A cause for excitement is the potential for linking the genetic, molecular, cellular, anatomical, and physiologic defects in this disease. The products of PKD1 and PKD2 genes are the large integral membrane proteins polycystin 1 and 2, respectively. These two proteins interact in normal epithelial growth and proliferation programs. All cells contain the mutated gene in ADPKD, but the expression of disease in tissue may require a second mutation or injury. The renal cysts develop anywhere along the tubule, and the epithelium may retain the functional properties of its origin. Perhaps only 2% of nephrons develop cysts that appear to disconnect from the parent tubules as their size increases with time. Cysts may grow to diameters larger than 10 cm, but most measure 2 to 5 cm. The kidneys enlarge such that they are palpable in about half of patients. Progressive renal failure is not due to the cysts, which are markers of the disease. Rather, enlargement of the interstitium with matrix deposition and cellular infiltrates seems to lead to loss of normal noncystic parenchyma.

Back or flank pain (60%) and gross hematuria (30%) are the major causes of distress. Renal stones (20%), cyst infections, and retroperitoneal hemorrhage also occur. Extrarenal manifestations are diverse and often important. Hypertension develops in 60% of patients before the onset of measurable renal failure. The mechanism probably includes a role for the renin–angiotensin system induced by vascular compression. Liver cysts begin to appear in 30-year-old patients and increase in size and number in parallel with renal cyst progression, reaching an overall peak prevalence of about 60%. Sex hormones may account for more liver involvement in women. Liver function is well preserved, and complications are unusual. Mitral valve prolapse occurs in about 25% of patients with ADPKD, with significant regurgitation in about one third of these. Intracranial aneurysms occur in about 10% of patients, with an uncertain but important frequency of rupture. Colonic diverticulosis, ovarian cysts, and inguinal hernias appear to develop with increased frequency.

The diagnosis is usually readily established by renal ultrasonography; computed tomography is more sensitive but also more costly. In the absence of the typical image of many cysts in both kidneys, the presence of any renal cysts in persons younger than 40 years with a family history of ADPKD or liver cysts should be considered to indicate ADPKD. If clinically desirable, gene linkage analysis of multiple family members may provide a high level of inferential likelihood of the presence or absence of the gene in problematic cases, but this test is not recommended for screening or random testing. Screening of all patients with ADPKD for intracranial aneurysms is excessive, but magnetic resonance imaging angiography of the brain is reasonable if the patient has a family history of ruptured intracranial aneurysm. The timing and need for repetition are uncertain.

Treatment starts with genetic counseling to reduce the incidence of the disease. Blood pressure control with angiotensin-converting enzyme inhibitors and eradication of cyst infections are directed at preserving renal function. Infected cysts require the use of antibiotics that penetrate into cyst fluid, such as ciprofloxacin and trimethoprim-sulfamethoxazole. Severe pain or massive renal enlargement that compromises physical functioning may be treated by surgical cyst unroofing or percutaneous cyst drainage and ethanol sclerosis without apparent compromise, but also without improvement, of renal function. Patients with large kidneys should avoid potentially traumatic situations. Gross hematuria abates with rest; hydration and pain control are comfort measures. Once the diagnosis of ADPKD is established, imaging studies of the kidneys need not be performed routinely unless new symptoms require evaluation.

The prognosis is variable and difficult to predict. Renal function usually remains normal until after age 30 years. In about 90% of patients, some degree of renal failure develops, progressing to end-stage disease by age 70 in 50%. Factors associated with a worse prognosis include later age at diagnosis, male gender, hypertension, increased left ventricular mass, and larger renal volumes. ADPKD diagnosed before the age of 1 year may progress to renal failure during childhood, whereas ADPKD detected during childhood seems to follow a clinical course identical to that of patients diagnosed as adults.

MEDULLARY SPONGE KIDNEY

The intriguing disorder of medullary sponge kidney was so named because of a controversial gross resemblance to the sea sponge. Medullary sponge kidney has a strong association with calcium nephrolithiasis and medullary nephrocalcinosis, does not cause renal failure, and is distinctly different from renal medullary cystic disease, a variant of the nephrophthisis–cystic renal medulla complex.

This disorder is found in 1 in 100 to 200 persons who undergo routine excretory urography; the true prevalence is unknown. Medullary sponge kidney affects only the renal medulla, with development of ectasia of the papillary and medullary collecting ducts and formation of many tiny cysts (under 7.5 mm in diameter). The pathogenesis is unknown because of the lack of formal tissue studies and because of the difficulty in making the diagnosis. Provocative reports support the hypothesis that medullary sponge kidney is an autosomal dominant genetic disorder.

Many persons with medullary sponge kidney have no symptoms. The most common symptoms are renal or ureteral colic, gross hematuria, and dysuria. Calcium

stones occur in perhaps half of patients. Twenty percent of idiopathic calcium stone formers have medullary sponge kidney, with probably a higher frequency in women. The stones are composed of calcium oxalate or a calcium oxalate/phosphate mixture. The most likely cause appears to be hypercalciuria, which is found in 45% of men and 26% of women with medullary sponge kidney. The mechanism of hypercalciuria is unclear, but evidence exists supporting intestinal hyperabsorption and renal leak in different persons. Gross hematuria occurs in a few patients, with or without stones. Infection is common in women with medullary sponge kidney but uncommon in men. Several unusual or rare disorders accompany medullary sponge kidney, but congenital hemihypertrophy appears to have a nonrandom association. In the absence of secondary problems such as obstruction and pyelonephritis, the glomerular filtration rate remains normal. Incomplete distal renal tubular acidosis occurs in 40% of patients, and renal concentrating defect occurs in almost all patients.

Diagnosis depends exclusively on the characteristic appearance demonstrated by excretory urography. The opacification of the ectatic collecting ducts makes them look like a brush, and the cysts resemble grapelike clusters. If at least three papillae are affected, medullary sponge kidney is present. The interpretation of localized findings and papillary blush appearance is problematic.

Treatment is simple and usually highly successful. Thiazide diuretics effectively prevent stone formation. Vigorous treatment of infection is essential. The prognosis for patient and renal survival should approach that of unaffected persons.

MEDULLARY CYSTIC DISEASE

Medullary cystic disease is a rare disease that is one variety of an entity renamed the nephronophthisis–cystic renal medulla complex. The three major variants of this complex are juvenile nephronophthisis (50%), renal-retinal dysplasia (17%), and medullary cystic disease of adult onset (18%). Medullary cystic disease is characterized by progressive renal insufficiency terminating in renal failure in about 4 years. An early urine concentrating defect appears to be invariable; renal salt wasting with volume depletion occurs much less often. It is an autosomal dominant genetic disorder of uncertain pathogenesis. Small cysts are present in the medulla and corticomedullary areas of the shrunken, fibrotic kidneys. Diagnosis is based on family history and demonstration of corticomedullary or medullary cysts in small kidneys by imaging, biopsy, or nephrectomy analysis. The role of the cysts in the renal failure and their necessity for diagnosis are uncertain. Treatment is supportive.

ACQUIRED RENAL CYSTIC DISEASE

Many patients on chronic hemodialysis (40% to 90%) have multiple bilateral renal cortical and medullary cysts. Such cysts are much less common in chronic peritoneal dialysis patients (5%) and undialyzed patients with chronic renal failure. These acquired cysts are much more common in men than in women.

The clinical importance of these cysts is based on two features: the potential for renal cell carcinoma to develop in the cysts and the potential for serious hemorrhage from the cysts. As many as 7% of patients with acquired cysts develop renal cell carcinoma, although several large imaging studies have failed to find tumors in any patient. Part of the difficulty is distinguishing between renal adenomas and carcinomas in the absence of metastases. Masses with diameters exceeding 3 cm are considered malignant and should be removed. Another difficulty is the lack of firm guidelines to determine surveillance programs. Regular computer tomographic scanning, the preferable study, appears excessive. The clinician should use the symptoms to instigate investigation. Hemorrhage into a cyst or from cyst rupture can cause severe pain, gross hematuria, blood loss anemia, and even shock. Usually conservative observation, volume maintenance, and analgesia suffice, but occasionally nephrectomy or arterial embolization is necessary. The pathogenesis is unknown, but the resemblance of the renal cysts to ADPKD is intriguing.

OTHER RENAL CYSTIC DISEASES

Chronic hypokalemia causes tubular hyperplasia, hypertrophy, and dilatation. In one study, 44% of patients with primary hyperaldosteronism and hypokalemia were found to have renal cysts; about half of patients had more than two. Cysts appear common in other chronic hypokalemic states. Correction of the hypokalemia appears to cause cyst regression. This exciting observation demonstrates a humoral influence on renal cystogenesis.

Autosomal recessive polycystic kidney disease is a rare disorder affecting 1 in 14,000 newborns. Four varieties occur, dominated by the manifestations of either progressive renal failure or liver failure due to fibrosis. End-stage renal failure appears inevitable, although it may be delayed until early childhood. Glomerular cystic disease bears clinical resemblance to this disorder, but it spares the liver and might have variable forms of heredity.

Congenital multicystic kidney is the most common cause of abdominal mass in the newborn (1 in 2,000 hospitalized infants). It is more often unilateral. It is not functional and is often removed surgically. This disorder is one of the causes of unilateral functioning kidney in adults (1 in 1,000). It and related dysplastic disorders are associated with many other developmental abnormalities and rare syndromes.

Tuberous sclerosis and von Hippel–Lindau disease are inherited systemic disorders that involve the kidneys, occasionally with cysts.

The important features of the more important cystic disorders are listed in [Table 156.1](#).

Disorder	Autosomal				Acquired Renal Cystic Disease
	Simple Cysts	Dominant Polycystic Disease	Medullary Sponge Kidney	Medullary Cystic Disease	
Frequency	25% over 50 y	1:200–1000	20% of stone formers	Rare	5% in hemodialysis
Pathogenesis	Uncertain	Inherited autosomal dominant	Inherited autosomal dominant probable	Inherited autosomal dominant, autosomal recessive	Unknown
Symptoms	Usually none	Hypertension, pain	Hematuria	Variable	None, mass
Complications	Rare	Liver cysts, aneurysms, mitral valve prolapse	Stones, nephrocalcinosis	Salt wasting	Hemorrhage, tumor
Diagnosis	Ultrasound	Ultrasound, gene linkage	Excretory urography	Chlral scan	Computed tomography
Prognosis	Excellent	End-stage renal failure in 50% at 50 y	Excellent	End-stage renal failure in 4 y	5–7% cancer

CHAPTER 157: HEREDITARY NEPHROPATHIES

MARTIN C. GREGORY

[Alport's Syndrome](#)
[Thin Basement Membrane Disease](#)
[Nail Patella Syndrome](#)
[Fabry's Disease](#)
[Other Conditions](#)

Hereditary renal disease is more common than is generally realized. Underdiagnosis results in part from subtleties of inheritance. Whereas the familial pattern is readily apparent in autosomal dominant conditions such as adult polycystic disease, recessive or X-linked conditions can be much harder to spot. A classic example is Alport's syndrome (hereditary nephritis). Although best defined by hematuria as an X-linked dominant trait, the penetrance and severity of the condition are both usually greater in males. This means that if renal failure is used to define affectedness, Alport's syndrome appears to behave as an X-linked recessive. An affected man is likely to have a family history of renal failure only in his mother's male relatives—further afield than the family history may be known.

Many renal diseases not generally considered hereditary disorders occasionally run in families. This is particularly noteworthy in the case of vesicoureteral reflux, which can show autosomal dominant transmission with variable penetrance. The significance of this familial clustering is that the children of a parent with familial reflux are at risk for urinary tract malformations and should be screened by radionuclide cystography, or at least watched closely for urinary infections.

ALPORT'S SYNDROME

Alport's syndrome is progressive hereditary hematuric glomerulonephritis that generally affects male individuals much more severely than female individuals. There is a juvenile form of the disease in which boys develop renal failure at a mean age of 18 years, and an adult type in which renal failure occurs in men around the age of 35. Alport's syndrome is often associated with progressive hearing loss and, occasionally, with other nonrenal defects.

GENETICS

Inheritance is X-linked dominant in 85% of families. Over 300 different mutations of the COL4A5 gene, which codes for the α_5 chain of type IV collagen, have been described. COL4A5 is located on the X chromosome at Xq22. In 15 of families, typically those with early development of renal failure in both genders, autosomal recessive Alport's syndrome results from mutations of COL4A3 or COL4A4, both on chromosome 2 at 2q36. About 1 of patients, particularly those with associated hematologic abnormalities, display autosomal dominant inheritance, with as yet obscure mutations.

PATHOGENESIS

The fundamental lesion in most variants of Alport's syndrome is a defect in one of the genes coding for the α_3 , α_4 , or α_5 chains of type IV collagen in the glomerular basement membrane (GBM). Fetal GBM is composed of collagen α_1 and α_2 chains. Around birth, a developmental switch to collagen composed of α_3 , α_4 , and α_5 heterotrimers occurs. If one of these α chains is defective, normal assembly of a α -chain heterotrimers cannot occur. This is believed to lead to formation of imperfect collagen. The defect of basement membrane collagen may be more susceptible to proteolysis or less capable of orderly repair. The glomerular basement membrane becomes irregularly thickened and splits into multiple lamellae.

INCIDENCE AND EPIDEMIOLOGY

Alport's syndrome occurs worldwide. The incidence is probably 1 in 5,000 but many cases go unrecognized.

CLINICAL FEATURES

With X-linked disease, all hemizygous males have uninterrupted microscopic hematuria from birth, as do affected males and females with autosomal disease. In contrast, most heterozygous females with an X-linked gene show early but milder signs, and a few are clinically normal.

In childhood, hematuria may be episodically macroscopic, often after minor infections, and this may cause confusion with post-infectious and other forms of glomerulonephritis. Microscopy of the urine sediment shows dysmorphic erythrocytes with occasional tubular cells and erythrocytic, blood, and granular casts. Proteinuria is variable.

Some families with Alport's syndrome have associated abnormalities; the most common is high-frequency sensorineural hearing loss. This was true of Alport's original kindred, but overt hearing loss is not found in all families. When present, premature hearing loss in many family members is a valuable clue to the diagnosis, but requiring it as a condition for diagnosing Alport's syndrome results in many cases being overlooked. Hearing impairment worsens roughly in step with increasing renal dysfunction and becomes profound in severe cases. Tinnitus troubles some patients.

Less common than hearing loss but nearly pathognomonic of Alport's syndrome is anterior lenticonus. It occurs in families with juvenile type Alport's syndrome and is readily apparent if the examiner uses a series of strong convex lenses in the ophthalmoscope to examine the anterior structures in the eye through a dilated pupil. The "oil drop" seen on the anterior surface of the lens explains the severe refractive error that impairs vision and prevents a clear view of the fundus. In many families, white or yellowish retinal flecks are seen, particularly near the macula.

LABORATORY FINDINGS

Renal biopsy shows a mixture of glomerular and tubular lesions with progressive scarring as the disease advances. Foam cells may be prominent but are not diagnostic, and glomerular crescents can occur in juvenile type nephritis. Routine immunofluorescence is negative, but examination of the biopsy with fluoresceinated anti-GBM sera or with monoclonal antibodies to the α_3 chain of type IV collagen reveals striking findings. The normal distinct linear staining of the GBM is usually absent in males who are hemizygous for an X-linked gene and often shows interrupted staining in heterozygous females. Electron microscopy of early cases may show thinning of the GBM. More advanced cases show a characteristic thickening of the GBM, which is frayed into several lamellae, often separated by small electron-dense granules. Basement membrane splitting is not pathognomonic of Alport's syndrome because similar appearances can occur in many glomerular diseases; however, only in Alport's syndrome is the splitting prominent and widespread at a time when there are few other changes in the kidney. A renal biopsy is unnecessary for diagnosis in a patient with hematuria if he or she has an extensive family history of hematuria and of renal failure in male relatives.

The blood in advanced cases shows the findings expected with renal insufficiency. Rare families have thrombocytopenia with giant platelets or pale blue, peripheral, cytoplasmic Fechtner inclusions in granulocytes.

Specific genetic tests are available for identifying the more than 300 known mutations of COL4A5. At present, these are of value to perhaps 50 of known families with Alport's syndrome. It is likely that the number of identified mutations will increase and that genetic screening and diagnosis will become increasingly practicable. Some adult type families, both with and without overt hearing loss, contain many hundreds of known gene carriers and there are likely many more undiscovered. Tests for the more common mutations may be appropriate in adults with familial or unexplained glomerulonephritis.

COURSE AND PROGNOSIS

All affected males eventually develop renal failure, at varying ages in different kindreds. The few women with X-linked disease who develop renal failure are mostly

elderly. Boys and girls with homozygous autosomal recessive disease commonly develop renal failure in childhood or early adult life.

TREATMENT

There is no specific treatment. Control of hypertension is important, and modest protein restriction could be advised when renal function begins to deteriorate. Surprisingly, preliminary trials have not shown benefit from angiotensin-converting enzyme inhibitors, but in one small uncontrolled study, cyclosporin appeared to retard deterioration.

Appropriate plans should be made for dialysis or transplantation. Rarely, anti-GBM nephritis may develop in the renal allograft of a patient with Alport's syndrome, but this is not a bar to transplantation unless other members of the same family have lost grafts to anti-GBM nephritis. As in any familial nephropathy, great care should be taken in the selection of living donors.

Hearing aids help the hearing loss to some degree. If vision becomes severely impaired by lenticonus, intraocular lens implantation is feasible. Genetic counseling is vital but is complicated by the genetic heterogeneity of Alport's syndrome. For this reason, it is desirable to assemble as complete a pedigree as possible and perhaps to attempt molecular diagnosis before counseling the patient.

THIN BASEMENT MEMBRANE DISEASE

Thin basement membrane disease differs from Alport's syndrome in that hearing loss and renal failure rarely occur, even at advanced ages. Inheritance is autosomal dominant in most families, although many sporadic cases occur. Some studies have indicated that up to 3 of the population might have thin GBMs. The term *benign familial hematuria* is sometimes used to encompass both these patients and those who have unexplained glomerular hematuria with GBMs of normal thickness. Thin basement membrane disease is important to recognize so that unnecessary alarm, cystoscopies, and usurious insurance premiums can be avoided.

Many families with thin GBM disease have mutations in COL4A3 or COL4A4. Cases have been described in which homozygotes or mixed heterozygotes in these families have all the manifestations of Alport's syndrome.

Electron microscopy of a renal biopsy shows uniform thinning of the GBM to about half its normal thickness. Although this finding is highly characteristic, similar appearances occur in early cases of Alport's syndrome, so that a careful family history for longevity of affected males is at least as important as the biopsy in reaching a precise diagnosis of familial thin basement membrane disease.

NAIL PATELLA SYNDROME

Nail patella syndrome is an uncommon but striking autosomal dominant condition marked by abnormalities of bones, joints, nails, and sometimes the kidney. Partial dysplasia of the nails, most marked in the thumb and index finger, and absence or hypoplasia of the patella with a tendency to genu valgum and recurrent subluxation are the most obvious features. On radiographs bilateral posterior iliac horns are visible; these can be palpated in thin subjects. About 30 of gene-carrying persons have proteinuria and some become uremic.

Nail patella syndrome arises from dominant mutations (haploinsufficiency) of the LIM homeodomain gene LMX-1B at 9q34. There is a very characteristic ultrastructural lesion of the GBM, which is thickened and irregularly fenestrated or "moth-eaten." High-resolution pictures of these lucent areas and of the subendothelial space show fibers of collagen with regular 64-nm periodicity. There is no specific treatment, but dialysis and transplantation are appropriate.

FABRY'S DISEASE

Fabry's disease is an X-linked disorder of sphingolipid metabolism that affects about one in 40,000; manifestations are much more common and severe in males. The disease arises from mutations of the α -galactosidase A gene at Xq21. Deficiency of α -galactosidase A permits accumulation of ceramide trihexoside in many tissues. Characteristic dark red macules and papules (angiokeratomata) may be found on the abdomen and scrotum, and subtle whorled corneal opacities occur in most patients. Glycolipid-laden macrophages are shed in the urine and are easily recognized by their "Maltese cross" appearance under crossed polarization. Electron microscopy shows remarkable lamellated "zebra bodies" in the cytoplasm of glomerular epithelial cells. Renal impairment begins in early adulthood in affected males and progresses to renal failure. Dialysis controls uremia but may not relieve the limb pains that torment many patients. Successful renal transplantation replaces the missing enzyme and might bring about regression of nonrenal manifestations.

OTHER CONDITIONS

CYSTINOSIS

Homozygous or mixed heterozygous mutations in the CTNS gene on chromosome 17 that codes for cystinosis, the putative cystine transporter, impair cystine transport out of liposomes. This allows cystine to accumulate in many tissues, including renal tubules, interstitium, and glomerular epithelial cells. Fanconi's syndrome develops in infancy or childhood; uremia soon follows. In adult forms of cystinosis, glomerular lesions may be severe and tubular damage mild. Deposits of cystine in the superficial layers of the cornea and conjunctiva can be seen on slit-lamp examination or by careful direct ophthalmoscopy. Renal rickets is a deforming consequence of acidosis, hypophosphatemia, and renal failure. Excessive intracellular cystine stores can be depleted to a degree by therapy with reducing reagents such as ascorbic acid, cysteamine, or dithiothreitol, but it is too early to judge the long-term benefits of these treatments. Rickets should be treated with alkali, calcium, and vitamin D analogs, and uremia with transplantation.

PRIMARY HYPEROXALURIA

Rare recessively inherited deficiency of either of two enzymes, alanine-glyoxalate aminotransferase or D-glyceric dehydrogenase, results in overproduction, generalized deposition, and overexcretion of oxalate. Urolithiasis and renal failure are the important sequelae. About one third of all patients respond to large doses of pyridoxine. Results of dialysis are poor as have been those of renal transplantation, although greater success may be obtained with vigorous peritransplantation dialysis and treatment with pyridoxine, orthophosphate, and magnesium starting immediately after transplantation. Hepatorenal transplantation is effective, but hepatic transplantation before widespread oxalate deposition occurs may be the best option.

CHAPTER 158: OBSTRUCTIVE NEPHROPATHY

NELSON LEUNG, AMIT K. GHOSH AND KARL A. NATH

- [Incidence and Etiology](#)
- [Functional Changes in Obstructive Nephropathy](#)
- [Clinical Features](#)
- [Laboratory Features](#)
- [Radiographic Techniques](#)
- [Optimal Management](#)

In its role of defending the constancy of the internal milieu, the kidney elaborates urine of appropriate chemical composition and volume. The egress of urine from the kidney, its unimpeded flow through the urinary tract, and its excretion are the subsequent and essential steps critical to processes in the kidney that maintain homeostasis. Excretion of urine requires a patent urinary tract, effective ureteral peristalsis, a hydrostatic pressure gradient in the urinary tract, and normal micturition. Impairment in any of these requirements by lesions at any site from the renal calyx to the external urethral meatus—conditions designated as obstructive uropathies—can exert damaging effects locally within the urinary tract and also systemically, by virtue of impairment of renal function.

Obstructive nephropathy is defined as the functional and structural changes in the kidney sustained by obstructive uropathy. Obstruction is thus an important and potentially reversible cause for renal insufficiency. Delay in considering or securing this diagnosis incurs the risk of irreversible loss of renal function and enhances the susceptibility to such complications as infection and stone formation. Upper tract obstruction refers to lesions proximal to the bladder; obstruction at the level of the bladder and urethra is referred to as lower tract obstruction. Obstruction may be acute or chronic, intermittent or sustained, complete (or high-grade) or incomplete (low-grade). Renal failure arises if high-grade obstruction involves both kidneys or a solitary kidney, or if one kidney is obstructed and there is intrinsic disease in one or both kidneys.

Dilatation is designated by the prefix *hydro*, so hydronephrosis refers to dilatation of the ureter and hydronephrosis refers to dilatation of the renal pelvis and calyces. Dilatation of the urinary tract usually indicates underlying obstructive uropathy because the caliber of the urinary tract increases when obstructed. However, dilatation may exist without true obstruction to the urinary tract and, conversely, obstructive uropathy may be present with little or no dilatation ([Table 158.1](#)).

Dilatation without Obstruction	Obstruction without Dilatation
Pregnancy	Low-grade obstruction
Any state of high urinary output	Intermittent obstruction
Vesicoureteral reflux	Early obstruction
Congenital megaureters	Anuric renal failure
After relief of obstruction	Severe volume contraction
Acute pyelonephritis	Restrictive processes such as retroperitoneal fibrosis
Bladder distention	Masking of dilatation on ultrasound because of acoustic shadowing from staghorn calculi

TABLE 158.1. CLINICAL CIRCUMSTANCES IN WHICH DILATATION AND URINARY TRACT OBSTRUCTION MAY NOT COEXIST

INCIDENCE AND ETIOLOGY

Urinary tract obstruction in children is overwhelmingly due to congenital or developmental lesions, but in adults the causes are acquired and depend on the patient's age and sex. In persons ages 20 to 60 years, obstructive uropathy is more likely to afflict women than men, largely as a consequence of pregnancy and pelvic malignancies. Malignant obstruction in women is most commonly caused by carcinoma of the cervix; less common malignant causes are endometrial and ovarian carcinoma. In young to middle-aged adults, especially men, renal and urinary calculi are relatively common causes of obstructive uropathy, and these calculi usually consist of calcium oxalate; patients with recurrent infections may progress to struvite stones, which are prone to form staghorn calculi and cause obstruction. In patients older than 60, obstructive uropathy predominates in men because of the mounting incidence of benign prostatic hypertrophy and prostatic carcinoma. Indeed, transurethral resection of the prostate is the most common operation performed in men. Prostatic carcinoma is the most commonly diagnosed non-skin cancer in males, with approximately 200,000 new cases diagnosed in 1998.

Obstructive nephropathy contributed 5,358 cases of end-stage renal disease in the United States from 1993 to 1997. This number represents 2% of the total patients with end-stage disease. Of these, a little more than 75% were men. Similarly, in European studies, about 4% of patients with end-stage renal disease exhibited obstructive nephropathy, largely as a consequence of prostatic disease. In autopsy studies, the incidence of urinary tract obstruction is about 4%; many such lesions may remain undetected in older, relatively asymptomatic patients.

The causes of obstructive uropathy are summarized in [Table 158.2](#). Lesions may be intrinsic or extrinsic to the urinary tract, and intrinsic lesions are subdivided into intraluminal and intramural causes. Intraluminal lesions, in turn, may either be intrarenal or extrarenal. Intrarenal intraluminal obstruction may arise from the deposition of crystalline material such as uric acid in uric acid nephropathy or medications such as acyclovir; intraluminal obstruction may also occur from casts due to paraproteins from plasma cell dyscrasias. Intraluminal causes in the upper tract include urinary calculi, blood clots, sloughed renal papillae, and fungus balls. Intramural lesions may be functional, as in motility disorders affecting the ureteropelvic or the ureterovesical junctions, or structural lesions anchored within the walls of the ureter. Extrinsic lesions obstructing the upper tract may originate in several major sites, including vascular lesions, diseases involving the female reproductive system, disorders of the gastrointestinal tract, and retroperitoneal processes. Obstruction to the lower tract in older patients may arise from mass lesions in the bladder, prostatic hypertrophy, or carcinoma. In younger men, lower tract obstruction may be due to strictures, valves, stones, meatal stenosis, or phimosis.

(The content of Table 158.2 is illegible in the provided image.)

