs. The diagnostic yield is greatest for lesions larger than 3 cm. Percutaneous needle aspiration has a greater yield but a higher rate of complications such as pneumothorax.

MANAGEMENT

An SPN usually can be resected by means of either video-assisted thoracoscopic (VATS) techniques or minithoracotomy. These techniques have less morbidity than conventional thoracotomy and are ideally suited to identification and resection of benign SPNs. If the lesion proves to be malignant at surgery, many surgeons extend the incision and perform conventional thoracotomy with curative intent. Because of the low risk of surgery for benign lesions, and the potentially fatal outcome if malignant lesions are not promptly resected, the prudent approach is to resect SPNs when there is not clear evidence of calcification on chest radiographs or CT scans and when ancillary studies (such as FFB or needle aspiration) have not supplied enough information to confirm a specific benign diagnosis.

The decision to proceed with surgery depends on many factors, including the likelihood that a lesion is malignant, the patient's overall physical condition and ability to withstand surgery, and the patient's desires. For example, for a patient with an asymptomatic SPN but such severe pulmonary disease that thoracic resection would be impossible, the clinician could justify following the lesion with serial chest radiographs. In contrast, "watching" a noncalcified SPN of indeterminate causation in a healthy 50-year-old patient cannot be justified. For a 30-year-old nonsmoker with a 1 cm, smooth-margined SPN, the decision to repeat chest radiography in 3 months would be reasonable. This approach would be ill-advised, however, if the same person had a history of heavy smoking, a larger nodule, or a lesion with irregular borders.

[Chapter 359](#)

APPROACH TO THE PATIENT WITH SUSPECTED PNEUMONIA

DEFINITION AND EPIDEMIOLOGY

Pneumonia is acute inflammation of the lung parenchyma. Lower respiratory tract infection affects 3 million persons annually in the United States, is the leading cause of death of infection in the United States, and is the sixth most common cause of death overall.

PATHOPHYSIOLOGY

The lungs are repeatedly inoculated with microorganisms from the upper airways and from inhaled aerosols. Inoculum size, bacterial virulence, and the state of host defenses determine the pathogenic potential of a microbial challenge. Host defense mechanisms normally include secretory immunoglobulin A, the epiglottis,

bronchial ciliary action, the cough reflex, and a variety of cellular and noncellular host factors at the level of the alveolus.

DIFFERENTIAL DIAGNOSIS

The most common pathogens associated with pneumonia are listed in [Table 361.4](#). Although the clinical presentation does not allow the clinician to make a specific etiologic diagnosis for patients with community-acquired pneumonia, certain pathogens cause pneumonia more commonly among persons with specific risk factors. Pneumococcal pneumonia occurs more commonly among the elderly and among patients with chronic obstructive pulmonary disease (COPD), cardiovascular disease, HIV infection, immunoglobulin deficiency, asplenia, and hematologic malignant disease. *Legionella* is an opportunistic pathogen; it is an important cause of pneumonia among patients with COPD who smoke, patients with renal failure, and organ transplant recipients. *Staphylococcus aureus* pneumonia often occurs among intravenous drug users and among patients in the convalescent phase of influenza. Gram-negative bacilli cause severe pneumonia almost exclusively among patients with COPD, alcoholism, and diabetes mellitus.

CLINICAL FINDINGS

Community-acquired pneumonia syndrome: Symptoms include coughing, with or without sputum production, change in the color of respiratory secretions, dyspnea, chest discomfort, fever or hypothermia, shaking chills, sweats, and pleuritic chest pain. Abdominal pain, anorexia, myalgia, and headache also occur. Physical examination may show fever, tachycardia, and tachypnea. In advanced cases, confusion, cyanosis, splinting, and labored breathing may occur. Localized, fine, crepitant rales are heard initially over the involved portion of the lung, and signs of lobar consolidation (bronchial breath sounds, whispered pectoriloquy, vocal fremitus, and dullness to percussion) may occur as the disease progresses. Extension to pleural surfaces is associated with pleuritic pain and signs of pleural effusion.

Cavitary pneumonia syndrome: Anaerobic infection usually manifests as a 3 to 5 week history of chronic, productive coughing. The sputum commonly smells putrid; the presence of this sign almost always confirms the diagnosis of anaerobic infection. Fever and chest pain occur in 50% of cases, hemoptysis and weight loss in about 30%. About 75% of patients have a risk factor for aspiration of oropharyngeal secretions (alcoholism, seizure disorder, dysphagia, cerebrovascular accident, and undergoing general anesthesia). Poor dental hygiene and periodontal disease often are present. Non-anaerobic infections that can manifest in a similar manner include tuberculosis, blastomycosis, coccidioidomycosis, cryptococcosis, and nocardiosis.

Laboratory and radiographic findings: Most patients have an elevated white blood cell count. Although a localized bronchopneumonia pattern is the most frequent finding, chest radiographs may show multilobar consolidation, cavitation, or large pleural effusions. Although the chest radiograph almost never allows conclusive identification of a specific infectious agent, certain features can be of diagnostic aid. Multiple, bilateral, cavitary infiltrates suggest infection by *S. aureus*. Cavitation also suggests gram-negative, *Streptococcus pneumoniae* type 3, or anaerobic infection. Anaerobic cavitations involve the right lung in 75% of cases and usually are in dependent segments, such as the posterior segment of the right upper lobe.

DIAGNOSTIC EVALUATION

Sputum staining: Sample collection should be directly supervised by a physician; otherwise, there is a 75% chance that the specimen will be of poor quality. Large numbers of epithelial cells (more than 25 per low-power field) reflect contamination with oral secretions. A predominance of gram-positive lancet-shaped diplococci on a Gram stain suggest *S. pneumoniae* infection. The presence of small gram-negative coccobacillary organisms likewise suggests *Haemophilus influenzae* infection. The presence of gram-positive cocci in tetrads and grape-like clusters suggests *S. aureus* infection. An acid-fast smear should be performed whenever a patient has subacute, chronic, or cavitary pneumonia; it may provide the first evidence of tuberculous infection. In these cases, examination of a potassium hydroxide wet-mount preparation may allow rapid diagnosis of blastomycosis, coccidioidomycosis, and cryptococcosis.

Sputum cultures: Culture of expectorated sputum is neither specific nor sensitive. It may be difficult to determine whether an isolated bacterial species is a pulmonary pathogen, a colonizer of the oropharynx, or a contaminant. Sputum cultures are valuable, however, in the diagnosis of certain subacute and cavitary types of pneumonia, such as tuberculosis and fungal pneumonitis.

Other tests: Two specimens for blood culture should be obtained from all patients who need hospitalization. A positive culture result occurs among only about 25% of patients with pneumococcal and gram-negative bacillary pneumonia but does offer definitive identification of the causative organism. A polymerase chain reaction assay for *Mycobacterium tuberculosis* can be performed. Rapid diagnostic tests are being developed in which nucleic acid amplification will be used to detect other microbes.

PROGNOSIS AND MANAGEMENT

Prognosis and indications for hospitalization: A rule to predict 30-day hospital mortality among patients with community-acquired pneumonia has been developed ([Table 361.2](#)). The prognosis is sufficiently good in categories I and II to consider outpatient management. Category III patients can be hospitalized briefly or treated as outpatients. Patients in categories IV or V need admission to the hospital.

Antibiotic selection: Selection of antibiotics is straightforward if a causative agent has been identified. However, initial therapy for community-acquired pneumonia is necessarily empiric because clinical and radiographic findings are nonspecific, and diagnostic testing cannot confirm the responsible microbe in most instances. Initial antibiotic therapy must be broad and should be administered promptly after the diagnosis is established. A delay from the time of admission to initiation of antibiotic therapy exceeding 8 hours is associated with an increase in mortality. Therapy can be adjusted to narrow-spectrum agents if an etiologic agent is identified and results of antimicrobial susceptibility tests are available.

A macrolide antibiotic is reasonable empiric treatment of outpatients. Erythromycin (250 mg by mouth every 6 hours for 14 days) provides excellent coverage for *S. pneumoniae*, *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, and *Legionella* organisms but is relatively inactive against *H. influenzae*. Clarithromycin (500 mg by mouth every 12 hours for 14 days) or azithromycin (500 mg by mouth on the first day then 250 mg by mouth each day for 4 days) can be used to treat smokers, who are at greater risk of *H. influenzae* infection, and of patients who experience unacceptable gastrointestinal symptoms with erythromycin. Acceptable alternatives include doxycycline (100 mg by mouth twice a day for 14 days) and levofloxacin (500 mg by mouth daily for 7 to 14 days).

Patients who need hospitalization usually are treated with parenteral antibiotics. Intravenous (IV) therapy with cefuroxime (750 to 1500 mg every 8 hours), ceftriaxone (1 g every 12 hours), or cefotaxime (1 g every 8 hours) plus erythromycin (1 g every 6 hours) is appropriate and has good activity against *S. pneumoniae*, *H. influenzae*, anaerobic, and *Legionella* organisms and many gram-negative bacilli. IV therapy with levofloxacin (500 mg daily) alone also is appropriate. Among patients with severe community-acquired pneumonia, likely pathogens include *S. pneumoniae* and *Legionella* organisms. *Pseudomonas aeruginosa* infection is rare except among patients with bronchiectasis, those who have received broad-spectrum antibiotics for 1 week, and those with deficient phagocytosis. Patients with one of these risk factors should receive piperacillin–tazobactam (3.375 g IV every 6 hours), imipenem (500 mg IV every 6 hours), or cefepime (1 to 2 g IV every 6 hours) plus erythromycin (1 g IV every 6 hours). An alternative regimen is levofloxacin (500 mg IV daily) plus gentamycin or tobramycin (1.7 mg per kilogram IV every 8 hours). Clindamycin is the drug of choice for anaerobic pulmonary infection. If clinical suspicion of tuberculosis is high, antituberculous therapy should be initiated while culture results are pending.

ADRENAL INSUFFICIENCY

DEFINITION, EPIDEMIOLOGY, AND ETIOLOGY

Adrenal insufficiency occurs when there is inadequate production of one or both of the two major adrenocortical hormones, cortisol and aldosterone. It can develop as a consequence of destruction or suppression of the adrenal cortex (primary adrenal insufficiency) or as a result of a failure of pituitary corticotropin production or renal renin secretion (secondary adrenal insufficiency).

Primary adrenal insufficiency usually occurs sporadically; the reported prevalence is 4 to 6 cases per 100,000 population. In the United States, the most common cause is autoimmune adrenalitis, which can be associated with other autoimmune disorders such as Hashimoto's thyroiditis, Graves' disease, type I diabetes mellitus, and pernicious anemia. Other causes include infection (tuberculous, fungal, cytomegalovirus), bilateral adrenal hemorrhage (sepsis, pneumonia, recent abdominal surgery, anticoagulation), infiltrative disease (lymphoma, amyloidosis, metastatic neoplasia), and congenital enzyme deficiencies. The most common cause of secondary adrenal insufficiency is suppression of corticotropin secretion with chronic glucocorticoid therapy. Other causes of decreased corticotropin production include pituitary tumors and pituitary infarction. Renin deficiency occurs with diabetic nephropathy, chronic renal failure, or the administration of indomethacin or angiotensin-converting enzyme inhibitors.

PATHOGENESIS

In primary adrenal insufficiency, there is destruction of the adrenal cortex with resultant inability to synthesize all major adrenal cortical hormones, including cortisol, aldosterone, and androgens. Secondary adrenal insufficiency develops as a consequence of either corticotropin or renin deficiency, leading to an isolated deficiency of either cortisol or aldosterone.

CLINICAL FEATURES

History: Symptoms of cortisol deficiency include fatigue, anorexia, weight loss, generalized muscle and joint aches, and abdominal pain. Patients with primary adrenal insufficiency, owing to the elevated production of corticotropin precursors, may have hyperpigmentation. They also may have postural light-headedness because of the loss of aldosterone production. Patients with secondary adrenal insufficiency from corticotropin deficiency may have symptoms related to the deficiency of other pituitary hormones, such as amenorrhea, erectile dysfunction, dry skin, cold intolerance, and lethargy.

Physical examination: Patients with primary adrenal insufficiency have hyperpigmentation of the skin and mucous membranes, particularly the dorsum of the hands, the palmar creases, the elbows and knees, and the nipples. Orthostatic hypotension can occur. Women have a decrease in body hair. Patients with pituitary corticotropin deficiency appear pale because of a decrease in the pigmentation of the skin. The presence of hypogonadism (decreased sexual hair, mammary gland atrophy among women, decreased testicular size) indicates concomitant deficiency of other pituitary tropic hormones.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

Aldosterone deficiency is associated with hyponatremia, hyperkalemia, metabolic acidosis, and urinary sodium excretion more than 20 mEq per liter. Because of intravascular volume contraction, serum urea and creatinine are increased. Cortisol deficiency is associated with normocytic anemia and leukopenia with relative lymphocytosis and eosinophilia. Fasting hypoglycemia may occur among patients who have been eating poorly.

Patients whose clinical features suggest adrenal insufficiency should undergo biochemical confirmation of the diagnosis. Because these tests can take a long time to process, therapy should be initiated and continued until the results are available. The corticotropin stimulation test serves as a good screening tool. Patients receive 250 µg of synthetic corticotropin, and serum cortisol levels are checked at baseline, 30 minutes, and 60 minutes. Increments of more than 10 µg per deciliter or peak values more than 20 µg per deciliter usually exclude adrenal insufficiency. A diagnosis of primary adrenal insufficiency is based on the finding of low random serum cortisol and aldosterone levels together with high levels of corticotropin and renin. Patients with secondary adrenal insufficiency related to inadequate corticotropin production have low corticotropin and cortisol levels but normal levels of aldosterone and renin. Those with secondary adrenal insufficiency related to diminished renin production have low renin and aldosterone levels but normal levels of corticotropin and cortisol. Additional studies may be useful in the evaluation of adrenal insufficiency, including adrenal computed tomography and tests of pituitary function.

MANAGEMENT

Chronic adrenal insufficiency: Physiologic doses of hydrocortisone usually are administered in a way that mimics the normal circadian rhythm of cortisol secretion (e.g., 10 to 15 mg on arising, 5 to 10 mg in the early afternoon, and 5 mg before bed). The maintenance therapy should be altered under conditions of physical stress (e.g., infection, trauma, or surgical procedures). Systemic infections associated with fever necessitate a doubling of the usual oral dose. Patients undergoing general anesthesia should receive about 300 mg parenteral cortisol in divided doses throughout the day of the procedure. Patients with primary adrenal insufficiency also need therapy with fludrocortisone, which has mineralocorticoid activity similar to that of aldosterone. The usual dose is 0.05 to 0.2 mg daily, adjusted according to serum electrolyte and blood pressure response. During hot, humid weather, a higher dose may be needed.

Acute adrenal insufficiency: Acute adrenal insufficiency is a medical emergency. It may develop as a result of progression of undiagnosed or untreated chronic insufficiency or in patients with chronic insufficiency who undergo acute physical stress without a concomitant increase in hydrocortisone doses. Patients have nausea, vomiting, rapid weight loss, and hypotension. Therapy should begin with an infusion of 5% dextrose in 0.9% saline solution (1 L in the first hour). If adrenal insufficiency has not previously been diagnosed, blood samples for hormone levels should be obtained as outlined earlier. A dose of 100 mg intravenous hydrocortisone should be given immediately and followed by a continuous infusion of 10 mg per hour for the next 5 hours.

[Chapter 407 and Chapter 408](#)

APPROACH TO AMENORRHEA

PATHOGENESIS AND ETIOLOGY

The menstrual cycle is controlled by the interaction of the hypothalamus (pulsatile secretion of gonadotropin-releasing hormone), pituitary (secretion of luteinizing hormone [LH] and follicle-stimulating hormone [FSH]), ovaries (follicular growth, ovulation, and corpus luteum formation), and uterus (cyclic growth and shedding of the endometrium). Abnormalities in any of these systems can cause menstrual abnormalities.

Primary amenorrhea is present when the first menses has not occurred by 16 years of age. It is usually caused by a genetic or congenital defect, particularly gonadal dysgenesis, and often is associated with disorders of puberty. Secondary amenorrhea is present when a woman who has undergone menarche experiences the absence of periods for a time greater than three of her previous cycle intervals. One common cause, of course, is pregnancy. Once that is excluded the causes can be listed as follows: hypothalamic dysfunction (35%, usually related to stress, poor nutrition, or strenuous exercise), pituitary disease (17%, usually hyperprolactinemia), which is the single most common cause of secondary amenorrhea, ovarian disease (10% with ovarian failure and another 30% with the polycystic ovary syndrome), and uterine disease (7%, often Asherman's syndrome of intrauterine synechiae). Adrenal hyperplasia, hypothyroidism, and ovarian and adrenal tumors also can cause secondary amenorrhea.

DIAGNOSIS

Primary amenorrhea: Evaluation should focus on breast development, the presence or absence of the uterus and cervix, and FSH level. If there is no breast development and the FSH level is elevated, the probable diagnosis is gonadal dysgenesis. If the uterus is absent, the probable diagnosis is müllerian agenesis. Karyotyping is indicated for patients with gonadal dysgenesis.

Secondary amenorrhea: Pregnancy must be excluded. Height and weight should be measured. Women who are more than 10% below their "ideal" body weight should be evaluated for anorexia nervosa. The evaluation includes a measurement of prolactin and FSH levels for all patients and thyroid testing and serum testosterone levels when there is still diagnostic uncertainty. High levels of prolactin suggest prolactinoma, though hypothyroidism, medications, and renal failure can be responsible. FSH levels are elevated in ovarian failure, which may be caused by premature menopause (women older than 30 years) or chromosomal abnormalities (women younger than 30 years). Patients also should undergo a progestin withdrawal test, which is performed by means of administration of medroxyprogesterone acetate (10 mg a day for 5 days) and monitoring any uterine bleeding. The absence of uterine bleeding suggests that endogenous estrogen levels are particularly low or that Asherman's syndrome is present. Uterine bleeding indicates that Asherman's syndrome is not present.