TABLE 158.2. DIFFERENTIAL DIAGNOSIS OF OBSTRUCTION TO THE URINARY TRACT

FUNCTIONAL CHANGES IN OBSTRUCTIVE NEPHROPATHY

ALTERATIONS IN RENAL HEMODYNAMICS

Acute total unilateral ureteral obstruction elevates renal pelvic and intratubular pressures. Renal blood flow is initially increased owing to dilatation of the afferent arteriole, a process that probably reflects increased production of vasodilatory prostaglandins. During the first few hours after the onset of obstruction, the tendency for increased intratubular pressures to decrease the glomerular filtration rate (GFR) is counteracted by increased glomerular capillary pressure and glomerular plasma flow rates, so GFR is not appreciably decreased. As obstruction persists, vasoconstrictive autacoids (thromboxanes and angiotensin II) are increasingly produced by the kidney, leading to the normalization and then the reduction in renal blood flow rates; GFR is now severely compromised as vasoconstriction is maintained. By 24 hours, sustained reductions in renal blood flow and GFR occur, although tubular pressures are relatively normal.

Acute bilateral complete obstruction is characterized by changes in GFR and renal blood flow directionally similar to those occurring in unilateral obstruction and more marked elevations in tubular hydrostatic pressures. When vasoconstriction supervenes in bilateral obstruction, the postglomerular vasculature is preferentially affected. In chronic partial obstruction, the degree to which GFR is diminished is determined by the severity of obstruction and any deficits in extracellular fluid volume. With adequate extracellular fluid volume, GFR is preserved by elevations in the glomerular capillary pressure, which is achieved by preferential efferent arteriolar constriction.

When bilateral ureteral obstruction is relieved, there is pronounced postobstructive diuresis and natriuresis and a slow recovery of GFR. The duration of obstruction determines the extent of recovery of renal function. A remarkable recovery of GFR, often to normal values, may occur in kidneys subjected to obstruction lasting several days. The longer the period of obstruction, the more attenuated is the regain of renal function after decompression. However, as demonstrated by studies of experimental obstructive uropathy, obstruction for as little as 24 hours incurs a loss of up to 15% of nephrons. The recovery of function that occurs, as assessed by GFR or serum creatinine, is partly due to hyperfunction in functioning remnant nephrons and does not truly reflect the irreversible scarring imposed by even relatively short periods of obstruction.

Vesicoureteral reflux provides a functional form of obstructive uropathy and nephropathy in which alterations in glomerular hemodynamics may contribute to the progressive glomerulosclerosis and renal insufficiency seen in some of these patients. In this disorder, there is reflux of urine from the bladder into the ureter during micturition. Such reflux does not normally occur because of the oblique course of the ureter through the detrusor muscle and the arrangement of the muscle fibers of the ureterotrigonal unit. Vesicoureteral reflux predisposes to recurrent infections, and infected urine refluxing into the kidney is the chief determinant of scar formation. Reflux also induces obstruction, albeit temporarily and intermittently; as described previously, obstruction is associated with renal hyperemia followed by vasoconstriction. Such repetitive cycles of glomerular hyperemia and vasoconstriction during vesicoureteral reflux may predispose to glomerulosclerosis.

ALTERATIONS IN TUBULAR FUNCTIONS

Alterations in tubular function are also determined by the chronicity of obstruction of the urinary tract. During acute partial obstruction, the fractional excretion of sodium may decrease. With chronic obstruction, however, sodium reabsorption by the kidney is reduced, as is the concentrating ability of the nephron. Reduction in concentrating ability reflects diminished responsiveness of the collecting duct to antidiuretic hormone, in conjunction with decreased interstitial medullary tonicity. The causes of decreased interstitial medullary tonicity include the washout of solute owing to persisting medullary blood flow in the face of diminished delivery of solute to the thick ascending limb of Henle. Additional mechanisms arise from the impaired reabsorption of solute by the thick ascending limb of Henle. High concentrations of solutes in the medullary interstitium are maintained by continued reabsorption of sodium chloride by the thick ascending limb of Henle, a reabsorptive process that is inhibited by prostaglandins and requires intact Na-K-ATPase activity. In the obstructed kidney, Na-K-ATPase activity is diminished but prostaglandin production is increased: these two biochemical alterations may impair the reabsorption of solute by the thick ascending limb, and in turn the maintenance of high concentrations of solute in the medullary interstitium. Prostaglandins also render the collecting ducts resistant to antidiuretic hormone, and such effects may provide an additional mechanism by which enhanced production of prostaglandins impairs concentrating ability.

Obstruction impairs urinary acidification. This may take the form of a type IV renal tubular acidosis (RTA) that results from resistance to the effects of aldosterone or from hyporeninemic hypoaldosteronism. In type IV RTA, hyperkalemia is a characteristic feature and arises because of the deficiency of aldosterone or the refractoriness of the potassium-secreting sites in the distal nephron to aldosterone. The inability of the chronically obstructed kidney, in some instances, to produce renin and to respond to aldosterone may represent the injurious effects of sustained obstruction or the effects of the interstitial infiltrate in the obstructed kidney. Obstruction may also impose a type I or classic distal RTA in which the distal nephron cannot initiate or maintain a maximal pH gradient. Studies in experimental models of obstructive nephropathy have uncovered defects in the proton ATPase, an enzyme critical in urinary acidification. With type I RTA, there is a tendency to urinary potassium wasting; the serum potassium level is normal or low. Tubular defects may persist for several months after the release from an obstructing lesion.

The relief of bilateral obstruction of a solitary kidney usually gives rise to postobstructive diuresis, but this does not occur after the relief of unilateral obstruction. Postobstructive diuresis can result in striking urinary output and natriuresis. Several mechanisms contribute to postobstructive diuresis, including the appropriate natriuresis for salt and water retained during the phase of compromised renal function and in excess of that required for adequate expansion of the extracellular fluid, the effects of a natriuretic factor accumulated during the anuric/oliguric phase, osmotic diuresis due to increased luminal concentrations of urea, resistance of the collecting duct to antidiuretic hormone, and impaired tubular reabsorption of sodium in the thick ascending limb of Henle and the medullary collecting ducts.

PATHOLOGIC CHANGES IN OBSTRUCTIVE NEPHROPATHY

Complete occlusion to the ureter dilates the pelvis and flattens the papillae. Increased water content in the acutely obstructed kidney accounts for increased kidney weight. Calyces dilate at the expense of the progressively thinning cortex, and it is such pelvicalyceal dilatation that enlarges the chronically obstructed kidney. On histologic examination, the medullary tubules are dilated and the epithelia of the distal nephron are flattened and simplified. An interstitial leukocytic infiltrate appears soon after the onset of obstruction. Proximal tubules exhibit dilatation and atrophy; the latter accounts for cortical thinning. The end-stage chronically obstructed kidney may be grossly cystic.

Such changes reflect the combined effects of ischemia due to sustained renal vasoconstriction, disuse atrophy, and the interstitial cellular infiltrate. Disuse atrophy is thought to occur in renal tubular epithelia that are reabsorbing less solute and water—and are thus metabolically less active—because of decreased GFR. The overriding importance of the interstitial infiltrate as a determinant of renal functional and structural impairment is supported by considerable recent evidence. Obstruction provokes the synthesis and release of chemotactic substances from the renal tubular epithelium that recruit the interstitial cellular infiltration engendered by urinary tract obstruction. The interstitial infiltrate produces various autacoids (e.g., prostanoids), cytokines, degradative enzymes, and reactive oxygen species that exert vascular effects, effects on tubular transport, and effects that are ultimately damaging to the kidney. This infiltrate may produce such fibrogenic cytokines as TGF- β 1, which could contribute to scarring of the kidney. Upregulation of the renin-angiotensin system within the acutely obstructed kidney, and, in turn, activation of the transcription factor NF- κ B by angiotensin II, are assigned critical roles in the initiation of the inflammatory events after obstruction to the urinary tract. Another mechanism by which injury arises may involve Tamm-Horsfall protein, a large-molecular-weight protein produced by the distal nephron and a major constituent of urinary casts. Tamm-Horsfall protein is detected in the interstitium in urinary tract obstruction, and the inspissation of protein in the interstitium may incite an inflammatory response.

CLINICAL FEATURES

The presenting features of obstructive uropathy depend on the cause of the obstruction, location, severity, and duration. Acute obstruction arising from calculi and blood clots is often associated with severe abdominal pain radiating into the groin. During these episodes, the patient experiences intense paroxysms superimposed on a background of unremitting pain. Such pain arises from acute distention of the renal capsule. Chronic hydronephrosis may be asymptomatic or may cause low-grade discomfort. With chronic obstructive conditions, the circumstances that surround the exacerbation of pain may suggest the underlying condition. For example, flank pain occurring after a large intake of fluid or diuretics intimates the presence of obstruction at the ureteropelvic junction, but pain in this area during micturition points to vesicoureteral reflux.

Alterations in urine output may also be a presenting feature. Complete bilateral obstruction may impose anuria, partial obstruction may underlie polyuria and nocturia, and intermittent obstruction may lead to oliguria alternating with polyuria. Bladder neck obstruction may present with a palpable bladder, suprapubic pain, frequency, urgency, hesitancy, and a weak urinary stream with terminal dribbling. Symptoms of dysuria, urgency, and discolored or cloudy urine may indicate underlying urinary tract infection.

Other clinical findings suggestive of obstructive uropathy are abdominal fullness or an abdominal mass, gross hematuria, or the presence of tissue or gravel in the urine. Patients may also present with hypertension that is dependent in part on impaired sodium excretion or activation of the renin–angiotensin system. Uremic symptoms may be the presenting feature in patients with advanced renal insufficiency due to obstructive uropathy.

In addition to these presenting features that directly result from the complications of obstructive uropathy, patients may display local or systemic manifestations of the disease or condition provoking obstruction to the urinary tract.

A careful physical examination should be performed, in particular attempting to ascertain the presence, cause, and complications of obstruction to the urinary tract. General examination may reveal such features of the uremic syndrome as fetor, pigmentation and pallor of the mucous membranes, or cachexia arising from an underlying malignancy. Hypertension and signs of volume overload may be present. Superimposed infection may be suggested by fever. Abdominal, rectal, and pelvic examinations should be done with special care. Obstructive uropathy may complicate prior surgical procedures, so abdominal incisions should be noted. The abdomen should be palpated for the presence of tenderness, enlargement of the bladder, organomegaly, masses, and ascites. The abdomen should be auscultated, as obstructive uropathy may present as an ileus. Rectal and pelvic examinations are essential components of the physical examination in patients suspected of having underlying obstructive uropathy. The rectal examination may reveal an enlarged prostate, nodularity of the prostate, or rectal or pelvic masses. The pelvic examination may reveal a vaginal, pelvic, or rectal mass.

LABORATORY FEATURES

Patients with obstructive nephropathy may present with hyperkalemia and hyperchloremic normal anion metabolic acidosis due to type IV RTA. Plasma bicarbonate concentrations may also be decreased because of type I RTA. Hyponatremia may arise from excess free-water intake in the setting of renal insufficiency or renal salt wasting. Alternatively, hypernatremia results from polyuria and excess free-water loss. Compromised GFR elevates blood urea nitrogen and serum creatinine levels. The serum calcium concentration may be decreased along with an elevation in the serum phosphate level. With progressive renal disease, normochromic, normocytic anemia is observed, but rarely polycythemia may be a complication of hydronephrosis.

Urinalysis may reveal hyaline and granular casts. Proteinuria is absent or present in trace to 1+ amounts. The presence of leukocytes and bacteria points to an underlying infection. Hematuria suggests calculi, blood clot, tumors, or a sloughed papilla. In patients with calculi, crystals of calcium oxalate, calcium phosphate, or cystine can be detected on urinalysis.

Acute urinary tract obstruction may decrease the fractional excretion of sodium and increase urine osmolality, thereby mimicking prerenal causes of renal insufficiency. However, in chronic obstructive nephropathy, sodium reabsorption is reduced, as is the kidney's concentrating ability.

RADIOGRAPHIC TECHNIQUES

These clinical and laboratory findings raise the suspicion of urinary tract obstruction, but establishing the diagnosis invariably requires procedures that visualize the kidneys and urinary tract.

PLAIN ABDOMINAL FILM

A kidney-ureter-bladder (KUB) film detects calculi along the course of the ureter in 80% to 90% of cases. A KUB may provide information on the size and shape of the kidneys and any differences in kidney size. Tomograms may provide better visualization of the renal size and shape and small areas of calcification. Other germane findings—such as the presence of bladder enlargement, abdominal or pelvic masses, or bony metastatic disease—may be revealed on a KUB.

ULTRASONOGRAPHY

Ultrasound is the screening procedure of choice in assessing the presence of obstructive uropathy. It is noninvasive and especially suitable for demonstrating obstruction in the setting of renal insufficiency because it does not depend on renal function. In the normal kidney, the relatively hypoechoic parenchyma surrounds a hyperechoic central complex comprising peripelvic fat, blood vessels, and the renal pelvis. Hydronephrosis is diagnosed on ultrasound by a dilated intrarenal central collecting system containing anechoic fluid. Cortical thinning, which may arise in chronic obstructive nephropathy, is also readily detected. Ultrasound examination has 90% sensitivity and 80% specificity in the diagnosis of obstructive uropathy. A false-positive diagnosis of urinary obstruction may occur in nonobstructive dilatation of the upper tract; on the other hand, obstruction may be present without ultrasound-detectable dilatation. Calculi can also be detected by ultrasound.

Although useful as a screening procedure, ultrasound examination is limited by its inability to define the site and cause of obstruction. Obtaining such information often requires other procedures.

INTRAVENOUS PYELOGRAPHY

Intravenous pyelography (IVP) visualizes the kidney, calyces, pelvis, and ureter and may detect the site of obstruction. It should be used in the initial assessment of patients suspected of having obstructive uropathy and in whom renal function is normal. The chronicity and severity of obstruction determine the findings on IVP. In acute cases, the nephrogram is delayed but is of higher density, because contrast medium is concentrated to a greater extent. The calyces, renal pelvis, and ureter are dilated above the obstruction, and the renal contour may be increased in size. The calyceal fornices promptly dilate after obstruction. With the persistence of urinary tract obstruction, the papillae are blunted and become frankly concave, the calyces assume a clubbed contour, and the overlying cortex progressively thins. Such structural derangement is accompanied by functional impairment leading to a faint nephrogram. In some cases, the kidney subjected to sustained obstruction is contracted and reduced in size. Whatever the size of the chronically obstructed kidney, the contralateral, uninvolved kidney undergoes hypertrophy. Retroperitoneal fibrosis causes a characteristic medial deviation of the ureters on IVP. Bladder neck obstruction causes dilatation of the bladder and ureters, bladder trabeculation, and sometimes the formation of bladder diverticula and tortuosity of both ureters.

The adverse effects of IVP include allergy to contrast dye and the nephrotoxicity of these agents. The latter is more likely to occur in patients with renal insufficiency, multiple myeloma, or diabetes mellitus, or in older patients.

RETROGRADE AND ANTEGRADE PYELOGRAPHY

Retrograde and antegrade pyelography involves direct injection of contrast dye into the collecting system. It may be indicated in patients suspected of having obstructive uropathy in whom the diagnosis is not secured by other means, or in patients in whom IVP is contraindicated because of dye allergy or renal insufficiency. These procedures can localize the level of obstruction, determine whether obstruction is intraluminal or intramural, and decompress the urinary tract.

Retrograde pyelography involves catheterization of the ureter after cystoscopy and may require general anesthesia. The absence of contrast 10 minutes after retrograde injection argues against the presence of underlying obstruction. Antegrade pyelography involves entry into the collecting system by a percutaneous route under local anesthesia. This procedure also allows immediate relief of unilateral obstruction, urodynamic studies, and sampling of urine and tissue. The risks include bleeding, infection, and extravasation of urine.

RADIONUCLIDE IMAGING

Although it lacks the anatomical clarity of IVP, renal scintigraphy allows assessment of renal function, especially the relative function of the two kidneys, and allows monitoring of the recovery of renal function in a previously obstructed kidney. Diuretic renography is helpful in differentiating a dilated nonobstructed collecting system from true obstruction. In this test, renal scintigraphy is performed, a loop diuretic such as furosemide is administered, and additional scans are obtained. Diuresis facilitates washout of the isotope that accumulates in the dilated nonobstructed renal pelvis but not in a renal pelvis with true anatomical obstruction.

ABDOMINAL COMPUTED TOMOGRAPHY

Although not usually used in the initial evaluation of the patient suspected of having obstruction, computed tomography (CT) is particularly useful in determining the cause of obstruction because of the remarkable anatomical visualization it provides. In addition, CT is especially useful in evaluating patients in whom IVP is contraindicated because of dye allergy or renal insufficiency. Features that may be present on CT scans are dilatation of the collecting system, delayed excretion of dye in studies using contrast, and atrophy of the renal parenchyma. CT scanning of the abdomen is particularly useful in determining such causes of obstruction as retroperitoneal fibrosis and malignancies, abdominal lymphadenopathy, abdominal and pelvic masses, hematomas, and calculi.

MAGNETIC RESONANCE IMAGING

The exact role magnetic resonance imaging (MRI) will play in diagnostic evaluation is currently being defined. MRI provides enhanced soft-tissue contrast resolution, freedom from adverse effects of contrast material, and, in combination with gadolinium compounds, determination of GFR. It may thus assess obstruction structurally and functionally. MRI allows visualization of the kidney, even without any function, and dilatation of the urinary tract, the site of obstruction, and the presence of urinary tract infection. Lesions such as malignancies, enlarged lymph nodes, other mass lesions, and processes in the retroperitoneum (e.g., fibrosis, masses) may also be detected by MRI.

OTHER DIAGNOSTIC PROCEDURES

The Whitaker test may be used to diagnose obstruction of the upper urinary tract if other diagnostic tests are unclear. In this test, the hydrostatic pressure difference between the renal pelvis and bladder is determined at ambient urinary flow rates and again after fluid is infused into the renal pelvis at a specific rate. A pressure differential greater than 20 cm H₂O usually indicates ureteral obstruction. A voiding cystourethrogram is used to investigate the presence of vesicoureteral reflux and the function of the bladder. Obstruction to the lower urinary tract may be evaluated by cystoscopy, contrast studies, and urodynamic tests. Cystoscopy inspects the urethra and bladder. The anterior and posterior urethra can be assessed by contrast studies. Urodynamic evaluation is used in the diagnosis of neurogenic bladder dysfunction and includes cystometrography, electromyography, a urethral pressure profile, and urine flowmetry.

OPTIMAL MANAGEMENT

The goals of management are the relief of symptoms, the correction of fluid and electrolyte abnormalities, the restoration and preservation of renal function, and the prevention or effective treatment of complications such as infection or stone formation. The clinical circumstances determine management, so the therapeutic approach may be conservative or may require instrumentation, endourologic techniques, or surgical procedures. High-grade obstruction involving both kidneys or high-grade obstruction in a solitary kidney should be relieved as soon as possible, using retrograde ureteral catheters or percutaneous nephrostomy tubes. Obstruction of any severity should be promptly relieved if there is concomitant urosepsis. In some patients with renal failure as a complication of bilateral obstruction, the severity of volume overload, hyperkalemia, or acidosis may mandate acute dialysis before the relief of obstruction.

Acute obstruction to the upper tract is commonly caused by calculi. Stones less than 7 mm usually pass spontaneously, and patients can be managed on an outpatient basis if they can tolerate large amounts of oral liquids. Larger stones usually necessitate intervention. Extracorporeal shock-wave lithotripsy can be used for most types of kidney stones lying in the pelvis and the upper and mid-ureter. Calculi distal to the pelvic brim are usually treated by ureteroscopy combined with stone extraction or stone fragmentation. A surgical approach is used for some lesions that cause upper tract obstruction, including intramural lesions, ureteropelvic junction obstruction, mass lesions of the renal pelvis or ureter, retroperitoneal fibrosis, or fibrosis secondary to such conditions as an abdominal aneurysm. Sometimes repair is impossible, and urinary diversion may be necessary.

Lower tract obstruction may require prostatectomy, urethral dilatation, endoscopic urethrotomy, or an open procedure, depending on the underlying cause. Occasionally, suprapubic cystostomy is required before definitive correction. Clean intermittent catheterization is indicated for most forms of neurogenic bladder; for certain types of dysfunction, pharmacologic therapy may be beneficial. Chronic indwelling catheters should not be used in patients with neurogenic bladder because of the risks of infection, stone formation, and bladder carcinoma. In patients with neurogenic bladder and other forms of lower tract obstruction, surgical diversion using an ileal conduit may be required.

Postobstructive diuresis may lead to marked contraction of the extracellular fluid and, depending on the relative losses, hyponatremia or hypernatremia; hypokalemia, hypomagnesemia, and hypophosphatemia may also occur. If patients are euvoletic, half-normal saline should be infused at 50 to 75 mL per hour, with careful assessment of orthostatic changes in blood pressure, pulse, plasma electrolytes, and renal function. This regimen usually allows the excretion of salt and water retained during the obstructive phase and avoids excessive fluid administration, which may sustain continued diuresis and natriuresis. If extracellular fluid volume contraction develops on this regimen, then additional amounts of fluid, and solutes where appropriate, should be provided to repair the loss.

CHAPTER 159: RENAL LITHIASIS

DAVID A. BUSHINSKY

[Calcium Stones](#)
[Uric Acid Stones](#)
[Magnesium Ammonium Phosphate \(Struvite\) Stones](#)
[Cystinuria](#)

The incidence of renal lithiasis (kidney stones), although difficult to determine precisely, appears to be slightly over 1 case per 1,000 hospitalized patients per year and has been slowly increasing in recent decades. Stones lead to considerable morbidity, often requiring hospitalization, shock-wave lithotripsy, or surgery. Understanding the mechanisms of stone formation leads to rational treatment and a decreased incidence of stone disease and its associated morbidity.

Kidney stones are generally composed of calcium salts, uric acid, magnesium ammonium phosphate (struvite), or cystine. They develop from urine that is oversaturated with the components of the stone. Saturation depends on chemical free-ion activity. The chemical free-ion activity of the components of a stone, in a solution in which the stone will neither grow nor dissolve, is said to be at the equilibrium solubility product. If the free-ion activity decreases, the urine becomes undersaturated and the stone does not grow and may even dissolve. If the free-ion activity increases, the solution becomes oversaturated, and the stone may grow.

The chemical free-ion activity is influenced by many factors, including the concentration of the relevant ions, the urine pH, and complexation with substances in the urine. The chemical free-ion activity is directly related to the ion concentration, a function of how much of the particular ion is excreted in a specific volume of urine. Increased ion excretion and decreased urine volume increase free-ion activity. Urine pH is particularly important with respect to uric acid oversaturation. Citrate forms soluble complexes with calcium and thus reduces its free-ion activity.

Kidney stones can form and grow through homogeneous or heterogeneous nucleation. With homogeneous nucleation, increasing chemical free-ion activity leads to oversaturation with respect to a solid phase. Once this oversaturation reaches the formation product, the relevant ions form small clusters, which can grow to form a permanent solid phase. With heterogeneous nucleation, crystals grow on the surface of a dissimilar but complementary crystal or on another, often foreign, substance. *In vivo*, heterogeneous nucleation predominates over homogeneous nucleation, as the presence of a solid phase allows for crystal growth at a lower level of oversaturation (a so-called metastable solution) than if no solid phase is present. Microscopic crystals take longer to grow into clinically significant stones than the passage time for fluid through the renal tubule. It is thought that crystals must adhere to tubular cells, allowing time for further growth.

Urine from stone-formers is generally more oversaturated than urine from persons who do not form stones. However, despite similar degrees of oversaturation, some persons form stones but others do not. This may be due to the presence of inhibitors of crystallization. Uropontin, nephrocalcin, and pyrophosphate inhibit the formation of calcium-containing crystals. Some studies have shown a decrease in inhibitor activity when the urine of stone-formers is compared with that of controls, but the influence of abnormalities in the composition or quantity of inhibitors on the occurrence or frequency of stone formation is unclear.

Clinicians generally determine the lithogenic potential of urine by measuring the rates of solute excretion, in mass per unit time, of the principal components of stones, but the critical determinant of crystallization is oversaturation. Computer programs that calculate saturation from measured ion concentrations are available and will increasingly be used for more accurate determination of the lithiasis risk. Even with sophisticated calculations of saturation, because of variations in hourly urine output of both water and solute, any mean collection underestimates the maximum oversaturation.

CALCIUM STONES

About 70% of all kidney stones contain calcium and are composed of calcium oxalate or calcium phosphate or a combination ([Table 159.1](#)). Pure calcium oxalate stones are more common than pure calcium phosphate stones. In general, once a patient forms a calcium-containing stone, he or she will form another in less than 7 years, with a decreasing time interval to subsequent stone events. Although pregnancy causes an increase in urine calcium excretion, it does not accelerate stone formation. Calcium stones may form secondary to excess calcium, oxalate, or uric acid excretion, or they may be idiopathic.

Type	%
Calcium oxalate and calcium phosphate	37
Calcium oxalate	26
Calcium phosphate	7
Uric acid	5
Struvite	22
Cystine	2

TABLE 159.1. TYPE AND PERCENTAGE OF RENAL STONES

EXCESS CALCIUM EXCRETION

Idiopathic Hypercalciuria

Patients with idiopathic hypercalciuria have a normal serum calcium concentration, but their urine calcium excretion rate exceeds 300 mg per 24 hours (men) or 250 mg per 24 hours (women), or 4 mg per kilogram in either sex. These patients lack an apparent disorder that would elevate urine calcium excretion. Idiopathic hypercalciuria tends to be familial and is more prevalent in men, and initial stone formation often occurs in the third decade of life. The cause of idiopathic hypercalciuria is not known, but it may result from disordered regulation of calcium handling at sites where large fluxes of calcium must be tightly regulated. This disordered regulation may occur in the intestine, the kidney, or the bone, resulting in an increase in urine calcium excretion ([Table 159.2](#)). Increased intestinal calcium absorption may occur either by a direct mechanism or through excess calcium absorption mediated by 1,25-dihydroxyvitamin D₃.

Parameter	Increased Intestinal Ca Absorption		Decreased Renal Reabsorption		Enhanced Bone Demineralization
	Direct	Excess 1,25(OH) ₂ D ₃	Calcium	Phosphorus	
Ca absorption	↑	↑	↑	↑	↓
Serum 1,25(OH) ₂ D ₃	↓	↑	↑	↑	↓
Serum PTH	↓	↓	↑	↓	↓
Bone Ca	↑	↑	↑	↑	↑
Excreting serum Ca	↑	↑	↑	↑	↑
Excreting serum P	↓	↓	↓	↓	↓
Excreting urine Ca	↑	↑	↑	↑	↑
Urine Ca after low Ca diet	↑	↑	↑	↑	↑

Ca, calcium; 1,25(OH)₂D₃, 1,25-dihydroxyvitamin D₃; PTH, parathyroid hormone; P, phosphorus; ↓, normal.

TABLE 159.2. EXPECTED SERUM AND URINE VALUES IN ALTERNATIVE MECHANISMS OF IDIOPATHIC HYPERCALCIURIA

The increase in intestinal calcium absorption results in a slight increase in the serum calcium level, a fall in the parathyroid hormone (PTH) level, and an increase in the amount of calcium filtered by the glomerulus and entering the renal tubule. Because PTH increases renal tubule calcium reabsorption, a fall in PTH, combined with an increase in the filtered load of calcium, results in hypercalciuria. Decreased renal reabsorption of either calcium or phosphorus (the latter through a hypophosphatemia-induced increase in 1,25-dihydroxyvitamin D₃) results in hypercalciuria. A primary increase in bone mineral resorption increases the serum calcium level, suppresses PTH, and results in hypercalciuria.

Patients with idiopathic hypercalciuria have eluded efforts to be characterized into any of these specific diagnostic groups. Although there are expected serum and urine values for the alternative mechanisms of hypercalciuria, in formal metabolic studies there has been enough day-to-day variation among individual patients to preclude specific categorization. Among large numbers of patients, there appear to be smooth transitions in these metabolic parameters between patients, again precluding meaningful grouping. However, several general concepts have emerged from studies of patients with idiopathic hypercalciuria. Most investigators agree that patients have an increase in net intestinal calcium absorption, have increased 1,25-dihydroxyvitamin D₃ levels, have increased intestinal calcium absorption relative to the 1,25-dihydroxyvitamin D₃ levels, and have mild decreases in bone mineral density. These abnormalities appear to point to a systemic dysregulation of the effect of 1,25-dihydroxyvitamin D₃ acting on the intestine, bone, and possibly kidney. Studies in a genetic hypercalciuric rat model support this concept.

Reducing urine calcium excretion, especially with long-acting thiazide diuretics, and increasing fluid intake are the cornerstones of treatment. Limiting sodium and protein intake are advantageous in decreasing urine calcium excretion and stone formation.

Hyperparathyroidism

Patients with hyperparathyroidism have an elevated serum calcium concentration, elevated urine calcium excretion, and decreased serum phosphorus concentration, all associated with an increase in the serum level of PTH. The elevation in serum calcium can be very mild, and measurement of ionized calcium may be helpful for diagnosis. The disorder is more common in elderly females, and generally a single parathyroid adenoma is found at surgery. Patients generally form hydroxyapatite or calcium oxalate stones.

PTH increases renal tubule calcium reabsorption, increases net bone resorption, and increases the synthesis of 1,25-dihydroxyvitamin D₃. Thus, excess, unregulated secretion of PTH results in hypercalcemia, which increases the renal filtered load of calcium. When this increased filtered load exceeds tubule calcium reabsorption, which is increased by PTH, hypercalciuria ensues. PTH also decreases renal tubule phosphate reabsorption, resulting in hypophosphatemia despite the increased phosphate absorption mediated by increased 1,25-dihydroxyvitamin D₃. A reduction in serum phosphate results in further elevations of 1,25-dihydroxyvitamin D₃, and thus calcium absorption, worsening the hypercalcemia and hypercalciuria.

Other hypercalcemic disorders occasionally lead to stone formation. The granulomatous tissue found in sarcoidosis and tuberculosis may convert 25-hydroxyvitamin D₃ to 1,25-dihydroxyvitamin D₃, resulting in hypercalcemia and hypercalciuria; however, PTH levels are depressed. Excess vitamin D supplementation, especially with ample calcium intake, results in hypercalciuria, and PTH levels again are depressed. Lithium therapy may directly increase the PTH level and result in hypercalcemia and hypercalciuria. Malignant cells can secrete PTH-related peptide, which acts in a manner similar to PTH but is not detected on standard PTH assays. Specific assays for PTH-related peptide are available.

Renal Tubular Acidosis

Two thirds of patients with classic distal renal tubular acidosis (type I RTA), either of the spontaneous or inherited variety, have nephrocalcinosis or nephrolithiasis; the stones are generally composed of calcium phosphate. Patients with proximal RTA (type II) generally do not have nephrocalcinosis or stones.

The mechanism of stone formation in patients with distal RTA is multifactorial. These patients have increased urinary excretion of calcium and phosphate, a high urinary pH, and decreased excretion of citrate. Increased urinary calcium excretion is due to a direct effect of acidosis, which reduces renal tubule calcium reabsorption. There is no concomitant increase in intestinal calcium absorption, so the increased urinary calcium must be derived from bone stores. The increased urinary pH decreases the solubility of calcium phosphate complexes, resulting in greater urinary oversaturation at any urinary calcium and phosphorus concentration. Citrate, the most prevalent organic anion in the urine, is freely filtered by the glomerulus and reabsorbed in the proximal tubule. Acidosis increases proximal tubule citrate reabsorption and decreases its excretion. Citrate binds calcium, lowering its concentration, and appears to inhibit crystallization. Thus, an acidosis-induced reduction in urinary citrate excretion increases the available calcium, raising oversaturation with respect to calcium phosphate complexation, and decreases an important crystallization inhibitor. Alkali administration, best given as the potassium salt, is thought to reduce nephrocalcinosis and nephrolithiasis, despite maintenance of an elevated urinary pH.

DECREASED CITRATE EXCRETION

Urinary citrate is decreased in many patients who form calcium stones. The decreased citrate excretion may be secondary to excessive protein intake, which leads to increased production of endogenous acid and increased net acid excretion. Decreasing dietary acid intake or ingesting potassium bicarbonate or potassium citrate increases citrate excretion and may help prevent stone formation.

EXCESS OXALATE EXCRETION

Most patients who form calcium oxalate stones excrete amounts of urinary oxalate (less than 40 mg per day) similar to those who do not. However, some excrete excessive oxalate, leading to calcium oxalate oversaturation and stone formation.

Oxalate is an end product of metabolism. Excessive urinary oxalate comes either from enhanced intestinal absorption or production. Normal humans absorb less than 5% of dietary oxalate. However, foods rich in oxalate, such as spinach and rhubarb, chocolate, peanuts, and cocoa, can increase urinary oxalate by 25% to 50%. Intestinal oxalate absorption, mainly in the colon, is increased by a reduction of dietary calcium, as oxalate forms insoluble and unabsorbable salts with calcium. Conversely, absorption is decreased by the use of oral calcium carbonate. Gastrointestinal disorders such as Crohn's disease, celiac sprue, and intestinal bypass surgery, which result in dietary fat malabsorption, lead to enhanced oxalate absorption, because the long-chain fatty acids and bile increase colonic permeability to oxalate. Binding the fatty and bile acids with cholestyramine decreases oxalate absorption.

Glycolate oxidation produces the bulk of urinary oxalate. There are two types of hereditary hyperoxaluria; in both cases, oxalate production is increased. The more common type, type I, is an autosomal recessive disease in which the excretion of glyoxylate, glycolate, and oxalate is increased. In type II, excretion of L-glyceric acid and oxalate is increased. Pyridoxine administration decreases oxalate excretion in some patients with type I.

A not uncommon cause of acute calcium oxalate crystal deposition, in the form of nephrolithiasis or nephrocalcinosis, is the accidental or intentional ingestion of ethylene glycol, used as an antifreeze, which is metabolized to oxalate.

EXCESS URIC ACID EXCRETION

Calcium stone-formers have an increased frequency of hyperuricosuria (more than 800 mg per day in men, more than 750 mg per day in women) than do persons who do not form stones. In general, excess uric acid excretion is a consequence of increased dietary purine intake derived from meat, poultry, and fish. Reducing uric acid excretion with allopurinol decreases the formation of calcium oxalate stones.

The mechanism by which hyperuricosuria promotes calcium oxalate stones is uncertain. The dimensions of uric acid crystals closely match those of calcium oxalate,

and uric acid crystals appear to promote heterogeneous nucleation of calcium oxalate from a metastable urine. Alternatively, the excess uric acid may adsorb inhibitors of calcium oxalate crystallization, allowing stone formation to occur at modest degrees of oversaturation.

IDIOPATHIC

Even after extensive evaluation, in some patients a clear cause of stone formation cannot be found. Excretion of calcium, oxalate, and uric acid is normal, and the urine is not oversaturated with respect to solid phases of calcium oxalate or calcium phosphate. It is impossible to determine a mechanism for stone formation, so decisions regarding treatment to prevent another stone are speculative. The results of stone analysis, if available, can guide treatment.

URIC ACID STONES

Urine pH is a major determinant of uric acid oversaturation and subsequent stone formation. Uric acid is a weak acid in which two H⁺ may, in theory, be dissociated. However, as the pK of the first H⁺ dissociation is 5.4 and of the second is 10.0, only the first can be dissociated at an attainable urine pH. Uric acid (with two H⁺) is far less soluble than urate (with one H⁺), indicating that solubility increases with increasing urine pH. At an acid urine pH of 5, even the normal uric acid excretion of less than 800 mg per 24 hours (in men) in 1 L of urine may result in oversaturation and potential stone formation. Urine pH is determined by endogenous acid production and the proportion of net acid excreted as NH₄⁺ compared with that excreted as titratable acidity. The more net acid that can be excreted as the base NH₄⁺, the higher the urine pH. Several studies indicate that uric acid stone-formers excrete less net acid as NH₄⁺ and more as titratable acidity, lowering the urine pH.

Other than urine pH, the main determinants of urinary saturation with respect to uric acid are uric acid production and excretion and urinary volume. In normal persons, uric acid production is a direct function of dietary purine intake from meat, poultry, and fish. Increasing purine intake (especially more than 4 mg per kilogram per day) increases uric acid excretion. Some patients with gout have mild overproduction of uric acid; others with genetic defects of purine reuse, such as the Lesch–Nyhan syndrome, have massive overproduction of uric acid. Patients with myeloproliferative disorders often overproduce uric acid and during treatment may have massive release of preformed uric acid.

The kidneys are responsible for over 50% of daily uric acid excretion, with the rest degraded in the intestine. Some patients have a relative decrease in renal tubule uric acid reabsorption, resulting in increased uric acid excretion and decreased intestinal degradation. Up to 25% of patients with clinical gout have uric acid nephrolithiasis. These patients tend to have excess uric acid excretion, even when they consume a low-purine diet and have a very acidic urine pH. Patients with chronic diarrhea are particularly at risk for uric acid stones, because they tend to be dehydrated and the alkaline diarrheal fluid causes metabolic acidosis and an acidic urine. Probenecid and large doses of salicylates promote uric acid excretion and predispose to stone formation.

The main tenets of treatment are hydration, dietary purine moderation, urinary alkalization, and, if necessary allopurinol. Increasing fluid intake and decreasing the amount of dietary purine decrease urinary oversaturation. Alkalinization with bicarbonate or a bicarbonate precursor such as citrate should be aimed at maintaining a urine pH over 6.0 throughout the day and night. During the day, multiple doses of bicarbonate—to match the endogenous acid production of about 1 mEq kilogram per 24 hours—can be used. If the nocturnal urine pH falls, acetazolamide can be used. If these measures are unsuccessful, allopurinol can be instituted.

MAGNESIUM AMMONIUM PHOSPHATE (STRUVITE) STONES

Magnesium ammonium phosphate stones form only when the urinary tract is infected with urea-splitting bacteria. Most *Proteus* and *Providencia* species have urease that splits urea, as do some species of *Klebsiella pneumoniae* and *Serratia marcescens*. Bacterial urease hydrolyzes urea to form NH₃, CO₂, and H₂O, consuming H⁺ during the hydrolysis; the urine pH rises. NH₃ spontaneously hydrolyzes to form NH₄OH, and the CO₂ is hydrated to form HCO₃⁻, which becomes CO₃⁼ in the alkaline urine. Concentrations of NH₄OH and CO₃⁼ are elevated, and any phosphate present is deprotonated (PO₄³⁻). The struvite (MgNH₄PO₄ · H₂O) stones are readily formed on the PO₄³⁻ backbone, as are carbonate apatite [Ca₁₀(PO₄)₆ · CO₃] stones due to the presence of CO₃⁼. The carbonate apatite is usually present within the struvite and can even be the predominant species.

Without bacterial urease, this cascade of events cannot occur. Infection often occurs in the presence of structural abnormalities, either congenital or acquired. Struvite stones may form secondary to another stone that causes infection and obstruction. In the presence of bacteria, local oversaturation occurs and crystals form around the bacteria. The infection is difficult to control because normal urine flow, which can wash away bacteria, is disrupted. The stones rapidly grow and can fill the renal collecting system, resulting in staghorn calculi. Hematuria is common, and renal failure can result from obstruction and infection. Surgical stone removal is difficult, because any retained stone fragment often contains bacteria and can be the nidus for new calculi formation.

CYSTINURIA

Cystinuria is a rare hereditary disorder in which a tubular defect in dibasic amino acid transport results in increased cystine, ornithine, lysine, and arginine (COLA) excretion. The stone disease often presents by the fourth decade. Owing to the sulfur content of the cystine molecule, the stones are apparent on plain radiographs and often present as staghorn calculi or multiple bilateral stones. Cystinuria, in which cystine accumulates only in the lumen of the renal tubules, is distinct from cystinosis, in which there is widespread intracellular cystine deposition.

Cystine is poorly soluble, at about 300 mg per liter at neutral pH. Thus, the normal cystine excretion of about 30 to 50 mg per day is readily soluble in the daily urine output. However, homozygote cystinurics generally excrete 250 to 1,000 mg of cystine per day, with heterozygotes excreting an intermediate amount. There are at least three distinct types of cystinuria, which can be classified by intestinal transport studies.

Treatment must be directed at decreasing the urinary cystine concentration below the limits of solubility. The dietary precursor of cystine, methionine, is an essential amino acid, and it is impractical to reduce intake and thus excretion. Increasing urinary volume so that cystine remains below the limits of solubility is often practical, but sometimes 4 L of urine is necessary. Increasing urine pH above 7.5 increases the solubility of cystine, but this is often difficult on a chronic basis. D-penicillamine or tiopronin bind cystine and reduce urinary oversaturation, but side effects limit their use.

[Cancer of the Renal Collecting System](#)
[Benign and Miscellaneous Tumors](#)

CANCER OF THE KIDNEY

DEFINITION

Renal neoplasms are uncommon, accounting for 3% of all adult malignancies in Western society. Most of these cancers are renal cell carcinomas, although other rare tumors of the kidney have been described, including transitional cell carcinoma, sarcoma, adult Wilms' tumor, and germ cell tumor (teratoma).

INCIDENCE AND EPIDEMIOLOGY

Renal cell carcinoma (RCC) affects 30,600 people in the United States annually, and the incidence is steadily rising. More than 10,000 deaths occur each year. Patients with this cancer usually present during the fifth to seventh decades of life; the median age at diagnosis is 60. Men are affected twice as frequently as women. RCCs are found in all ethnic groups with no racial predilection. Most RCCs occur sporadically; however, about 4% of cases are an inherited pattern. Such familial renal cancers include von Hippel–Lindau disease (VHL) and familial papillary renal cell cancers. Approximately 1.6% of RCCs are part of the autosomal dominant VHL disease, characterized by retinal and central nervous system hemangioblastoma, pheochromocytoma, pancreatic cyst, and RCC. Compared with sporadic cases, RCCs in the von Hippel–Lindau syndrome tend to be multifocal and bilateral and appear at a younger age in life. RCC and malignant angiomyolipoma are also associated with tuberous sclerosis complex, an autosomal dominant disorder of unknown cause characterized by seizures, mental retardation, and hamartomas.

ETIOLOGY

The cause of RCC remains largely undefined. Smoking is linked to an increased risk of renal cell carcinoma in men, but the association is somewhat weaker in women. Obesity and hypertension are two other independent risk factors. The relation between RCC and the use of antihypertensive agents such as calcium channel blockers and diuretics remains unclear. Patients with autosomal dominant or recessive polycystic kidney disease do not have an increased risk for RCC compared with the general population. However, a 3- to 6-fold higher incidence of RCC has been found in the chronic dialysis population as well as in renal transplant recipients, presumably owing to the development of acquired cystic kidney disease. Occupational exposure to chemicals appears to have little consistent significance, although a range of different occupations has been implicated in isolated case-control studies. Data are inconsistent on the role of diet in the development of RCC.

The isolation of the VHL gene in 1993 on chromosome 3p25 came as a breakthrough in the area of molecular genetics of RCC. Subsequently, the gene was found to encode for a tumor suppressor protein. This protein competes with elongin A in binding with elongin B and C, thus preventing the formation of a transcriptional elongation complex and thereby inhibiting the transcription of certain target genes in cell proliferation. At the molecular level, both copies of the VHL gene must be inactivated for tumors to develop; therefore, the first mutation in the VHL gene is inherited in the germline, and inactivation of the remaining wild-type allele occurs as a somatic event. Inactivation of the VHL gene could also be responsible for the nonhereditary forms of RCC, since somatic mutation of the VHL gene has been found in 75% to 80% of sporadic RCC cases. To date, the VHL gene does not appear to be involved in the development of papillary renal carcinomas.

PATHOGENESIS

Recent immunohistochemical studies suggest that RCCs arise from the proximal convoluted tubular cells. Therefore, “hypernephroma” is a misnomer because Grawitz, who introduced the term to describe the clear cell variant of RCC, thought the tumor originated from heterotopic adrenal (hypernephroid) rests in the kidney.

Most RCCs are solitary lesions affecting either kidney with equal frequency. However, the tumors can be multicentric in the same kidney (4%) or bilateral (3%). Grossly, the tumors are often well-demarcated round masses protruding from the cortex. The clear cell tumors are usually yellow owing to high lipid content. On cross section, areas of necrosis, cystic degeneration, hemorrhage, and calcification are commonly present. Histologically, RCCs are classified into clear cell type (75% to 85%), chromophilic type (12% to 14%), chromophobic type (5%), oncocytic type (2% to 4%), and collecting duct type (1%).

CLINICAL FINDINGS

With the increasing application of ultrasonography and computed tomography (CT) scans for the diagnosis of nonspecific abdominal symptoms and other conditions, 20% to 30% of cases are discovered incidentally as small tumors in a clinically asymptomatic stage. The classic triad of hematuria, flank pain, and a palpable mass is seen only in less than 10% of patients with RCC and usually portends an unfavorable outcome. However, presentation with one or two of these three symptoms is common, since about 70% of patients with RCC have gross or microscopic hematuria, 50% have abdominal or flank pain, and 40% have a palpable mass. An approach to the investigation of hematuria is summarized in [Figure 160.1](#). When the tumor grows, it may extend into and invade surrounding structures, such as the perinephric fat, posterior abdominal wall, inferior vena cava, ureter, adrenal gland, spleen, liver, and pancreas. Patients with left-sided RCC can present with acute left varicocele from obstruction of the spermatic vein. Hypertension may occur if the tumor compresses the parenchymal vasculature, causing increased renin production. Renal failure may result from tumor replacing the normal kidney tissue or from secondary amyloidosis. Constitutional symptoms, such as fever, night sweats, anorexia, and weight loss are common.

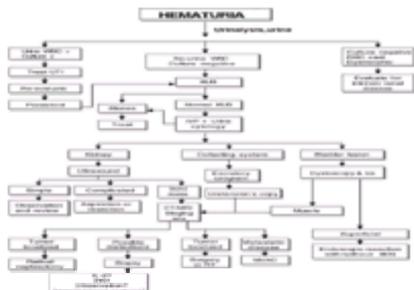

FIGURE 160.1. Approach to the investigation of hematuria.
EVIDENCE LEVEL: C. Expert Opinion.

Because the renal bed is a clinically silent area, only 40% of patients have disease confined to the kidney at diagnosis, and over 20% of patients present with symptoms of metastatic lesions. Tumor spreads by either hematogenous or lymphatic routes. The common sites of distant metastasis are the lungs, lymph nodes, liver, bone, and brain, although metastatic lesions have been described in virtually every organ of the body.

Paraneoplastic syndromes are relatively common features in RCC, the most notable ones being hypercalcemia and erythrocytosis, from the tumor secretion of parathyroid hormone-like immunoreactive protein and erythropoietin, respectively. Anemia may often be present. Hyponatremia with inappropriate secretion of

antidiuretic hormone and Cushing's syndrome from ectopic adrenocorticotrophic hormone production can also be seen. Hypercoagulable states with venous thrombosis or pulmonary emboli have been described. Moreover, other rare paraneoplastic syndromes, such as amyloidosis, nonmetastatic hepatic dysfunction, limbic encephalitis, erythema gyratum repens, myopathy, and polymyalgia rheumatica, have been reported.

For reasons that are unclear, patients with RCC may be at increased risk for the development of second malignancies, such as those of the breast, prostate, colorectum, and bladder, malignant melanoma, and lymphoma.

LABORATORY FINDINGS

In a patient with a history or physical findings that suggest a renal malignancy, the initial characterization of a mass lesion is usually achieved with intravenous pyelography (IVP) or ultrasonography. IVP is a simple, noninvasive screening test. It may differentiate between renal cysts and malignant lesions and may reveal complications such as ureteral obstruction and hydronephrosis. Ultrasonography is another convenient screening method to evaluate a suspicious renal mass and is especially useful in differentiating between solid and cystic lesions. When combined with IVP, ultrasound differentiates benign cysts from solid masses with an accuracy near 98%. It can also be used to evaluate the size of the contralateral kidney and to rule out obstruction and hydronephrosis. However, ultrasound cannot be reliably used to assess the renal vein, intrahepatic inferior vena cava, and retroperitoneal lymph nodes.

CT scan is the most commonly used diagnostic and staging modality and remains the technique of choice. Performed with intravenous contrast, it accurately defines the renal topographic anatomy, the size and location of the tumor, and the relation of tumor to the surrounding vessels (renal vein and inferior vena cava). It also evaluates possible extracapsular spread, involvement of blood vessels or regional lymph nodes, and invasion of adjacent organs, such as the adrenals, spleen, pancreas, and liver. However, CT is less sensitive in detecting lesions less than 2 cm or tumor extension to the perinephric fat.

Magnetic resonance imaging (MRI) may have some additional benefit over CT in detecting tumors less than 2 cm or extracapsular extension and in delineating local anatomy more clearly. However, because of its expense and limited availability, MRI is often reserved for patients with known contraindications to iodine contrast or for patients whose CT results are equivocal. The role of positron-emission tomography (PET) has not been defined in the context of renal tumors. Because 80% of RCCs are hypervascular, angiography is sometimes used to depict the lesion and provide a vascular map for the surgeon. Angiography is expensive and invasive and should therefore be used only for tumors in a solitary kidney, for vascular mapping before surgery, or for tumors in which angioinfarction is planned.

The staging process of RCC should include a detailed history and physical examination, basic hematologic parameters, liver and kidney functions, serum electrolytes, and a chest radiograph. CT scanning of the chest is sometimes necessary to rule out occult pulmonary and mediastinal metastasis. A bone scan should be obtained to rule out skeletal metastasis, although the yield is particularly low in asymptomatic patients with normal blood levels of serum alkaline phosphatase. Imaging of the brain with CT or MRI should be done in patients with neurologic symptoms or signs. If the tumor is apparently localized only to the kidney, the patient should undergo surgical resection. Fine-needle aspiration (FNA) is usually not necessary, because if the FNA is negative the lesion must still be excised owing to the possibility of a false-negative result. On the other hand, if there is extrarenal involvement of tumor, a CT- or ultrasound-guided biopsy of the primary lesion may be indicated.

The pathologic stage of RCC is the most important prognostic factor. Stage I (tumor confined within the kidney capsule) has a 5-year survival rate of 65% to 85%, stage II (tumor invading through the capsule but confined within Gerota's fascia) 45% to 80%, stage III (tumor invading into the renal vein, inferior vena cava, or regional lymph node) 15% to 35%, and stage IV (metastatic disease) 0% to 10%. In the past, patients with tumors less than 3 cm in diameter were thought to have a better prognosis, but some recent studies have contradicted this view. It is still generally held that those with asymptomatic tumors have a better prognosis than those with significant tumor-related symptoms. Other important prognostic factors are microscopic vascular invasion, nuclear grade, and DNA ploidy.

OPTIMAL MANAGEMENT

For stages I to III, the standard treatment is surgical resection. Conventional surgery is radical nephrectomy, which involves the en bloc removal of Gerota's fascia with its contents and usually ipsilateral adrenalectomy. Regional lymph nodes are resected during surgery. However, in patients with bilateral tumors, tumors in a solitary kidney or in the presence of a poorly functioning contralateral kidney, nephron-sparing surgery (partial nephrectomy or enucleation) may be considered. Recent studies have shown that for tumors of 4 cm or less, nephron-sparing surgery provides the same rate of survival as radical nephrectomy. However, nephron-sparing surgery does carry some risk of postoperative complications, namely, hemorrhage and fistula formation. Therefore, the selection of candidates for this surgery is important. Preoperative or postoperative radiation does not add any benefit in reducing local recurrence or improving survival.

The outcome for patients with stage IV disease is very poor, because RCCs are resistant to chemotherapy in general. Most clinical studies in the past have shown response rates of less than 6%. Continuous infusion of floxuridine has reportedly produced response rates between 14% and 27%, although the responses are usually partial and short lived. Surgical intervention is recommended in patients with solitary metastatic lesions that are resectable. Radiation can be used to palliate symptoms from metastases to the bone or brain and to reduce spinal cord compression.

Spontaneous regression of metastatic RCC lesions has been reported in the literature, with an incidence of 0.8% to 3%. This has been reported for metastatic sites, including the brain, bone, regional and distant lymph nodes, liver, and most commonly the lungs. Complete and durable disappearance of tumors has been documented. The mechanism for this phenomenon is unknown, although immunologic factors have been postulated. Many of the spontaneous regressions were associated with surgical removal of the primary tumor, but nephrectomy does not appear to be the crucial event, because regression has been observed without primary tumor manipulation. Therefore, for patients with stage IV RCC, nephrectomy should not be recommended for the sole purpose of achieving spontaneous regression. It should be considered only when palliation of local symptoms such as pain and hematuria is required.

During the last decade, extensive research has been conducted to evaluate the role of immunomodulators in the treatment of metastatic RCCa. Interleukin-2 (IL-2) works through the activation of cytotoxic T-cell subgroups and stimulation of cytokine release. In a multicenter trial, IL-2 demonstrated 4% complete response rate and 8% partial response rate, with median duration of response of 23 months. However, the toxicities of high-dose intravenous IL-2 is substantial, mainly from a capillary leak syndrome, which can cause cardiovascular ischemia, renal failure, and shock. Supportive measures such as vasopressors and intensive care unit monitoring are often needed. Interferon- α is found to have an overall response rate of 12%, but with less common complete responses. A recent randomized study comparing IL-2, interferon- α , and both found a significantly higher response rate in the combination group (18.6% compared with 6.5% and 7.5%). Event-free survival at 1 year was also higher in the combination group, although there was no difference in overall survival. However, other studies using similar combinations have failed to show any benefit over IL-2 used alone.

CANCER OF THE BLADDER

DEFINITION

Bladder cancer is the sixth most common cancer in the United States, causing over 10,000 deaths each year. It accounts for more than 90% of urinary tract malignancies. Management of this disease—which exhibits stem cell function, is associated with expression of several common oncogenes, and is responsive to surgical intervention, radiation, and chemotherapy—has become one of the recent paradigms of our approach to solid tumor malignancy.

INCIDENCE AND EPIDEMIOLOGY

Cancer of the bladder affects 50,000 people annually in the United States. Its incidence rises with age and peaks during the seventh decade of life. The male:female ratio is about 4:1. It is seen more often in the white than in the black population. The incidence of bladder cancer is higher in urban areas, suggesting a possible role of environmental factors in carcinogenesis. Cigarette smoking is by far the leading risk factor, with a confirmed dose- and time-response relation for both sexes. Occupational exposure to carcinogenic compounds found in dye, rubber, paint, plastics, metal, and motor vehicle exhaust significantly raises the risk of bladder cancer. Other established risk factors are chronic infection of the lower urinary tract, history of external-beam radiation to the pelvis, chronic indwelling urinary catheter, the use of cyclophosphamide, and high-fat diet. In the Mediterranean basin, schistosomiasis is still the main causative agent of bladder cancer and is classically associated with squamous cell carcinoma.

PATHOGENESIS

Most bladder cancers are transitional cell carcinomas (90%). The less common cell types are squamous cell carcinoma (7%), adenocarcinoma (1% to 2%), and small

cell carcinoma; rare histologic types such as sarcoma, lymphoma, and melanoma comprise less than 1% of cases. Although the histogenesis is not fully understood, it is clear that there is a stem cell tumor of origin, and dominant transitional cell carcinoma may coexist with squamous and glandular differentiation. Bladder cancer is often associated with a field defect of the urinary mucosa, with the result that the entire lining of the urinary tract may be at risk for malignancy. Transitional cell carcinoma may be classified into two prognostic groups. Superficial tumors are those that occur at the level of the bladder mucosa, including carcinoma in situ (Tis), papillary lesions (Ta), and those that invade into (but not through) the lamina propria (T1). These superficial tumors constitute 80% of incident bladder cancers. They can be solitary but are often multifocal with a strong tendency to recur.