MANAGEMENT

Primary amenorrhea: In many cases, long-term therapy with estrogen and progesterone is needed to stimulate development of secondary sex characteristics and to protect bone mass. Women with gonadal dysgenesis due to 45X are at high risk of thyroid disease and diabetes mellitus.

Secondary amenorrhea: The underlying cause should be managed when possible (e.g., prolactinomas can be controlled with surgical resection or bromocriptine therapy). Because women with secondary amenorrhea are at risk of osteoporosis, some authorities recommend that all be treated with estrogen-progestin hormone replacement.

[Chapter 393](#)

CUSHING'S SYNDROME

DEFINITION AND ETIOLOGY

Cushing's syndrome is the clinical expression of the metabolic effects of persistent, inappropriate hypercortisolism. Exogenous administration of glucocorticoids is the most common cause. Pituitary corticotropin hypersecretion (Cushing's disease), usually from microadenoma, accounts for about 60% of noniatrogenic cases; ectopic production of corticotropin by tumors (most often lung cancer) accounts for an additional 10%. The diseases that cause corticotropin-independent elevations in cortisol secretion (adrenal adenoma, adrenal carcinoma, and adrenal hyperplasia) each account for approximately 10% of noniatrogenic cases.

CLINICAL FEATURES

History: Patients with Cushing's disease usually have had symptoms for 2 to 3 years before diagnosis. The earliest symptoms include weight gain, hypertension, and glucose intolerance. A redistribution of adipose tissue causes facial rounding, increased central adiposity, and thinning of the upper and lower extremities. Patients may have striae, easy bruising, and increased growth of body hair. Women may have irregularities of menses; men may have gynecomastia. Proximal muscle weakness and peripheral edema are common. Back pain and loss of height may occur if osteoporosis and vertebral compression fractures have developed. Cognition and affect may be impaired.

Patients with adrenal adenoma and adrenal hyperplasia have signs and symptoms similar to those of patients with Cushing's disease. Patients with ectopic corticotropin syndrome usually have a shorter duration of symptoms. Some have minimal symptoms of Cushing's syndrome because of the short duration of hypercortisolemia. Among these patients, very high levels of cortisol often are associated with manifestations of mineralocorticoid excess, including weakness from hypokalemia. Symptoms related to the underlying tumor also may be evident. Patients with adrenocortical carcinoma also have a shorter duration of symptoms before they seek medical attention. They typically have severe manifestations of androgen excess; for this reason, muscle atrophy may be less prominent.

Physical examination: The examination reveals plethora, a round face with preauricular fullness, a prominent upper lip, supraclavicular fossa fullness, and a cervicodorsal fat pad (buffalo hump) disproportionate to the degree of obesity. Patients have torso obesity but thin extremities with decreased muscle mass. Peripheral edema may be present. The skin is thin, and there are wide, purple striae over the abdomen and chest. Other skin lesions include tinea versicolor, verruca vulgaris, acne vulgaris, and hirsutism. Patients with ectopic corticotropin production or adrenocortical carcinoma may have abnormalities related to the underlying tumor, such as a palpable mass.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

Laboratory evaluation first requires confirmation of hypercortisolism by means of detection of either an elevated level of free cortisol in a 24-hour urine collection or an abnormal result of an overnight dexamethasone suppression test (the failure of 1 mg of dexamethasone given at 11 P.M. to suppress the serum cortisol level to less than 5 µg per deciliter at 8 A.M. the following day). If the screening test result is abnormal, further testing is needed to determine the cause of hypercortisolism ([Fig. 407.3](#)).

MANAGEMENT

Cushing's disease: Transsphenoidal selective resection of the pituitary microadenoma is the most effective therapy for pituitary corticotropin-dependent Cushing's disease. If the operation fails or cannot be performed, pituitary irradiation can be useful. When these treatments have failed, bilateral total adrenalectomy is the preferred treatment. The main disadvantage of this approach is that the pituitary tumor may continue to grow and become locally invasive and difficult to control (Nelson's syndrome). Various inhibitors of adrenal function have been used to suppress cortisol secretion, including aminoglutethimide, ketoconazole, and mitotane.

Other etiologic factors: Management of ectopic corticotropin syndrome entails surgical resection of the primary tumor followed by radiation therapy or chemotherapy if necessary. If the neoplasm cannot be resected, the use of adrenal inhibitors can be considered. Adrenocortical adenoma should be surgically removed. Adrenal hyperplasia can be managed with adrenalectomy or adrenal inhibitors. Adrenocortical carcinoma typically responds poorly to attempts at resection or chemotherapy.

[Chapter 407](#)

DIABETES MELLITUS

DEFINITION AND EPIDEMIOLOGY

Diabetes mellitus is a chronic metabolic syndrome caused by a relative or absolute deficiency of insulin. Although the condition is recognized because of hyperglycemia, the metabolism of fats and proteins also is affected. One in every 20 persons in the United States has diabetes. The condition with its complications is

the seventh leading cause of death of disease in the United States.

CLASSIFICATION, PATHOPHYSIOLOGY, AND ETIOLOGY

Type I diabetes accounts for 5% to 10% of cases of diabetes in the United States and usually has its onset in the first two decades of life. There is a familial predisposition. The disease is characterized by immune-mediated destruction of pancreatic islet β cells, absolute insulin deficiency, and a dependence on insulin therapy for the preservation of life. These patients are prone to ketosis.

Type II diabetes accounts for 90% to 95% of cases of diabetes in the United States and usually begins after 40 years of age. As with type I disease, there is a genetic predisposition. The disease is characterized by altered insulin secretory dynamics but retention of endogenous pancreatic insulin secretion, the absence of ketosis, and insulin resistance in target cells. Most patients are obese. Other associations include a family history of diabetes mellitus, hypertension, dyslipidemia, or a particular ethnic background (African American, Hispanic, Native American).

Secondary diabetes can occur with pancreatic disease or surgery, chronic liver disease, Cushing's syndrome, acromegaly, pregnancy, and the use of glucocorticoids. Women with gestational diabetes usually return to normal glucose tolerance after parturition.

DIAGNOSIS

Diabetes mellitus can be diagnosed when at least one of the following criteria is met: (a) unequivocal symptoms (polyuria, polydipsia, polyphagia, unexplained weight loss) and a random plasma glucose level of 200 mg per deciliter or more; (b) fasting plasma glucose (FBG) level 126 mg per deciliter or more; or (c) 2-hour plasma glucose level 200 mg per deciliter or more after the ingestion of 75 g glucose during an oral glucose tolerance test. In the absence of unequivocal hyperglycemia with acute metabolic decompensation, such as ketoacidosis, these criteria should be confirmed by means of another test on a different day.

COMPLICATIONS

Acute complications include diabetic ketoacidosis and hyperosmolar hyperglycemic nonketotic coma (described in the next entry). Two infections occur almost exclusively among patients with diabetes. Malignant otitis externa is potentially fatal, erosive *Pseudomonas aeruginosa* infection of the soft tissue and cartilage around the external auditory canal. It can cause progressive destruction of the temporal and petrous bones and requires vigorous debridement and prolonged therapy with intravenous (IV) antibiotics. Rhinocerebral mucormycosis is a very rapidly progressive invasive infection caused by the mycelia of *Mucor* and *Rhizopus* fungi. Aggressive surgical debridement and IV amphotericin B are the mainstays of therapy.

Chronic complications include neurologic deficits and accelerated vascular disease. The vascular disease is of two types: microangiopathy, characterized by thickening of capillary basement membranes and manifested principally in the retina and kidney, and macroangiopathy, increased frequency and severity of arterial atherosclerotic disease. The development of diabetic complications is likely multifactorial and caused by a combination of protein glycation, sorbitol accumulation within cells, glycosylation of basement membranes, platelet and endothelial dysfunction, and hemodynamic abnormalities. The Diabetes Control and Complications Trial (DCCT) firmly established the beneficial effects of improved glucose control on the risk of retinopathy, neuropathy, and nephropathy among patients with type I diabetes. Subsequent studies extended these findings to patients with type II disease.

Diabetic retinopathy: Diabetic retinopathy is the leading cause of blindness among working-age adults in the United States. The earliest stage is background retinopathy, which consists of microaneurysms, dot and blot hemorrhages, and exudates. It affects 80% of patients within 5 years of the onset of diabetes. With advancing disease, proliferative retinopathy develops and is characterized by neovascularization. Because laser photocoagulation has a dramatic effect in preventing visual loss among patients with high-risk retinal characteristics, a yearly comprehensive ophthalmologic examination is recommended for all patients who have had diabetes for more than 5 years.

Diabetic nephropathy: Diabetic nephropathy is the leading cause of end-stage renal disease in the United States. The risk increases with the duration of diabetes, although it is rare for nephropathy to develop after 25 to 30 years. The earliest clinical manifestation is a slightly elevated level of urinary albumin excretion (microalbuminuria) of 30 to 300 mg per day. There is associated glomerular hyperfiltration at this stage. With advancing disease, the amount of proteinuria increases to more than 300 mg per day, and the patient eventually has hypertension and a progressive decline in creatinine clearance. The development of nephropathy can be slowed with meticulous blood pressure control and the use of angiotensin-converting enzyme inhibitors by patients whose daily albumin excretion exceeds 30 mg, even if they have normal blood pressure.

Diabetic neuropathy: Diabetic neuropathy manifests as a peripheral neurologic deficit or autonomic dysfunction ([Table 411.6](#)). Among patients with distal symmetric neuropathy, neuropathic foot ulceration can necessitate limb amputation. There is no effective means of reducing the risk of neuropathy other than improved glycemic control. The risk of amputation, however, can be reduced by patient education about appropriate foot care, regular inspection of the feet by health care providers and patients, use of appropriate shoes and footwear, appropriate podiatric and podiatric referral, aggressive early control of foot ulcers, and appropriate use of vascular surgical intervention. Painful neuropathy can be managed with tricyclic antidepressants, gabapentin, carbamazepine, or topical capsaicin cream. Narcotics should be avoided because of the high risk of addiction in this setting and a predictable loss of effectiveness due to tachyphylaxis.

MANAGEMENT

Type I diabetes: There are three major components of therapy—a nutritional plan, exercise, and insulin dosage. Patient education is essential to successful therapy, and the treatment program must be sufficiently flexible to allow highly varied and changing lifestyles without sacrificing careful metabolic control. Dietary protein should contribute about 10% to 20% of the total daily calories, leaving 80% to 90% of the total to be distributed between dietary fat and carbohydrate. Foods that cause rapid increases in blood glucose level should be avoided.

Monitoring consists of measurement of glycosylated hemoglobin every 3 months and patient monitoring of blood glucose level, typically before meals and at bedtime and whenever hypoglycemia is suspected. Therapeutic objectives are listed in [Table 399.1](#). The insulin dosage needed for meticulous glucose control is typically 0.5 to 1.0 U per kilogram per day. During the honeymoon period of relative remission early in the disease, insulin requirements are less. During intercurrent illness, the necessary dosage may increase markedly.

Because patients with type I diabetes lack both basal and prandial insulin secretion, contemporary flexible insulin programs have multiple components. The most precise way to mimic normal insulin secretion is to use an insulin pump in a program of continuous subcutaneous insulin infusion. More commonly, basal therapy, usually about 40% to 50% of the daily insulin dose, is given as either intermediate-acting human insulin (NPH or lente) at bedtime with or without a small morning dose or as two daily injections of long-acting ultralente human insulin. Prandial insulin secretion is best duplicated by giving preprandial injections of rapid-onset regular insulin before each meal. Regular human insulin takes at least 20 minutes to become effective, but lispro insulin acts rapidly enough to be given immediately before a meal. Typically, 50% to 60% of the daily insulin is divided among the meals in proportion to carbohydrate content, although any given dose can be adjusted if the amount of food to be ingested differs from the patient's usual pattern or if the simultaneous blood glucose reading deviates from the target range.

Type II diabetes: The recommended treatment goals are fasting and preprandial glucose levels less than 120 mg per deciliter with glycosylated hemoglobin levels normal or near normal. Differing patient circumstances, however, such as advanced age and comorbid conditions, may dictate that higher degrees of hyperglycemia be tolerated. Normalizing weight among obese patients also is important. Because atherosclerotic risk is substantial among these patients, attention should be given to smoking cessation and meticulous control of hypertension and hyperlipidemia. Glycosylated hemoglobin levels should be obtained quarterly. Patient monitoring of FBG should be performed every day, and preprandial and bedtime levels should be checked periodically.

The treatment program consists of diet and exercise for all patients, and pharmacologic therapy for most. Moderate calorie restriction (250 to 500 calories less than average daily intake) usually is recommended for obese patients. Additional dietary principles include (a) balanced nutrient intake, (b) emphasis on appropriate alterations as necessary to achieve lipid and blood pressure goals, (c) adequate spacing of meals (4 to 5 hours), (d) consideration of consuming additional dietary fiber, and (e) avoidance of intake of rapidly absorbed simple sugars (sucrose, glucose, maltose) unless they are substitutes for other carbohydrates.

Many oral antidiabetic drugs are available. Sulfonylurea drugs such as glipizide and glyburide augment insulin secretion but may cause weight gain and hypoglycemia. Meglitinides such as repaglinide and nateglinide also augment endogenous insulin secretion. Because of their short duration of action, these agents

can be given at meals for extra flexibility. They also may cause hypoglycemia and weight gain. Metformin decreases hepatic glucose output and increases peripheral glucose utilization. It does not cause weight gain or hypoglycemia but may cause nausea, abdominal discomfort, and diarrhea. It is contraindicated in the care of patients with elevated serum creatinine levels, hepatic disease, or congestive heart failure, who are at increased risk of lactic acidosis. Metformin should be withheld in the period surrounding the use of intravenous contrast agents.

Thiazolidinediones such as rosiglitazone and pioglitazone enhance insulin sensitivity and augment uptake of glucose in muscle and adipose tissue. They work best in combination with insulin or other oral agents. Because use of troglitazone has been associated with hepatotoxicity, monthly monitoring of liver enzymes is recommended. α -Glucosidase inhibitors such as acarbose compete with carbohydrates for binding to the enzymes in the intestinal brush border that digest complex carbohydrates. They therefore retard gastrointestinal glucose absorption. The primary role of these drugs is in combination with other agents when glycemic targets have not been met. Unabsorbed carbohydrates can cause flatulence, nausea, abdominal pain, and diarrhea.

If diet and exercise do not yield satisfactory glucose control, an oral agent (generally a sulfonylurea, meglitinide, or metformin) usually is chosen as first-line therapy. Glycemic control is then assessed at intervals. The dose of the oral agent can be increased or additional oral agents with different mechanisms of action can be added to achieve optimal control. Because of the number of oral agents that can be used alone or in combination, insulin therapy may be unnecessary for patients with mild disease. For those with moderate disease, a single dose of NPH or lente insulin can be added at bedtime (usually 0.3 to 0.6 U per kilogram per day) to provide basal insulin therapy. For patients with severe disease (those with FBS greater than 250 mg per deciliter), more intensive insulin programs usually are necessary (0.5 to 1.2 U per kilogram per day) to attain glucose control. Options include continuous insulin infusion and the use of twice-daily injections of 70/30 insulin, which contains 70% NPH and 30% regular insulin. Although oral agents have traditionally been discontinued when insulin therapy is initiated, current strategies often combine insulin with one or more oral agents, particularly the agents that enhance the peripheral effects of insulin, such as metformin or the thiazolidinediones.

SCREENING

Because 35% to 40% of cases of type II diabetes mellitus are undiagnosed, screening is considered an important public health measure. Asymptomatic patients older than 45 years should have a FBG determination every 3 years. Screening at a younger age should be considered for persons who are at higher risk.

[Chapter 411](#)

DIABETIC KETOACIDOSIS AND HYPEROSMOLAR HYPERGLYCEMIC NONKETOTIC COMA

DEFINITIONS, EPIDEMIOLOGY, AND ETIOLOGY

Diabetic ketoacidosis (DKA) is acute, life-threatening, metabolic acidosis that represents the most extreme result of uncontrolled diabetes mellitus. It occurs most commonly among patients with type I diabetes mellitus but can occur with type II diabetes, particularly when there is a severe intercurrent illness. Hyperosmolar hyperglycemic nonketotic coma (HHNC) is an acute syndrome that occurs with uncontrolled type II diabetes mellitus. It usually affects elderly patients, particularly those with other underlying medical problems and concurrent infections.

PATHOPHYSIOLOGY AND DIAGNOSIS

Diabetic ketoacidosis: DKA develops as a consequence of severe insulin deficiency and an excess of the glucose counterregulatory hormones such as glucagon, cortisol, and the catecholamines. Hyperglycemia is caused by both decreased glucose uptake and utilization and increased hepatic gluconeogenesis. The hyperglycemia causes osmotic diuresis, hypovolemia, and large urinary losses of potassium and phosphate. Uninhibited lipolysis stimulates production of ketones (acetoacetate and β -hydroxybutyrate) from free fatty acids and produces metabolic acidosis and compensatory hyperpnea. The cardinal diagnostic features are hyperglycemia (250 mg per deciliter or more), ketosis (ketonemia or ketonuria), and acidosis (arterial pH less than 7.3 and serum bicarbonate less than 15 mEq per liter). Other features include an elevated anion gap, volume depletion, and Kussmaul's respirations. The degree of hyperglycemia need not be great; a large proportion of patients have a glucose concentration less than 350 mg per deciliter.