Recurrence can occur at the same site or any other site along the urothelial tract. Invasive tumors penetrate into (T2) and beyond (T3, T4) the muscularis propria. They are aggressive and tend to metastasize early. About 20% of patients have invasive cancer at presentation. The most important prognostic factor is the depth of tumor invasion (stage). Tumor grade is also an important factor. Low-grade (I) tumors rarely progress, whereas most high-grade (III) tumors progress and are associated with a rate of poor survival. Vascular or lymphatic invasion predicts an increased risk of invasion and metastasis. The presence of a Tis tumor significantly increases the risk of invasion when identified in association with other foci of superficial disease. Other prognostic factors are the absence of expression of blood group antigens on the tumor cell surface, DNA ploidy, expression of epidermal growth factor receptor, and p53 mutations.

CLINICAL FINDINGS

Most patients with bladder cancers present with painless, gross or microscopic hematuria, which can occur suddenly and intermittently. Symptoms of urinary frequency and urgency can be the result of bladder wall irritation or volume loss due to space-occupying lesions and is often misdiagnosed as "chronic interstitial cystitis." Abdominal discomfort, flank pain, or a palpable mass can occasionally be the first clinical evidence of invasive bladder cancer. Obstruction of the ureteral orifice with subsequent hydronephrosis and renal insufficiency is possible from an invasive tumor, although it can remain clinically silent until locally advanced. Invasive bladder cancer may extend locally into the prostate, seminal vesicles, rectum, uterus or vagina, sacral vertebra, and the retroperitoneal soft tissue. It spreads through the lymphatics and blood vessels to distant lymph nodes, the lungs, the liver, and the bones and may even cause brain metastases or carcinomatous meningitis. Five to 20% of patients present with symptoms from metastatic lesions. Constitutional symptoms may occur with disseminated disease, but paraneoplastic syndromes are rare in transitional cell cancers.

LABORATORY FINDINGS

Routine urinalysis almost invariably shows hematuria, the degree of which does not correlate with the extent of the lesion or lesions. Intravenous urography reveals an intravesical filling defect in 60% of cases. It also provides anatomical information about the urinary tract, such as hydronephrosis or hydroureter. Ultrasound is sometimes used to assess the bladder wall and to evaluate the kidneys and ureters. Urine cytology is a convenient and inexpensive method of obtaining a tissue diagnosis and provides a specificity and sensitivity of 80% in grade III tumors but relatively low sensitivity for grade I and II tumors (10% and 50%, respectively). Direct visualization and biopsy of the tumor are usually achieved by cystoscopy, which has been facilitated in recent years by the introduction of flexible instrumentation.

The staging process for bladder cancer should include a thorough history and physical examination, laboratory studies with complete blood cell count and hepatic and renal functions. Chest radiograph should be obtained in all patients. CT scan of the abdomen and pelvis is the standard noninvasive diagnostic modality to evaluate lymphadenopathy and other organ involvement.

OPTIMAL MANAGEMENT

For superficial papillary bladder cancer, the initial treatment is endoscopic resection of the tumor or tumors. For patients at high risk for recurrence, bacille Calmette-Guérin (BCG) may be administered into the bladder through a catheter as an adjuvant to transurethral resection. A common schedule is weekly administration of BCG for 6 weeks, followed by monthly doses for 6 to 12 months. The mechanism of action is incompletely understood, but there is evidence that the attachment of the bacillus to bladder cells elicits an immune response, which eradicates the malignant cells; or, the effect may simply be due to nonspecific immune stimulation with alteration of local suppressor:helper T-cell ratios. The adjuvant treatment has been proved to reduce the rate of recurrence and prolong disease-free time but may not affect the ultimate frequency of disease progression to invasive stage. During BCG treatment, the patient may experience dysuria, frequency, hematuria, or a general flu-like syndrome. Because BCG is a living organism, it can produce local, regional, and systemic infections. Granulomatous infections can occur at extravesical sites, including the prostate, epididymis, testes, kidney, liver, and lungs. BCG sepsis is the most serious complication and can be life threatening. When the diagnosis of extravesical involvement is made, combination antituberculous antibiotic therapy should be given for 6 months.

For patients with organ-confined invasive bladder cancer, cystectomy is viewed as the standard treatment in North America and Europe. Radical cystectomy involves the en bloc removal of the anterior pelvic organs, which includes the bladder, prostate, and seminal vesicles in men and the bladder, urethra, uterus, ovaries, and vaginal cuff in women. Bilateral pelvic lymph node dissection is often performed. The ureters are reconnected to an intestinal conduit as a urinary diversion. Traditionally, the conduit drains into an external collecting bag attached to the abdominal wall. Recently, continent reservoirs such as Koch's pouch (using the ileum) and Indiana pouch (using ileocecal segment) have become popular. The procedures involve the creation of an internal conduit with an antireflux mechanism that is either brought to the abdominal wall or sutured to the urethra, thus allowing patients to self-catheterize or void in the normal position, which greatly improves their self-image and increases acceptance rates. Also, the technology for creating orthotopic (artificial) bladders has improved. Radical cystectomy results in a 60% to 75% 5-year survival rate with T2 disease and 20% to 40% with T3 or T4 disease.

For patients with localized invasive disease, who are not surgical candidates, radiation is the alternative definitive therapy in North America, although radical radiation therapy is used as definitive treatment in some British and European centers. To date, there have not been any well-designed, randomized studies comparing radiation with surgery among patients with similar characteristics. Toxicities of radiation are dermatitis, proctitis that is occasionally complicated by bleeding and obstruction, cystitis or bladder fibrosis, impotence, incontinence, and development of secondary malignancies in the radiation field.

Combined-modality approaches, incorporating systemic chemotherapy with definitive local modalities, have been studied extensively in the past few years in the hope of sparing the bladder or improving overall survival. This has been predicated on the concept that systemic chemotherapy may reduce the extent of local tumor while controlling occult metastases. In a randomized, prospective trial assessing the benefit of concurrent chemoradiation, a protocol of single-agent cisplatin administered during the period of radiation therapy resulted in a 67% rate of sustained pelvic tumor control compared with 45% from radiation alone; however, overall survival was not significantly different. The role of neoadjuvant (first-line) systemic chemotherapy, followed by definitive radiation therapy or cystectomy, is still being investigated. Although earlier studies with the combination of cisplatin, methotrexate, and vinblastine (with or without adriamycin) demonstrated higher local tumor response, recent randomized trials have failed to show any survival benefit from the combination approach, although one major North American trial has not yet been analyzed.

Adjuvant (postoperative) chemotherapy has shown some promise in improving the outcome of definitive treatment. Randomized trials assessing the usefulness of combination regimens (e.g., the combination of methotrexate, vinblastine, adriamycin, and cisplatin, or MVAC), administered after radical cystectomy for patients with involved lymph nodes, have suggested that improved disease-free survival may be achieved. However, in the extant trials, which have been flawed by poor design and inadequate sample size, overall improvement in rate of survival has not been demonstrated.

For patients with metastatic bladder cancer, chemotherapy is the treatment of choice. A landmark study, conducted by an international consortium, compared the MVAC regimen with single-agent cisplatin. The MVAC regimen produced a response rate of 39% with a median survival of 12.5 months, which was statistically superior to the response rate of 12% and an overall survival of 8.2 months in the group that received cisplatin alone. The survival benefit persisted after a minimum follow-up of 6 years. Newer agents are being actively studied; in recent years, paclitaxel, gemcitabine, docetaxel, and ifosfamide have been shown to produce response rates of 20% to 40% as single agents. Combination of these agents has resulted in response rates of 50% to 80%, with apparently less toxicity than the conventional combination MVAC regimen. A phase III trial comparing gemcitabine and cisplatin with the standard MVAC regimen has been completed and awaits analysis.

CANCER OF THE RENAL COLLECTING SYSTEM

DEFINITION

The renal pelvis and the ureters form the upper collecting system. Histologically, they share the same transitional cell epithelium as that of the bladder. Therefore, neoplasms arising in these structures differ very little from their bladder counterparts, with the exception that the upper tracts do not have the investing tissues, such

as fat and muscle, characteristic of the bladder.

INCIDENCE AND EPIDEMIOLOGY

Cancers of the renal pelvis and ureters are uncommon, constituting about 5% of all urinary system neoplasms. Men are affected more than women (4:1), and median age of onset is 65 years (range 32 to 88).

Cigarette smoking is the primary risk factor for the development of cancers of the renal collecting system, with a clear dose-response relationship. Occupational exposure to carcinogenic chemicals, such as those found in petroleum, plastics, coal, asphalt, and tar products, is another well-documented risk factor. Heavy use of analgesics, especially phenacetin, can cause analgesic nephropathy with papillary necrosis, which leads to a 2- to 6-fold higher risk of urothelial malignancy. Ten to 50% of patients with bladder cancer can have synchronous or metachronous cancers of the upper collecting system, due to field defect or to intraluminal seeding or both. Other reported risk factors are a history of external-beam radiation, prior use of cyclophosphamide, chronic urinary calculi, and chronic interstitial nephritis from urinary stasis. A particularly high incidence of urothelial cancers is found in populations at risk for the Balkan endemic nephropathy—a unique familial kidney disease of unknown cause that appears in restricted rural areas of the Balkans.

PATHOGENESIS

Neoplasms of the ureter and renal pelvis can appear at any part of the upper collecting system, but the distal third of the ureter and the extrarenal portion of the pelvis are affected more often. Tumors are usually solitary, although multiple lesions are not rare. Pathologically, these epithelial malignancies do not differ from those of the bladder. Most are transitional cell carcinomas. Other histologic types, including squamous cell carcinoma, adenocarcinoma, and soft-tissue sarcoma, have also been reported.

CLINICAL FINDINGS

Painless hematuria, macroscopic or microscopic, is the most common presenting symptom (over 75%). Flank pain or palpable mass occurs less frequently. About 15% of patients present with symptomatic urinary tract infection. Ureteral obstruction or hydronephrosis often remains clinically silent until late-stage disease. Hypertension results from vascular compression leading to increased renin secretion. Local invasion causing ureterocolic fistula, thrombosis of the inferior vena cava, and unilateral lower extremity edema due to lymphatic obstruction are other less common presentations. Paraneoplastic syndromes such as hypercalcemia and amyloidosis have been reported, although this may reflect misreporting of RCCs. Common sites of metastasis are regional lymph nodes, lungs, liver, lumbar vertebrae, and peritoneal cavity.

LABORATORY FINDINGS

The common initial screening test for cancer of the renal collecting system is intravenous urography, which may reveal a filling defect, calyceal obliteration, hydronephrosis, or hydroureter. Retrograde pyelography may define more clearly the morphologic features of tumors visualized on IVP, may identify a tumor missed on IVP, and may help to evaluate a nonfunctioning kidney. Ultrasonography is useful to differentiate tumors from nonopaque calculi. CT scanning may confirm the presence of a tumor and may provide staging information. MRI is useful in its ability to detect vascular invasion and in defining local anatomy more clearly. For tissue diagnosis, urine cytology has a sensitivity of 50%. Fluoroscopic guided brush cytology has a sensitivity and specificity of approximately 90%. With the introduction of ureterorenoscopy, direct visualization of the tumor as well as endoscopic biopsy is now possible.

OPTIMAL MANAGEMENT

Tumors arising from the renal pelvis and calyces are treated with nephroureterectomy, including excision of a cuff of the bladder. For patients with solitary kidney, multifocal lesions, or poor function of the contralateral kidney, renal-sparing surgery may be indicated. Recent studies have focused on endoscopic ablation of low-grade tumors, with adjuvant topical instillation of agents such as BCG or mitomycin C, a cytotoxic agent. For locally extensive or metastatic disease, combination chemotherapy with MVAC or equivalent regimens has a response rate of 40% to 50%, with a median survival of 12.5 months, an outcome not different from that achieved for transitional cell carcinoma of the bladder. As yet, the role of adjuvant chemotherapy has not been determined.

BENIGN AND MISCELLANEOUS TUMORS

Papillary renal adenomas are the most common benign neoplasms arising from the renal tubular epithelium, occurring in up to 40% of adults. Metanephric adenoma and metanephric adenofibroma are closely related benign tumors, affecting all age groups and with a slight female predominance, and are often accompanied by polycythemia. Tuberous sclerosis is known to associate with hamartoma and angiomyolipoma. The latter often grows rapidly in pregnancy and can be complicated by hemorrhage. Other rare benign tumors are hemangioma, lipoma, leiomyoma, myxoma, and neurofibroma. These tumors are usually diagnosed incidentally and require intervention only when they become clinically symptomatic.

As mentioned earlier in this section, rare malignancies of the urinary tract include sarcoma, melanoma, and teratoma. They should be managed in the same fashion as their counterparts from other primary sites and have been reviewed in detail elsewhere. Metastatic cancers to the kidney are usually derived from primary cancers of the breast, lung, pancreas, liver, or gastrointestinal tract or may be due to malignant lymphoma or leukemia. These are frequently asymptomatic, especially in the context of metastatic solid tumors, and are mostly found during autopsies.

CHAPTER 161: CONGENITAL ANOMALIES OF THE KIDNEY, URETER, AND BLADDER

PATRICK BROPHY AND JEAN E. ROBILLARD

[Embryology of the Kidney](#)
[Syndromes Involving Congenital Anomalies of the Kidney, Ureter, and Bladder](#)

Congenital abnormalities of the kidneys, urinary collecting system, and bladder are seen first and primarily in children. The widespread application of prenatal ultrasonography has led to the in utero detection of genitourinary (GU) abnormalities, especially after 28 weeks of gestation, at an incidence of roughly 1% of total births. With such early identification, prenatal diagnosis of urinary tract anomalies will probably continue to decrease the number of uncorrected anomalies discovered de novo in older children and in adults. However, because some apparent abnormalities appear to be developmental without clinical importance after birth, multidisciplinary consultation is wise before any intervention.

EMBRYOLOGY OF THE KIDNEY

The development of the kidney in mammals proceeds in three stages with three sets of kidneys developing successively: the pronephros, the mesonephros, and the metanephros. The first stage (pronephros) is characterized by the emergence of paired tubules that arise from the cephalic end of the nephrotomes to form the pronephros, a rudimentary organ that appears at about the third week of gestation and undergoes complete involution within 2 weeks. The mesonephros develops more caudally on about day 24 of gestation in humans. The mesonephros is induced by the pronephric duct and consists of approximately 20 pairs of glomeruli and thick-walled tubules. By the fifth week of gestation, the mesonephric kidneys are able to form urine, which drains into the mesonephric duct and in turn opens into the cloaca. The mesonephros, the permanent kidney in amphibians, degenerates by the eleventh to twelfth week of gestation in humans. The most important role of the mesonephros is to induce the formation of the ureteric bud, which is required for the formation of the metanephros. Failure of mesonephric differentiation often leads to renal agenesis and renal hypoplasia, as well as to anomalous development of the gonads and adrenal glands. The metanephros begins to develop around the seventh week of gestation and is the result of reciprocal inductive interactions between the metanephric blastema and the ureteric bud. Renal tubular function begins in the human metanephric kidney by the ninth week of gestation. By the fourteenth week, the loop of Henle is functional and tubular reabsorption occurs. Nephron formation ceases by the thirty-sixth week of gestation in humans.

Several genes have now been implicated in the development of the kidney. One of the earliest genes responsible for lateral mesoderm differentiation and mesonephric development is the homeobox gene *Lim1*. Homozygous *Lim1* mutant newborn mice completely lack kidney and gonads. Other genes such as *Pax2* and *WT1* have been identified as essential for development of the metanephric mesenchyme and differentiation of the renal epithelium. *Pax2*, a transcription factor of the paired box family, is normally expressed in the mesonephric duct, the ureteral bud, and metanephric mesenchyme. Heterozygous *Pax2* mutant newborn mice often present with hypoplastic kidney with reduced calyces and upper parts of the ureters, suggesting defects in branching of the ureteric bud and in epithelial transformation of metanephric mesenchyme. Heterozygous *Pax2* mutation in humans is associated with optic colobomas and vesicoureteral reflux. Homozygous *Pax2* mutant mice present with complete lack of kidneys, ureters, and genital buds.

The Wilms' tumor suppressor gene, *WT1*, a transcription factor with zinc finger binding domains, is expressed in mesonephric tubules and in derivatives of the metanephric mesenchyme. Mutations in the tumor suppressor function of the *WT1* gene are found in 10% to 20% of patients with Wilms' tumor and are associated with the Denys–Drash syndrome, a triad of pseudohermaphroditism, nephropathy, and Wilms' tumor. Heterozygous for null mutations of the *WT1* gene in humans may also present with the WAGR syndrome (Wilms' tumor, aniridia, GU malformation, and mental retardation).

C-ret, a gene encoding a tyrosine urinate receptor, is expressed at the tip of the ureteric bud and is required for ureter bud growth. Homozygous *c-ret* mutant exhibits a high degree of renal agenesis and often a complete absence of ureters. In addition to *c-ret*, the development and growth of the ureteric bud is also dependent on GDNF (glial cell line–derived neurotrophic factor), a member of the transforming growth factor- β (TGF- β) super family. GDNF, which is expressed in the metanephric mesenchyme, has been identified as the ligand for the *c-ret* receptor and is essential for the development and branching of the ureteric bud. Another gene, the *la* (limb deformity) gene, also plays an important role in ureteric bud and metanephric development. Absence of *la* expression is associated with renal agenesis secondary to a failure of the ureteric bud to induce the metanephric mesenchyme.

Wnt4, a member of the Wnt family of secreted glycoproteins, plays an important role in condensing metanephric mesenchyme cells and in transforming these cellular aggregates into epithelial vesicles. Mutant mice lacking Wnt4 fail to form peritubular cell aggregates, although other aspects of mesenchymal and ureteric development are preserved.

In addition to these important genes, many other genes are involved in kidney development. Among these, insulin-like growth factors (IGF-I, IGF-II), transforming growth factor- β , and fibroblast growth factors have been shown to be involved in renal epithelium differentiation and renal growth and maturation.

SYNDROMES INVOLVING CONGENITAL ANOMALIES OF THE KIDNEY, URETER, AND BLADDER

Abnormalities of the urinary tract are noted in approximately 1 in 500 routine obstetric sonographic studies. There are now well over 100 syndromes involving some abnormality of the GU system. [Table 161.1](#) provides a summary of our current understanding of the genetic underpinnings responsible for some of the phenotypic presentations of GU abnormalities. Discussion of these is beyond the scope of this chapter. Readers are referred to the review by Woolf (1998). Many of these syndromes are evident in the neonatal period and require full investigation ([Table 161.2](#)). Renal function and urinary abnormalities, electrolyte disturbances, growth and development issues, and coexisting deformities (i.e., ear/umbilical) should alert the clinician to the potential underlying pathologic condition.

Disease Entity	Mode of Inheritance	Mutations or Genetic Lesions
VR and left renal cisterna	Autosomal dominant	<i>PKD</i> mutation
Apart syndrome	Autosomal dominant	<i>FGF3</i> receptor mutation
Hydronephrosis, digital and cranial malformations		
Kallmann syndrome	X-linked recessive	<i>KAL</i> mutation
Renal agenesis, ectopic testis, and hypoplasia defects	Autosomal recessive	Pericentromeric factor 1 mutation
DiGeorge syndrome		
Renal cysts and dysplasia with neurological and hepatic defects	Autosomal recessive	Lesion on 21q22
Bardet-Biedl syndrome		
Renal dysplasia with dwarfism, hypoplasia, and polydactyly	Autosomal dominant	Lesion on 8q
Bardet-Biedl syndrome	Autosomal dominant	Lesion on 15q
DiGeorge syndrome	Autosomal recessive	Lesion on 22q11.2
WAGR syndrome	Autosomal recessive	Lesion on 11p15.5
Multicystic dysplastic kidney with renal/urinary defect	Autosomal dominant	Unknown
Isolated renal dysplasia	Autosomal dominant	Unknown
Isolated vesicoureteral reflux	Autosomal dominant	Unknown

(From Woolf AJ. Molecular control of nephrogenesis and the pathogenesis of kidney malformations. *J Clin Invest* 1998;101:1-11)

TABLE 161.1. SOME GENETIC MUTATIONS ASSOCIATED WITH RENAL MALFORMATIONS

Current classification of UPJO is based on the following anatomical criteria:

- Intrinsic stenosis/valves—this results in functional absence of peristalsis and inadequate luminal distention
- Insertional anomalies—the ureter inserts abnormally high, and often obliquely, into a dilated renal pelvis
- Fibrous bands/adhesions—dense periureteral fibrosis likely secondary to inflammatory processes
- Crossing vessels—blood vessels that erroneously cross at the UPJ level resulting in obstruction

The initial diagnosis and treatment of UPJO can be difficult. The functional obstructions can be particularly hard to define and may be volume dependent. Most cases of UPJO are found in childhood, with an abdominal mass being the most common clinical presentation. Other presentations are abdominal pain secondary to hydronephrosis, hematuria, and increased renal susceptibility to minor trauma. Assessment of renal function, electrolytes, urinary concentrating ability and imaging are very important in the initial workup. Nuclear renal scanning with diuretic is also a particularly valuable tool in assessment of UPJO.

Early neonatal intervention by experienced pediatric nephrologists and urologists may help to maintain or restore renal function in a GU system that would otherwise be destined to become nonfunctional. This is especially true in patients with confirmed bilateral involvement.

OTHER TYPES OF URETERAL OBSTRUCTION

Ureteric vesical junction obstruction (UVJO) with megaureter is less common than UPJO. This malformation appears to be sporadic, with a male predisposition. UVJO also has been associated with other anomalies, including duplicated renal collecting system, ectopic ureterocele, VUR, contralateral renal agenesis, multicystic kidney disease, and Hirschsprung's disease. Megaureter usually occurs secondarily to UVJO and in the absence of a dilated bladder. Diagnosis is often made by ultrasound in the prenatal period. There may or may not be associated pelvic dilation, depending on the severity and duration of the UVJO and megaureter.

Vesicoureteral Reflux

VUR can be defined as regurgitation of urine from the bladder into the ureters and in some cases the kidneys themselves. This occurs through the vesicoureteral junction, which is either aberrantly placed, lax, or immature. The defect is essentially an insufficient valve mechanism, owing to an abnormality in the diameter, length, innervation, or musculature of the submucosal intravesicular ureter. The specific cause of the abnormality is likely related to an abnormal morphogenesis of the ureteric bud, resulting in a congenital lateral ectopia of the ureteric orifice.

VUR can be divided into primary and secondary groups. Primary VUR is not associated with any underlying obstructive or nervous system/muscular abnormality or with pathologic bladder dynamics, whereas secondary VUR is associated with those factors. The degree of VUR is graded I through V, with grade V reflux being the most severe (Fig. 161.2). Patients may remain clinically quiescent, with VUR resolving on its own or proceeding to end-stage renal disease with scar formation.

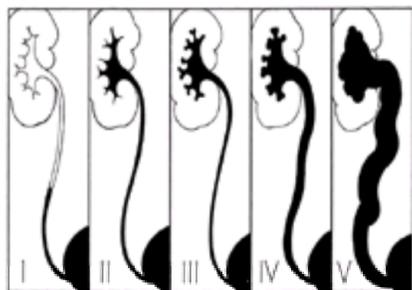

FIGURE 161.2. Classification of vesicoureteral reflux by the international grading system. I, lower ureteral filling only; II, ureteral and pelvicalyceal filling without dilatation; III, ureteral and pelvicalyceal filling with mild dilatation of renal pelvis and mild blunting; IV, moderate dilatation and/or tortuosity of ureter, dilated renal pelvis, and blunted calyces; V, gross dilatation of ureter, renal pelvis, calyces, with intrarenal reflux.

Most persons with VUR are asymptomatic, making it difficult to determine the exact incidence. General estimates place the incidence to be 1 in 100 to 1 in 1,000. Epidemiologic data available for VUR are equally unclear. The prevalence in healthy persons is unknown, because most primary cases of VUR have been demonstrated in patients being evaluated for urinary tract infections. Certainly, the most important and controversial fact is that VUR is an inherited trait. It is consistently demonstrated in approximately 30% of siblings of patients with VUR and appears to be present in an even higher percentage in offspring of those with known VUR. The type of inheritance is unclear but has been demonstrated in most kindreds to follow an autosomal dominant pattern with variable expression and reduced penetrance. Some have suggested sex-linked transmission, but the evidence for this is less clear. The specific genetic aberrations causing isolated VUR remain to be defined, although the incidence of the gene has been estimated at 1 in 600, which would make it the most common dominantly inherited condition in mankind. VUR associated with other disease entities (coloboma-ureteral-renal syndrome, prune-belly syndrome, Apert's disease, chromosome 8 and 10 short arm abnormalities, among many) has been attributed to developmental pathway gene mutations, more specifically, a *Pax2* gene mutation. Mutations in other genes required for nephrogenesis, such as FGF receptor (FGFR2) and the GDNF receptor (RET), known to be expressed in the developing ureter, have been excluded as the cause of primary VUR. Although it appears that primary VUR has genetic heterogeneity, severity of scar formation and subsequent end-stage renal disease/reflux nephropathy appear to be related to angiotensin-converting enzyme gene polymorphism, with homozygosity conferring the greatest risk of scarring on its carriers.

Diagnosis and management of VUR are becoming more homogeneous. Most persons presenting with a urinary tract infection in early childhood have a renal sonogram performed, with a subsequent voiding cystourethrogram in conjunction with renal function blood work. Nuclear renal scan is also performed to evaluate the kidneys for scarring after the infection is cleared. Depending on the severity of the VUR, clinicians have a variety of options available for further patient management. These include prophylactic antibiotics with regularly scheduled follow-up imaging studies, and close observation by or referral to a urologist for potential surgical intervention. The usefulness of screening in siblings or offspring of affected persons is still debated.

ANOMALIES OF THE BLADDER AND URETHRA

The urinary bladder arises from the primitive urogenital sinus, and bladder anomalies are relatively rare. Structural abnormalities range from agenesis to megacystasis secondary to distal obstruction. These conditions are primarily associated with other GU anomalies or severe developmental abnormalities. Bladder extrophy is one of the more notable anomalies of this structure. It has a male predominance and refers to an anteriorly open bladder from a lack of abdominal wall closure. This anomaly may result from interference with inferolateral abdominal mesenchymal closure by an overdeveloped cloacal membrane. Thus, upon rupture of the cloacal membrane, the bladder cavity is exposed because the inferior abdominal wall has not completely closed. Surgical intervention in the neonatal period is the treatment of choice. Surgical options range from primary closure to full bladder reconstruction.

Urethral defects range from agenesis to duplication to posterior urethral valves. Each defect has various associated syndromes. Both urethral agenesis and duplication are rare occurrences and tend to have a male predominance probably resulting from the increased embryonic complexity of the male urethra. Both can be demonstrated in prune-belly syndrome. This syndrome involves a triad of dilated urinary tracts, bilateral cryptorchidism, and deficient abdominal musculature and is

found mainly in males. However, the syndrome's inheritance pattern is uncertain.

Posterior urethral valve (PUV) is the most common cause of distal urinary tract obstruction and the most common cause of obstructive uropathy leading to renal failure in children. It appears to arise sporadically, although it has been observed in siblings and twins. PUV is thought to arise from abnormalities of two normal folds in the posterior urethra that are remnants of the mesonephric ducts. However, the specific pathologic lesion is not clear. PUV can often be found by routine prenatal ultrasound in the form of proximal urethral dilation with a thick-walled bladder. Potential outcome and intervention depends on prenatal age, renal function, and the presence or absence of other GU abnormalities or syndromes (i.e., prune-belly syndrome), which are observed in 25% of patients with PUV. Patients that survive the prenatal period (primarily those diagnosed postnatally or after 24 weeks of gestation) have 5% mortality, and approximately 25% progress to chronic renal failure. Urinary tract decompression is the initial treatment choice, followed by endoscopic fulguration of the PUV.

HYPOSPADIAS AND EPISPADIAS

Hypospadias, or failure of the penile meatus to develop ventrally, is common, with an incidence of about 8 in 1,000 male births. Most cases are mild (87%), with glandular or coronal abnormalities. Only 3% of hypospadias is the severe penoscrotal type. In hypospadias, the prepuce is abnormally formed on its ventral surface, so the phallus itself often has a ventral curvature called a *chordee*. Ventral foreskin development is usually deficient, and circumcision should be avoided so that the foreskin may be used in repair. Renal anomalies are not more common in those with hypospadias. If cryptorchidism is associated with hypospadias, the possibility of an intersex problem should be considered. Parental counseling or corrective surgery of the hypospadias is required.

Epispadias, or failure of the dorsal surface of the penile urethra to form normally, is rare, occurring in 1 of every 140,000 live births. This anomaly may be associated with dorsal penile curvature caused by penile deformity and separation of the pubis. Evaluation of the upper and lower GU tract is essential; ureteral reflux and incontinence are possible associated problems. Staged surgical procedures may be necessary. Complications are similar to those seen in hypospadias.

CHAPTER 162: PREGNANCY, THE KIDNEY, AND HYPERTENSION

MARSHALL D. LINDHEIMER AND ADRIAN I. KATZ

[Approach to the Pregnant Patient With Renal Disease](#)
[Approach to the Pregnant Patient With Hypertension](#)

The renal system has a distinctive place in the history of obstetric care. Long before recognition of the marked anatomical and functional changes in the urinary tract characteristic of gestation, physicians diagnosed pregnancy by the sweet taste of the urine (due to increased filtration and excretion of glucose), and demonstration of proteinuria was among the first signs identified in the diagnosis of preeclampsia, at first believed to be a form of Bright's disease. This chapter reviews the striking changes in the renal system and the control of blood pressure in pregnancy, stressing their relevance to the diagnosis and management of pregnant women with kidney disorders or with hypertension complicating pregnancy.

Both kidney volume and length increase—the latter by ~1 cm—and there is substantial dilation of the calyces, pelves, and ureters, most prominently on the right. These changes, which have been ascribed to both hormonal factors and mechanical obstruction, begin in early pregnancy. They are most pronounced in the last trimester and may persist through the third postpartum month. The clinical relevance of these changes includes the difficulty in obtaining timed urine collections from pregnant women, a rare “overdistention” syndrome, characterized by abdominal pain, hydronephrosis (more marked than the usual degree of physiologic dilation), and hypertension, which may require the placement of ureteral stents. Elective assessment of the urinary tract should be deferred until ³12 weeks postpartum. These changes may also complicate management of pregnant women with underlying reflux nephropathy or chronic pyelonephritis of infectious origin.

Functional changes during pregnancy are even more striking. Glomerular filtration rate (GFR) and renal plasma flow (RPF) rise ~50%, ascribed mainly to humoral changes (e.g., increased circulating relaxin levels). These changes begin during the luteal phase of the last menstrual cycle and progress rapidly thereafter, reaching maximum values by mid-trimester. The relevance of the hormonal changes is that values considered normal in nonpregnant women may be ambiguous in pregnancy; for example, a $P_{\text{creatinine}}$ and $P_{\text{urea N}}$ exceeding 0.8 mg per deciliter (70 μmol per liter) and 13 mg per deciliter (5 mmol per liter), respectively, are associated with abnormal renal function in a pregnant woman. Furthermore, increased filtered loads of many solutes (e.g., glucose and amino acids) as well as proteins results in increments in their urinary excretion (e.g., the excretion of up to 300 mg per day of protein is considered normal).

There are also changes in tubular function, the most clinically relevant relating to urate and acid—base metabolism. Both the absolute and fractional clearance of urate rise and plasma levels exceeding only 5 mg per deciliter (298 μmol per liter) are abnormal. Blood pH, which is ~7.40 in the nonpregnant state, averages 7.44 in pregnancy, the mild alkalemia being attributed to the effect of progesterone on respiration that results in a decrement in P_{CO_2} to ~30 mm Hg, as well as alterations of renal proton handling, so that plasma HCO_3^- falls to about 20 mEq per liter. Thus, a pregnant woman with a blood pH of ~7.38 is already acidemic, whereas a P_{CO_2} of 40 mm Hg signals substantial carbon dioxide retention.

Pregnancy affects volume regulation and the control of body tonicity. Pregnant women gain an average of 12.5 kg, and total body water increases 6 to 9 L. Four to seven of these liters are in the plasma (~1.2 L) and interstitial spaces, so that edema, observed in over 50% of normotensive pregnancies, is a *normal occurrence of gestation*. The osmotic thresholds for both thirst and vasopressin (AVP) release decrease by ~10 mOsm per liter. These changes are maximal between the eighth and tenth gestational week and are accompanied by a decrement in P_{Na} of 5 mEq per deciliter. Thus, if P_{Na} exceeds 140 mEq per liter, a search for causes of hypernatremia is warranted. Pregnant women experience a fourfold increase in the metabolic clearance of AVP, ascribed to the placental production of vasopressinase, yet they concentrate their urine normally. There is, however, a rare syndrome of transient diabetes insipidus of pregnancy that includes women with subclinical partial central diabetes insipidus whose disease is unmasked by the increments in AVP disposal during pregnancy and other women whose placentae produce excessive amounts of vasopressinase or who experience reductions in hepatic inactivation of the enzyme (as occurs in some women with preeclampsia). These patients can be treated with DDAVP (desmopressin acetate), an analogue resistant to inactivation by vasopressinase.

Finally, profound cardiovascular changes occur during pregnancy. Mean blood pressure decreases soon after conception, with diastolic levels falling by ~10 mm Hg to a nadir by mid-gestation. Pressures then rise slowly approaching nongravid levels near term and may transiently rise above preconception values in the puerperium. Simultaneously, cardiac output rises 30% to 50%. Given the magnitude of this increment, the simultaneous decline in pressure must be due to a striking decrease in peripheral vascular resistance, making gestation a *markedly vasodilated state*. The causes of these changes are incompletely understood, but are believed to relate to alterations in the production of vasodilatory prostanoids, as well as to enhancement of the activity of endothelium-derived relaxing factors (both nitric oxide-dependent and oxide-independent in origin).

APPROACH TO THE PREGNANT PATIENT WITH RENAL DISEASE

ASSESSMENT OF RENAL FUNCTION

Pregnancy may be the first time a woman's urine is monitored and abnormalities uncovered, another cogent reason for practitioners to be familiar with the normal changes of gestation. Urinary excretion of red blood cells rises so that a urinalysis demonstrating two to three red blood cells per high-power field can still be regarded as normal. Whether leukocyturia also increases normally is unclear. Proteinuria up to 300 mg per day is still considered normal, and in the absence of timed collections protein:creatinine ratios performed on spot urine samples are acceptable. Urine concentration and dilution are similar in nongravid and gravid populations, but one should be aware that an upright or supine position interferes with the ability of pregnant women to produce a maximally dilute urine, whereas lateral recumbency interferes with optimal concentration. In addition, the lower limit of normal for endogenous creatinine clearance in nongravid populations should be increased by 30% to 110 to 120 mL per minute. Finally, although renal biopsy for most indications may be deferred until after delivery, the procedure can be performed on pregnant women and should be considered in the following situations: sudden deterioration of function without apparent cause; the appearance of symptomatic nephrotic syndrome (or when its biochemical abnormalities are marked); and, rarely, when there is need to differentiate an acute glomerular disorder (e.g., lupus nephritis) from preeclampsia. The procedure is not indicated after gestational week 31 because its risk:benefit ratio increases markedly at this time.

URINARY TRACT INFECTION

This topic is discussed in detail in [Chapter 271](#), but the following caveats are pertinent to pregnancy. Pregnant women should be screened for covert bacteriuria, and if present it should be treated, because there is a greater propensity for asymptomatic urinary tract infections to progress to symptomatic upper and lower tract infections in gestation. Pyelonephritis tends to be more virulent in gestation and more apt to be associated with sepsis, including acute respiratory distress syndrome, renal failure, and intravascular coagulation, as well as fetal loss. Thus, many practitioners treat covert bacteriuria for 10 to 14 days, and symptomatic infections for 3 weeks, although recent studies suggest that shorter periods of treatment may suffice.

ACUTE RENAL FAILURE

Acute renal failure (ARF) is an extremely rare complication in pregnancy, acute tubular necrosis severe enough to require dialysis having an incidence of 1 in 10,000 to 20,000, and cortical necrosis 1 in 70,000. Maternal mortality, once considerable in pregnant women with ARF, is practically nonexistent in the industrial world, primarily because women seeking abortion early in pregnancy now have easy access to sterile terminations.

The cause of ARF in pregnant women is often similar to that in nonpregnant populations (see [Chapter 140](#)), but there are also several pregnancy-specific causes. As noted, septic abortions (illegal; nonsterile) were once a major cause of ARF and were associated with high lethality, especially when due to *Clostridia* sepsis (see [Chapter 290](#)). In late gestation, acute fatty liver and a variant of preeclampsia known as the HELLP syndrome (see Preeclampsia-Eclampsia) are associated with ARF. Although very rare, cortical necrosis occurs more readily in pregnancy, and it is often linked to placental abruption, especially in the presence of a concealed hemorrhage. Another rare complication unique to the gravid state is labeled idiopathic postpartum renal failure, which may be manifest 24 hours to several weeks after delivery. It is irreversible and is associated with a surprisingly high incidence of maternal morbidity and death. The renal pathologic character of the lesion has been described as being similar to the adult hemolytic-uremic syndrome when biopsies are performed early in the course of the disease and to scleroderma kidney when tissue is obtained at a later period. Its cause remains unknown and has been linked to mechanisms similar to those postulated for the thrombotic

microangiopathies, that is, dysfunction of the vascular endothelium with a deficiency in endothelium-derived relaxing factor or the prostanoid system. Idiopathic postpartum renal failure is the cause of ARF related to pregnancy most often resulting in end-stage renal disease.

CHRONIC RENAL DISEASE

Table 162.1 summarizes the relation of pregnancy to several specific renal diseases. The following are general guidelines for the management of pregnant women with preexisting renal disease (**Table 162.2**): (a) Women who before conception have only mildly decreased and stable kidney function (creatinine ≤ 1.4 mg per deciliter; $125 \mu\text{mol}$ per liter), do well in pregnancy—live births exceeding 95%. Exacerbation of the underlying kidney disorder is unusual, and the pregnancy does not influence adversely its long-term prognosis. Fetal growth is adequate in more than 75%, but these women have an increased incidence of superimposed preeclampsia. (b) Women whose renal dysfunction is moderate ($P_{\text{creatinine}}$ between 1.5 and 3 mg per deciliter; 133 to $275 \mu\text{mol}$ per liter) or worse have a more guarded prognosis, with one third or more experiencing renal functional deterioration or the appearance of hectic hypertension after mid-pregnancy (often superimposed preeclampsia), or both. Prognosis is better for the pregnancy, of which ~90% succeed, but growth restriction and preterm deliveries occur in more than 50%. (c) Women with advanced or end-stage renal disease (especially those requiring renal replacement therapy), although relatively infertile, do occasionally conceive and therefore require contraceptive counseling. Only about 50% of these pregnancies succeed and are accompanied by considerable maternal risk, including cardiac failure, severe hypertension with cerebrovascular accidents, and maternal death.

Renal Disease	Effects
Diabetic nephropathy	Gestation does not appear to accelerate functional loss, more overt bacteriuria and increased incidence of nephrotic-range proteinuria and hypertension after mid-gestation
Chronic glomerulonephritis (CGN) and focal glomerulosclerosis (FGS)	Increased incidence of hypertension in late pregnancy, but no apparent adverse effects if function preserved and hypertension absent before conception
Systemic lupus erythematosus	More problems than in most glomerular disorders, but prognosis favorable if disease in remission 18 months before conception, maternal and fetal outcomes poorer when antiphospholipid antibodies or lupus anticoagulant present
Scleroderma and periarteritis nodosa	Many reports of accelerated hypertension, maternal death, and poor fetal prognosis; this therapeutic abortion should be considered in both conditions
Reflex nephropathy and chronic interstitial nephritis	Prognosis favorable when function is preserved, but patients require frequent urine cultures and may need chronic suppressive antibiotic therapy
Polycystic kidney disease	Pregnancy tolerated well when function is preserved. See cysts management; more gestational hypertension and preeclampsia
Urolithiasis	Prognosis guarded except for a greater risk of urinary tract infections; patients with calcium oxalate stones do best; those with uric acid stones more problematic; stones placed successfully in gravid

TABLE 162.1. PREGNANCY IN WOMEN WITH RENAL DISORDERS

1. Characteristics of renal function in all patients with chronic renal disease are similar to those in nonpregnant women, but the incidence of hypertension is increased in pregnancy. (a) Women with mild renal disease (creatinine ≤ 1.4 mg per deciliter; $125 \mu\text{mol}$ per liter) do well in pregnancy—live births exceeding 95%. Exacerbation of the underlying kidney disorder is unusual, and the pregnancy does not influence adversely its long-term prognosis. Fetal growth is adequate in more than 75%, but these women have an increased incidence of superimposed preeclampsia. (b) Women whose renal dysfunction is moderate ($P_{\text{creatinine}}$ between 1.5 and 3 mg per deciliter; 133 to $275 \mu\text{mol}$ per liter) or worse have a more guarded prognosis, with one third or more experiencing renal functional deterioration or the appearance of hectic hypertension after mid-pregnancy (often superimposed preeclampsia), or both. Prognosis is better for the pregnancy, of which ~90% succeed, but growth restriction and preterm deliveries occur in more than 50%. (c) Women with advanced or end-stage renal disease (especially those requiring renal replacement therapy), although relatively infertile, do occasionally conceive and therefore require contraceptive counseling. Only about 50% of these pregnancies succeed and are accompanied by considerable maternal risk, including cardiac failure, severe hypertension with cerebrovascular accidents, and maternal death.

TABLE 162.2. GUIDELINES FOR MANAGING RENAL DISEASE AND HYPERTENSION IN PREGNANCY

The above préis of pregnancy in women with preexisting renal disease requires the following qualifications: (a) These guidelines are based on retrospective data, and more definitive strategies require prospective studies. (b) Prognosis at all stages of renal dysfunction is more guarded when pregnant women have poorly controlled hypertension. (c) Certain specific entities appear to be adversely affected by gestation. These are renal scleroderma and periarteritis (in which most practitioners proscribe or interrupt pregnancy), some instances of severe lupus nephritis, and perhaps instances of membranoproliferative glomerulonephritis. Some investigators also believe that gestation exacerbates IgA nephropathy, focal glomerulosclerosis, and reflux nephropathy, even when function is preserved. However, careful review of the literature regarding these entities supports a favorable prognosis conforming to the general guidelines previously described.

RENAL TRANSPLANTATION

The maternal and fetal prognosis in women with renal transplants is similar to those in women with disease in their native kidneys. Allograft recipients with preserved function do well, but the prognosis for graft and pregnancy is more guarded when hypertension is present and the functional loss is greater. Recipients are counseled to wait 2 years after transplantation before attempting conception to ensure kidney function stability. Concerning immunosuppression, abundant retrospective data suggest that corticosteroids and azathioprine at dose schedules used in transplant patients do not appear to have serious fetal effects. Cyclosporin A is associated with more hypertension and possibly a greater degree of fetal growth restriction. There are insufficient data to rate the newer agents. Finally, although the issue is still disputed, most investigators failed to find an adverse effect of gestation on long-term allograft survival.

APPROACH TO THE PREGNANT PATIENT WITH HYPERTENSION

Hypertension complicates 5% to 10% of all pregnancies and is a major cause of morbidity and death for both mother and unborn child, especially in underdeveloped parts of the world. Most of these adverse outcomes are due to preeclampsia, either pure or superimposed on another form of hypertension or on renal disease. This is because preeclampsia is more than hypertension. It is a multisystem disease, with complications in various organs often being the cause of the morbidity rather than the high blood pressure per se. There is considerable confusion in the literature concerning detection, classification, and management of the hypertensive disorders of gestation. Much of the text that follows is in accordance with the views and recommendations of the 1999 Working Group Report on High Blood Pressure in Pregnancy issued by the National High Blood Pressure Education Program (NHBPEP).

DETECTION AND CLASSIFICATION

Hypertension is defined as a systolic and diastolic pressure of ≥ 140 and ≥ 90 mm Hg, respectively, using the fifth Korotkoff sound (disappearance) to determine the diastolic level. Nevertheless, considering the physiologic decrease in blood pressure that occurs early in pregnancy, women with levels of 75 mm Hg before mid-gestation or 85 mm Hg at any time in pregnancy require close scrutiny, because a number of epidemiologic studies demonstrate that patients with such findings are at risk. Similarly, pregnant women manifesting increments of 15 and 30 mm Hg in diastolic and systolic pressures, respectively, should be closely observed even when their levels remain below 140/90 mm Hg.

There are many classification schemes, a major source of confusion in the literature. We believe that terms such as toxemia, pregnancy-induced or pregnancy-associated hypertension, and gestosis, often misunderstood or misinterpreted by the reader should be discouraged, and we endorse the most recent Working Group definition. The definition is concise, separates accurately the more benign from the serious disorders, and uses only four categories: chronic hypertension (of whatever cause), preeclampsia-eclampsia, preeclampsia superimposed on chronic hypertension, and gestational hypertension.

Chronic Hypertension

Most pregnant women with chronic hypertension (defined as high blood pressure before gestational week 20 or persisting after the puerperium) have the essential variety (accounting for 50% of all high blood pressure in pregnancy). In most pregnant women and especially in younger patients (under 35 years), blood pressure

elevations are mild, there is little evidence of end-organ damage, and pregnancies are uneventful. However, 25% of these women develop superimposed preeclampsia with more guarded outcomes (see next section, Preeclampsia-Eclampsia). Secondary hypertension in pregnancy is extremely rare, but must be considered in pregnant women with moderately severe hypertension resistant to therapy. Such women should be screened for underlying kidney disease, renal artery stenosis, pheochromocytoma, and other disorders, as directed by the degree of suspicion. Pheochromocytoma may be particularly lethal in pregnancy, but risks decline dramatically when it is detected and the patient is managed appropriately.

Preeclampsia-Eclampsia

As noted, the pregnancy-specific disorder of preeclampsia-eclampsia is the complication with manifestations most likely to imperil mother and fetus, especially when superimposed on renal disease or chronic hypertension (category 3). It occurs mainly in nulliparas (7% to 10%), most often after mid-trimester and mainly near term. Its cardinal features are hypertension and proteinuria, and the more severe forms are associated with disordered coagulation (primarily thrombocytopenia) and liver function abnormalities. Preeclampsia may rapidly progress to a convulsive phase (eclampsia), whose premonitory signs and symptoms include hemoconcentration, severe headaches, visual disturbances, hyperreflexia, and epigastric and right upper quadrant pain. Eclampsia is particularly ominous and life-threatening (often because of concomitant cerebral bleeds) as is another variant of the disorder, termed the HELLP syndrome (Hemolysis, usually with schistocytes on the peripheral smear, Elevated Liver enzymes, Low Platelet counts). Both entities should be treated by rapid termination of the pregnancy.

Gestational Hypertension

Women with gestational hypertension have mild, or rarely moderate, nonproteinuric hypertension late in gestation or in the immediate puerperium. Blood pressure normalizes rapidly postpartum, when the diagnosis is changed to transient hypertension of pregnancy. The gestations are usually uneventful, the difficulty being in differentiating this entity from early manifestations of the more ominous preeclampsia. Women in this category are most apt to have essential hypertension later in life, for which pregnancy acts as a predictor.

PATHOGENESIS, PREDICTION, DIFFERENTIAL DIAGNOSIS, AND PREVENTION

Preeclampsia is the most common complication with potentially ominous additional complications in pregnancy. Knowing its cause, the pathogenesis of its manifestations and how to anticipate it should lead to better strategies that include prediction, prevention, and ideal management. Unfortunately, these goals have not yet been achieved. One major hypothesis attributes a key role in pathogenesis to placental ischemia, which results in the excessive production of cytokines deleterious to the endothelium. Other investigators consider preeclampsia a heterogeneous disorder, implicating genetic traits in susceptible populations. These include those with aberrations of the angiotensin gene, those with genes responsible for a variety of thrombophilic disorders, and those said to have a genetic disposition toward lipid and carbohydrate abnormalities, as well as early atherosclerosis (syndrome X).

Searches for tests to predict imminent preeclampsia or to distinguish the disease from other hypertensive disorders of pregnancy have included measurements of a variety of circulating hormones, autacoids, serum lipids, and oxidant and antioxidant activity; markers of endothelial dysfunction; evidence of neutrophil activation, adhesion molecules, a host of circulating cytokines; and measurement of urinary excretion of kallikrein, calcium, and albumin. All are based on plausible hypotheses as well as known pathophysiologic aspects of preeclampsia. However, to date the sensitivity of all these approaches is too weak to recommend them for clinical practice. Similarly, several large randomized, placebo-controlled and blinded multicenter studies regarding the ability of low-dose aspirin or calcium supplementation to prevent preeclampsia (in either low- or high-risk populations) have produced only marginal or negative results. Therefore, such strategies cannot be recommended.

MANAGEMENT

Suspicion of preeclampsia is grounds for hospitalization, given the unpredictably explosive nature of this disorder. Near term, induction of labor is the treatment of choice, but earlier in pregnancy (34 gestational weeks) temporization may be attempted. Delivery, regardless of gestational age, is indicated when hypertension is severe and cannot be controlled within the first 24 to 48 hours or if ominous signs are present that include evidence of cerebral irritability, progressing liver and coagulation abnormalities (especially signs and symptoms of the HELLP syndrome), and fetal jeopardy. Parenteral magnesium should be used to prevent or treat eclampsia, an approach once disputed but now supported by the results of randomized clinical trials.

Antihypertensive Therapy

Few, if any, studies are available that demonstrate the complete fetal safety of any antihypertensive drug prescribed to pregnant women. Methyldopa remains the agent with the longest postmarket history of safety, and results of a randomized study with a 7.5-year follow-up of the neonates are the reasons why the Working Group considers it the drug of choice for hypertension during pregnancy. Because of remaining uncertainties regarding drug safety, women whose hypertension is mild (diastolic levels between 90 and 100 mm Hg for most and up to 110 mm Hg for some) are not treated if they are asymptomatic and have no evidence of end-organ damage.

When methyldopa is unsuccessful, oral hydralazine can be used as a second drug, and labetalol (a combined α - and β -receptor antagonist) also has a relatively good safety record. β -blocking drugs may be associated with fetal growth restriction. Although the use of calcium channel blocking agents looks promising, the synergism of these agents used with $MgSO_4$ may lead to precipitous decreases in pressure and even respiratory arrest. Most other drugs have insufficient pregnancy data to discuss, with two exceptions. Diuretics, when prescribed before pregnancy in patients with chronic hypertension may be continued during gestation, especially in patients with volume-sensitive hypertension. However, such drugs should not be used in those with preeclampsia in whom intravascular volume and placental perfusion are already compromised. Angiotensin-converting enzyme inhibitors are associated with neonatal renal failure, which is at times irreversible, and are therefore contraindicated in pregnancy. On theoretical grounds, a similar contraindication has been assigned to angiotensin receptor-blocking agents.

Parenteral hydralazine is the drug of choice for treating acute hypertension, especially at term or during delivery. This drug is prescribed when pressures rise to ≥ 105 mm Hg, with a goal of maintaining pressures below these levels, but preferably above 90 mm Hg to avoid fetal distress. Experience is growing with parenteral labetalol, used in the rare instance in which blood pressure control cannot be achieved with hydralazine.

CHAPTER 163: LABORATORY EVALUATION OF RENAL DISORDERS

MAJD I. JARADAT AND BRUCE A. MOLITORIS

Urinalysis
 Measurement of Renal Function
 Evaluation of Tubular Function
 Radiologic Evaluation of the Renal System

Clinical laboratory and radiologic tests are of paramount importance in the diagnosis and management of patients with renal disorders. This chapter reviews tests that are useful to the internist for evaluating renal function and disease processes.

URINALYSIS

Since the earliest microscopic observation of urine in the early 1600s, urinalysis has evolved immensely and remains an extremely important diagnostic tool. Nevertheless, it is underutilized in clinical practice, although it can reflect and provide important clues to the presence of specific diseases. A complete urinalysis consists in visual inspection of the urine ([Table 163.1](#)), dipstick examination, and then microscopic examination of the urinary sediment.

Color	Common Cause(s)
Yellow	Normal
Red	Hemoglobinuria, myoglobinuria, hematuria, beets, rifampin, levodopa, methylodopa, phenolphthalein, deferoxamine
Orange	Bilirubin, Pyridium (phenazopyridine)
Brown	Bilirubin, methemoglobin (Hb in acid urine), levodopa, methylodopa
Black	Melanin, hemoglobinuria, homogentisic acid (alkaptonuria)
Blue, blue-green, green	Amitriptyline, methylene blue, vitamin B complex, triamterene
White	Chyluria, pus

TABLE 163.1. URINE COLORS AND THEIR CAUSES

URINE PH

The dipstick is a practical tool for determination of urine pH and is accurate to ± 0.5 pH units. pH is determined by two classic indicators: methyl red and bromothymol blue. The most accurate measurement of urinary pH requires a metered determination on urine collected under oil to protect loss of HCO_3^- via CO_2 . The normal value for urine pH is 4.5 to 6.5. A high value almost always reflects bicarbonaturia (with the exception of the presence of urease-releasing organism in the urine, e.g., *Proteus* and *Klebsiella*). For example, an alkaline urine in the presence of metabolic acidosis may be seen when hydrogen ion secretion by the kidney is impaired, indicating renal tubule acidification problems.

URINE SPECIFIC GRAVITY

The specific gravity of urine is the mass of 1 mL of urine compared with 1 mL of distilled water; a specific gravity near 1.010 indicates isosthenuria, with a urine osmolality matching plasma. Urine specific gravity is used to determine whether the urine is or can be concentrated. It is elevated when urine is concentrated or when dense solutes such as protein, glucose, or radiographic contrast are present.

GLYCOSURIA

Dipstick glucose testing is both specific (95%) and sensitive (90%) to the concentration of approximately 50 mg per deciliter. Glycosuria occurs in the setting of excessive filtered load of glucose that exceeds the capacity for tubular reabsorption (diabetes mellitus). Blood glucose spills into urine variably, depending on individual renal thresholds. Hence, urine glucose concentration correlates poorly with serum levels. Glycosuria can also occur with a normal filtered load of glucose when there is a proximal tubule defect in glucose reabsorption (isolated glycosuria of Fanconi's syndrome). Any time that the patient is spilling glucose in the urine and yet has normal serum glucose, chronic tubulointerstitial disease should be considered.