Hyperosmolar hyperglycemic nonketotic coma: Because insulin levels are sufficient to suppress lipolysis, ketosis and acidosis do not occur. For this reason, the syndrome tends to last longer than DKA before it is recognized clinically. The severity of hyperglycemia, hyperosmolarity, and dehydration tends to be worse than with DKA because of the more prolonged period of osmotic diuresis. The extreme hyperosmolarity causes dehydration of the brain and altered mental status. The diagnosis is confirmed when a patient with abnormal mental status has severe hyperglycemia (usually 600 to 1,200 mg per deciliter), elevated serum osmolarity (more than 350 mOsm per kilogram), and minimal or absent ketonemia or ketonuria.

MANAGEMENT

Diabetic ketoacidosis: Patients with mild acidemia can be treated at home as long as they can tolerate large amounts of oral fluid. For patients with more severe illness, hospitalization is necessary. Because average fluid losses are 10% of body weight, vigorous fluid supplementation is necessary to restore intravascular volume (1 to 2 L of isotonic saline solution over the first hour, 1 L per hour for the next 3 to 4 hours, then a decrease in rate based on clinical assessment). Insulin administration is initiated rapidly, unless there is evidence of severe hypovolemia or hypokalemia. An initial priming dose of 0.1 units of regular insulin IV per kilogram body weight is followed by a continuous infusion of regular insulin at a rate of 0.1 U per kilogram per hour. Because too rapid a decline in serum glucose levels can lead to cerebral edema, the insulin infusion rate should be adjusted about every 2 hours so that glucose levels decrease at a rate of approximately 100 mg per deciliter per hour.

Hyperglycemia usually resolves more quickly than metabolic acidosis. For this reason, when the glucose level reaches 200 to 300 mg per deciliter, glucose or dextrose is added to the intravenous fluids to allow continuation of the insulin infusion without the risk of hypoglycemia. At the same time, the insulin infusion rate is decreased to 0.05 U per kilogram per hour and maintained for at least 6 hours after the acidosis has resolved.

Serum potassium levels in DKA do not reflect total body levels, which are almost invariably reduced, because the acidosis and insulin deficiency cause a redistribution of potassium from the intracellular to the extracellular compartment. The potassium deficiency therefore becomes more evident as treatment progresses. If the patient is not treated, the deficiency places the patient at risk of cardiac arrhythmia. Potassium supplementation is given immediately unless the patient has anuria, has an initial serum potassium level more than 6.0 mEq per liter, or has hyperkalemic T-wave changes on an electrocardiogram. The recommended rate of potassium infusion ranges from 10 mEq per hour for those with initial levels of 5 to 6 mEq per liter to 40 mEq per hour for patients with initial serum potassium levels less than 3 mEq per liter.

The use of bicarbonate in the management of DKA is controversial. Bicarbonate should probably be restricted to cases of very severe acidemia (pH less than 7.0), although it may be beneficial for patients with marked acidemia (pH 7.0 to 7.1) who have severe underlying medical problems such as myocardial infarction, cardiac arrhythmia, or sepsis.

Hyperosmolar hyperglycemic nonketotic coma: The first priority is to restore intravascular volume. The rate of saline infusion is generally slower than in DKA, because the patients are usually elderly and may have cardiac or renal insufficiency. The initial rate usually is restricted to 1 L per hour until peripheral perfusion is normalized. Then hypotonic fluids are given at a rate that approximates twice urine output. The goal is gradual restoration of the normal metabolic state. Insulin therapy should be withheld until volume status is normalized because the movement of glucose and water from the extracellular to the intracellular compartment can precipitate shock. Even without insulin therapy, the plasma glucose level begins to decrease in response to intravenous fluids owing to hemodilution and improvement in renal blood flow and glucose excretion.

[Chapter 149](#)

APPROACH TO THE PATIENT WITH HYPERCALCEMIA AND HYPOCALCEMIA

DEFINITIONS AND PATHOPHYSIOLOGY

The normal range for total serum calcium level is about 8.9 to 10.1 mg per deciliter. Total serum calcium level reflects both bound calcium and ionized, or free, calcium. Only the former is metabolically active; it typically comprises about 50% of the total. Changes in the amount of bound hormone must be excluded as a cause of spurious hypocalcemia or hypercalcemia. For example, hypoalbuminemia decreases total serum calcium level by reducing the amount of bound calcium. The level of ionized calcium can be obtained directly in many laboratories and eliminates this potential source of confusion. Hypercalcemia is caused by disturbances of the calcitropic hormones (parathyroid hormone [PTH], calcitonin, and calcitriol) or from abnormal processes directly affecting bone resorption, intestinal calcium absorption, or mineral excretion. In contrast, defects in PTH secretion or resistance to PTH are the primary causes of permanent hypocalcemia.

DIFFERENTIAL DIAGNOSIS

Hypercalcemia: Many disorders can cause hypercalcemia ([Table 402.1](#)), but the most common are primary hyperparathyroidism (PHP) and malignant disease. Malignant hypercalcemia is caused by osteolytic metastasis, such as cancer of the breast, kidney, lung, or thyroid; hematologic malignant disease with skeletal infiltration, such as multiple myeloma; or secretion of humoral agents by nonparathyroid tumors, such as squamous cell carcinoma, carcinoma of the kidney or bladder, and malignant tumors of the ovary.

Hypocalcemia: The most common disorders are hypoparathyroidism and vitamin D deficiency associated with conditions such as chronic renal failure, malabsorption, or dietary deficiency. Other causes include pseudohypoparathyroidism (end-organ unresponsiveness to PTH), magnesium deficiency, medications (e.g., calcitonin, bisphosphonates, phosphates, foscarnet, pentamidine, citrated blood), osteoblastic metastasis, phosphate excess (e.g., tumor lysis syndrome or rhabdomyolysis), and pancreatitis.

CLINICAL CONSEQUENCES

Hypercalcemia: Because of the widespread use of multiphasic laboratory screening, many patients do not have symptoms at the time of diagnosis. Nephrolithiasis may cause renal colic, hematuria, and the passage of stones or gravel. Bone pain and tenderness may develop. Nonspecific symptoms include muscle weakness, depression, memory impairment, personality changes, pruritus, anorexia, constipation, polyuria, and polydipsia. Associations with peptic ulcers, pancreatitis, and hypertension are controversial. With severe or prolonged hypercalcemia, anemia, weight loss, coma, and death can occur. Symptoms and signs of any underlying disease also occur.

Hypocalcemia: Patients experience paresthesia, particularly in the oral area, muscle spasm, carpopedal spasm, and facial grimacing. In extreme cases, laryngeal spasm and convulsion occur. Central nervous system manifestations include irritability, depression, impaired memory, and psychosis. Cardiovascular effects include arrhythmia, bradycardia, hypotension, and impaired cardiac contractility. At physical examination, the Chvostek or Trousseau signs can be used to confirm latent tetany.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

Hypercalcemia: Current PTH immunoassays reliably confirm or exclude the diagnosis of PHP, although the hypercalcemia associated with use of thiazide diuretics and lithium can be associated with elevated levels. In PHP and malignant hypercalcemia, serum phosphate levels typically are depressed. Serum chloride levels tend to be mildly elevated in PHP but mildly depressed in malignant conditions. Other laboratory tests and imaging studies can be useful for investigating the possibility of malignancy or the other disorders listed in [Table 402.1](#).

Hypocalcemia: Among patients with PTH deficiency, serum phosphorus levels usually are increased, and PTH levels are low or undetectable. Serum vitamin D levels are low in this disorder and in vitamin D deficiency. Other laboratory tests and diagnostic studies can be useful in confirming or excluding other disorders in the differential diagnosis.

MANAGEMENT

Hypercalcemia: The necessity for short-term therapy is signaled by the occurrence of anorexia, nausea, mental status changes, hypertension, or worsening renal function in association with a serum calcium level greater than 13.5 mg per deciliter. Initial therapy is saline hydration, which increases renal calcium clearance. After any volume deficits have been restored, calciuresis can be further enhanced by combining large volumes of saline solution (up to 6 L per day) and intravenous furosemide (in doses up to 100 mg every 2 hours). Careful monitoring is required to prevent hypovolemia, hypervolemia, hyponatremia, or hypokalemia. Bisphosphonates inhibit osteoclasts and block mobilization of calcium from bone. Of these, pamidronate is the preferred agent; the effective dose is 30 to 90 mg administered as a single intravenous infusion over 24 hours. Glucocorticoids (40 to 100 mg prednisone in divided doses each day) are useful in treating hypercalcemia from vitamin D intoxication and granulomatous disease. Calcitonin (25 to 50 U parenterally every 6 to 8 hours) is particularly effective in treatment of patients with vitamin D intoxication, thyrotoxicosis, or immobilization. Because of adverse effects and the emergence of other effective therapies, mithramycin is now best reserved for particularly difficult or unusual situations.

Long-term therapy is best directed at the underlying disease. If hypercalcemia persists despite optimal management, options include hydration with or without furosemide, combination therapy with subcutaneous injections of calcitonin and low-dose prednisone, and therapy with bisphosphonates. For patients with PHP, parathyroidectomy is indicated if there is a history of symptomatic or asymptomatic renal stones, substantial or progressive bone loss, symptoms attributable to hypercalcemia, or a serum calcium level more than 11.5 mg per deciliter.

Hypocalcemia: The objectives of short-term therapy for hypocalcemia with tetany are to relieve symptoms and prevent laryngeal obstruction. The serum calcium level is best maintained at more than 7 mg per deciliter. For adults, 10 to 20 mL 10% calcium gluconate is given by means of intravenous push. If a patient can take oral medications, 100 mg calcium should be given every 2 hours with an increase in the dose to 500 mg if necessary. Otherwise, continuous infusion of 10 mL 10% solution added to 500 mL saline solution should be given over 6 hours. Long-term treatment depends on the cause. Vitamin D deficiency is managed with supplementation of that vitamin. In states of parathyroid deficiency or resistance, calcium and vitamin D supplements are used. However, this therapy can cause hypercalciuria owing to the PTH deficiency, and careful monitoring for nephrocalcinosis and nephrolithiasis is critical. Chlorthalidone often is added to decrease urinary calcium excretion.

[Chapter 402](#)

APPROACH TO HYPERLIPIDEMIA

PRESENTATION

Elevated total cholesterol and low-density lipoprotein cholesterol (LDL-C) levels, elevated triglyceride levels, and reduced high-density lipoprotein cholesterol (HDL-C) levels all are independently associated with increased risk of atherosclerotic cardiovascular disease (ASCVD). Markedly elevated triglyceride levels (more than 1,000 mg per deciliter) also are associated with risk of acute pancreatitis.

HISTORY AND PHYSICAL EXAMINATION

A complete history should be obtained, including the presence of ASCVD and calculation of the number of cardiovascular risk factors other than total cholesterol and LDL-C. Risk factors include age older than 45 years for men and older than 55 years for women (or premature menopause without estrogen replacement); definite myocardial infarction or sudden death before 55 years of age of a male first-degree relative or before 65 years of age of a female first-degree relative; current cigarette smoking; hypertension; diabetes mellitus; and an HDL-C level less than 35 mg per deciliter. Because an elevated HDL-C level is protective, one risk factor is subtracted from the total if the HDL-C level is more than 60 mg per deciliter. Evidence of the secondary causes of hyperlipidemia ([Table 31.3](#)) should be sought. The physical examination should include examination of the eyes for arcus corneae, the eyelids for xanthelasma, the palms for palmar xanthoma, the knuckles and Achilles tendons for tendon xanthoma, and the elbows and knees for cutaneous and tuberoeruptive xanthoma. The thyroid should be palpated and the major arteries

should be examined for vascular bruits.

DIFFERENTIAL DIAGNOSIS

[Table 31.3](#) outlines the diagnostic considerations for patients with dyslipidemia.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

All adults older than 20 years should undergo screening for hypercholesterolemia. For adults without established ASCVD, the total and HDL-C cholesterol should be measured in the fasting state. Patients with established ASCVD should undergo a full lipid profile, which consists of triglyceride, total cholesterol, and HDL-C levels after an overnight fast of at least 12 hours. The LDL-C level usually is calculated by means of subtracting the HDL-C level and one-fifth of the triglyceride level from the total cholesterol; however, this formula is not accurate if the triglyceride level exceeds 400 mg per deciliter. Once a lipoprotein disorder has been diagnosed, common secondary causes should be excluded by means of measurement of thyroid-stimulating hormone and fasting glucose; liver enzymes and serum albumin are measured in selected cases.

MANAGEMENT

Secondary causes should be actively sought and controlled. Obese persons should be encouraged to lose weight and sedentary persons to exercise. Every effort should be made to modify other cardiovascular risk factors. Additional management decisions depend on whether ASCVD or other cardiovascular risk factors are present (see [Table 31.2](#)). Aggressive management of hypercholesterolemia for patients with established ASCVD (secondary prevention) has been shown to reduce cardiovascular events and total mortality. For patients without ASCVD, primary prevention trials have shown that lowering total or LDL-C cholesterol among patients at high risk reduces the likelihood of cardiovascular events and mortality. The higher the level of LDL-C and the greater the number of risk factors, the greater is the potential benefit of drug therapy to lower LDL-C levels. Among persons considered to be at lower risk, the emphasis is more on dietary modification and less on drug therapy.

Diet therapy: To lower LDL-C level by means of diet modification, the intake of saturated fats must be restricted. Decreasing the intake of total fats and cholesterol also is beneficial although less important. Useful diet programs include those developed by the American Heart Association and the National Cholesterol Education Program. If therapeutic goals are not reached after 3 months, the patient should be referred to a registered dietitian for more detailed dietary instruction and implementation of a stricter diet (step II). If there is an inadequate response after another 3 months, drug therapy should be strongly considered. For patients with established ASCVD or numerous risk factors, the period of observation with diet alone can be shortened, and the stricter diet can be recommended initially.

Drug therapy: HMG-CoA reductase inhibitors (statins) are considered the drugs of first choice in most settings. They reduce hepatic cholesterol biosynthesis and generally lower LDL-C level by 20% to 30% at initial doses. Patient acceptance is high. Side effects include elevated liver enzyme levels (transaminases should be measured periodically), muscle or joint pain, and gastrointestinal upset. Among the lipid-lowering drugs, nicotinic acid (niacin) has the greatest effect in raising HDL-C level. The mechanism of action is unclear but probably involves a reduction in hepatic production of very low density lipoprotein (VLDL). It is particularly useful in combination with statins in the treatment of patients who cannot achieve LDL-C goals with a statin alone and patients who have combined hyperlipidemia and a persistently elevated triglyceride level or low HDL-C level with statin therapy. Patient acceptance of immediate-release niacin can be limited by the cutaneous flushing and pruritus it causes, although pretreatment with aspirin can relieve these symptoms in many cases. Sustained-release forms are better tolerated but may be more likely to cause hepatotoxicity. Other side effects include hyperglycemia, hyperuricemia, and exacerbation of peptic ulcer disease.

Bile acid sequestrants (resins), including cholestyramine and colestipol, accelerate the loss of bile acids in the stool and promote increased hepatic conversion of cholesterol to bile acids. They are a good choice for young, motivated patients with mild hypercholesterolemia and are useful in combination therapy with niacin or statins. They may aggravate hypertriglyceridemia. Other adverse effects include bloating, constipation, and interference with the absorption of other medications. Fibric acid derivatives, such as gemfibrozil, stimulate lipoprotein lipase activity and may reduce hepatic production of VLDL. They lower triglyceride levels effectively and generally raise HDL-C levels modestly, but they have limited ability to lower LDL-C levels. Their primary use, therefore, is in the management of moderate to severe hypertriglyceridemia. They are generally well tolerated but can cause gastrointestinal upset and muscle pain. The risk of myopathy increases when fibrates are used in combination with statins.

[Chapter 31](#)

HYPOGLYCEMIA

PRESENTATION

Symptoms may begin at plasma levels of about 60 mg per deciliter, impairment of brain function at approximately 50 mg per deciliter. The rate of decline in glucose level is not an important factor. Symptoms vary among patients but are usually consistent from episode to episode for each patient. Autonomic symptoms (sweating, trembling, anxiety, nausea, palpitation, hunger, and tingling) do not always precede symptoms of neuroglycopenia (confusion, abnormal behavior, visual disturbance, and seizure) and may not be present at all.

CLASSIFICATION

The long-established classification of hypoglycemia as fasting or nonfasting is less useful than one based on the clinical characteristics of the patient ([Table 400.1](#)). Persons who appear healthy are likely to have hypoglycemic disorders different from those experienced by persons who are ill.

DIAGNOSTIC EVALUATION

Healthy-appearing patients: Because the symptoms of hypoglycemia are nonspecific, it is necessary to verify a low plasma glucose level when spontaneous symptoms occur and to demonstrate that symptoms are relieved through correction of the hypoglycemia. Patients with frank hypoglycemia at evaluation should undergo immediate laboratory evaluation (see later); otherwise, a prolonged fast (up to 72 hours) should be undertaken (often starting in the outpatient setting and continuing in the hospital if necessary) until the patient has both symptoms of hypoglycemia and a plasma glucose level less than 45 mg per deciliter. Calorie-free and caffeine-free beverages are permitted during the fast.