PROTEINURIA

Detection of proteinuria is an important part in the evaluation of every patient with a renal disorder. For example, the detection of microalbuminuria is a useful predictor of subsequent nephropathy in diabetic patients. Microalbuminuria and albuminuria have been shown to be associated with increased cardiovascular disease risk in patients both with and without diabetes mellitus. The most widely used screening test for proteinuria is the dipstick, which detects primarily albumin and is 95% sensitive to the 30 mg per deciliter upper limit of normal albumin excretion. The protein reaction may be scored from trace to 4+; the equivalence is as follows: trace, 5 to 20 mg per deciliter; 1+, 30 mg deciliter; 2+, 100 mg per deciliter; 3+, 300 mg per deciliter; 4+, greater than 2,000 mg per deciliter. The disadvantages of the dipstick test are that it misses proteinuria when excretion is less than 300 to 500 mg per day. Therefore, it cannot distinguish between physiologic and low-grade pathologic protein excretion (microalbuminuria). In addition, dilute samples may be falsely negative, whereas false-positives occur in very alkaline, concentrated, or bloody specimens.

The dipstick results must be confirmed with a 24-hour urine collection for quantification of proteinuria. The normal value is less than 150 mg per day, and patients excreting more than 3 g per day are considered to have nephrotic-range proteinuria. Collections obtained over a shorter period of time (8 to 12 hours) are subject to alterations in protein excretion induced by postural changes and other fluctuations in daily protein excretion. The adequacy of urine collection should be examined by measuring the urinary creatinine excretion in the same collection, because urinary creatinine excretion is relatively constant (20 to 25 mg per kilogram per day for men, 15 to 20 mg for women). The disadvantages of this test are inconvenience and the difficulty of accurately collect a complete 24-hour specimen. One can eliminate these two disadvantages by calculating the protein: creatinine ratio milligram per milligram in a random (preferably upright) untimed urine specimen. A value greater than 0.02, for example, suggests a protein excretion of greater than 20 mg per day. This method provides a convenient, reliable, and inexpensive method for monitoring proteinuric patients. Finally, urine negative by dipstick but positive with use of sulfosalicylic acid is likely to have proteins other than albumin (i.e., multiple myeloma proteins).

HEMATURIA

Testing for hematuria by dipstick is based on the pseudoperoxidase activity of hemoglobin. Red blood cells (RBCs) are lysed on the test pad resulting in a colorful dot, whereas free pigment distributes color evenly. The sensitivity is 78% to 99%. However, this test is not specific and also detects myoglobin, which has intrinsic peroxidase activity. A urine that is positive for heme pigments by dipstick, but shows no RBCs on microscopic examination, is suspect for myoglobinuria or hemoglobinuria resulting from RBC rupture. False-negatives occur with acidic, highly concentrated, or protein-rich samples and with improper storage (air exposure of

strips).

Hematuria should be confirmed by microscopic examination. The presence of more than two to three erythrocytes per high-power field usually indicates a pathologic condition. In glomerular disease, erythrocytes are dysmorphic, with spicules, blebs, submembrane cytoplasmic precipitations, membrane folding, and vesicles. These dysmorphic RBCs are reportedly easier to distinguish using phase-contrast microscopy. Note, however, that osmolality and pH significantly influence RBC morphology; a change toward eumorphism and lysis of erythrocytes in the urine occurs at less than 700 mOsm per kilogram and at a pH of 7 or higher. A three-tube urine collection test is used to locate the source of bleeding within the urinary tract. The first few milliliters of urine, a midstream sample, and the last few milliliters are collected. A urethral lesion is most likely if the hematuria occurs primarily in the first sample, and a lesion near the trigone is likely with terminal hematuria. Intrinsic renal, ureteric, and diffuse bladder lesions result in equivalent degrees of hematuria in all three specimens. The presence of casts and significant proteinuria in a patient with hematuria indicates a nephritic picture and glomerular disease.

LIPIDURIA

In the nephrotic syndrome, tubular cells reabsorb filtered lipids composed of cholesterol esters to form oval fat bodies in sloughed tubular cells in the urine. Fatty casts contain lipid-laden tubular cells or free lipid droplets. By light microscopy, lipid droplets appear round and clear with a green tinge. Cholesterol esters are anisotropic; cholesterol-containing droplets rotate polarized light, producing a Maltese-cross appearance. Lipiduria requires increased glomerular permeability and indicates glomerular disease. However, in polycystic kidney disease, lipid droplets may be seen both in the urine and in cyst fluid samples.

EOSINOPHILURIA

The presence of eosinophils requires clinical investigation. Wright's stain is the most commonly used stain for detection, but it is not a sensitive method. Hensel's stain greatly improves identification of eosinophils by their brilliant red to pink granules. Urine specimens should be fresh, because leukocytes lyse with aging of the urine. Eosinophiluria is seen in patients with acute interstitial nephritis, rapidly progressive glomerulonephritis, atheroembolic disease, and prostatitis (in some cases).

WHITE BLOOD CELLS

Granulocyte esterase can cleave pyrrole amino acid esters producing free pyrrole that reacts with a dipstick chromagen. The dipstick threshold is 5 to 15 white blood cells (WBCs) per high-power field. False-negatives occur with glycosuria and high specific gravity. The polymorphonuclear neutrophils in urine signify inflammation in the kidney or urinary tract. The actual number correlates poorly with the degree of inflammation. Pyuria often indicates urinary tract infection, especially when associated with bacteriuria, and urine culture should be obtained. Sterile pyuria might be seen in partially treated infection, urinary tract tuberculosis, tubulointerstitial disease, and glomerular diseases.

LEUKOCYTE ESTERASE AND NITRITE

Unique to granulocytes are esterases that can hydrolyze an intermediary, which then couples to a diazo compound causing a characteristic color change. This reaction can be inhibited by high concentrations of glucose, albumin, and some antibiotics such as cephalosporins, but bacteria and blood do not interfere. Sensitivity for urinary tract infection of the leukocyte esterase (LE) test is 76% to 96%, and specificity is 79% to 98%. Urine tests positive for LE when granulocytes are present, regardless of their source. Nitrite is more specific than LE but a far less sensitive dipstick test for urinary infection. Gram-negative bacteria convert excreted dietary nitrates to nitrites, which react with aromatic amines and diazo indicators in a color reaction similar to that seen with LE. Sensitivity ranges from 25% to as high as 70% for first morning-voided samples. Specificity for gram-negative organism is superb (92% to 98%). False-negative results can occur with decreased dietary nitrates or recent-onset infections. False-positives occur with improper storage (air exposure) of the strips.

CASTS

Tamm–Horsfall protein is a mucoprotein with unclear function, which is secreted by the thick ascending limb of Henle. It represents the matrix of all urinary casts. The casts may contain only the matrix (hyaline casts). These casts are nonspecific and occur in normal concentrated urine as well as numerous pathologic conditions. When casts include degenerated cells or filtered proteins, they are called *granular casts*, which can have fine granules (derived from altered serum proteins) or coarse granules (resulting from degeneration of embedded cells). Granular casts are nonspecific and may be seen after exercise or with simple volume depletion, glomerulonephritis, and tubulointerstitial disease. Large muddy-looking granular casts are found in acute tubular necrosis. Waxy casts are made of hyaline material with a much greater refractive index than hyaline casts; hence, their waxy appearance. These casts usually form in tubules that are atrophic owing to chronic parenchymal disease. Cellular casts contain intact cells. RBC casts are the hallmark of glomerulonephritis. They may exhibit intact erythrocytes or may be composed of erythrocytes in various stages of degeneration. They also have been described along with hematuria in healthy persons after exercise.

Phase-contrast microscopy is helpful in distinguishing erythrocyte membranes within the casts. WBC casts consist of white cells in a protein matrix. They are characteristic of those with pyelonephritis and are useful in distinguishing it from lower tract infection. WBC casts may also be seen with interstitial nephritis, other tubulointerstitial disorders, and glomerular diseases.

Tubular cell casts consist of sloughed epithelial cells in a hyaline matrix. They occur in concentrated urine, but are more frequently seen with sloughing tubular cells in patients with acute tubular necrosis, pyelonephritis, renal transplant rejection, and interstitial nephritis.

CRYSTALS

Urinary crystals do not always indicate pathologic condition; they may be present spontaneously or may precipitate with refrigeration of the specimen. The most distinctive crystal forms are calcium oxalate (often described as envelope-shaped), uric acid (diamond-shaped) triple phosphate (coffin lid-shaped), and cystine crystals (hexagonal plates). Urinary pH is a useful clue; the only stones made more likely by alkaline urine are apatite (calcium phosphate) and struvite (magnesium ammonium phosphate). They occur with infection by urease-producing organisms. Massive oxalate crystalluria is seen with ethylene glycol (antifreeze) poisoning.

MEASUREMENT OF RENAL FUNCTION

GLOMERULAR FILTRATION RATE

Glomerular filtration rate (GFR) is the rate at which an ultrafiltrate of plasma is produced per unit of time (milliliter per minute). It is dependent on the permeability of the glomerular membrane barrier and the difference between the hydraulic and oncotic pressures (Starling forces). In healthy persons, GFR is approximately 125 mL per minute per 1.73 m² or 180 L per day per 1.73 m². It averages 8% lower in women than in men. The level of GFR is the sum of the filtration rates of all the nephrons:

$$\text{GFR} = n \cdot \text{sglGFR}$$

where n is the number of nephrons and sglGFR is single-nephron GFR.

When renal mass is lost during disease processes, remaining nephrons hyperfiltrate to maintain adequate GFR and renal function. If a substance is freely filtered across the glomerular capillary wall and excreted only by glomerular filtration, its rate of filtration is equal to its rate of urinary excretion. Therefore, the ideal substance to measure GFR accurately would be a substance freely filtered but not secreted, reabsorbed, or metabolized, meaning that GFR would equal the urinary clearance of the marker after its intravenous infusion. Inulin and ¹³¹I (iodine)-iothalamate are such substances. However, they require constant intravenous infusion, which is time-consuming and expensive.

Nuclear medicine techniques are also available to measure GFR; ^{99m}technetium (Tc)-diethylene triaminopentaacetic acid (DTPA) is excreted by glomerular filtration, and GFR can be estimated after a single injection of the radioisotope by determining the amount in plasma samples obtained 60 and 180 minutes after injection.

Imaging clearances are obtained by measuring the increase in counts over the kidney for 3 to 6 minutes.

SERUM CREATININE

Creatinine is an end product of muscle metabolism and is excreted solely by the kidneys. The production rate is relatively stable over time for an individual because it is proportional to muscle mass. The normal range for plasma creatinine is 0.8 to 1.3 mg per deciliter (70 to 114 μ moles per liter) in men and 0.6 to 1.0 mg per deciliter in women. Serum creatinine is used as an endogenous marker of GFR because it is freely filtered across glomeruli—not metabolized or reabsorbed—and it has constant generation. However, it is secreted by proximal tubular cells. In healthy persons, creatinine secretion accounts for 5% to 10% of urinary creatinine; hence, creatinine clearance exceeds GFR by approximately 10 mL per minute per 1.73 m². This is important for evaluating patients with reduced GFR, because enhanced secretion of creatinine in these patients leads to a greater disparity between creatinine clearance and GFR. Therefore, with reduced GFR, the value for creatinine clearance can markedly overestimate the GFR. In addition, significant renal function is lost before the plasma creatinine rises, and, with early renal dysfunction, relatively small changes in P_{Cr} reflect large decrease of GFR (Fig. 163.1).

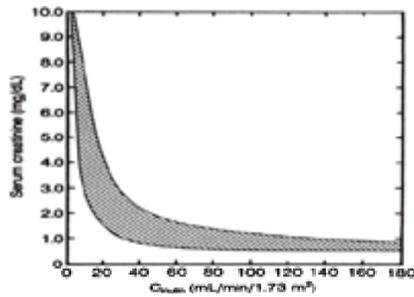

FIGURE 163.1. The shaded area represents the variation in GFR, measured by inulin clearance, which corresponds to a given level of serum creatinine. A serum creatinine of 2 mg/dL may reflect a GFR from 18 to 45 mL/min. At lower levels of serum creatinine concentration, this variability increases. (Adapted from Shemesh O, Golbetz H, Kriss JP, et al. Limitations of creatinine as a filtration marker in glomerulopathic patients. *Kidney Int* 1985;28:830–838.)

Many substances can affect P_{Cr} . It can rise acutely without a change in GFR because of decreased creatinine secretion or interference with the plasma assay. Creatinine is secreted by the organic cation pump in the proximal tubule. Trimethoprim and the H₂-blocker cimetidine can inhibit this pump causing a rise in serum creatinine by as much as 0.4 to 0.5 mg, but the effect is reversible with discontinuation of the drug.

Because of differences among individuals in creatinine generation and excretion, creatinine clearance provides a more accurate estimate of GFR than does serum creatinine. Creatinine clearance is defined as the volume of plasma that is cleared of creatinine by the kidney per unit time and is calculated from a 24-hour urine collection for creatinine:

$$\text{GFR} = \text{Cr clearance} = (U_{Cr} \cdot V) / P_{Cr} \text{ [mL/min]}$$

This method of estimating GFR from creatinine clearance does not require a steady state, in contrast to measuring GFR from serum creatinine which is only valid in a steady state:

$$\text{GFR} = ([140 - \text{age}] \cdot \text{weight}) / (P_{Cr} \cdot 72) (-0.85 \text{ for women})$$

In patients with moderate to severe renal dysfunction, an alternative method for estimation of GFR is to take the average of the creatinine and urea clearances. Urea clearance underestimates GFR, because about 40% to 50% of the filtered urea is reabsorbed. Because the magnitude of the two errors tends to be similar but in opposite directions, the average is more accurate.

BLOOD UREA NITROGEN

Urea is synthesized primarily by the liver and is the end product of protein catabolism. One third of synthesized urea is metabolized in the intestine to carbon dioxide and ammonia. The generated ammonia returns to the liver, where it is converted to urea. Urea is also excreted principally by glomerular filtration. In a steady state, urea level varies inversely with GFR. However, it is not a useful marker of changes in the GFR owing to the renal reabsorption and the various factors affecting the serum level (Table 163.2). The normal serum value is 8 to 12 mg deciliter; therefore, the normal ratio of blood urea nitrogen (BUN) to creatinine is approximately 10:1. This ratio is useful to indicate alterations in urea reabsorption or generation, because a reduction in GFR would lead to a rise in BUN but would not alter the BUN:creatinine ratio. Urea reabsorption occurs in proximal and distal nephrons and is influenced by the patient's volume status in the medullary collecting duct, which is relatively impermeable to urea in the absence of antidiuretic hormone (ADH). In volume depletion, ADH stimulation raises the duct's permeability to urea. Subsequently, BUN is reabsorbed and serum BUN rises out of proportion to the decline in GFR.

Increased BUN	Decreased BUN
Increased catabolic rate	Decreased catabolic rate
Trauma	Liver disease
Fever	Decreased protein intake
Cell lysis	
Infection	
Hyperthermia	
Therapy with tetracycline or corticosteroids	
Increased protein intake	
Gastrointestinal bleeding (with volume depletion)	
Reduced renal perfusion (volume depletion, congestive heart failure)	

TABLE 163.2. CAUSES OF CHANGES IN BLOOD UREA NITROGEN (BUN) INDEPENDENT OF RENAL FUNCTION

EVALUATION OF TUBULAR FUNCTION

Tests of tubular function reflect the ability of the kidney to maintain homeostasis.

URINARY SODIUM AND FRACTIONAL EXCRETION OF SODIUM

Normally, the 24-hour urine sodium excretion equals 24-hour sodium intake minus small losses in stool and sweat. Urinary Na⁺ concentration reflects both Na⁺ and H₂O intake. In volume-depleted states, the kidney conserves sodium; hence, the U_{Na} level is useful in assessing volume status. A low urine sodium concentration (less than 20 mEq per liter) suggests the diagnosis of volume depletion, whereas a high value points toward Na⁺ wasting, which can be appropriate or inappropriate. Variations in the rate of water reabsorption can result in a U_{Na} between 20 and 40 mEq per liter, even in volume-depleted patients. Therefore, a more dependable

index is the fractional excretion of sodium FE_{Na} defined as the fraction of filtered sodium that is excreted in the urine.

$$\text{Na absorption} = \text{filtered Na} - \text{urinary Na excretion}$$

or,

$$\text{Na absorption} = (\text{GFR} \cdot P_{Na}) - (V \cdot U_{Na})$$

where U_{Na} is the urinary sodium concentration, P_{Na} is the plasma sodium concentration. FE_{Na} is equal to $(U_{Na}/P_{Na}) / (U_{Cr}/P_{Cr})$.

Sodium reabsorption is appropriately enhanced in hypovolemic states, and the FE_{Na} is usually less than 1% (i.e., more than 99% of the filtered Na has been reabsorbed). In contrast, tubular damage leads to a FE_{Na} of more than 2% in most cases of acute tubular necrosis.

Several conditions other than hypovolemia (prerenal azotemia) present with an elevated serum creatinine and a low FE_{Na} . Moreover, several factors can interfere with sodium conservation and may result in a high FE_{Na} in the setting of prerenal azotemia (Table 163.3).

$FE_{Na} < 1\%$, $U_{Na} < 20$ mEq/L	$FE_{Na} > 1\%$, $U_{Na} > 40$ mEq/L
Prerenal azotemia	ATN (90%)
Acute urinary tract obstruction (few hours)	Chronic urinary tract obstruction (days to months)
Acute glomerulonephritis	Poorly reabsorbable solute (glycosuria, bicarbonaturia, mannitol diuresis)
Contrast-induced acute tubular necrosis (ATN) (early)	Preexisting chronic renal failure
Rhabdomyolysis with myoglobinuria-induced ATN (sometimes)	Diuretic administration
Early sepsis	
Nonoliguric ATN (10%)	

TABLE 163.3. CAUSES OF HIGH OR LOW FE_{Na} AND U_{Na} IN PATIENTS WITH ACUTE RENAL FAILURE

The FE_{Na} is most useful in oliguric states after ruling out obstruction. It should be noted that a high FE_{Na} cannot be interpreted in patients who received diuretics, but a low value can be. Chloride is another urinary electrolyte that is very useful in determining volume status in patients with metabolic alkalosis. A value less than 15 mEq per liter implies decreased effective or absolute arterial blood volume or very low salt intake. It differentiates chloride-responsive metabolic alkalosis (contraction alkalosis) from other causes (e.g., hyperaldosteronism, severe hypokalemia, alkali loading) in which the urine chloride is usually higher than 20 mEq per liter, provided that the patient is not receiving diuretics.

URINARY ACIDIFICATION

The typical Western diet yields a net of close to 1 mmol of H^+ per kilogram of body weight per day. These H^+ ions are removed for the most part by combining with bicarbonate ions (HCO_3^-) forming H_2O and CO_2 (which is exhaled). As a result, the body is left with an overall deficit of HCO_3^- . To maintain acid-base balance, the kidney must not only reclaim all filtered HCO_3^- , but also generate new bicarbonate. This latter task is achieved by excreting $H_2PO_4^-$ and NH_4^+ . The rate of excretion of $H_2PO_4^-$ and NH_4^+ must exceed that of HCO_3^- to have a positive renal balance of HCO_3^- ; hence, the principle of net acid excretion. Renal tubular acidosis occurs when there is excessive excretion of HCO_3^- , low excretion of NH_4^+ , or excessive excretion of metabolizable organic anions, which represent a potential source of HCO_3^- .

$$\text{Net acid excretion} = NH_4^+ + H_2PO_4^- - HCO_3^- - \text{metabolizable organic anions.}$$

The fractional excretion of bicarbonate can provide useful information. In general, a high FE_{HCO_3} could be due to either a very large defect in H^+ secretion in the proximal tubule, or a smaller defect in proximal tubule H^+ secretion combined with a reduced distal capacity for H^+ secretion or lastly, normal proximal but a near complete defect in distal H^+ secretion.

The kidney's ability to excrete H^+ as ammonium is the basis for the concept of urinary anion gap (UAG), which is the most commonly used surrogate for urinary ammonium excretion. It is the difference between major urinary cations ($Na^+ + K^+$) and urinary anions ($Cl^- + HCO_3^-$). Because the amount of bicarbonate is very small in acid urine (pH < 6.5), the difference between urinary ($Na^+ + K^+$) and Cl^- reflects the ammonium, and the UAG would equal: $[Na^+ + K^+]_u - [Cl^-]_u$. In an extrarenal cause of acidosis (e.g., gastrointestinal bicarbonate wasting), the excretion of NH_4^+ (and of Cl^- to maintain electroneutrality) increases several-fold (intact renal acidification), resulting in a negative UAG (urinary $Na^+ + K^+$ is less than Cl^-). In contrast, NH_4^+ excretion remains low in renal tubular acidosis, resulting in a positive UAG. Urine pH in patients with RTA is useful when such patients are found to have a low rate of excretion of NH_4^+ . A low urine pH in this setting suggests a decreased NH_3 availability in the renal medullary interstitium to match the increased H^+ secretion by the distal nephron, whereas a high value suggests a defect in distal or proximal H^+ secretion ($H^+ + NH_3 \rightleftharpoons NH_4^+$).

WATER BALANCE

Under ADH control from the posterior pituitary, the kidney can achieve a wide range of osmolality (50 to 1,200 mOsm per kilogram), resulting in water excretion (diuresis) or conservation, with a target serum osmolality of 280 to 290 mOsm per kilogram. A urine of 300 mOsm per kilogram osmolality is called *isosmotic*. Hypotonic urine would then represent a urine that has all the solute excreted with free water added that would make the urine dilute; hence, the concept of free-water clearance (C_{H_2O}), which is the difference between the amount of water excreted and the amount of water needed to excrete the urinary solute load in isotonic urine.

$$V = C_{osm} + CH_2O,$$

where C_{osm} is the osmolar clearance ($[U_{osm} \cdot V]/P_{osm}$),

$$CH_2O = V \cdot (1 - [U_{osm}/P_{osm}]),$$

where P_{osm} is the plasma osmolality and V is urine vol (liters per day).

C_{H_2O} is inappropriately increased in patients with diabetes insipidus, causing a dilute urine and hypernatremia, and is appropriately increased after a water load. Conversely, hypertonic urine would represent a urine containing all the urinary solute in an isotonic solution with free water removed from this urine by tubular reabsorption, resulting in a hyperosmotic value; hence, the concept of free-water reabsorption (T_{H_2O}):

$$V = C_{osm} - T_{H_2O} \text{ or } T_{H_2O} = C_{osm} - V$$

$$= V \cdot ([U_{osm} / P_{osm}] - 1)$$

$T_{H_2O}^C$ is appropriately increased in volume depletion and is inappropriately increased in the syndrome of inappropriate ADH secretion, resulting in hyponatremia.

Water handling by the kidney may be evaluated by the water deprivation test, which involves following the changes in plasma and urine osmolality for 12 to 24 hours. At plasma osmolality of 295 to 300 mOsm per kilogram (osmolality at which stimulation of ADH is maximum), 5 units of aqueous vasopressin is given subcutaneously and urine osmolality is measured. Patients with central diabetes insipidus have a concentrated urine, whereas patients with nephrogenic diabetes insipidus maintain a dilute urine. Patients with primary polydipsia have a maximally concentrated urine at the end of water deprivation and do not need to receive ADH.

RENAL BLOOD FLOW

An estimation of renal blood flow (RBF) can be derived from the renal clearance of any compound that is totally cleared (excreted) by a single pass through the kidney and completely eliminated into the urine. Para-aminohippurate (PAH) is an organic acid that is both filtered at the glomerulus and extensively secreted by the proximal tubule, with a first-pass clearance approaching 100%. PAH is experimentally used to calculate RBF by measuring its clearance in a fashion similar to creatinine or inulin clearance: infusing PAH to achieve a steady-state plasma level and carefully collecting timed urine samples:

$$RBF = (U_{PAH} \cdot V) / P_{PAH}$$

RADIOLOGIC EVALUATION OF THE RENAL SYSTEM

Radiologic tests evaluate renal morphology and function ([Table 163.4](#)).

Test	Primary Use
Plain abdominal x-ray	Identify calcifications (e.g., ureteral calculi)
Ultrasound	Measure kidney size, detect hydronephrosis, cysts, and masses
Duplex Doppler ultrasonography	Assess renal perfusion and detect renal artery stenosis
Computed tomography (CT)	Detect renal masses, hydronephrosis, and ureteral calculi
Magnetic resonance imaging (MRI)	Evaluate renal masses and renal artery stenosis
Renal scintigraphy (MAG-3)	Assess renal function and detect obstruction
Intravenous pyelography (IVP)	Visualize the collecting system and detect obstruction
Direct pyelography	Visualize the collecting system and detect obstruction
Urography	Visualize the collecting system and detect obstruction
Renal biopsy	Diagnose renal parenchymal disease

TABLE 163.4. TESTS FOR EVALUATION OF RENAL SYSTEM AND THEIR USES

SONOGRAPHY

On plain abdominal x-ray, a normal kidney is the height of 3.5 vertebrae. However, this overestimates the kidney length by 10% to 15%, and the renal outline is sometimes difficult to discern. Ultrasound is a good test for evaluating renal size and ruling out obstruction. It provides precise measurement of the length and volume and can differentiate cortex from medulla. It can also identify cortical thinning and increased echogenicity, which indicate chronic renal disease. In general, an ultrasound is also the first investigation performed to evaluate renal cysts and masses. It can detect cysts as small as 1 to 1.5 cm in diameter and can differentiate a simple cyst from a carcinoma or abscess in most cases. Simple cysts are sharply demarcated, with smooth walls and a strong posterior wall echo due to strong transmission through the cyst.

Duplex Doppler ultrasonography in experienced hands is valuable in detecting renal hypoperfusion. It has also proved to be valuable in assessment of patients with acute renal failure, most of whom show elevated renal resistive index. Patients with acute tubular necrosis have markedly abnormal Doppler flow profiles, with increased pulsatility and loss of diastolic flow. A renal resistive index (RI) value of 0.75 has been reported as optimal in attempting differential diagnosis between renal and prerenal acute renal failure. In addition, in kidneys with a dilated collecting system, a RI value of 0.70 or more is suggestive for obstruction, whereas lower values are suggestive of nonobstructive dilation. Duplex Doppler ultrasonography can also have some predictive value for subsequent development of kidney dysfunction and hepatorenal syndrome in patients with liver disease when the RI value is elevated.

COMPUTED TOMOGRAPHY

Computed tomography (CT) scan is a useful test to evaluate renal masses and cysts. It can detect simple cysts as small as 0.5 cm. Cysts are characterized by smooth, thin walls and cystic fluid with a consistency similar to that of water. Simple cysts do not enhance after radiocontrast. Enhancement implies vascularity and strongly suggests a tumor. Unenhanced CT adds clinically important information when sonograms are indeterminate. CT is as sensitive as ultrasonography in detecting hydronephrosis and is much more sensitive in detecting ureteral calculi. Dilated ureters can be traced to the point of obstruction. ARF induced by iodinated contrast media accounts for about 10% of all hospital cases of renal failure, especially in azotemic patients. Nonionic, low-osmolality media should be used in high-risk patients because these media have been shown to be significantly less nephrotoxic than ionic contrast media—in patients with and without renal insufficiency. Spiral CT scan is superior to conventional CT. It minimizes artifacts and reduces the amount of contrast needed. Non-contrast spiral CT is 97% accurate in detecting ureteral calculi and obstruction and is even more sensitive than intravenous pyelograms. It is superior for precise evaluation of renal volume and detection of mild hydronephrosis. Contrast-enhanced spiral CT has become the major initial study in acute pyelonephritis in addition to detecting structural abnormalities.

MAGNETIC RESONANCE IMAGING

The images produced by magnetic resonance imaging (MRI) are higher in contrast resolution than those from a CT scan. Unlike CT, multiplanar imaging is possible, and although contrast medium is used, no significant nephrotoxicity was reported for paramagnetic contrast agents, either ionic or nonionic, with the concentrations used in common clinical practice. Sensitivity reactions have been extraordinarily rare. Corticomedullary differentiation is shown best with this modality. Magnetic resonance is exquisitely sensitive to blood flow and produces superb depiction of the larger renal vessels. Therefore, magnetic resonance angiography has been an important modality in the evaluation of renal artery and vein obstructions from any cause.

Indications for renal MRI are evaluation and characterization of renal masses and fluid collections, accurate staging of renal cancer, semiquantitative evaluation of renal function using contrast-enhanced dynamic studies (magnetic resonance renography), and evaluation of renal vessels using magnetic resonance angiography (MRA). It can also be used as an alternative imaging modality to CT for patients allergic to iodine or patients with an inconclusive CT study, in addition to patients at high risk for contrast nephrotoxicity. MRA is rapidly becoming the most useful screening test for significant renal artery stenosis, with a sensitivity of 87% and a specificity of 97%, which compare favorably with those of conventional angiography. However, it cannot detect distal or intrarenal stenoses, and is therefore not recommended when fibrodysplastic stenosis is suspected.

MRI is the method of choice for the diagnosis of renal vein thrombosis in patients with impaired renal function. Dynamic functional MRI allows the evaluation of renal excretory function, even in patients with diffuse functional impairment. Dynamic examinations can be quantitatively evaluated by plotting the signal intensity values in the renal cortex and medulla as a function of time. MRI can also differentiate between acute and chronic obstruction and hydronephrosis. In acute obstruction, the corticomedullary demarcation is preserved, and the renal cortex shows enhancement similar to that of a normal kidney after injection with gadolinium-DTPA (diethylenetriamine pentaacetic acid), but medullary enhancement is greater and sustained. In chronic obstruction, the demarcation is often absent, and cortical enhancement is lower than in the normal kidney, with a prolonged tubular phase.

SCINTIGRAPHY (RADIONUCLIDE IMAGING)

The flow of radioisotopes through the kidney may be monitored, resulting in imaging of vascular perfusion, parenchymal integrity and outflow tract anatomy. Radiopharmaceuticals available for assessing renal function and anatomy are grouped into three categories: those excreted by glomerular filtration (^{99m}Tc -DTPA), those excreted by tubular secretion (iodine orthoiodo-hippurate [^{131}I -OIH] and ^{99m}Tc -mercaptoacetyltriglycine [MAG₃]), and those retained in the renal tubules for long periods of time (^{99m}Tc -dimercaptosuccinic acid [DMSA]). DTPA is used to measure GFR. It has a low extraction fraction, which limits its use in patients with renal impairment. Extraction of ^{99m}Tc -MAG₃ requires delivery of the compound to the kidney (renal plasma flow) and extraction from the plasma (proximal tubules) and has a higher extraction fraction, which provides better images than ^{99m}Tc -DTPA, particularly in patients with impaired renal function. DMSA is an excellent cortical imaging agent and is used when high-resolution anatomical images are required, as in detecting pyelonephritis. Scintigraphy, then, is useful in measuring renal function (GFR) and renal plasma flow in addition to the measurement of each kidney's contribution to the total renal plasma flow and total GFR (split renal function).

Captopril-scintigraphy is useful in diagnosing functionally significant renal artery stenosis. This is done by obtaining a baseline scan, followed by a scan after its administration. The angiotensin-converting enzyme (ACE) inhibitor, by causing efferent arteriole vasodilation, induces a decline in the GFR in the kidney on the side of the stenosis, thus enhancing the difference in the function of the two kidneys. An ACE inhibitor renogram is considered positive if there is decreased uptake of the radioisotope by one kidney such that the GFR of that kidney accounts for less than 40% of the total GFR. Another criterion is delayed peak of uptake of isotope by the kidney. However, the test has a sensitivity of only 70%, which can be higher in high-risk patients, but is 90% specific for high-grade stenotic lesions. Scintigraphy is useful in providing valuable functional information about the significance of obstruction in obstructive nephropathy (diuresis renography). This is important in the differentiation of hydronephrosis (dilated, obstructed tract) from hydroureteronephrosis (dilated, nonobstructed tract). In this test, a diuretic during dynamic scintigraphy can induce a rapid washout of the tracer from a dilated, nonobstructed, renal pelvis, but not from an obstructed one.

ANGIOGRAPHY

Renal angiography can be diagnostic in patients with suspected renal artery stenosis or occlusion, most of whom are hypertensive or thought to be at high risk for renal artery occlusive disease. It is also diagnostic in suspected arteritis, renal vein thrombosis, and persistent unexplained hematuria. This test has therapeutic applications in angioplasty, angio-occlusion, and thrombolysis. Complications of angiography include thrombosis, aneurysm, and bleeding and are rare in experienced hands. However, the major concern is deterioration of renal function in patients with renal insufficiency. This can be minimized by using the minimal amount of low-ionic-strength contrast media and proper hydration before the test.

PYELOGRAPHY

Intravenous pyelography (IVP) is commonly requested when an obstructive calculus or lesion is suspected. It is also the study of choice in medullary sponge kidney disease. Contrast stasis and delayed excretion of contrast material into collecting system after IV injection are indicative of obstruction. A standing column of contrast within the ureter and dilatation of the collecting system are signs of ureteral obstruction. Direct retrograde and antegrade injection of contrast into the renal collecting system or ureter is considered when precise anatomical information is required, which is particularly valuable when the IVP is suboptimal owing to poor renal function and inadequate contrast excretion. Retrograde and antegrade pyelography are also used for defining level and degree of obstruction and whether or not the obstruction is intraluminal or not. They are particularly useful in planning interventions such as stenting and percutaneous nephrostomy.

RENAL BIOPSY

INDICATIONS

Many indications exist for renal biopsy in a patient with glomerular disease. The most common of these is to establish the diagnosis for a renal-limited process or a systemic disease that has renal involvement (e.g., systemic vasculitis). A renal biopsy diagnosis provides insight into the natural history of the disease and guides the initiation of choice of therapy. Renal biopsy results provide an estimation of prognosis based on the type of disease identified and the pathologic aggressiveness and chronicity of the renal injury. A biopsy frequently relieves uncertainty in the patient and the physician regarding the nature of the patient's illness. A specific pathologic diagnosis also obviates further investigations that would be necessary in the absence of a conclusive diagnosis. For example, in patients with persistent hematuria of uncertain cause, a renal biopsy diagnosis of IgA nephropathy or thin basement membrane nephropathy renders unnecessary repetitive urologic evaluations such as cystoscopy and intravenous pyelography.

[Table 164.1](#) lists the major clinical manifestations of glomerular diseases that prompt renal biopsy. The many glomerular diseases in [Table 164.1](#) have differing natural histories, and affected patients have different responses to therapy. Most therapies for active, progressive forms of glomerulonephritis require anti-inflammatory or immunosuppressive agents, or both. Because these agents have significant side effects, some of which are life-threatening, their use is justified only if the risk:benefit ratio is favorable. This chapter focuses on the use of renal biopsy in specific clinical syndromes that suggest underlying glomerular disease, the possible diagnosis in each of these syndromes, and therapeutic options that are indicated by the renal biopsy findings. Renal biopsies also are useful in the management of some forms of tubulointerstitial and vascular disease, but these are considered in [Chapter 151](#) and [Chapter 152](#).

Asymptomatic microscopic hematuria	Acute renal failure
Thin basement membrane nephropathy	Acute diffuse proliferative GN
IgA nephropathy	Endocapillary GN
Membranoproliferative glomerulonephritis	Crescentic GN
Alport's syndrome	Acute GN ESR
Thin basement membrane nephropathy	Chronic crescentic GN

Clinical patterns also suggest which glomerular disease is the most probable cause of renal dysfunction (Fig. 164.2). Clinicopathologic syndromes include asymptomatic microscopic hematuria with or without recurrent gross hematuria, asymptomatic proteinuria, nephrotic syndrome, acute nephritis, rapidly progressive glomerulonephritis with or without systemic illness, pulmonary–renal vasculitic syndrome, and chronic nephritis.

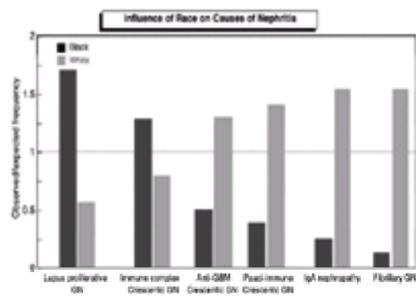

FIGURE 164.2. An estimation of the frequency of glomerular lesions by race. A value of “1” indicates the expectation that the white:black ratio will be equivalent. *GBM*, glomerular basement membrane; *GN*, glomerulonephritis.

The clinical course of a glomerular disease can be acute and self-limited (e.g., acute poststreptococcal glomerulonephritis), persistent and indolent (e.g., focal segmental glomerulosclerosis [FSGS]), or fulminant (e.g., rapidly progressive glomerulonephritis, pulmonary–renal vasculitic syndrome). The clinical manifestations of a glomerular disease can change over time. For example, any form of proliferative glomerulonephritis can present with asymptomatic hematuria and proteinuria. Later, a more acute or even rapidly progressive nephritic picture may emerge (Fig. 164.3). Certain glomerular diseases, such as anti–glomerular basement membrane (GBM) crescentic glomerulonephritis, usually progress to severe failure within weeks to months. Others, such as lupus nephritis, tend to cause focal or diffuse proliferative glomerulonephritis, which may progress to end-stage disease over several years. Diseases such as IgA nephropathy tend to begin as mild mesangioproliferative lesions and progress into more severe lesions over several decades, whereas diseases such as poststreptococcal glomerulonephritis initially cause an active proliferative glomerulonephritis and then resolve through a mesangioproliferative phase to normal. Because the treatment of most of these diseases involves immunosuppressive agents or other expensive and inherently dangerous modalities (i.e., plasma exchange), a precise renal biopsy diagnosis is imperative.

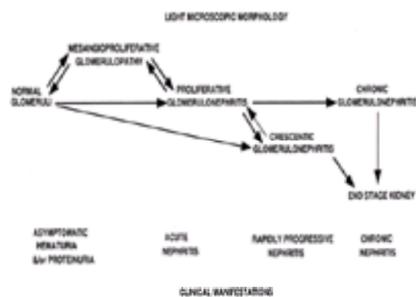

FIGURE 164.3. Morphologic stages of proliferative glomerulonephritis (top) aligned with the usual clinical manifestations (bottom). (Jennette JC, Mandal AK. Syndrome of glomerulonephritis. In: Mandal AK, Jennette JC, eds. *Diagnosis and management of renal disease and hypertension*, second ed. Durham, NC: Carolina Academic Press, 1994:207.)

RENAL BIOPSY EVALUATION

For optimum clinical value, a renal biopsy specimen should be evaluated by a pathologist with extensive experience in renal pathology. Renal biopsy specimens should be examined by light, immunofluorescence, and electron microscopy when a glomerular disease is suspected. These three modalities are always complementary or confirmatory, and, in particular diseases, each is essential for making a diagnosis. For example, IgA nephropathy cannot be diagnosed without immunohistology, and thin basement membrane nephropathy cannot be diagnosed without electron microscopy. A detailed discussion of the histologic patterns of various forms of glomerulonephritis is presented in [Chapter 150](#).

Light microscopic evaluation of glomerular diseases begins with the identification of structural changes in glomeruli, which then must be characterized with respect to type and distribution. Glomerular lesions are considered focal if 50% or fewer glomeruli are involved and considered diffuse if more than 50% of glomeruli are involved. A segmental lesion affects only a portion of a glomerular tuft, whereas a global lesion affects the entire tuft.

Glomerular changes that can be identified by light microscopy include glomerular hypercellularity, capillary wall thickening, sclerosis, and necrosis. For example, normal glomeruli by light microscopy are consistent with minimal change glomerulopathy, early membranous glomerulopathy, or thin basement membrane nephropathy. Thick capillary walls without hypercellularity suggest membranous glomerulopathy, whereas thick walls with hypercellularity suggest some form of membranoproliferative glomerulonephritis or, possibly, diffuse proliferative lupus glomerulonephritis. Diffuse global hypercellularity with conspicuous neutrophils strongly suggests acute postinfectious (especially poststreptococcal) glomerulonephritis. Focal or diffuse hypercellularity indicative of a focal or diffuse proliferative or mesangioproliferative glomerulonephritis can be caused by a variety of glomerular diseases. Focal and diffuse proliferative or mesangioproliferative glomerulonephritis are merely morphologic categories of glomerular inflammation. These terms must be modified with specific disease designations before they become meaningful diagnoses. For example, immunohistologic and ultrastructural data could be used in combination with the light microscopic pattern of glomerular hypercellularity to reach a diagnosis, such as focal proliferative IgA nephropathy or diffuse proliferative lupus glomerulonephritis.

Focal segmental glomerular scarring raises the possibility of FSGS, but other causes, such as the sclerotic phase of a focal proliferative glomerulonephritis or hereditary nephritis, must be ruled out by immunohistology and electron microscopy before this diagnosis can be made.

Light microscopic evaluation of glomerular diseases should include an evaluation of histologic features that indicate the activity and chronicity of the disease. For example, glomerular necrosis and crescents are indicators of active aggressive inflammatory disease, whereas glomerular sclerosis, interstitial fibrosis, and tubular atrophy are indicators of chronic injury.

Crescents result from the rupture of glomerular capillaries with the release of proinflammatory plasma constituents into Bowman's capsule. This causes the accumulation of macrophages and the proliferation of epithelial cells, that is, crescent formation. Therefore, crescent formation is an indicator of severe capillary injury; however, crescent formation can be caused by many different types of glomerular disease and is etiologically nonspecific. The term *crescentic glomerulonephritis* is not a specific diagnosis until it is modified by additional information derived from other pathologic, serologic, or clinical data (i.e., anti-GBM, antibody-mediated crescentic glomerulonephritis, antineutrophil cytoplasmic autoantibodies [ANCA]-associated crescentic glomerulonephritis, or crescentic type I membranoproliferative glomerulonephritis associated with cryoglobulins). The pathologic term crescentic glomerulonephritis usually is reserved for specimens with

crescents in more than 50% of glomeruli. When fewer crescents are present, this is indicated in the diagnosis as a percentage, such as focal proliferative IgA nephropathy with 25% crescents.

Immunofluorescence or immunoenzyme microscopy is essential for optimum examination of renal biopsy specimens. The presence or absence of staining for various immunoglobulins and complement components is important for differentiating among most of the diseases in [Table 164.1](#). The pattern (e.g., granular, linear, band-like), distribution (e.g., mesangial, capillary wall, both), and composition (e.g., IgA-dominant, C3-dominant) of glomerular immune deposits is characteristic, if not diagnostic, for many antibody-mediated glomerulonephritides. The absence of immunohistologic evidence for immune deposits can be as useful as positive staining in pointing to the appropriate diagnosis. For example, no granular or linear glomerular immunoglobulin staining in a specimen with crescentic glomerulonephritis is about 90% predictive of ANCA-associated crescentic glomerulonephritis.

Examination of renal biopsy specimens by electron microscopy may be required for diagnosis or may add complementary data to a diagnosis made by light and immunofluorescence microscopy. For example, electron microscopy is required for making a pathologic diagnosis of fibrillary glomerulonephritis, immunotactoid glomerulopathy, collagenofibrotic glomerulopathy, or thin basement membrane nephropathy. Occasionally, the electron microscopic observations constitute the feature in a biopsy specimen that guides the pathologist to a diagnosis that otherwise might have been overlooked, such as hereditary nephritis, type II membranoproliferative glomerulonephritis, and Fabry's disease. Sometimes, the electron microscopic findings do not alter the basic diagnosis but provide additional refinement or insight into the patient's disease. For example, the finding of mesangial immune deposits in a patient with membranous glomerulopathy increases the likelihood of secondary membranous glomerulopathy, such as hepatitis B–induced membranous glomerulopathy. The finding of microtubular configurations in a specimen with type I membranoproliferative glomerulonephritis increases the likelihood of hepatitis C–induced cryoglobulinemic glomerulonephritis.

The light, immunofluorescence, and electron microscopy data from a renal biopsy specimen should be correlated and integrated with clinical data to yield a final pathologic diagnosis. Individual uncorrelated reports of each microscopic procedure should be avoided. Any time that the pathologist feels that the report might be confusing to the clinician or the clinician is not absolutely certain about the reported pathologic diagnosis, it is important for the pathologist and clinician to discuss the findings personally.

RENAL BIOPSY AND THE TREATMENT OF PATIENTS WITH ISOLATED HEMATURIA

Asymptomatic hematuria is caused most often by a urologic disease, such as urinary tract infection, urolithiasis, or a tumor of the urinary epithelium or renal parenchyma. Occasionally, however, asymptomatic microscopic hematuria is the harbinger of glomerular injury. The morphology of the red blood cells in the urine is useful for differentiating between bleeding derived from the glomerulus and that derived from the urinary tract. Glomerular hematuria typically is dysmorphic. For example, the red blood cells in the urine include many acanthocytes and other misshapen cells rather than biconcave discs. This is one of the most specific manifestations of glomerular injury. The association of asymptomatic hematuria with proteinuria or formed elements such as casts (especially red blood cell casts) provides supportive evidence for glomerular injury. In the absence of these findings, patients with asymptomatic hematuria without urinary tract infection usually undergo excretory urograms and cystoscopy in search of a cause for the hematuria ([Chapter 134](#)). If no cause is found, a renal biopsy may be performed. Of patients with hematuria, a serum creatinine level of less than 1.5 mg per deciliter, and proteinuria of less than 1 g per day who undergo renal biopsy, about 85% are relatively evenly divided among patients with IgA nephropathy, thin basement membrane disease, and normal glomeruli. The other 15% have miscellaneous other glomerular lesions ([Table 164.1](#)).

Thin basement membrane nephropathy is a group of conditions in which there is thinning of the GBM. The clinical course typically is benign, manifested by occasional bouts of macroscopic hematuria with viral infections. Commonly, first-degree relatives also have microscopic hematuria. There is no known therapy for this condition, and renal failure is uncommon. A more severe variant of hereditary basement membrane nephropathy that is associated with hearing loss is known as Alport's syndrome. At the time of diagnosis, this disease usually manifests with proteinuria and renal insufficiency along with hematuria. These patients progress to end-stage renal disease and there is no known treatment.

IGA NEPHROPATHY

IgA nephropathy is the most common form of glomerulopathy in the world. The renal biopsy findings in IgA nephropathy include conspicuous glomerular IgA-dominant or IgA-codominant mesangial immunostaining. Electron microscopy reveals electron-dense deposits corresponding to the immune deposits seen by immunohistology. Light microscopic lesions range from mild mesangial hypercellularity to diffuse inflammation with necrosis and crescent formation ([Fig. 164.3](#)). Consistent with the relapsing nature of this disease, renal biopsy specimens often have areas of glomerular and tubulointerstitial scarring, suggesting prior acute inflammation adjoining regions of active ongoing inflammation. Once mistakenly considered a uniformly benign disease, IgA nephropathy has many different clinical expressions, including mild asymptomatic hematuria, acute nephritis, rapidly progressive glomerulonephritis, chronic nephritis, and even the nephrotic syndrome. In most patients, the disease process follows a course of exacerbation and remission.

End-stage renal disease develops in 15% to 20% of patients after 10 years and in 20% to 40% of patients after 20 years. Should all patients with IgA nephropathy receive treatment? In this disease that waxes and wanes, should therapy be aimed at aggressive episodes of disease? Should patients who have mild disease be treated in the same way as those who have aggressive IgA nephropathy with crescent formation? Patients who have substantial proteinuria and an elevated creatinine level are more likely to undergo renal biopsy. These patients probably have more severe structural changes than patients who do not undergo biopsy and tend to have a worse long-term prognosis. Should these patients be selected for special study? Unfortunately, there are few answers for these questions.

Several treatment protocols have been suggested for IgA nephropathy, usually for patients with proteinuria or renal insufficiency. There are few data that support the use of daily corticosteroid therapy. Anecdotal data in children suggest that alternate-day therapy for 1.5 to 3 years is associated with less proteinuria and, perhaps, preservation of renal function. In the absence of firm positive data, no compelling reason supports this therapy in light of the potential adverse consequences of long-term prednisone treatment. However, prednisone treatment is effective in IgA nephropathy coexisting with minimal change glomerulopathy. In this condition, the renal biopsy shows typical immunohistologic features of IgA nephropathy, no or mild glomerular changes by light microscopy, and diffuse foot process fusion of glomerular epithelial cells by electron microscopy. Proteinuria is diminished rapidly by prednisone therapy in a manner consistent with its response in minimal change disease. A renal biopsy is crucial to identify this combined process.

More aggressive treatment of IgA nephropathy has been tried, including concurrent therapy with cyclophosphamide, warfarin, and dipyridamole. Although this approach is associated with a reduction in proteinuria, no significant preservation of renal function has been observed.

Treatment with omega-3 fatty acid products is gaining favor. A controlled trial has been performed comparing fish oil with placebo. In this study of patients with at least 1 g of proteinuria, 55 patients received omega-3 fatty acid and 51 received placebo. Treatment consisted of about 1.6 g of eicosapentaenoic acid per day. Hypertension was controlled in both groups. Decline in renal function was significantly more rapid in the placebo group than in the fish oil group. Forty percent of the placebo group reached end-stage disease after 4 years, compared with only 10% of the fish oil group. IgA nephropathy may be ameliorated by this simple, relatively nontoxic therapy. However, two smaller studies using omega-3 fatty acids in similar patients did not find preservation of renal function. The nature of the discrepancy in these studies is not clear, but may relate to the complete lack of uniformity of this form of treatment. Omega-3 fatty acid preparations are not controlled by the Food and Drug Administration. These preparations contain varying amounts of eicosapentaenoic acid, and many are laden with vitamins E, A, and D. Whether this treatment stabilizes renal function in all patients with IgA nephropathy or just those with proteinuria and progressive renal insufficiency is not known. Lifelong therapy with even this benign agent is cumbersome and marked by gastrointestinal complaints. Patients should know that their hematuria and proteinuria is a consequence of biopsy-proven IgA nephropathy before embarking on such a program.

Because anti-inflammatory agents have shown few beneficial effects, other potentially less toxic regimens have been considered. These include angiotensin-converting enzyme (ACE) inhibitors, which have a salutary effect, at least to diminish proteinuria and perhaps to sustain renal function.

RENAL BIOPSY AND THERAPY IN THE NEPHROTIC SYNDROME

MEMBRANOUS GLOMERULOPATHY

Membranous glomerulopathy is the most common cause of nephrotic syndrome in persons older than 30 years of age. Membranous glomerulopathy can be an idiopathic disease (no specific cause), or it can result from infections, toxins, drugs, autoimmune diseases, neoplastic diseases, renal transplantation, or many other conditions ([Table 164.2](#)). The issue of malignant tumors associated with membranous glomerulopathy is especially pertinent for patients older than 55 years. In these

patients, the tumors may precede the membranous glomerulopathy by 18 to 24 months. In some cases, simultaneous detection of tumors and renal disease occurs, whereas in others, tumors develop only 18 to 24 months after the membranous glomerulopathy is first detected. Therefore, in elderly patients with the nephrotic syndrome, a renal biopsy diagnosis of membranous glomerulopathy mandates vigilant screening for cancer with tests, such as chest radiography, mammography, pelvic examination, and colonic evaluation.

TABLE 164.2. SECONDARY CAUSES OF MEMBRANOUS NEPHROPATHY

Idiopathic membranous glomerulopathy has a variable clinical course. The prognosis of patients with this disease depends on their geographic location in the world. Ten-year renal survival rates vary from as low as 50% to as high as 90%. Data at 20 years reflect the continued loss of renal function in this chronic disease. Many patients who progress to end-stage renal disease do so within the first 3 years after diagnosis. Fortunately, 20% to 35% of patients have a spontaneous remission within 1 to 4 years after diagnosis.

Several factors that portend a worse prognosis are hypertension, renal insufficiency, male gender, older age, and persistent proteinuria for more than 8 months. Massive proteinuria is an additional independent risk factor. Some genetic phenotypes, such as DRW 3, are associated with a rapid downhill course. Young women with membranous glomerulopathy who do not have nephrotic-range proteinuria have a better prognosis.

A variable clinical course complicates the evaluation of treatment regimens. In many patients, the disease is relatively benign, whereas in others, end-stage renal disease rapidly ensues. For more than a decade, the standard therapy for membranous glomerulopathy was based on an American collaborative placebo-controlled study suggesting that high-dose, alternate-day, oral corticosteroids decreased the number of patients in whom renal failure developed. Although the amount of proteinuria improved transiently in the prednisone-treated group, the long-term effects on proteinuria were the same regardless of whether patients received corticosteroids.

This trial has been subject to much criticism. The serum creatinine level doubled in more than 40% of the control patients during 2 years of follow-up—a more rapid decline in renal function than is typical of patients with membranous glomerulopathy. Because of this criticism, two other long-term prospective trials have evaluated the use of corticosteroid therapy in patients with membranous glomerulopathy. The Toronto collaborative group tested corticosteroid therapy for 6 months. In this study, both the control group and the corticosteroid group fared well, with no differences in renal dysfunction. In a study performed in the United Kingdom, patients were treated with corticosteroids or placebo; progressive renal insufficiency developed in both groups of patients and corticosteroids did not have a beneficial effect. A meta-analysis and pooled analysis confirms these findings and suggests that prednisone therapy does not alter renal survival and has only a minimal effect on the nephrotic syndrome.

More aggressive therapies for membranous glomerulopathy have been proposed. One protocol for patients with new-onset membranous glomerulopathy involves a combination of pulse methylprednisolone (Medrol) and oral prednisone for 1 month, followed by oral chlorambucil for another month. This 2-month cycle is repeated for three cycles (a total of 6 months). In a controlled prospective trial with 5 years of follow-up, treated patients had a substantial stabilization in renal function when compared with control patients, and complete remission of the nephrotic syndrome was observed in 57% of treated patients but only 23% of control patients. Whether this effect is a consequence of the pulse methylprednisolone or the chlorambucil by itself has been examined. In a separate study, treatment with methylprednisolone and chlorambucil led to an improvement in the number of patients who had remission of membranous glomerulopathy for at least 3 years. By 4 years, however, the effect of the alkylating therapy over that of methylprednisolone alone dissipated. Methylprednisolone alone resulted in the same degree of preservation of renal function as did methylprednisolone and chlorambucil together.

The controversy remains. Corticosteroids by themselves do not appear to be efficacious, whereas alkylating therapy may improve the chances of remission of nephrosis. These drugs are associated with significant side effects, including life-threatening infections and the development of malignant tumors ([Table 164.3](#)).

Corticosteroids	Cyclophosphamide	Alkylating
Infections	Infections	Neutropenia
Fluid and electrolyte disturbances	Neurologic sequelae	Hypotension
Sulfonamide resistance	Malignancy	Hypocalcemia
Fluid retention	Impairment of fertility	Disseminated intravascular coagulation
Proteinuria	Blurred and waxy vision	Secondary hyperparathyroidism
Hypertension	Lack of response	Leukopenia
Mucositis	Interstitial pulmonary fibrosis	Neutropenic sepsis
Secondary hyperparathyroidism	Alkylating	Myelosuppression
Asymptomatic hypocalcemia and hypercalcemia		Myelosuppression
Gastrointestinal		Myelosuppression
Peptic ulcer		Myelosuppression
Pancreatitis		Myelosuppression
Dehydration		Myelosuppression
Impaired wound healing		Myelosuppression

Diabetes mellitus		Myelosuppression
Osteoporosis		Myelosuppression
Pulmonary interstitial nephritis		Myelosuppression
Cataracts		Myelosuppression

TABLE 164.3. COMPLICATIONS OF IMMUNOSUPPRESSIVE THERAPY

The current focus of treatment is aimed at detecting patients with poor prognostic signs at the outset of disease who are destined to have renal failure. Several trials have examined the effect of alkylating therapy and corticosteroids in patients with renal insufficiency. Data suggest that patients with renal insufficiency who are given intravenous cyclophosphamide and corticosteroids for 6 months do not experience any additional benefit over those who receive corticosteroids alone. Whether other protocols for salvage therapy, such as a year of oral cyclophosphamide or chlorambucil, produce improved results is still under study.