The main diagnostic consideration is insulinoma. The diagnosis of endogenous hyperinsulinemic hypoglycemia is made at the end of the fast the laboratory findings are as follows: plasma insulin 6 μ U per milliliter or more (radioimmunoassay) or 3 μ U per milliliter or more (immunochemiluminescent assay), C-peptide 200 pmol per milliliter or more, proinsulin 5 pmol per milliliter or more, b-hydroxybutyrate 2.7 mmol per liter or less, increment of plasma glucose in response to 1 mg glucagon intravenously 25 mg per deciliter or more, and absence from the plasma of sulfonylureas. The insulin-secreting tumor can be localized with transabdominal ultrasonography, endoscopic ultrasonography, computed tomography, angiography, or a selective arterial calcium stimulation test.

Ill-appearing patients: It may be sufficient to recognize the underlying disease and its association with hypoglycemia and to take action to minimize recurrences of hypoglycemia. Confirmation of the suspected etiologic factor may be sought, such as low insulin and C-peptide levels in ethanol hypoglycemia, elevated insulin-like growth factor II levels in non-b-cell tumor hypoglycemia, low cortisol levels in adrenal insufficiency, and blunted plasma glucose responses to intravenous glucagon in hypoglycemia due to conditions that impair liver function, such as glycogen storage disease, sepsis, and congestive heart failure.

MANAGEMENT

Ultimately, hypoglycemia is managed best by controlling any underlying illnesses. Insulinoma is managed by means of surgical excision.

[Chapter 400](#)

HYPOTHYROIDISM

DEFINITIONS, PATHOGENESIS, AND ETIOLOGY

Thyroid deficiency can be caused by a primary defect in the thyroid gland (primary hypothyroidism, 95% of cases) or by inadequate production of thyroid-stimulating hormone (TSH) by the pituitary gland (secondary hypothyroidism, 5% of cases). In the United States, the most common cause is lymphocytic (Hashimoto's) thyroiditis, in which cytotoxic antibodies directed against thyroid follicular cells cause thyroid atrophy and fibrosis. This condition can be associated with other autoimmune diseases and occasionally occurs as part of a polyglandular endocrine deficiency state in which various autoantibodies impair the function of the thyroid, adrenal glands, parathyroid glands, and gonads.

Another variant of autoimmune hypothyroidism is caused by production of TSH-receptor blocking antibodies. Next in frequency is probably iatrogenic hypothyroidism caused by therapy for Graves' disease. Hypothyroidism among adults also can be caused by incomplete forms of hereditary enzymatic defects, medications that induce defects in hormone synthesis (e.g., aminosalicylic acid and lithium), and iodine deficiency. A self-limited interval of hypothyroidism typically occurs during the course of subacute (de Quervain's) thyroiditis, lymphocytic (painless) thyroiditis, and postpartum thyroiditis and among patients with functioning thyroid glands whose suppressive doses of thyroid supplementation are abruptly discontinued. Secondary hypothyroidism may be caused by pituitary tumor, postpartum pituitary necrosis (Sheehan's syndrome), or autoimmune hypophysitis.

CLINICAL PRESENTATION

The signs and symptoms vary greatly depending on the severity and duration of the thyroid deficiency, the patient's age, and the effects of concomitant illnesses. Among adults, early symptoms often are nonspecific and insidious in onset. These may include fatigue, lethargy, constipation, cold intolerance, muscle stiffness and cramping, carpal tunnel syndrome, and menorrhagia. There is a slowing of mental agility and motor activity, reduced memory, and weight gain in spite of a reduced appetite. The skin and hair become dry, and the hair thins and begins to fall out. Edema of the vocal cords may cause deepening of the voice. In severe hypothyroidism (myxedema), the patient appears pallid, depressed, and hypokinetic and has hoarseness, an expressionless face, sparse hair, and a large tongue. The skin is cool to touch, dry, and rough, and there are facial and periorbital puffiness and generalized edema. Goiter may or may not be present, depending on the cause hypothyroidism. With Hashimoto's thyroiditis, there is usually goiter in the early phases of the disease, but the gland later atrophies and is not palpable. Neurologic findings include a delayed relaxation phase of deep tendon reflexes, muscle weakness, and ataxia.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

The single most important test is measurement of the serum TSH, which is elevated among patients with primary thyroid disease of any kind and is in the low-normal to undetectable range among patients with pituitary or hypothalamic disease. Levels of serum total and free thyronine (T_4) are decreased in all forms of hypothyroidism. Measurement of total triiodothyronine (T_3) is less useful, because it is within the normal range among most patients. Thyroid autoantibodies (anti-thyroglobulin and anti-microsomal) are detectable in most patients with Hashimoto's thyroiditis. Radioiodine uptake studies have little diagnostic utility in this setting. Nonthyroid laboratory abnormalities include hyperlipidemia, anemia, and elevated levels of creatine kinase and lactate dehydrogenase. Electrocardiographic changes include bradycardia, low-amplitude QRS complexes, and flattened or inverted T waves.

MANAGEMENT

Subclinical primary hypothyroidism: Patients with early hypothyroidism often have only mildly elevated TSH levels (between 4 and 10 mU per liter) and T_4 levels within the normal range. The symptoms may be so minimal as to be overlooked, but studies have shown mild hyperlipidemia to be present in such cases. About 50% of such cases progress to overt hypothyroidism within 5 to 7 years. Early initiation of levothyroxine replacement in low dosage has been recommended, because it may eliminate progression from mild to overt disease and may reduce the cardiovascular risks of ongoing atherogenesis.

Overt primary hypothyroidism: Almost all patients can be treated with a single daily dose of synthetic levothyroxine. Because T_4 is converted to T_3 , normal serum concentrations of T_3 can be restored with levothyroxine alone. In general, the initial dose is 25 to 50 μg levothyroxine each day, with increments of 25 to 50 μg at 4 to 6 week intervals until a normal metabolic state is attained. This gradual approach to thyroid repletion is especially important for elderly patients and those with heart disease, because a sudden increase in metabolic rate may tax cardiac or coronary reserve. For patients with primary hypothyroidism, the best indication that a normal metabolic state has been achieved is a reduction in serum TSH level to the range of 0.5 to 1.5 mU per liter. On average, this requires a replacement dose of approximately 1.7 μg per kilogram per day for patients with Hashimoto's thyroiditis and 2.1 μg per kilogram per day for those who have undergone total surgical or radioiodine thyroid ablation. Dosage increases may be necessary during pregnancy or with progression of the underlying thyroid disease.

Overt secondary hypothyroidism: For patients with pituitary or hypothalamic disease, measurements of free T_4 usually are an accurate guide to the adequacy of replacement. In such circumstances, because of the theoretical risk of precipitating acute adrenocortical deficiency through augmentation of cortisol metabolism, it is traditional to treat patients with glucocorticoids for the first 10 to 14 days of thyroid replacement.

Myxedema coma: Any patient with long-standing hypothyroidism is at risk of stupor or coma. Patients also may have hypothermia, hypotension, hypoglycemia, hyponatremia, hypoventilation with hypercapnia, and seizures. Even with aggressive management, mortality ranges from 30% to 60%. When this condition is suspected, blood samples for TSH, free T_4 , and cortisol should be obtained. Intravenous treatment with thyroid hormones (e.g., 3 to 4 μg per kilogram levothyroxine followed by 100 μg per day thereafter and 10 μg of liothyronine every 8 hours) and hydrocortisone should follow immediately. Supportive care is essential, with special attention to ventilation. The dosages of some medications, such as digoxin, may have to be modified because of the altered distribution and slowed metabolism associated with profound hypothyroidism.

[Chapter 406](#)

HYPERTHYROIDISM AND THYROTOXICOSIS

DEFINITIONS, PATHOGENESIS, AND ETIOLOGY

Thyrotoxicosis is the term applied to the clinical and biochemical findings caused by the presence in the body of excess thyroid hormone. Not all patients with thyrotoxicosis have hyperthyroidism, a sustained overproduction of hormone by the thyroid gland. For example, in some types of thyroiditis, an inflammatory process causes leakage of preformed hormone from the gland. The patient has thyrotoxicosis, but the suppression of thyroid-stimulating hormone actually decreases new hormone formation and may cause a period of transient hypothyroidism after the stores are depleted. Thyrotoxicosis without true hyperthyroidism also can be caused by exogenous sources of excess hormone or by thyroid hormone derived from follicular cells outside the thyroid gland, such as functioning metastatic thyroid carcinoma and struma ovarii.

True hyperthyroidism can be caused by a hyperfunctioning autonomous nodule or toxic multinodular goiter, but the most frequent cause is Graves' disease, which occurs most commonly among women in their third or fourth decades. In Graves' disease, it is speculated that infectious factors initiate an immunologic cascade in susceptible individuals that stimulates lymphocytes that secrete immunoglobulins that stimulate the TSH receptor. The pathogenesis of the ophthalmopathic and dermopathic manifestations of Graves' disease is less clear, although pathologic examination shows inflammatory infiltration of the orbital muscles and lymphocytic infiltration of the dermis.

CLINICAL PRESENTATION

Thyrotoxicosis: Common symptoms include anxiety and nervousness, emotional lability, easy fatigability, insomnia, increased perspiration, heat intolerance, palpitations, dyspnea, weakness, hyperdefecation, and weight loss despite increased appetite. Signs common to all patients with thyrotoxicosis include hyperactivity; eye lid retraction; thyroid enlargement; hair thinning; warm, moist skin with a velvety texture; onycholysis; tremor; muscle weakness; hyperreflexia; and tachycardia with or without evidence of atrial fibrillation. The presentation may depend on the age of the patient; irritability, heat intolerance, and increased appetite are more

prevalent among younger persons, whereas weight loss and cardiac manifestations are more common among the elderly. Some elderly patients may have paradoxical apathy rather than hyperactivity (apathetic thyrotoxicosis).

Graves' disease: Patients may have any of the manifestations of thyrotoxicosis. Graves' ophthalmopathy is characterized by impaired eye muscle movement and periorbital edema with or without proptosis. When severe, the ophthalmopathy can be associated with corneal ulceration, optic neuritis, and optic atrophy. Infiltrative dermopathy, when present, usually occurs over the dorsum of the leg or feet, and has been called *pretibial myxedema*. The affected area usually is raised, plaque-like, and hyperpigmented and has a peau d'orange appearance.

Thyrotoxic storm: Thyrotoxic storm is a syndrome of exaggerated signs and symptoms of thyrotoxicosis with systemic decompensation likely to be fatal unless the patient is vigorously treated. The diagnosis is made clinically when a patient has proven thyrotoxicosis as well as fever (temperature usually greater than 38.5°C), tachycardia out of proportion to the fever, central nervous system signs (irritability, confusion, delirium or coma), and gastrointestinal disturbances such as nausea, vomiting, and diarrhea. Events known to precipitate thyrotoxic storm include withdrawal of antithyroid drug therapy, sepsis, surgical procedures, use of iodinated contrast agents, hypoglycemia, parturition, emotional stress, diabetic ketoacidosis, burn injury, vigorous palpation of the thyroid, pulmonary thromboembolism, and stroke.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

Thyrotoxicosis usually is associated with inability to detect TSH (when it is measured with a sensitive assay) and with an increase in levels of total and free thyronine (T_4) and triiodothyronine (T_3). Some patients have so-called T_3 thyrotoxicosis, in which only the T_3 level is elevated, or hyperthyroidism due to a TSH-secreting pituitary tumor, in which case the TSH level is normal or elevated. Once thyrotoxicosis is confirmed, the diagnosis of Graves' disease can be made clinically if either ophthalmopathy or dermopathy is present. Otherwise, additional studies are necessary to differentiate the possible etiologic factors. Patients with hyperthyroidism have increased thyroid radioiodine uptake. Patients with nonhyperthyroid thyrotoxicosis have decreased uptake. An ultrasound or radionuclide scan discloses whether there is a hyperfunctioning autonomous nodule or a toxic multinodular goiter. An immeasurably low thyroglobulin level suggests an exogenous source of thyroid hormone. Elevated titers of thyroid-stimulating immunoglobulin in the blood is strong evidence of Graves' disease. It is not possible to differentiate patients with thyrotoxic storm from those with uncomplicated thyrotoxicosis on the basis of routine thyroid studies. Other laboratory abnormalities associated with thyrotoxicosis include hypercalcemia and elevations in lactate dehydrogenase, transaminases, alkaline phosphatase, and angiotensin-converting enzyme activity. Bone densitometry may show osteopenia or osteoporosis.

MANAGEMENT

Thyrotoxicosis and hyperthyroidism: The adrenergic symptoms of thyrotoxicosis can be managed with β -blockers. Iodine (100 to 200 mg per day) acutely inhibits proteolysis of colloid within the gland and reduces release of hormone. Hyperthyroidism itself requires one of three therapies—antithyroid medications that block hormone synthesis, thyroidectomy, or thyroid ablation with radioactive iodine. Treatment with radioiodine is generally considered to be the most efficient and cost-effective, although it not appropriate for treatment of young patients (younger than 25 years) and pregnant women. Most patients need thyroid supplementation after treatment. Patients with Graves' ophthalmopathy may have an exacerbation after radioiodine therapy; the use of glucocorticoids for several weeks lowers this risk. The primary advantage of antithyroid drugs such as methimazole or propylthiouracil is that patients have an opportunity to remain euthyroid after discontinuation of therapy, if they enter a sustained remission (as sometimes occurs with Graves' disease). Leukopenia is a severe, though uncommon, side effect.

Thyroidectomy is infrequently performed. Candidates for surgery include those who decline radioiodine therapy and have had severe allergic reactions to antithyroid drugs or habitually do not take them; pregnant patients who cannot tolerate antithyroid therapy or who need very large doses; patients with unusually large goiters; and those in whom concomitant malignant disease is suspected. The most important side effect is hypothyroidism; laryngeal nerve injury and hypoparathyroidism also can occur.

Other manifestations of Graves' disease: Eye disease may occur independently of the thyroid disease and it may not improve with therapy for the hyperthyroidism. Initial therapy consists of elevation of the head of the bed, methylcellulose eye drops, nocturnal eye patching, and diuretics. In more severe cases, prednisone or orbital radiation may be needed. Graves' dermopathy may improve with therapy for the thyrotoxicosis. If not, potent topical or injected glucocorticoids may be beneficial.

Thyrotoxic storm: Supportive therapy includes control of dehydration and intravenous administration of glucose, vitamin B complex, and glucocorticoids. Propranolol may be used to suppress the adrenergic effects of thyrotoxicosis but must be given cautiously. Intravenous pressor agents may be needed to control hypotension. Large doses of an antithyroid medication should be given immediately (e.g., 100 mg propylthiouracil every 2 hours). Soon after antithyroid medication is given, potassium iodide is added to block further hormone release from the gland.

Chapter 406

PHEOCHROMOCYTOMA

DEFINITION, EPIDEMIOLOGY, AND ETIOLOGY

The term *pheochromocytoma* may be used for all catecholamine-secreting tumors, adrenal or extraadrenal, but is sometimes reserved for adrenal tumors only. Pheochromocytoma may be present in 0.1% to 0.5% of patients with hypertension. Most cases are sporadic and of unknown causation, although associations with some hereditary syndromes have been identified, such as multiple endocrine neoplasia [MEN] and von Hippel–Lindau disease.

PATHOGENESIS

Pheochromocytoma originates in chromaffin tissue. Most tumors (90%) are intraadrenal. The most common extraadrenal site is the organ of Zuckerkandl near the aortic bifurcation. The clinical manifestations vary somewhat depending on the relative proportions of secreted epinephrine and norepinephrine. Manifestations such as hypercalcemia and polycythemia are not explained by catecholamine excess and implicate the secretion of other neuropeptides in some cases.

CLINICAL FEATURES

Hypertension is the cardinal abnormality. In many cases it is sustained. In the others, baseline hypertension is associated with paroxysms of greater severity. Truly intermittent hypertension is unusual. Other features of the hypertension include severity, early onset, resistance to conventional therapy, and exacerbation by β -blockers. Patients have paroxysmal episodes characterized by various combinations of throbbing headache, anxiety, drenching sweats, tachycardia, palpitations, chest and abdominal pain, nausea and vomiting, tremor, and blanching followed by flushing. These episodes may occur spontaneously or after provocation by stimuli such as exercise or meals. Extraadrenal tumors have a greater tendency to metastasize than do adrenal tumors. Metastasis to bones, lymph nodes, and the liver can cause local symptoms and signs. Physical examination may show only hypertension. In some instances, abdominal palpation triggers more severe hypertension. Intravascular volume constriction may cause postural hypertension. Among patients with familial syndromes, the other manifestations of those syndromes may be apparent.

DIFFERENTIAL DIAGNOSIS

The clinical features of pheochromocytoma overlap those of many other disorders, including essential and secondary hypertension, thyrotoxicosis, anxiety states (including panic attacks), carcinoid syndrome, mastocytosis, paroxysmal tachycardia, vasodilatory headaches, intracranial lesions, atypical diencephalic seizures, and hypoglycemia.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

If possible, laboratory studies should be performed when the patient is in a drug-free state. The diagnosis is made with demonstration of excessive catecholamine secretion. Although the choice of biochemical studies is controversial, 24-hour urine collection for measurement of catecholamines or their metabolites (e.g.,

metanephrines or vanillylmandelic acid) is the most common study. Measurement of plasma catecholamine levels is an alternative, although only 80% of patients have unequivocal elevations. When results of initial testing are ambiguous, a clonidine suppression test can be performed. In this test patients with pheochromocytoma fail to have normal suppression of serum catecholamines with administration of clonidine. Preoperative tumor location is best accomplished with computed tomography (which is less effective for extraadrenal tumors), magnetic resonance imaging, or scintigraphy with metaiodobenzylguanidine.

MANAGEMENT

The only definitive cure is surgical resection of the tumor. Meticulous preoperative preparation is essential to avoid intraoperative hypertensive crisis. Phenoxybenzamine, a noncompetitive α -adrenergic blocker, is given at an initial dose of 10 mg by mouth twice a day with a dose increase of 10 mg every other day. Prazosin is an alternative. After about 2 weeks, this α -blockade allows reexpansion of the contracted plasma volume. β -Blockade is only occasionally necessary to manage tachycardia or tachyarrhythmia. β -Blockers should not be used before α -blockade is well established, because unopposed α -adrenergic agonism can cause a hypertensive crisis. After surgery, as many as one-third of patients have residual hypertension despite normal catecholamine levels, probably because of damage to the renal blood vessels. All patients need long-term follow-up care because metastasis or second primary tumors may become evident after long periods.

Chapter 408

PITUITARY TUMORS

PATHOGENESIS

Pituitary tumors represent at least 10% to 15% of all intracranial tumors. The tumors are almost always benign and expand slowly over years. The most common functioning tumor is prolactinoma, followed by growth hormone (GH)-secreting adenoma and corticotropin-secreting adenoma. Thyroid-stimulating hormone-secreting and gonadotropin-secreting tumors are rare. About 10% to 20% of the tumors secrete more than one hormone; a roughly equal number appear to be nonfunctioning. Pituitary tumors may occur as part multiple endocrine neoplasia type 1 syndrome. A single-cell somatic mutation rather than hypothalamic stimulation is likely to be the initiating event.

CLINICAL FEATURES

Endocrinologic features: The tumors may cause hypopituitarism, hypersecretion of one or more hormones, or both. Patients with nonfunctioning tumors usually have hypopituitarism. Hypogonadism may reflect destruction of pituitary gonadotropes, but more often is caused by suppression of secretion of gonadotropin-releasing hormone because of an elevation in prolactin level. Among women, hyperprolactinemia causes oligomenorrhea or amenorrhea, infertility, and galactorrhea. Among men, the symptoms are reduced libido, infertility, and erectile dysfunction. Acromegaly is a chronic disorder caused by hypersecretion of GH and secondary overproduction of insulin-like growth factor I (IGF-I). An increase in shoe, glove, or ring size is typical, as is a gradual coarsening of facial features that leads to a large nose, thick lips, and accentuated nasolabial and frontal furrows. Other symptoms include severe snoring, deepening of the voice, skin tags, arthralgia, manifestations of carpal tunnel syndrome, and increased perspiration. Hypertension, cardiac hypertrophy, insulin resistance, and hyperlipidemia are common. Corticotropin-secreting adenoma is discussed with Cushing's syndrome.

Neurologic features: A dull, generalized headache is the most common feature. Visual field defects occur among patients who have large tumors and suprasellar extension. The classic defect is bitemporal hemianopsia from compression of the optic chiasm, but the defects are variable and often asymmetric. Less common problems include cranial nerve palsy, seizures, and cerebrospinal fluid rhinorrhea. Infarction after tumor hemorrhage (pituitary apoplexy) can manifest dramatically with the acute onset of severe headache and meningism, vomiting, and progressive loss of consciousness.

DIFFERENTIAL DIAGNOSIS AND DIAGNOSTIC EVALUATION

Laboratory findings: Basal levels of pituitary hormones should be obtained. Serum prolactin levels greater than 200 ng per milliliter virtually confirm the diagnosis of prolactinoma. The differential diagnosis for lesser elevations includes prolactinoma, severe primary hypothyroidism, hypothalamic or stalk disorders, renal failure, and use of medications that interfere with the synthesis or secretion of dopamine (such as phenothiazines or methyldopa). The diagnosis of acromegaly can be confirmed with the presence of an elevated IGF-I level and failure of plasma GH to be suppressed by an oral glucose load.

Radiologic findings: Plain radiographs of the skull can help identify an enlarged sella, but computed tomography or magnetic resonance imaging is needed to demonstrate intrasellar lesions and to define the extent of suprasellar extension. Failure of a target gland (thyroid, adrenal glands, or gonads) occasionally causes loss of negative feedback and leads to hyperplasia of the corresponding pituitary cells, a situation that can mimic a true pituitary tumor.

MANAGEMENT

Treatment is aimed at reducing any hormonal oversecretion, preventing loss of pituitary function, and halting progression of tumor growth. Medical therapy for prolactinoma with a dopamine agonist such as bromocriptine often is successful, as is therapy with bromocriptine or octreotide in some cases of acromegaly. In most other situations, medical therapy is ineffective and treatment consists of pituitary surgery (usually by the transsphenoidal route) or radiation therapy. In general, good results are obtained for microadenoma, but it is rarely possible to cure large tumors with surgery. Pituitary apoplexy is managed with intravenous fluids and hydrocortisone; urgent surgical decompression may be necessary.

Chapter 403

PRIMARY ALDOSTERONISM

DEFINITION, EPIDEMIOLOGY, AND ETIOLOGY

Primary aldosteronism (Conn's syndrome) is caused by renin-independent inappropriate hypersecretion of aldosterone. It is present in at least 1% to 3% of patients with hypertension. Approximately 60% of patients have a single, benign adrenal adenoma; the others have bilateral adrenal cortical hyperplasia.

PATHOGENESIS

Excessive production of aldosterone increases renal potassium excretion and sodium retention. The consequent volume expansion suppresses plasma renin and decreases generation of angiotensin II.

CLINICAL FEATURES

The principal clinical findings are hypertension and hypokalemia. The hypertension is moderate to severe and may be complicated by stroke or proteinuria. The manifestations of hypokalemia include muscular weakness and tetany, polyuria from nephrogenic diabetes insipidus, and impaired glucose tolerance.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

Laboratory testing reveals hypernatremia, hypokalemia, and metabolic alkalosis. Patients have elevated urine and plasma aldosterone levels and suppressed plasma renin levels. The high ratio of aldosterone to renin (greater than 50) confirms the diagnosis of primary aldosteronism. For patients with equivocal results, one may test for the absence of aldosterone suppression by saline infusion or for an inability to stimulate renin production with captopril. Adenoma can be differentiated from hyperplasia by means of assessment of the response of aldosterone to changes in posture. Patients with adenoma have a decrease in aldosterone level with standing; those with hyperplasia have an increase. Adenoma can be localized with computed tomography or magnetic resonance imaging of the adrenal glands, adrenal scintigraphy, or selective adrenal venous catheterization and sampling.

MANAGEMENT

Patients with a single adenoma should undergo laparoscopic unilateral adrenalectomy. Hypertension is cured in 50% to 70% of cases, the electrolyte abnormalities invariably. Patients with bilateral adrenal hyperplasia do not benefit from bilateral adrenalectomy. Although hypertension improves, most patients continue to be hypertensive. Treatment with high doses of spironolactone, an aldosterone antagonist, is effective.

[Chapter 407](#)

APPROACH TO THE PATIENT WITH A THYROID NODULE

DEFINITIONS, EPIDEMIOLOGY, AND ETIOLOGY

Thyroid nodules are discrete swelling within the thyroid gland that are present in about 5% of the adult population. They are more common among women and older persons. Nodules are considered solitary if they are found within a gland that is otherwise normal to palpation. Adenomatous colloid nodules are the most common. These hyperplastic lesions are histologic features of multinodular goiter, which can manifest as a large dominant nodule in an apparently normal gland. Follicular adenoma is a benign neoplasm that is somewhat less common than colloid nodules. Thyroid cancer represents fewer than 10% of all clinically apparent nodules. Papillary carcinoma is the most common type (75%), followed by follicular (15%), medullary, and anaplastic carcinoma. Persons with a history of radiation exposure are at increased risk of papillary thyroid carcinomas; those with a family history of medullary thyroid carcinoma or multiple endocrine neoplasia type 2 are at substantial risk for that cancer. Lymphocytic or subacute thyroiditis occasionally manifests as regional or nodular thyroid enlargement. Additional causes include thyroid lymphoma, thyroid metastasis, abscess, and infiltrative or granulomatous disease.

PRESENTATION

Thyroid nodules usually are asymptomatic and discovered as a visible or palpable neck mass by the physician or patient. A few patients report dysphagia or hoarseness. Pain is infrequent and suggests subacute thyroiditis or spontaneous bleeding into a preexisting nodule. Physical characteristics of the nodule are not usually helpful in differentiating benign from malignant lesions, although the presence of a hard nodule, fixation to adjacent structures, vocal cord paralysis, and regional lymphadenopathy all substantially increase the likelihood of malignancy. A solitary nodule discovered during radiologic imaging of the neck should be evaluated if it exceeds 1 cm in diameter.

DIAGNOSTIC EVALUATION

Thyroid function should be assessed routinely. Measurement of thyroid-stimulating hormone usually is sufficient. If there is a strong suspicion of hypothyroidism or hyperthyroidism, free thyronine and triiodothyronine also should be measured.

Abnormal thyroid function: In a patient with hypothyroidism, a nodule likely represents regional thyromegaly associated with Hashimoto's (lymphocytic) thyroiditis. Measurement of thyroid autoantibodies is helpful in such cases. Patients with hyperthyroidism should undergo radionuclide scanning. A hyperfunctioning, or hot, nodule generally is a benign, autonomously functioning nodule. The presence of a hypofunctioning, or cold, nodule within a gland that otherwise has diffusely increased uptake necessitates fine-needle aspiration (FNA) because it may represent a malignant tumor associated with Graves' disease.

Normal thyroid function: Most patients have normal thyroid function. In these cases, FNA is the initial procedure of choice. Cytologic evaluation of the aspirate can indicate whether the nodule is benign (features consistent with colloid nodules, thyroiditis, or benign cysts), suspicious (hypercellular follicular lesions or Hürthle cell changes), or malignant. The designation of an aspirate as *suspicious* stems from the inability to differentiate benign follicular and Hürthle cell adenomas from their carcinomatous counterparts on the basis of cytologic appearance. If FNA does not provide a specimen adequate for a diagnosis, the procedure must be repeated. Although it is not recommended in the initial evaluation of a thyroid nodule, ultrasonography can be useful in guiding FNA when conventional techniques have not provided a specimen sufficient for diagnosis. Patients with multiple nodules larger than 1 cm in diameter should be treated with near-total thyroidectomy without FNA.

MANAGEMENT

About 65% of patients have a benign aspirate. These patients are best treated expectantly by means of assessment of the nodule over time with or without ultrasonography. Nodules that show considerable growth should be aspirated again. Suppressing therapy with thyroid hormone usually is not indicated for benign nodules. Patients with suspicious or indeterminate aspirates should be referred for surgery, because the possibility of malignancy cannot be excluded. Patients with malignant aspirates are treated surgically, usually with total or near-total thyroidectomy.

ALZHEIMER'S DISEASE

DEFINITION

Dementia is a progressive decline in intellectual function and clear consciousness. Alzheimer's disease (AD), the most common cause, is a heterogeneous neurodegenerative illness that produces progressive memory loss, changes in behavior and personality, psychotic symptoms, and impairments in insight, judgment, and executive abilities.

DIFFERENTIAL DIAGNOSIS

Late-life dementia can be caused by conditions other than AD, including ischemic vascular dementia, Parkinson dementia, Pick's disease, frontotemporal dementia, and dementia with Lewy bodies.

EPIDEMIOLOGY, ETIOLOGY, AND PATHOPHYSIOLOGY

The prevalence of AD is about 3% among persons between 65 and 74 years of age. This figure climbs to 47% among persons older than 85 years. The pathologic features of AD are extensive neuron loss, numerous amyloid plaques, and abundant neurofibrillary tangles in vulnerable regions of the brain. Risk factors include age, the presence of an ApoE e4 allele, female sex, a history of head trauma, and having a first-degree relative with AD-like dementia. A small number of patients have an autosomal dominant form of AD.

CLINICAL FEATURES AND DIAGNOSIS

AD is characterized by the insidious onset of memory failure. Symptoms most commonly begin between the ages of 70 and 85 years but can occur as early as 40 years of age and as late as 90 years. During the first several years, patients may have difficulty with problem solving and word finding. They often have subtle personality and behavioral changes. As they withdraw from social situations, they may have symptoms that mimic mild depression. Although they may be aware that their memory is failing, persons with AD usually do not appreciate the extent of the problem. It is almost always a family member who brings the patient to medical attention.

A key diagnostic feature is documentation of memory loss as the earliest manifestation of the illness. Elements that strengthen the diagnosis include a family history of similar late-life dementia, normal results of routine blood studies (including those for thyroid disease and vitamin B₁₂ deficiency), the presence of one or more ApoE e4 alleles, an elevated cerebrospinal fluid t level, and magnetic resonance images that is either normal for age or shows mild generalized cortical atrophy. Findings that cast doubt on the diagnosis include the following: parkinsonism (slow gait, decreased arm swing, en bloc turning), early prominence of language impairment or confusion, symptoms or signs of frontal lobe involvement (disinhibition, perseveration, delusions, or hallucinations) within the first several years, the finding of any focal neurologic signs at examination, and seizures or myoclonus early in the course.

Diagnostic criteria are used to place patients into one of three categories—definite AD, probable AD, and possible AD. A diagnosis of probable AD requires (a) dementia with onset between 40 and 90 years of age, (b) cognitive deficits in two or more areas, (c) progressive memory and cognitive deterioration, (d) no other illness that could account for the dementia, and (e) no disturbance of consciousness. A definite diagnosis requires neuropathologic examination and the clinical criteria for probable AD.

PROGNOSIS AND MANAGEMENT

AD lasts 6 to 12 years on average. There are several components of treatment. First is education of the primary caregiver about the illness, the need for long-range planning, and how to maintain an appropriate living environment. Donepezil has become the standard symptomatic treatment. Its benefits are modest and do not occur for all patients. High-dose vitamin E (α-tocopherol) has been adopted as the standard disease-slowng treatment. Therapy for the behavioral, psychotic, and mood changes is accomplished through the gentle and short-term use of psychotropic, anti-anxiety, and hypnotic medications.

[Chapter 466](#)

CEREBROVASCULAR DISEASES

DEFINITIONS

Ischemic cerebrovascular events may be divided into three categories. *Transient ischemic attacks* (TIAs) are ischemic episodes of focal cerebral dysfunction that last less than 24 hours, usually only a few minutes, and are followed by complete recovery. Modern imaging techniques can depict evidence of cerebral infarction in a high percentage of cases. Therefore, TIAs, especially those of long duration, are best considered small strokes with transient signs and symptoms. *Stroke in evolution* describes signs and symptoms that worsen while the patient is being observed. *Completed stroke* denotes a relatively stable neurologic deficit caused by cerebral infarction. *Lacunar infarctions* are subcortical strokes almost always associated with hypertension.

ETIOLOGY AND PATHOPHYSIOLOGY

Transient ischemic attacks: The cause usually can be limited to one of three broad categories—vascular, cardiologic, or hematologic. The most common mechanism is probably platelet embolization from atherosclerotic extracranial or intracranial cerebral arteries.

Ischemic cerebral infarction: The cause is a reduction in blood flow below the level necessary to maintain tissue viability. Atherosclerotic disease of large arteries is the main cause and can trigger stroke either through occlusion at the site of atherosclerosis (thrombotic stroke) or through embolization to the cerebral vasculature (embolic stroke). Hypertension is the most important risk factor. Others include diabetes mellitus, hyperlipidemia, smoking, family history of vascular disease, and use of oral contraceptives. The extent of infarction is determined by the effectiveness of collateral circulation, possible vasospasm, development of brain edema, hemorrhage from damaged arterioles, and systemic factors such as hyperglycemia and hyperviscosity.

Hypertensive vascular syndromes: Lacunar infarction and hypertensive hemorrhage are caused by hypertensive damage to small arteries deep in the brain. If cases of trauma and ruptured saccular aneurysm or arteriovenous malformation are excluded, the classic type of intracerebral hemorrhage is almost always caused by hypertension.

CLINICAL FEATURES

Transient ischemic attacks: The most common presentation in the carotid artery territory is sudden onset of weakness, paralysis, or clumsiness in one or both extremities on the same side. Sensory symptoms also may be present. If the TIA involves the hemisphere dominant for language function, dysphasia is present. A transient loss of vision in one eye or part of one visual field may occur. In vertebrobasilar TIAs, the most common symptom is a motor defect such as weakness, clumsiness, or paralysis of any combination of extremities with or without sensory changes. The patient may have an unsteady gait, dysequilibrium, and vertigo. Diplopia or loss of vision (varying from complete blindness to partial blindness in homonymous fields) may occur.

The differential diagnosis includes classic migraine with scotoma, hemiplegic migraine, focal convulsive events, Ménière's disease, and peripheral vestibulopathy. Unlike TIAs, migrainous phenomena generally worsen gradually over several minutes. Headache may accompany TIAs but is generally brief and not severe. Focal seizures generally progress from the distal to the proximal portions of an extremity and may produce persistent neurologic deficits. Isolated vertigo without other motor and sensory symptoms rarely can be attributed to a TIA.

Ischemic cerebral infarction:

Middle cerebral artery: Infarction of the cortex supplied by the superior and inferior divisions of the middle cerebral artery causes contralateral hemiplegia (involving the face, hand, and arm, but sparing the leg), hemisensory deficit, homonymous hemianopsia, and if the dominant hemisphere is affected, both expressive and receptive aphasia. Occlusion of the superior division of the middle cerebral artery produces greater weakness and sensory loss in the face and arm than in the leg, with no visual field defect. If the dominant hemisphere is involved, expressive (Broca's) aphasia is present with impaired speaking, naming, and writing ability but relative preservation of comprehension. With occlusion of the inferior division, contralateral sensory loss predominates, and weakness may be minimal or absent. If the dominant hemisphere is involved, receptive (Wernicke's) aphasia is present with impaired comprehension and fluent speech output with jargon and paraphrasia.

Anterior and posterior cerebral arteries: Involvement of the former produces weakness, clumsiness, and sensory loss affecting mainly the contralateral leg and foot. Occlusion of the latter causes contralateral homonymous hemianopsia and may cause transient disturbance of memory due to infarction of the medial temporal lobe.

Basilar artery: Emboli tend to affect the distal portion, whereas atheromatous occlusion affects the proximal and middle portions. Distal vessel effects include loss of consciousness, unilateral or bilateral palsies of the third cranial nerve, and hemiplegia or quadriplegia with decerebrate or decorticate posturing. Consequences of occlusion of the proximal and middle segments include hemiplegia or quadriplegia and unilateral damage to the sixth cranial nerve or nucleus that causes impairment of horizontal eye movement.

Vertebral artery: Unilateral occlusion causes severe vertigo, nausea and vomiting, nystagmus, and loss of pain and temperature sensation in the ipsilateral face. Damage to the inferior cerebellar peduncle causes ipsilateral ataxia and Horner's syndrome and loss of pain and temperature sensation in the contralateral part of the body. Damage to the ninth and tenth cranial nerves causes hiccups and dysphagia.

Cerebellar infarction: Manifestations include difficulty standing and walking, headache, nausea, vomiting, dizziness, clumsiness, and slurred speech. With progression, most patients have lateral gaze palsy, nystagmus toward the side of the lesion, facial palsy, impaired cognitive function, or depressed consciousness.

Hypertensive vascular syndromes: Lacunar infarctions are the most common cerebrovascular lesions and occur most frequently in the deep nuclei of the brain, the pons, and the posterior limb of the internal capsule. Many are not recognized clinically. The onset usually is gradual, developing over several hours or days. Headache and alterations in consciousness are absent. The four major syndromes are (a) pure motor hemiparesis, with weakness of the face, arm, and leg but no associated sensory, visual or cortical deficits; (b) pure sensory stroke of the face, arm, and leg; (c) homolateral ataxia and crural (distal leg) paresis characterized by weakness of one leg, especially the toes and ankle, with Babinski's sign and striking incoordination of the ipsilateral arm and leg; and (d) lacunar state, a syndrome in which lability of affect, dementia, small-stepped rigid gait, dysarthria, incontinence, and bilateral long-tract signs are present.

Hypertensive hemorrhage most often occurs among persons older than 50 years. It occurs without warning while the patient is awake and often during exertion. Headache may be severe but is absent or trivial in one-half of cases. Vomiting is common; in thrombotic or embolic strokes it is rare. Blood pressure almost always remains elevated after onset. Once hemorrhage has occurred, the patient's condition worsens steadily over a period of minutes to days until the neurologic deficit stabilizes or the patient dies. Because much of the deficit is caused by compression rather than destruction, return of function as swelling subsides can be dramatic. Pontine hemorrhage produces coma, pinpoint pupils, impaired horizontal eye movements, quadriparesis, and hyperthermia. Deep cerebral hemorrhage occurs most commonly in the putamen and thalamus. The motor deficit is more severe in the former and the sensory defect more prominent in the latter. Either may be associated with aphasia if there is pressure on cortical speech areas. Cerebellar hemorrhage is sudden without loss of consciousness. Within several minutes, the patient cannot stand or walk and must vomit repeatedly. Headache and dizziness occur in about 50% of cases. Almost 90% of patients become comatose within 24 hours.

ANCILLARY STUDIES AND DIAGNOSTIC TESTS

Transient ischemic attacks: The evaluation is directed at detection of vascular disease. Risk factor assessment should be performed (see earlier). Abnormalities in the vascular system can be detected noninvasively with Doppler ultrasonography or magnetic resonance angiography, although cerebral angiography remains the most definitive test. Transesophageal echocardiography can help identify intracardiac thrombus or lesions such as patent foramen ovale. Testing for hypercoagulable states (such as factor V Leiden and deficiencies of protein C, protein S, and antithrombin III) may be indicated.

Ischemic cerebral infarction: The evaluation is similar to that described earlier. Computed tomography (CT) or magnetic resonance imaging (MRI) of the brain should be performed as soon as possible to rule out cerebral hemorrhage and tumor. In many instances, the CT findings are normal even when the patient has a severe clinical deficit. For these patients, immediate MRI or additional CT performed within 24 to 48 hours will reveal the area of infarction. Cerebral arteriography is not needed unless vasculitis or a cerebral aneurysm is suspected. Ultrasound evaluation of the cervical and intracranial vessels may be used to define the site of occlusion. In patients without evidence of atherosclerotic disease of the cervical carotid arteries, a thorough search should be made for a cardiac source of emboli.

Hypertensive vascular syndromes: Associated hypertension is present. The diagnosis is made clinically and with imaging studies.

MANAGEMENT

Transient ischemic attacks: Risk factor modification is mandatory. Studies of heparin or warfarin therapy have demonstrated little benefit except among patients with a hypercoagulable state or TIAs due to cardiac-origin emboli. Antiplatelet drugs such as aspirin (one to four 325-mg tablets daily) have been shown to reduce the incidence of TIAs and stroke. Clopidigrel or ticlopidine, antiplatelet agents more potent than aspirin, can be used to treat patients with recurrent TIAs taking aspirin who are not candidates for surgery. Carotid endarterectomy is the treatment of choice of patients with TIAs in the carotid distribution who have ipsilateral high-grade stenosis (greater than 60%) without complete occlusion.

Ischemic cerebral infarction: All patients with acute ischemic stroke who are seen within 3 hours of the time of symptom onset and have no evidence of hemorrhage on CT should be evaluated for treatment with tissue plasminogen activator, a thrombolytic agent. In a recent trial, thrombolytic therapy under these circumstances produced a 12% increase in the number of patients with a good clinical outcome 3 months after the stroke but also resulted in a 6% incidence of cerebral hemorrhage, almost one-half of them fatal. Anticoagulation with heparin may be used to treat patients with acute ischemic cardioembolic strokes. Its use to manage ischemic strokes is controversial owing to the increased risk of intracranial hemorrhage. The mainstay of treatment is good nursing care to prevent pneumonia and deep venous thrombosis in paralyzed or paretic limbs. Medical care is focused on the judicious management of hypertension, arrhythmias, and cardiac failure. Seizures, if present, should be controlled to prevent further cerebral damage.

There is extreme variation in outcome from stroke. The overall mortality rate is about 25% in the first month and approaches 50% at 5 years. Neurologic complications account for most deaths in the first week; later deaths usually are caused by heart disease and intercurrent infection. Most patients show some improvement after 14 to 21 days when the cerebral edema of infarction has resolved. In general, 50% of the potential recovery is attained 1 month from onset, 75% at 3 months, 90% at 6 months, and 100% at 1 year. Rehabilitation should begin early (days after onset).

Hypertensive vascular syndromes: Lacunar stroke syndromes are self-limited and relatively benign. Anticoagulation is not needed and may actually be dangerous because lacunar infarction often is associated with microhemorrhages. The prognosis for almost complete recovery is good; the likelihood of future lacunar strokes is reduced with adequate control of blood pressure. Cerebellar hematoma is managed by means of early surgical decompression, which may be life saving and often leads to complete reversal of the neurologic deficits. Surgery is not indicated for pontine or deep cerebral hypertensive hemorrhage, unless a large superficial hemorrhage has caused midline shift and herniation. There is no effective medical treatment. Glucocorticoids and dehydrating agents have given only temporary benefit. Attempts to lower blood pressure may compromise cerebral blood flow, but continued hypertension may cause cerebral edema. It seems reasonable to lower blood pressure carefully to normal levels with initial small doses of the less potent antihypertensive agents.

[Chapter 432](#)

DEPRESSION

DEFINITION

Depression is an affective syndrome occurring in unipolar or bipolar forms.

EPIDEMIOLOGY

The incidence of depression is 1% among men and 3% among women. The age at first episode of major depression has steadily decreased, with the mean age now 40 years for both sexes. Concomitant psychiatric conditions are common, including anxiety disorders and alcohol and substance abuse.

ETIOLOGY AND PATHOPHYSIOLOGY

Depression is two to three times more frequent among first-degree relatives of patients with depression. No cause of the disorder is known. Theories include (a) excessive activity of the hypothalamic-pituitary-adrenal axis; (b) disturbed functioning of catecholamines; (c) sleep and circadian rhythm disruptions; and (d) left frontal hypometabolism.

CLINICAL FEATURES AND DIAGNOSIS

Major depression is characterized by at least 2 weeks of a sad mood or loss of interest. The patient also must have four of the following symptoms (remembered with the mnemonic *SIG E CAPS*): sleep disturbance (usually early morning awakening); loss of interest; guilt or worthlessness; energy loss; impairment of concentration; change in appetite, usually a decrease; psychomotor agitation or retardation; suicidal or death wishes. Depressed patients may report irritability, deny sadness, or have vague somatic symptoms. No laboratory tests exist to confirm the diagnosis.

Major depression can be subcategorized as (a) atypical with hypersomnia, appetite increase, and hypersensitivity to rejection; (b) with psychosis (presence of auditory hallucinations and delusions); (c) postpartum, occurring within 4 weeks of delivery; and (d) pseudodementia (abrupt cognitive decline associated with depressive symptoms, primarily among the elderly). Dysthymic disorder is similar to major depression but the symptoms are less severe and are intermittently present for 2 or more years. In adjustment disorder, symptoms of depression or anxiety develop after exposure to an identifiable precipitating stressor. These symptoms typically disappear when the stressor is gone. Seasonal affective disorder is characterized by development of depressive symptoms (often the atypical symptoms described earlier) in fall or winter and a return to baseline in spring and summer. Bipolar disorder is characterized by one or more manic episodes, which consist of an elevated, expansive, or irritable mood and three of four of the following: grandiosity, decreases in sleep, excessive talking, racing thoughts, distractibility, and excessive involvement in pleasurable activities that have high potential for negative consequences, such as spending sprees.

PROGNOSIS AND MANAGEMENT

Suicide risk must be assessed for each patient. As many as 15% of depressed patients die by suicide. Women are three to four times more likely to make an attempt, but men are three times more likely to be successful. Suicide risk factors include psychosis, absence of social support, chronic medical illness, substance abuse, particularly of alcohol, and an organized plan with little chance of rescue.

Various antidepressants are equally effective, response rates averaging 70%. Patients must be informed that antidepressants are not immediately effective and must be taken daily for at least 2 to 3 weeks before symptoms improve. Drug selection is based on side effect profile and potential drug-drug interactions. Selective serotonin reuptake inhibitors are currently the best initial choice for most patients. The starting dose for fluoxetine or paroxetine is 20 mg per day (maximum 40 mg per day) and for sertraline is 50 mg per day (maximum 200 mg per day).

For patients who have not responded to maximum dosages after 4 to 6 weeks, treatment alternatives include a change to a different agent (e.g., a tricyclic agent such as desipramine or nortriptyline or an agent such as bupropion or venlafaxine), augmentation with lithium or thyroid hormone, consultation with a psychiatrist, or electroconvulsive therapy (ECT). ECT is the most effective therapy for major depression. Once a patient's symptoms have responded, antidepressants should be continued for 4 to 9 months at the same dose. Maintenance treatment for several years or longer is indicated for patients with age at onset younger than 20 years and a family history of bipolar disease, two previous severe episodes with early recurrence, or three or more previous episodes. Patients with bipolar disease can be treated with lithium, sodium valproate, and carbamazepine. Monotherapy with antidepressants may cause a conversion to mania.

[Chapter 39](#)

APPROACH TO THE PATIENT WITH DIZZINESS AND VERTIGO

PRESENTATION AND PATHOPHYSIOLOGY

"Dizziness" encompasses a variety of symptoms. A feeling of light-headedness or impending fainting may suggest hypotension and a cardiovascular cause. Vertigo is an illusion of motion of self or of the environment. Patients may describe sensations of spinning or tumbling. Vertigo is caused by an acute imbalance in the vestibular inputs from the two labyrinths or in their central connections. Patients with symmetric vestibular lesions (e.g., aminoglycoside toxicity) and those with a slowly developing unilateral lesion (e.g., schwannoma) may not have vertigo. Dysequilibrium is a feeling of imbalance while standing or walking. It may occur among patients with sensory deficits (e.g., blurred vision or bilateral vestibular loss), cerebellar disease, or efferent motor disorders such as Parkinson's disease or stroke. Dizziness that cannot be further characterized often accompanies anxiety, phobias, and panic attacks.

HISTORY AND PHYSICAL EXAMINATION OF A PATIENT WITH THE VERTIGO

The first issue is whether symptoms are acute or chronic and whether they have occurred more than once. If vertigo is episodic, the duration of episodes is important. Brief (less than 1 minute) episodes of vertigo precipitated by a change in the attitude of the head with respect to gravity are typical of benign paroxysmal positional vertigo (BPPV). Vertigo lasting for several minutes up to an hour suggests transient ischemic attacks (TIAs). Longer episodes can be caused by migraine, Ménière's disease, labyrinthitis, or central nervous system infarction. Associated hearing loss, tinnitus, or ear fullness suggests a peripheral vestibular cause, whereas symptoms of brain stem or cerebellar dysfunction implicate a central cause. In general, symptoms provoked by head movements or changes in head position with respect to gravity are the hallmark of a disturbance in the peripheral vestibular system.

A complete neurologic examination must be performed with particular attention to eye movements (nystagmus), hearing, other cranial nerves, coordination, gait, and balance. The eyes must be examined in the absence of visual fixation, which may suppress spontaneous nystagmus. This may be done either with Frenzel lenses or by looking for movement of the optic disc during direct ophthalmoscopy with the opposite eye occluded. Positioning maneuvers may help identify BPPV.

DIAGNOSTIC TESTS

Every patient with vestibular symptoms should undergo an audiogram. Low-frequency hearing loss is characteristic of Ménière's disease. Unilateral hearing loss raises the possibility of a tumor involving the vestibulocochlear nerve, such as vestibular schwannoma. Magnetic resonance imaging of the posterior fossa should be ordered whenever symptoms or signs suggest a brain stem or cerebellar lesion. Patients believed to have TIAs should undergo magnetic resonance angiography of the head and neck and additional evaluation for stroke as indicated. Specific vestibular tests, including electronystagmography with caloric or rotatory chair testing and posturography, are helpful to a minority of patients.

SELECTED DISORDERS

BPPV is the most common cause of recurrent vertigo. It occurs when calcium carbonate crystals are released from the otolithic membranes and aggregate in a semicircular canal (usually the posterior canal). Many patients can identify a preceding event, such as an episode of labyrinthitis, trauma, or a prolonged period of having the head back. Symptoms are produced when a change in head position, such as looking up or rolling over in bed, causes the debris to move. The resultant shift of endolymph produces vertigo. Symptoms are usually worse in the morning. BPPV is diagnosed with the Dix-Hallpike maneuver. With the head turned 45 degrees to one side, the patient is moved rapidly from a seated to a supine position with the head hanging down. After a latency of several seconds, the patient experiences vertigo and nystagmus; the upper poles of the eyes beat toward the affected (down) ear. Fatiguing of nystagmus occurs with repeated maneuvers. BPPV is managed with a particle repositioning maneuver.

Vestibular migraine is a common cause of recurrent vertigo. Treatment consists of the usual migraine prophylactic agents. Ménière's disease is attributed to endolymphatic hydrops, which increases pressure in the inner ear. Attacks may be difficult to differentiate from vestibular migraine, but characteristic additional features include aural fullness, fluctuating hearing loss in the affected ear, and a low-pitched tinnitus. Evaluation should include screening for syphilis and autoimmune disorders. Treatment is aimed at reducing hydrops and includes a low sodium diet and diuretics. Vestibular suppressants may be helpful during an attack. Refractory cases can be managed with surgical labyrinthectomy.

Labyrinthitis and vestibular neuritis often are attributed to viral infection of the vestibular nerve or labyrinth. Severe vertigo, nausea, and vomiting appear suddenly and improve over several days. Central compensatory mechanisms produce further improvement over several weeks to months. Important differential diagnoses are labyrinthine and cerebellar infarction or hemorrhage. Treatment includes vestibular suppressants and antiemetics.

MANAGEMENT

In general, treatment is directed at the specific diagnosis, described earlier. Vestibular suppressant and antiemetic medications, such as diazepam, lorazepam, promethazine, and meclizine, can be useful in the initial phase of an acute vestibular syndrome (e.g., labyrinthitis) and in the management of recurrent attacks of vertigo that last at least several hours. Brief episodes of vertigo, such as those that occur with BPPV, are not amenable to such treatment. Chronic prophylactic vestibular suppression may be appropriate when attacks are frequent; however, prolonged use after an acute vestibular lesion may impede central adaptation and should be avoided. Vestibular rehabilitation may be beneficial in the management of both acute and chronic vestibular disorders.

Chapter 422

APPROACH TO THE PATIENT WITH HEADACHE

PATHOPHYSIOLOGY

Receptors responsible for pain registration are present in the proximal parts of the cerebral and dural arteries, the large veins and venous sinuses, and the extracranial arteries. Distention or displacement of these vessels by inflammation, an aneurysm, a hematoma, a tumor, or ventricular dilatation from obstruction of cerebrospinal pathways causes headache. Migraine and cluster headaches are accompanied by vascular dilatation that contributes to the headache. Pain also may be caused by irritation of the meninges, cranial nerves, or occipital nerves. Some forms of tension headache are associated with overcontraction of muscles.

DIFFERENTIAL DIAGNOSIS

See also History and Physical Examination.

Migraine: Migraine is an episodic cerebral disturbance (aura), headache, or both with intervening periods of relative freedom from headache and without evidence of primary structural abnormality. The headache is usually severe, unilateral, and associated with nausea, vomiting, and photophobia. About one-third of patients have some attacks in which an aura (visual changes, paresthesia, or speech disturbance) precedes the headache by 5 to 60 minutes. Migraine is common (20% of women of reproductive age), and women are affected twice as often as men. Many patients can identify triggers such as noise, perfume, stress, relaxation after stress, particular foods, ingestion of alcohol or other vasodilators, physical exertion, or menses.

Cluster headache: Cluster headache has a prevalence about 3% of that of migraine and tends to recur in bouts or clusters that last weeks or months and are separated by months or years of freedom. During a bout, patients (85% of whom are men) each day or night have one or more attacks of severe pain in and around the eye or adjacent areas of the head and face; these attacks last from 10 minutes to hours at a time. The ipsilateral eye usually becomes red and waters; there is ipsilateral nasal congestion or rhinorrhea. Ocular Horner's syndrome may be present.

Tension headache: This term is applied to the sensation of tightness around the head or pressure at the top of the head that may recur daily in its chronic form. It affects women more commonly than men and may start at any age.

Pain arising from extracranial structures: Temporal arteritis occurs among women more than men and primarily affects persons older than 50 years. It is an immune disorder of the arterial wall associated with a giant cell arteritis. The scalp arteries are most commonly involved but involvement of the ophthalmic arteries may produce sudden blindness. There is an association with polymyalgia rheumatica. The diagnosis is supported when the erythrocyte sedimentation rate (ESR) is greater than 40 mm per hour. Results of temporal artery biopsy confirm the diagnosis; treatment with glucocorticoids should be started before the biopsy if suspicion is high, in order to minimize the risk of blindness. Other extracranial disorders include acute angle-closure glaucoma, sinusitis, dental infection, temporomandibular joint syndrome, occipital neuralgia, and disorders of the cervical spine affecting the C2 and C3 nerve roots.

Pain arising from the cranial nerves: Headache can be caused by excessive stimulation of peripheral branches of the first division of the trigeminal nerve by exposure to cold air, food, or drinks. Herpes zoster or trigeminal neuralgia also cause pain in the distribution of the trigeminal nerve, commonly the first division.

Pain of intracranial origin: Headache is a symptom of many intracranial and systemic disorders and can be caused by meningeal irritation or displacement or dilatation of pain-sensitive blood vessels. Investigation determines whether the patient needs neurosurgical or medical management. Benign intracranial hypertension (pseudotumor cerebri) is chiefly a disorder of overweight young women with menstrual abnormalities. They have symptoms and signs of raised intracranial pressure (headache, vomiting, transient obscuring of vision, and papilledema) with no obvious systemic or local cause. Computed tomography demonstrates small ventricles, and results of lumbar puncture confirm the elevation in cerebrospinal fluid (CSF) pressure.

HISTORY AND PHYSICAL EXAMINATION

Acute headache may be accompanied by neck rigidity when there is meningeal irritation and by elevated temperature when there is systemic infection or meningitis. Aggravation of the headache by jarring, coughing, sneezing, or bending forward suggests an intracranial origin. Drowsiness, changes in mental status, seizures, or any neurologic deficits also increase the likelihood of intracranial abnormality.

The temporal pattern of headaches is of great importance. Sudden onset of pain raises the possibility of a life-threatening condition such as subarachnoid hemorrhage or meningitis. Headache increasing in severity over a period of days, weeks, or months also arouses suspicion of a serious organic disturbance. Recurrent episodic headaches include migraines, cluster headaches, paroxysmal hypertension (pheochromocytoma), post-alcohol hangover, and benign recurrent syndromes (benign only if an intracranial lesion has been excluded) such as headaches associated with coughing, exertion, or orgasm. Causes of chronic continuous

headache include tension headache, posttraumatic headache, postherpetic neuralgia, atypical facial pain, and psychogenic headache.

Careful examination of the nervous system and other systems is mandatory. The examiner needs to look for localizing neurologic signs and indications of systemic illness. The examination findings are normal if the patient has migraine, cluster, or tension headaches.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

Only a few patients need more than a careful history and physical examination. A complete blood cell count and ESR should be obtained when systemic infection is suggested or when the headache is of recent onset in a patient older than 50 years. Sudden onset of a headache or a progressive course warrants investigation. If a patient with acute headache has a fever and meningitis is suspected, immediate lumbar puncture may be justified, provided there are no signs of high intracranial pressure. Except for such an emergency, computed tomography (CT) of the brain usually is the first step because it demonstrates hemorrhage and structural causes of headache. Lumbar puncture rarely is necessary. It is used chiefly in the diagnosis of meningitis, for confirmation of subarachnoid hemorrhage if the story is typical but the CT findings are normal, and for measurement of CSF pressure in benign intracranial hypertension. Cerebral angiography and magnetic resonance angiography are reserved for patients with cerebrovascular problems such as cerebral aneurysm.

MANAGEMENT

Migraine: The management of migraine is outlined in [Figure 421.2](#). The treatment has been transformed by the triptans (5-HT_{1B/D} agonists), of which sumatriptan was the first. These agents relieve 50% to 60% of migraine headaches within 2 hours; subcutaneous, oral, and intranasal preparations are available. Because of a vasoconstrictive action, these drugs should not be prescribed for patients with suspected coronary artery disease, Prinzmetal's angina, or uncontrolled hypertension. For the same reason, they should not be administered for 24 hours after ergotamine tartrate.

Cluster headaches: Most episodes can be suppressed with ergotamine preparations. Inhalation of 100% oxygen at 7 L per minute relieves cluster pain within 10 minutes for most patients. Sumatriptan also is effective. Prednisone (40 to 50 mg per day) interrupts the cluster pattern in most cases. The dose can then be lowered progressively to the minimum necessary to control attacks for the rest of the bout. Lithium and verapamil also can provide control of cluster headache.

Tension headache: Management requires psychological counseling, readjustment of physical or emotional stress situations, and muscle relaxation therapy. Amitriptyline and other tricyclic agents are useful.

Headache syndromes with an identifiable cause: Many of the causes of headaches have specific treatments. For example, meningitis responds to intravenous antibiotics, temporal arteritis to prednisone, and benign intracranial hypertension to repeated CSF removal and acetazolamide. Tumors and aneurysms require neurosurgical approaches.

COMPLICATIONS AND PITFALLS

Misinterpretation of the acute or progressive subacute onset of headaches can have serious consequences. The abrupt onset of pain can be migrainous in origin, but it is important to exclude subarachnoid hemorrhage, sentinel headache (enlargement of a cerebral aneurysm without rupture), meningitis, acute obstruction of CSF pathways, or a precipitous increase in blood pressure. Intravenous antibiotics should be given immediately if meningitis is suspected. CT of the brain discloses most cases of subarachnoid hemorrhage. Reassurance that there is no shift of midline structures or other contraindications to lumbar puncture enables safe acquisition of CSF. Temporal arteritis may be overlooked in evaluations of older patients. The ESR is not always elevated, and temporal artery biopsy may be warranted if there is localized scalp tenderness. As with meningitis, specific therapy (glucocorticoids) must be instituted when suspicion is high, even before the definitive diagnostic test is performed.

[Chapter 421](#)

APPROACH TO THE PATIENT WITH IMPAIRMENT OF CONSCIOUSNESS

DEFINITIONS

Level of consciousness is defined by both arousal and conscious behavior. Changes in the level of consciousness depend on the activities of a brain stem regulatory system called the *reticular activating system* (RAS). Coma is a pathologic state in which neither arousal nor awareness is present. Stupor resembles coma except that the patient can be aroused if strong external stimulation is provided. In some cases, both cerebral hemispheres are severely damaged, but the brain stem RAS is preserved. In such cases, after a coma, wakefulness returns without evidence of purposeful behaviors or cognition. This is called the *vegetative state*.

PATHOPHYSIOLOGY AND DIFFERENTIAL DIAGNOSIS

All types of coma may be divided into three categories—supratentorial lesions, infratentorial lesions, and metabolic encephalopathy. Mass lesions of the cerebral hemispheres (e.g., deep midline tumor, large edematous hemisphere infarct, subdural hematoma, or an expanding mass in one hemisphere) cause coma by herniating beyond the confines of the supratentorial compartment and compressing the brain stem RAS. Two types of posterior fossa (infratentorial) lesions produce coma—lesions intrinsic to the brain stem that destroy the RAS (e.g., pontine hemorrhage or infarction) and lesions extrinsic to the brain stem that compress and distort it (e.g., cerebellar tumor and hematoma). Unconsciousness also follows direct blows to the RAS, as occurs with cerebral concussion. *Metabolic encephalopathy* refers to changes in levels of consciousness caused by diffuse failure of cerebral metabolism. Examples include anoxia, hypoglycemia, hyperglycemia, severe electrolyte disturbances, uremia, hepatic failure, meningitis, and drug intoxication.

NEUROLOGIC EXAMINATION AND DIAGNOSIS

The key to clinical diagnosis when the history is in doubt is to identify the initial anatomic distribution of the lesion and how it evolves ([Table 424.1](#)). Clinical neurologic signs can be correlated with specific anatomic sites to establish the severity and extent of central nervous system dysfunction ([Table 424.3](#)).

LABORATORY STUDIES AND DIAGNOSTIC TESTS

Computed tomography or magnetic resonance imaging (MRI) of the brain is best for identifying structural lesions; MRI has the greatest sensitivity for detection of lesions in the posterior fossa. Metabolic abnormalities can be detected with appropriate laboratory studies.

MANAGEMENT

The initial step in the care of a patient in a coma is stabilization. An adequate airway must be ensured, by intubation if necessary. Blood should be collected for measurement of blood glucose, routine chemical analysis, and toxicology studies. Immediately afterward, 25 to 50 g dextrose should be administered intravenously. Bedside glucose measurements are valuable but should never delay the administration of dextrose. Even in cases of hyperosmolar coma, infusion of one ampule of dextrose is not harmful. Naloxone (0.4 to 0.8 mg) and thiamine (100 mg) should be administered intravenously to all patients whether or not opiate or alcohol abuse is suggested. At this point, arterial blood gases should be analyzed to confirm that oxygenation is adequate. Placement of a nasogastric tube may be indicated to remove and examine the stomach contents, but a cuffed endotracheal tube should be in place first to minimize the risk of aspiration. The presence of fever demands lumbar puncture to exclude meningitis, provided mass lesions have been excluded with radiologic imaging. If the diagnostic evaluation has yielded a specific diagnosis for which the patient can be treated, therapy should be instituted without delay.

The mortality rate among all patients in coma for more than 48 hours is 77%. It must be ascertained whether a patient has brain death and cannot benefit from intensive care. Such patients have no cerebral function and no brain stem reflexes for at least 12 hours and have evidence of a structural cerebral lesion. Any possibility that the patient has drug poisoning, hypothermia, or a severe but reversible metabolic abnormality must be excluded. Within a few hours or days after the onset of coma, many patients show neurologic signs that differentiate with a high degree of accuracy the outcome extremes of death or vegetative state and good

recovery.

[Chapter 424](#)

MULTIPLE SCLEROSIS

DEFINITION

Multiple sclerosis (MS) is an inflammatory, demyelinating disease of the central nervous system (CNS).

ETIOLOGY AND PATHOPHYSIOLOGY

Evidence suggests that MS is precipitated by initial exposure of a genetically susceptible host to a relatively common infectious agent in the mid-teenage years. This exposure ultimately leads to an autoimmune process that pathologically targets CNS myelin, leading to inflammation and demyelination years after the initial exposure. Axonal loss or cerebral atrophy may occur early in the course of the disease.

EPIDEMIOLOGY AND CLINICAL FEATURES

The onset of MS is most common between 20 and 50 years of age. Women outnumber men about 2:1. The disease is somewhat arbitrarily divided into primary progressive (PP) and relapsing-remitting (R-R) forms. Approximately 15% of patients have the PP form, characterized by gradual accumulation of neurologic deficits without clear-cut exacerbations or remissions. About 75% of cases begin with an R-R course. The patients, at least after the initial attacks, tend to not return completely to their previous baseline status after many of the exacerbations, such that the R-R course is superimposed on a progressively worsening baseline. With time, many of these patients have a more gradually progressive course with few or no subsequent exacerbations.

Any region of CNS white matter can be affected. Involvement of the cerebral white matter may produce hemiparesis, a hemisensory deficit, or a cognitive deficit. Various brain stem syndromes may occur; internuclear ophthalmoplegia is common. Cranial nerve deficits may develop. Optic neuritis is common (the optic nerves are myelinated with CNS rather than peripheral nerve myelin) and may produce scotomata, loss of visual acuity, and color desaturation. Cerebellar involvement causes ataxia or intention tremor. Spinal cord disease may produce a spastic paraparesis or paraplegia with neurogenic bowel and bladder and sexual dysfunction.

DIAGNOSIS

The diagnosis rests on well-described criteria for possible, probable, and definite MS. The hallmark is dissemination in time and space, that is, multiple episodes of dysfunction and multiple areas of involvement within the CNS. Thus it is impossible to make the diagnosis with certainty at the onset of neurologic symptoms. The diagnosis of PP MS is difficult to make. Magnetic resonance imaging is superior to computed tomography in the detection of MS lesions, which typically appear as areas of increased signal intensity on T2-weighted and proton density images. Evoked potential studies can help detect slowing of conduction within demyelinated CNS pathways. Cerebrospinal fluid (CSF) abnormalities are present in 90% of patients. Mild mononuclear cell pleocytosis and modest protein elevation are common. CSF oligoclonal IgG bands are common and imply the production of large amounts of immunoglobulin by a small number of CNS plasma cell clones.

DIFFERENTIAL DIAGNOSIS

Other inflammatory diseases that mimic MS from clinical, radiologic, and CSF standpoints include syphilis, neuroborreliosis, CNS vasculitis, and sarcoidosis. Other entities to be considered include multiple infarcts caused by small-vessel atherosclerosis or hypertensive vascular disease, or hypercoagulable states. Vitamin B₁₂ deficiency should be excluded.

MANAGEMENT

Symptomatic treatment is used to ameliorate various physiologic abnormalities, such as constipation (fiber), muscle spasticity (baclofen) and bladder spasticity (anticholinergic agents). Amantadine frequently improves the fatigue that commonly accompanies MS. Treatments aimed at reducing inflammation in the CNS have included glucocorticoids, recombinant interferon- β , and glatiramer acetate. Glucocorticoids speed improvement in acute exacerbations but have no demonstrated effect on long-term prognosis. Progressive forms of MS are more difficult to manage; intravenous cyclophosphamide and oral methotrexate have been advocated by some neurologists but are of uncertain value. Mitoxantrone has been reported to be effective.

PARKINSON'S DISEASE

EPIDEMIOLOGY AND PATHOGENESIS

Parkinson's disease is the second most common degenerative disorder among adults, after Alzheimer's disease. It is estimated that more than 1 million Americans are affected. The pathologic hallmarks are degeneration of the dopaminergic neurons of the substantia nigra and the presence of eosinophilic, cytoplasmic inclusions known as *Lewy bodies*. Current hypotheses implicate varying combinations of genetic susceptibility, exogenous or endogenous toxicity, and aging. Drug-induced parkinsonism can occur with the use of neuroleptics, metoclopramide, methyl dopa, and reserpine.

CLINICAL FINDINGS

The *sine qua non* of PD is bradykinesia (slowness of movement) with either a rest tremor or cogwheel rigidity. Most patients have all three, but approximately 30% lack the tremor. The symptoms initially affect one side, but they eventually become bilateral within several years. Additional symptoms and signs encountered early in the course include micrographia; impaired dexterity, especially for rapid repetitive movements such as shampooing hair or brushing teeth; slowness when arising from a deep chair, the toilet, or a car; trouble turning in bed; a soft, monotone voice; diminished facial expression and blink rate; and diminished arm swing while walking. Later manifestations include dysequilibrium with falls and progressive difficulty initiating and maintaining movements. Non-motor manifestations include pain and autonomic problems such as constipation, erectile dysfunction, orthostatic hypotension, urinary bladder instability, and impaired thermoregulation. Depression is extremely common. Most patients do not have dementia, although it may appear in the later stages of the disease.

DIAGNOSIS

Parkinson's disease is a clinical diagnosis. It may be confused with essential tremor and parkinsonian syndromes such as progressive supranuclear palsy, multisystem atrophy, corticobasal degeneration, and Lewy body dementia. Alzheimer's disease and normal aging also are accompanied by parkinsonian features. The three most reliable clinical features that differentiate Parkinson's disease from these related disorders are classic rest tremor, unilateral or asymmetric onset, and sustained improvement with levodopa therapy.

PROGNOSIS AND MANAGEMENT

With therapy, most persons with Parkinson's disease have a normal life expectancy and, with some limitation, a fairly good lifestyle. Almost all current therapies are directed at increasing the levels of dopamine in the striatum.

Medical therapy: A patient with minimal symptoms may need to therapy initially. All patients eventually need treatment with levodopa, but it is usually withheld (see later) until there is marked compromise in the activities of daily living. Until that point, there are the following three options: dopamine agonists (including bromocriptine, pergolide and newer agents such as pramipexole and ropinirole); anticholinergics, such as benztropine, which are particularly effective for tremor; and

the antiviral agent, amantadine. Amantadine and the dopamine agonists also are useful later in the course of the illness as adjuncts to levodopa.

When it becomes necessary to begin therapy with levodopa, pills containing 100 mg levodopa and 25 mg carbidopa (to reduce nausea) are dispensed, and the patient starts with one-half or 1 tablet each day. The dose is then gradually escalated according to clinical response. Most patients improve with 300 mg levodopa per day. The usual approach is to keep the dosage at a modest level, between 600 and 1,000 mg per day, with the early introduction of a dopamine agonist. Central nervous system side effects may include acute confusion, hallucinations, and delusions. These can be managed with a reduction of the dosage of antiparkinsonian medications or with atypical antipsychotic agents such as clozapine. After several years of therapy, the effectiveness of levodopa wanes, and symptoms, such as dysequilibrium, falls, akinesia, and dysphagia, develop that do not respond to therapy. Moreover, the initial smooth response to levodopa begins to be punctuated by motor fluctuations that progress from being predictable (before the next dose) to unpredictable (the on-off effect). At this point, management should be overseen by a specialist.

Surgical therapy: Surgical options available for the small percentage of patients with a disabling, refractory tremor include thalamotomy or deep brain stimulation (DBS) of the motor thalamus. For other features of advanced disease, particularly motor fluctuations and dyskinesia, options include disruption or DBS of the internal segment of the globus pallidus or subthalamic nucleus. Implantation of fetal nigral tissue has demonstrated promise but is still considered experimental.

APPROACH TO DISORDERS OF THE PERIPHERAL NERVOUS SYSTEM

CLASSIFICATION

The two common patterns are a symmetric, usually distal, distribution (polyneuropathy) and an asymmetric or multifocal distribution (mononeuropathy). Polyneuropathy can be divided into distal axonopathy and myelinopathy (demyelinating neuropathy). Mononeuropathy can affect one nerve or can be multifocal (mononeuropathy multiplex).

CLINICAL FEATURES

Polyneuropathy: Negative symptoms (loss of function) predominate, such as weakness and numbness. Positive motor symptoms such as cramps and fasciculations can occur, and positive sensory symptoms such as tingling and pain are frequent. Imbalance is common and reflects a loss of proprioception. Signs found at examination correspond closely to the symptoms and are predominantly distal and symmetric. Weakness is common, and wasting, if present, signifies axonal loss. Sensory loss usually is in a glove-and-stocking distribution. Loss of tendon reflexes is common. Autonomic neuropathy can cause postural hypotension, urinary retention and incontinence, constipation, nocturnal diarrhea, impotence, and sweating abnormalities.

Mononeuropathy: Mononeuropathy generally affects the territory of individual nerves and usually is asymmetric. Symptoms are more abrupt in onset. The symptoms can be sensory alone or combined motor and sensory. Pain often is a feature.

DIFFERENTIAL DIAGNOSIS

[Table 446.2](#) lists some causes of polyneuropathy according to temporal course; [Table 446.3](#) lists causes of mononeuropathy multiplex. Mononeuropathy can be caused by nerve entrapment or compression; common examples include carpal tunnel syndrome (median nerve), meralgia paresthetica (lateral femoral cutaneous nerve), and Bell's palsy (facial nerve).

DIAGNOSIS

A thorough history is essential. The onset and progression vary greatly ([Table 446.2](#)). Stepwise progression suggests multiple mononeuropathy. A history of infection, travel, diet, toxic exposure, alcohol, and medications must be sought. Occupational factors can be important. The family history often is critical. The history and examination allow categorization of the nerve disorder. Nerve conduction studies and electromyography (EMG) provide a physiologic nerve "biopsy." The main utility is to determine whether the predominant pathologic process is demyelination or axonal loss. The former is characterized chiefly by slowed conduction velocity and conduction block. The latter is associated with modest slowing of conduction and evidence of denervation (e.g., fibrillation potentials) at needle EMG. Nerve biopsy, usually of the sural nerve, is reserved for difficult diagnostic situations, such as the suspicion of vasculitis. It also is valuable in the search for neuropathy due to amyloid, sarcoid, or leprosy. Many hereditary diseases formerly diagnosed in part by means of biopsy can be diagnosed better with genetic analysis.

MANAGEMENT

The management consists largely of therapy for associated diseases, such as hypothyroidism, vitamin B₁₂ deficiency, or vasculitis. Guillain-Barré syndrome is best managed with either plasma exchange or intravenous immunoglobulin. There is evidence that strict control of blood sugar for patients with diabetes can delay the development of neuropathy and retard its progression. Any implicated medication should be discontinued, if possible, and toxic exposures should be eliminated. When there are positive sensory symptoms such as pain and tingling, patients may respond to treatment with tricyclic agents (e.g., amitriptyline), gabapentin, or topical capsaicin cream.

[Chapter 446](#)

APPROACH TO THE PATIENT WITH SEIZURES

DEFINITION AND CLASSIFICATION

Epilepsy is an abnormal tendency for the brain to produce paroxysmal depolarization shifts within neurons. Clinically, a person may have motor, sensory, or behavioral symptoms, with or without alteration in consciousness. An individual seizure is differentiated from epilepsy. The latter term is reserved for patients with three or more recurrent seizures. Epileptic seizures can be classified as simple partial (focal motor, somatosensory, or psychic symptoms without impairment of consciousness), complex partial (partial seizures with impairment of consciousness at sometime during the event), generalized seizures (either convulsive episodes with tonic-clonic or myoclonic features or nonconvulsive absence seizures), and partial seizures evolving to secondarily generalized seizures.

DIFFERENTIAL DIAGNOSIS

First, seizures must be differentiated from syncope. Epileptic seizures should then be differentiated from nonepileptic convulsive seizures produced by processes such as cerebral ischemia or hypoxia, hypoglycemia, meningitis or encephalitis, cocaine use, and withdrawal from alcohol, barbiturates, and benzodiazepines. Pseudoepileptic behavior produced by conversion hysteria must not be mistaken for true epilepsy.

CLINICAL PRESENTATION AND DIAGNOSTIC EVALUATION

A detailed case history and description of the attacks must be obtained from the patient, friends, and family. [Figure 426.1A](#) shows an algorithm for diagnosis and initial management. Electroencephalography (EEG) is indispensable when epilepsy is first suggested. It should be performed with the patient awake and asleep, with photic stimulation and hyperventilation. Brain imaging (magnetic resonance imaging, computed tomography, or both) is recommended in the care of all patients with recurrent, symptomatic partial complex seizures. Seizures associated with fever and meningeal signs suggest meningitis or encephalitis and warrant lumbar puncture.

MANAGEMENT

Whom to treat: Antiepileptic therapy is obligatory for generalized or partial forms of epilepsy but is seldom indicated after a single tonic-clonic seizure. Most of these patients have no risk factors for epilepsy and have normal neurologic and EEG examinations. The seizures often can be attributed to sleep deprivation (more than 36 hours), stress, extreme fatigue, drug or alcohol withdrawal, or use of cocaine. However, patients with a strong family history, an aura, absence or complex partial

seizure, abnormal neurologic examination, or epileptiform EEG patterns need immediate evaluation and treatment.

Which drug to use: Treatment should begin with one antiepileptic agent, preferably the drug of choice ([Table 426.1](#)). Single-drug management of generalized seizures suppresses attacks among 80% of patients. Single-drug therapy for partial, complex partial, and secondary tonic-clonic seizures results in satisfactory long-term control for 60% to 90% of patients and complete eradication of seizures for 40% to 60%. If seizures persist, the dosage should be increased until seizures stop or toxic side effects develop. If seizure control is still unsatisfactory, a second drug of choice is substituted and the first agent is gradually withdrawn after therapeutic levels of the new drug have been attained. A third agent can be used for monotherapy, if necessary, and then two or three drugs can be given in combination, usually at low doses. Refractory seizures can be managed with epilepsy surgery or implantation of a vagus nerve stimulator.

Status epilepticus: Status epilepticus, a medical emergency, occurs when seizures persist longer than 30 minutes or when convulsions continue without recovery of consciousness. Three options are available as initial therapy: (a) Lorazepam 0.1 mg per kilogram IV bolus (no faster than 2 mg per minute) with a repeat dose in 15 minutes if control is not achieved. Fosphenytoin is then given immediately at a dose of 15 to 20 mg per kilogram IV and a rate of 75 to 150 mg per minute. (b) Diazepam infusion is given (no faster than 2 mg per minute) until seizures stop or a total of 20 mg has been infused. Simultaneously, fosphenytoin infusion 75 to 150 mg per minute is given until a total dose of 15 to 20 mg per kilogram has been achieved. If hypotension develops, the infusion rate is slowed (c) Phenobarbital is administered at 100 mg per minute IV until seizures stop or a total dose of 10 mg per kilogram has been administered. If seizures continue, the rate is slowed to 50 mg per minute until a total dose of 20 mg per kilogram has been reached. If first-line options do not control seizures. EEG monitoring and endotracheal intubation are undertaken. If seizures continue general anesthesia, usually pentobarbital, can be administered.

Withdrawal of antiepileptic treatment: Drugs usually can be withdrawn gradually after 4 years of complete control of simple partial epilepsy, complex partial epilepsy, absence associated with tonic-clonic seizures, and grand mal tonic-clonic seizures. EEG and clinic visits should be scheduled for 6 months and 1 year after treatment.

[Chapter 444](#)

APPROACH TO THE ELDERLY PATIENT WITH ACUTE CHANGE IN MENTAL STATUS

DEFINITIONS

Delirium, or acute confusional state, is a change in mental status characterized by inattention, disorganized thinking, acute onset, and a fluctuating course.

EPIDEMIOLOGY

Acutely altered mental status accounts for at least 30% of emergency evaluations of older persons and may be the only manifestation of serious underlying disease. Each year delirium complicates hospital stays for more than 2.3 million older persons in the United States.

ETIOLOGY, PATHOPHYSIOLOGY, AND PATHOGENESIS

Delirium usually involves a complex relation between a vulnerable patient and precipitating factors that culminates in widespread reduction of cerebral oxidative metabolism with resultant impairment of cholinergic transmission. Risk factors include preexisting dementia, severe underlying illness, functional impairment, advanced age, chronic renal insufficiency, dehydration, malnutrition, and impairment of vision or hearing. Medications contribute to more than 40% of cases of delirium; the most commonly implicated are sedative-hypnotics, narcotics, histamine 2 blockers, and those with anticholinergic effects. Other precipitating factors include immobilization, use of indwelling bladder catheters, use of physical restraints, dehydration, malnutrition, iatrogenic events, medical illness, infection, metabolic derangement (e.g. hyponatremia or hypernatremia, hypercalcemia, acid-base disorders, hypoglycemia or hyperglycemia, and thyroid or adrenal disorders), alcohol or drug intoxication or withdrawal, environmental influences, and psychosocial factors. Patients who are highly vulnerable, such as those with cognitive impairment or severe illness, may have delirium with just a single dose of a sedative medication, whereas those who are not vulnerable can tolerate multiple insults.

CLINICAL FEATURES

There is an acute onset, but lucid intervals are characteristic. Inattention is recognized as difficulty focusing, maintaining, or shifting attention. Patients are easily distracted, have difficulty following commands, and often have perseveration with an answer to a previous question. They have difficulty repeating five digits forward or reciting the months backward. Other features include disorganization of thought and altered level of consciousness. A hypoactive form, characterized by lethargy and reduced psychomotor activity, is the most common form among older patients. It is often unrecognized and is associated with a poor prognosis. The hyperactive form, in which the patient is agitated, vigilant, and often hallucinating, is rarely missed.

DIFFERENTIAL DIAGNOSIS AND EVALUATION

The leading differential diagnoses are dementia, depression, and nonorganic psychotic disorders. The most difficult challenge is differentiating dementia. The two conditions are differentiated according to the acuity of onset and the impairment of consciousness and attention seen in dementia. Disorientation and memory impairment may occur with either. A systematic approach to the evaluation of changes in mental status among older adults is presented in [Fig. 459.1](#).

MANAGEMENT

Prevention: Prevention is the most effective strategy. Effective interventions include nonpharmacologic sleep enhancement, early mobilization protocols, and measures to ensure optimal vision and hearing.

Nonpharmacologic management: Room and staff changes should be kept to a minimum. Patients should have access to eyeglasses, hearing aids, clocks, and calendars. Personal contact and communication are vital; patients must be allowed an uninterrupted period for sleep at night. Physical restraints should be avoided because of the adverse effects of immobility and increased agitation, questionable efficacy, and potential for injury.

Drug therapy: Any identified precipitating factors, such as occult infection, should be managed. Otherwise, pharmacologic approaches should be reserved for patients with severe agitation that endangers the patients' own safety or that of the staff. Drugs may further cloud mental status, so should be given in the lowest dose for the shortest time possible. Neuroleptics are the preferred agents. The recommended starting dose of haloperidol is 0.5 to 1.0 mg orally or parenterally, with repeated doses every 20 to 30 minutes (after vital signs have been checked) until sedation has been achieved. The end point should be an awake but manageable patient. A maintenance dose of one-half the loading dose should be administered in divided doses over the next 24 hours with tapering doses over the next few days. Side effects include hypotension, acute dystonia, extrapyramidal effects, and anticholinergic effects such as dry mouth, constipation, and urinary retention. Benzodiazepines are not recommended for the management of delirium, unless the cause is withdrawal from alcohol or sedative drugs, because of the tendency to cause oversedation and exacerbation of the confused state.

[Chapter 459](#)

APPROACH TO THE ELDERLY PATIENT WITH URINARY INCONTINENCE

DEFINITION AND EPIDEMIOLOGY

Urinary incontinence (UI) is involuntary loss of urine severe enough to be a social or health problem. As many as one-third of community-dwelling older adults and 50% to 70% of nursing home residents have some degree of UI.

ETIOLOGY AND PATHOPHYSIOLOGY

There are four basic types of UI, although they are not mutually exclusive. The most common type of UI among women younger than 75 years is stress incontinence,

in which abnormality of the bladder outlet causes urinary leakage with increases in intra-abdominal pressure. The most common type among men and patients of both sexes older than 75 years is urge incontinence with involuntary bladder contractions (detrusor instability, termed "detrusor hyperreflexia" when associated with a neurologic disorder). Older women commonly have mixed incontinence and have symptoms of both stress and urge UI. Overflow incontinence from urinary retention is less common but is important to recognize because chronic large postvoid residual urine volumes can cause recurrent infection or upper urinary tract damage.

Several potentially reversible factors can cause or contribute to UI. The most common can be remembered with the acronym DRIP (*d*elerium; *r*estricted mobility, *r*etention of urine; *i*nfection of the bladder, *i*nflammation of the lower urinary tract, *i*mpaction of stool; *p*olyuria [hypercalcemia, hyperglycemia, excessive fluid intake], *p*harmaceuticals). Implicated medications include anticholinergic and α -adrenergic drugs (urinary retention and overflow incontinence), psychotropic drugs (sedation and immobility), α -adrenergic antagonists (urethral relaxation and stress UI), and diuretics (increased urine output).

CLINICAL FINDINGS

Among older patients, the most common presenting symptoms are the irritative symptoms of urge incontinence. These include urinary frequency during the day (voiding more frequently than every 2 hours), nocturia (two or more voids during normal sleeping hours), and a precipitant urge to void. Older women also commonly have symptoms of stress incontinence (leakage caused by coughing, laughing, or bending) or a combination of irritative and stress symptoms. Older men often have obstructive symptoms, which include irritative symptoms and hesitancy, a weak or intermittent stream, and straining to void.

DIAGNOSTIC EVALUATION

General approach: All patients with UI undergo a focused history interview and physical examination, postvoid residual measurement, and urinalysis. The history should focus on medications and active medical problems, full characterization of the UI (onset, precipitating factors, timing, frequency, amount of urine loss), and any irritative, stress, or obstructive symptoms. Voiding diaries can be useful. Physical examination should focus on cognitive function, mobility, cardiovascular findings, neurologic status, and pelvic and rectal examinations. The pelvic examination of women can reveal urine loss with stress (e.g., forceful coughing), a cystocele, or atrophic vaginitis. The postvoid residual measurement is performed by means of catheterization or ultrasonography. Volumes greater than 200 mL are abnormal and should lead to additional evaluation.

Further evaluation: Some patients need additional testing ([Table 458.3](#)).

MANAGEMENT

Stress incontinence: Women should be instructed to perform pelvic muscle (Kegel) exercises and to void regularly to avoid a full bladder. Factors such as obesity and chronic cough should be addressed. If no contraindications exist, an α -adrenergic agonist (30 to 60 mg pseudoephedrine three times a day, 75 mg phenylpropanolamine twice a day) and estrogen (orally or vaginally) can be tried. If all of these measures fail, the patient needs further evaluation and consideration for bladder neck suspension (for hypermobility of the bladder neck) or periurethral injections of collagen (for urethral sphincter weakness).

Urge incontinence: Patients can be treated with behavioral therapy. Pelvic muscle exercises work because voluntary contraction of the pelvic floor muscles inhibits bladder spasticity and contraction. Other behavioral therapies include bladder training for functional and motivated patients and scheduled toileting or prompted voiding for patients with impaired cognitive or physical functioning. Bladder relaxant therapy with anticholinergic agents can be added as necessary. Dicyclomine, imipramine, oxybutynin, and propantheline all have systemic anticholinergic effects (such as dry mouth) that may limit their use. Newer agents such as tolterodine and extended-release oxybutynin have fewer side effects. Patients who take any bladder relaxant must be observed carefully for evidence of urinary retention, and some patients need periodic postvoid residual measurements. Men with irritative symptoms associated with benign prostatic hyperplasia may benefit from a trial of an α -adrenergic antagonist (e.g., terazosin, tamsulosin) if surgery for obstruction is neither indicated nor desired.

Overflow incontinence: Patients with overflow UI due to anatomic obstruction need surgical intervention unless an operation is contraindicated. Patients who have an acontractile bladder are treated with catheter drainage (intermittent rather than indwelling, if feasible) because pharmacologic treatment with a cholinergic agonist or α -adrenergic antagonist usually is ineffective.

[Chapter 458](#)