Alkylating therapy and corticosteroid treatment should be reserved for patients who have a poor overall prognosis. In young women who have membranous glomerulopathy and a minimal amount of proteinuria, general supportive care may be the best approach.

Supportive care is essential in the treatment of all patients with glomerular disease, including membranous glomerulopathy. Hypertension must be controlled, hyperlipidemia treated, and volume removed as needed. Substantial support has been garnered for the use of ACE inhibitors in patients with proteinuria with or without mild to moderate renal insufficiency. These agents decrease the amount of proteinuria and retard the progression of renal insufficiency. Whether the angiotensin II receptor antagonists have a similar salutary role is not certain.

MINIMAL CHANGE DISEASE

Minimal change glomerulopathy is characterized by the lack of alterations in glomerular architecture seen on light microscopy. Immunofluorescence microscopy shows an absence of immunoglobulin and complement deposition or only mild mesangial IgM or C3. On electron microscopy, characteristic fusion of epithelial foot

processes is observed without immune complex–type electron-dense deposits. In most cases, children are treated with a course of corticosteroids before renal biopsy. Renal biopsy is reserved for children who prove to be corticosteroid-resistant or those in whom a complicated clinical presentation or course of disease requires histopathologic identification. A renal biopsy is performed in the initial management of minimal change glomerulopathy in adults with the nephrotic syndrome.

Corticosteroids are the mainstay of therapy for minimal change disease. No other cause of the nephrotic syndrome is as sensitive to treatment with prednisone. Disappearance of proteinuria is rapid, especially in children, who usually respond within 4 to 6 weeks. Adults with minimal change disease usually are sensitive to prednisone therapy, but may require up to 16 weeks of daily corticosteroids to induce remission. The response to treatment is heralded by diuresis and decrement in proteinuria. The usual starting dosage of prednisone is 2 mg per kilogram body weight per day not to exceed 60 mg per day. A response rate of 80% to 90% has been documented in both children and adults.

One of the most useful ways of monitoring patients is to teach them to perform dipstick analysis of their own urine. Daily dipstick analysis allows precise documentation of the onset of protein-free urine—at which point prednisone therapy should be tapered, usually over the course of 3 to 4 weeks.

Several patterns of response to corticosteroid therapy have been observed ([Table 164.4](#)). Patients with frequently relapsing or corticosteroid-dependent minimal change disease pose some of the most difficult treatment dilemmas. Sudden massive nephrosis results in morbid complications and requires urgent attention. Bursts of high-dose corticosteroid therapy, even of relatively short duration, result in large cumulative doses in patients who relapse more than four times per year. In these persons, remission may be maintained on long-term, low-dose corticosteroid therapy. In others, cyclophosphamide has proved effective. Prednisone is used to induce remission, then cyclophosphamide is added (2 mg per kilogram per day) for 8 to 12 weeks. Long-term remission has been reported in 40% to 50% of patients. Cyclophosphamide often is useful in patients who are corticosteroid-dependent and occasionally in patients who are resistant to corticosteroid therapy.

Steroid-Responsive
Complete remission of proteinuria with infrequent relapses
Frequently Relapsing
Relapses more than 4 times per 12 months
Steroid-Dependent
Relapses during the taper of steroids
Relapses within 2 weeks of cessation of therapy
Steroid-Resistant
Failure to obtain complete remission within 12 to 16 weeks

(Adapted from Siegel NJ. Minimal change nephropathy. In: Greenberg A, ed. *Primer of kidney diseases*. San Diego: Academic Press, 1994:69.)

TABLE 164.4. PATTERNS OF STEROID RESPONSE IN MINIMAL CHANGE DISEASE

In some patients who are corticosteroid-resistant, a second renal biopsy must be considered. In these, a diagnosis of FSGS may have been missed in the original biopsy. FSGS is a focal lesion. It involves only a few glomeruli at the outset of the disease. The biopsy sample may miss one of the involved glomeruli, and a diagnosis of minimal change disease may be rendered. Because patients with FSGS do not usually respond to corticosteroid therapy, the clinician may wonder whether the patient has corticosteroid-resistant minimal change disease. A second renal biopsy will change the therapeutic strategy.

FOCAL SEGMENTAL GLOMERULOSCLEROSIS

FSGS is a glomerular lesion that can be idiopathic or result from many recognized causes ([Table 164.5](#)). The disease is more common in African Americans than in whites. The pathologic diagnosis depends on the identification in some glomeruli (focal) of areas of glomerular sclerosis in only parts of the glomerular tuft (segmental). The remainder of the glomerulus is not affected, although some degree of foot process effacement usually is observed on electron microscopy.

Focal Segmental Glomerulosclerosis (The Clinicopathologic Syndrome)
Primary (Idiopathic)
With glomerulopathy
Without glomerulopathy
Secondary
With glomerulopathy
Morbid obesity
Sickle cell disease
Cyanotic congenital heart disease
Reduced renal functional mass
Unilateral renal agenesis
Oligonephronia
Subacute bacterial endocarditis
Focal cortical necrosis
Nephrectomy
Glomerular Tip Lesion
With foot process effacement only
With other glomerulopathy (e.g., FSGS, membranous)
Focal Glomerulosclerosis with Epithelial Changes
HIV-associated nephropathy
Or drug abuse nephropathy
Collapsing glomerulopathy

FSGS, focal segmental glomerulosclerosis; HIV, human immunodeficiency virus; IV, intravenous.

TABLE 164.5. CAUSES OF FOCAL SEGMENTAL GLOMERULOSCLEROSIS

Several patterns of idiopathic FSGS have been described, but there is controversy over whether they represent significantly different diseases or simply different morphologic variants of little clinical significance. One of these idiopathic conditions, called the *collapsing variant of FSGS*, is more common in African Americans and results in a much more rapid decline in renal function than do other forms of FSGS. Collapsing FSGS is associated with a substantial increase in the amount of protein excretion. Another variant, called the *glomerular tip lesion variant of FSGS*, is characterized by cytoplasmic vacuolation, sclerosis, and hyalinosis in the portion of the glomerulus that is opposite the hilus and adjacent to the origin of the proximal tubule. This lesion is more common in older whites and may be more responsive to corticosteroid therapy. These patterns of FSGS with differing natural histories can be discovered only by renal biopsy.

A biopsy also may provide clues to secondary forms of FSGS. For example, in human immunodeficiency virus (HIV) nephropathy, a collapsing form of FSGS is found by light microscopy that differs from idiopathic collapsing glomerulopathy because of the presence in HIV-affected patients of numerous tubuloreticular inclusions in endothelial cells that can be identified by electron microscopy. Enlarged glomeruli associated with FSGS may suggest morbid obesity or a condition in which there is decreased oxygenation (sickle cell anemia or congenital cyanotic heart disease) or reduced functional renal mass (unilateral renal agenesis or aplasia).

Therapy for FSGS is controversial. Only one controlled trial has been performed, and it indicated the ineffectiveness of immunosuppressive therapy in children. Unfortunately, only a few patients experience spontaneous remission. In general, patients with FSGS and the nephrotic syndrome progress to end-stage renal disease. Patients with spontaneous remission of nephrosis, those with less than 3 g of proteinuria, and those who experience remission with therapy tend to have a better course. Only 10% to 30% of patients respond to corticosteroids with complete remission of proteinuria. The relapse rate after treatment is high. Reports suggest that up to 50% of patients respond to long courses of oral corticosteroids (i.e., between 4 and 5 months of daily therapy). In view of the common occurrence of corticosteroid resistance in patients with FSGS, several trials have evaluated therapy with low-dose cyclosporin A (4 to 6 mg per kilogram per day) for 2 to 6 months. Although patients do respond to this treatment, most experience a relapse when therapy is stopped. The hazard of interstitial fibrosis associated with long-term cyclosporin A therapy decreases the usefulness of this approach.

Except for administering ACE inhibitors, most clinicians do not treat patients with FSGS who have less than nephrotic-range proteinuria. In patients with substantial nephrotic syndrome, a trial of corticosteroid therapy may be considered. If remission is not induced after 4 to 5 months, this form of therapy should be discontinued.

The collapsing variant of FSGS and the glomerular tip lesion variant of FSGS may require different forms of therapy. Collapsing FSGS without evidence of HIV disease has a strong predilection for African Americans and is associated with massive proteinuria and rapid progression to renal insufficiency. Many of these patients

have extrarenal signs of a systemic illness that appears viral in nature. Anecdotal experience with corticosteroids in this population indicates that they are ineffective and may be contraindicated. In contrast, older whites with glomerular tip lesions discovered on renal biopsy may respond to corticosteroid therapy. Patients with FSGS secondary to a process such as sickle cell disease or obesity typically have less proteinuria (less than 3 g per day). In this population, therapy with ACE inhibitors may reduce proteinuria substantially. Whether it will result in long-term preservation of renal function is a matter of ongoing investigation.

RENAL DISEASE AND DYSPROTEINEMIA

Dysproteinemia, or paraproteinemia, encompasses a group of disorders characterized by the overproduction of immunoglobulin proteins or their components, which result in tissue damage ([Chapter 154](#)). The most common renal manifestation of glomerular involvement by dysproteinemia is proteinuria, often in the nephrotic range. Some patients with glomerular injury caused by immunoglobulin paraproteins have overt multiple myeloma, whereas others have dysproteinemia without other evidence of myeloma. Still others have no evidence of a paraprotein dyscrasia except for the abnormal glomerular deposits.

Sometimes, dipstick methods detect little proteinuria, whereas 24-hour urine collection indicates substantial proteinuria. Dipsticks are designed to detect anionic proteins such as albumin. Immunoglobulin light chains are commonly cationic and therefore are not detectable on dipsticks. In patients older than 60 years with renal insufficiency and mild proteinuria by dipstick analysis but with substantial proteinuria by sulfosalicylic acid analysis, renal biopsy is warranted. In such patients, immunoglobulin deposition diseases are found. These diseases include light-chain deposition disease, heavy-chain deposition disease, AL amyloidosis, and immunotactoid glomerulopathy. The renal biopsy is critical in determining the nature of the renal disease that is caused by immunoglobulin dysproteinemia. For example, amyloidosis is characterized by the deposition of fibrillar proteins and characteristic b-pleated sheet configurations. AL amyloidosis (primary) is caused by a plasma cell dyscrasia, whereas AA amyloidosis (secondary) is associated with high levels of nonimmunoglobulin serum amyloid protein (SAA).

Multiple myeloma often causes the overproduction of immunoglobulins or immunoglobulin fragments. Many lesions can be found on renal biopsy specimens from patients with multiple myeloma. Cast nephropathy is characterized by numerous paraprotein-containing casts in tubular lumina and usually manifests as acute renal failure. Light-chain deposition disease is the result of overproduction of a monoclonal immunoglobulin light chain. On deposition, these proteins do not form b-pleated sheets and do not stain with Congo red. Whereas AL amyloidosis usually is caused by lambda light chains, light chain deposition disease usually is caused by kappa light chains.

The treatment of paraproteinemia varies according to the biopsy findings. There is no specific therapy for AL amyloidosis. Chemotherapy and colchicine have been tried with varying degrees of success. The usefulness of ablative chemotherapy with stem cell transplantation is under investigation. In contrast, therapy for multiple myeloma and light-chain deposition disease initially is aimed at improving urine flow and decreasing the production of immunoglobulins with corticosteroids and chemotherapy. Plasma exchange, when added to chemotherapy, lowers myeloma protein levels more rapidly and may improve renal function. Patient survival has been better with plasmapheresis. Treatment with chemotherapy for light-chain deposition disease is similar to that for myeloma; however, long-term survival is poor.

TREATMENT OF NEPHRITIS

Glomerular inflammation (glomerulonephritis) often manifests clinically as acute, rapidly progressive, or chronic nephritis. In general, the aggressiveness of treatment is tailored to the aggressiveness of the glomerulonephritis. Renal biopsy evaluation is important for identifying the type of lesion that is causing the nephritis and for determining the activity and chronicity of the process, which influence the prognosis and treatment.

The treatment of glomerulonephritis usually involves the use of anti-inflammatory drugs such as corticosteroids, and alkylating agents such as cyclophosphamide, chlorambucil, or azathioprine. In patients who have pulmonary hemorrhage with the pulmonary renal vasculitic syndrome, plasma exchange is useful. In the following sections, we review each of these forms of treatment.

PREDNISONE

Therapy with prednisone remains as much an art as a science in that there is no appropriate means of assessing the pharmacokinetics of this drug. First, the dosage must be tailored to the individual patient, based on body weight or surface area and response to therapy. Second, the amount of corticosteroid used depends on the disease being treated. For example, the treatment of minimal change disease may require considerably less total prednisone than the treatment of lupus nephritis or systemic vasculitis. In rapidly progressive glomerulonephritis, much higher dosages of corticosteroids usually are required for longer periods. Patients are treated with 1 mg per kilogram of prednisone for 1 to 2 months; then the dosage is tapered during months 2, 3, and 4. Tapering schedules usually involve changing to alternate-day therapy, so that a patient receiving 60 mg of prednisone every day starts taking 60 mg on 1 day and 50 mg the next day. Each week, the alternate-day prednisone is reduced by 10 mg, so that within 4 to 6 weeks, the patient is not taking any prednisone on alternate days. The dosage then can be tapered by 10 mg per day for the next 6 weeks. If this protocol is followed, the patient is no longer receiving prednisone therapy by the end of the fourth month. Switching to alternate-day prednisone therapy at the beginning of the second month of treatment takes advantage of the reduced side effects associated with this approach.

For most glomerular diseases, prednisone tapering continues until the drug is discontinued altogether. There are exceptions to this approach. For example, in patients with lupus nephritis, the prednisone should not be discontinued altogether. Most patients with lupus nephritis require a dosage between 10 and 15 mg per day with slow tapering to prevent extrarenal lupus flares.

Intravenous methylprednisolone is warranted in at least two circumstances. First, oral corticosteroids are not effectively absorbed by the edematous bowel wall in patients with massive nephrosis, and intravenous methylprednisolone should be considered at a dosage equivalent to that of oral prednisone. Second, intravenous methylprednisolone should be used in patients who have rapidly progressive glomerulonephritis with crescentic disease. Pulse methylprednisolone is administered at a dose of 7 mg per kilogram, with a maximum dose of 1 g per day over 3 days or, alternatively, every other day for 6 days. The rationale for using pulse methylprednisolone stems from its rapid obliteration of inflammation and edema in areas of reduced blood flow. This form of therapy has never been subject to a large-scale trial. Pulse methylprednisolone has been used in diseases other than crescentic glomerulonephritis. For example, in the regimen for membranous nephritis, pulse methylprednisolone is given on alternate months, cycling with chlorambucil (see Membranous Glomerulopathy).

Complications of corticosteroid therapy are numerous ([Table 164.3](#)) and include life-threatening infections with bacteria, viruses, and unusual, opportunistic agents such as mycobacteria, *Pneumocystis carinii*, and fungi. The likelihood of infection increases with the duration of treatment. Patients following protocols using an alternate-day schedule have fewer associated side effects than those using daily high-dose (1 mg per kilogram) treatment. Divided daily doses of prednisone (e.g., two or three times a day) have the strongest anti-inflammatory action, but also the most side effects. The musculoskeletal complications of corticosteroid therapy are significant. Osteoporosis is accelerated, which commonly results in vertebral collapse. The most dreaded complication of long-term corticosteroid therapy, however, is aseptic necrosis of the femoral head. This crippling process requires joint replacement. Other complications of corticosteroid therapy include the development of diabetes mellitus, posterior subcapsular cataracts, glaucoma, gastritis, and pancreatitis.

CYCLOPHOSPHAMIDE AND CHLORAMBUCIL

Cyclophosphamide and chlorambucil are alkylating agents. Cyclophosphamide is converted in the liver to an active metabolite. Both drugs cross-link the nucleic acid that interferes with cell division and transcription. The usual oral dosage used for the treatment of glomerular disease reduces the leukocyte count to about 3,000 cells per microliter. At this dosage, the immune response to newly presented antigens is suppressed, although the cutaneous inflammatory response is unchanged.

Cyclophosphamide is administered orally or intravenously. Oral cyclophosphamide typically is given at a dosage of 2 mg per kilogram per day. Although the starting dosage may be prescribed, the maintenance dosage must be adjusted constantly based on the total leukocyte count. Cyclophosphamide therapy is targeted to lower the leukocyte count to between 3,000 and 5,000 cells per microliter. The dosage must be decreased continually to prevent leukopenia and, especially, neutropenia. The efficacy of cyclophosphamide may be limited by its toxicity.

Monthly intravenous administration of cyclophosphamide at a starting dosage of 0.5 g per square meter of body surface has been popularized for the treatment of lupus nephritis. This therapy has been used in other diseases, especially systemic ANCA vasculitis. The prescription is altered on the basis of the 2-week leukocyte nadir. During the second month of therapy, the dosage is increased to 0.75 g per square meter, and if the 2-week leukocyte nadir is greater than 5,000 cells per microliter, a final dosage of 1 g per square meter is used in subsequent months. Therapy is typically discontinued after 6 months. The advantages of intravenous cyclophosphamide include the certainty of drug administration, smaller total drug dose (about one third to one half the equivalent monthly dose of oral

cyclophosphamide), and reduced incidence of infection and hemorrhagic cystitis.

The dreaded complications of cyclophosphamide therapy are life-threatening infections and hemorrhagic cystitis ([Table 164.3](#)). Hemorrhagic cystitis is observed primarily with oral cyclophosphamide. Adequate hydration and the use of intravenous cyclophosphamide have decreased its incidence substantially. The risk of ovarian and testicular failure is associated with the use of any alkylating drug. Because the incidence of ovarian failure increases with age, perimenopausal women or those older than 35 years are most likely to be affected. The potential for decreasing the rate of ovarian and testicular failure with agents such as leuprolide acetate is under investigation. Mutagenesis is one of the most serious complications of cyclophosphamide therapy. Long-term treatment of Wegener's granulomatosis with oral cyclophosphamide is associated with a nearly 15% incidence of transitional cell carcinoma of the bladder. Whether this will occur with intravenous cyclophosphamide is not clear. Lymphoproliferative diseases occur at a rate at least 2.4 times above normal in patients taking cyclophosphamide. These long-term risks must be considered when therapy is initiated. A renal biopsy that identifies a lesion responsive to alkylating therapy provides the rationale for the use of this drug.

Chlorambucil usually is given at a dosage of 0.1 to 0.2 mg per kilogram per day. It is slower acting than cyclophosphamide and takes longer to produce myelosuppression. Like cyclophosphamide, chlorambucil induces life-threatening infections and malignant tumors. The unusual side effects of chlorambucil are pulmonary fibrosis, hepatic toxicity, and seizures.

AZATHIOPRINE

Azathioprine has been used to treat renal allografts for decades. It is an analogue of the purine-based hypoxanthine. Metabolites of azathioprine inhibit enzymes required for DNA synthesis. Azathioprine typically is used to treat aggressive glomerular diseases (lupus nephritis) or relapsing systemic vasculitis at a starting dosage of 1 to 3 mg per kilogram. Careful attention must be paid to leukopenia, especially in the setting of renal insufficiency. The leukocyte count should remain above 5,000 cells per microliter. Pancreatitis is an uncommon but concerning complication of therapy. Abdominal discomfort must be evaluated with serum amylase and lipase tests and careful history and physical examination. In the setting of allopurinol therapy or renal insufficiency that reduces clearance of the active drug, the major side effect is bone marrow suppression. Because this suppression primarily takes the form of neutropenia, infection is a major side effect. Azathioprine also carries a mutagenic potential, with some form of tumor (primarily dermal carcinomas) developing in up to 5% of transplant recipients.

CYCLOSPORIN A

The use of cyclosporin A in glomerular disease is an experimental therapy. Cyclosporin A is reserved for conditions in which other forms of anti-inflammatory or immunosuppressive therapy have failed. It is useful in patients with corticosteroid-resistant minimal change disease and massive nephrosis, in some patients with nephrosis and FSGS or membranous nephropathy who have not responded to other forms of therapy. The starting dosage is 5 mg per kilogram per day. Cyclosporin A levels must be measured regularly and the dosage titrated based on the serum creatinine level. Like other immunosuppressive drugs, cyclosporin A is associated with life-threatening infections. The major long-term complication of cyclosporin A therapy for glomerular disease is interstitial fibrosis resulting from chronic cyclosporin A toxicity. Cyclosporin A causes chronic, irreversible renal dysfunction and should be used for no more than a year.

PLASMAPHERESIS

Plasmapheresis is used in the treatment of pulmonary hemorrhage with anti-GBM disease, pulmonary hemorrhage with ANCA-associated systemic vasculitis, and thrombotic thrombocytopenic purpura. It usually is prescribed as one or two volume exchanges given daily for the first 5 days, then on alternate days for a total of 14 days. The efficacy of plasma exchange can be documented by the decrease in anti-GBM or ANCA titers during the course of therapy. The primary complications of plasma exchange occur immediately and are associated with hypocalcemia and allergic reactions. Albumin replacement is useful in the setting of anti-GBM disease. For the treatment of thrombotic microangiopathy, fresh frozen plasma or cryoprecipitate has been suggested. Allergic reactions to these proteins are more common. Long-term complications usually are associated with vascular thrombosis and sclerosis as a consequence of venous access.

RENAL BIOPSY AND THE TREATMENT OF SPECIFIC FORMS OF NEPHRITIS

POSTINFECTIOUS GLOMERULONEPHRITIS

Postinfectious glomerulonephritis is an episodic form of glomerulonephritis, especially poststreptococcal glomerulonephritis. Many infectious agents are associated with acute immune complex glomerulonephritis ([Table 164.6](#)).

Bacterial
β Hemolytic streptococci
Diplococcus pneumoniae
Staphylococcus aureus
Staphylococcus epidermidis
Leptospira
Viral
Hepatitis B
Hepatitis C
Cytomegalovirus
Varicella
Enteroviral infection
Parasites
Malaria
Toxoplasmosis
Schistosomiasis
Treponemiasis
Filariasis

TABLE 164.6. CAUSES OF POSTINFECTIOUS GLOMERULONEPHRITIS

The common clinical manifestations of acute poststreptococcal glomerulonephritis are hematuria, edema, hypertension, oliguria, and pulmonary congestion manifested by dyspnea and cough. Other systemic features are fever, nausea, and abdominal pain, with occasional central nervous system confusion, headache, somnolence, and, rarely, convulsions. A renal biopsy usually is not performed in patients with typical poststreptococcal glomerulonephritis because the diagnosis is apparent from clinical and laboratory data. Most renal biopsies that demonstrate postinfectious glomerulonephritis are performed in the setting of acute renal failure of uncertain cause that has not recovered in more than 3 to 4 weeks. In this setting, the diagnosis usually comes as a surprise.

In acute poststreptococcal glomerulonephritis, diffuse proliferation of endothelial and mesangial cells is found in association with infiltrates of leukocytes, especially numerous neutrophils. Rarely, there is crescent formation. The finding of more than 30% crescents by light microscopy portends a poor long-term prognosis. During the acute phase, immunohistology usually demonstrates coarsely granular capillary wall and mesangial staining for complement, with or without IgG. The finding of humplike subepithelial electron-dense deposits by electron microscopy is characteristic of this disease, although mesangial and small subendothelial deposits also are present and may be more important in the cause of glomerular inflammation.

The course of poststreptococcal glomerulonephritis usually is self-limited, and hematuria disappears within 6 months in most patients. Proteinuria resolves in one third of patients by 1 year and in two thirds by 2 years. The prognosis is less favorable in adults than in children. The development of crescentic glomerulonephritis appears to be more common in adults and may portend progression to end-stage renal disease. Nonetheless, long-term follow-up of adult patients for as long as 20 years indicates that recovery usually is complete. Therapy for poststreptococcal glomerulonephritis is largely symptomatic, aimed at treating hypertension and fluid overload with diuretics and dialysis as needed. Antibiotic therapy has no influence on the course of the disease.

In contrast to the treatment of postinfectious glomerulonephritis, antibiotics are the mainstay of therapy for subacute subendocardial bacterial endocarditis with associated glomerulonephritis. Endocarditis-induced glomerulonephritis has a variable pathologic and clinical expression. The course of the glomerulonephritis parallels that of the infective endocarditis. Active acute endocarditis usually causes an acute diffuse proliferative glomerulonephritis with numerous neutrophils that can be pathologically identical with the acute poststreptococcal glomerulonephritis caused by pharyngitis. More indolent (subacute) endocarditis usually causes a membranoproliferative (type I) or proliferative glomerulonephritis.

Therapy must be directed at eradication of the infection with bactericidal antibiotics. In patients with only mild to moderate renal insufficiency (a serum creatinine less than 3 mg per deciliter), antibiotic therapy usually results in the recovery of renal function and amelioration of glomerular inflammation. In patients with substantial renal failure associated with endocarditis, several forms of therapy have been suggested, including pulse methylprednisolone, plasma exchange, and even the use of immunosuppressive agents such as cyclophosphamide. These reports are only anecdotal. Because there may be a considerable delay from the initiation of antibiotic therapy and the recovery of renal function, it appears counterintuitive to use immunosuppressive therapy in the setting of severe endocarditis.

MEMBRANOPROLIFERATIVE GLOMERULONEPHRITIS AND CRYOGLOBULINEMIA

Membranoproliferative glomerulonephritis is a relatively uncommon form of glomerular injury. There are three types of membranoproliferative glomerulonephritis. Type I is the most common and has been associated with mixed essential cryoglobulinemia with hepatitis C virus infection. This association may have important therapeutic implications. An increasing number of reports suggest that long-term antiviral therapy with interferon- α and other agents have a beneficial effect in patients with membranoproliferative glomerulonephritis type I and mixed cryoglobulinemia. In a large prospective trial of 53 patients with serologic evidence for hepatitis C and cryoglobulinemia who were randomly assigned to interferon- α or conventional therapy, 60% of patients treated with antiviral therapy demonstrated improvement in cryoglobulin titers, plasma creatinine concentrations, and even cutaneous vasculitis. With cessation of therapy, a relapse in cryoglobulinemia was evident. Many patients with membranoproliferative glomerulonephritis do not have cryoglobulinemia or hepatitis C. Some of these patients have lymphoproliferative disease, but most appear to have an idiopathic condition. In general, one third of these patients has a spontaneous remission, one third has an indolent course, and one third will develop end-stage renal disease. As of yet, there is no useful treatment option.

HENOCH-SCHÖNLEIN PURPURA

Henoch-Schönlein purpura is a systemic disease, usually of children and adolescents, characterized by glomerulonephritis, a purpuric rash, arthritis, and gastrointestinal bleeding. Transient episodes of asymptomatic hematuria and proteinuria accompany self-limited cases of Henoch-Schönlein purpura. The pattern of this renal-dermal syndrome mimics that of systemic vasculitides, including microscopic polyangiitis (see ANCA-Associated Glomerulonephritis and Systemic Vasculitis). A renal biopsy is useful to determine whether the disease process is Henoch-Schönlein purpura characterized by IgA deposition in the kidney. Henoch-Schönlein purpura typically is associated with a focal or diffuse proliferative glomerulonephritis, although a crescentic form of glomerulonephritis can occur and usually portends an unfavorable prognosis. Anti-inflammatory and immunosuppressive therapy usually is not warranted in Henoch-Schönlein nephritis unless there is severe proliferative disease and crescents. In such cases, therapy with pulse methylprednisolone, prednisone, and cytotoxic drugs may prove useful.

RENAL BIOPSY AND THE TREATMENT OF LUPUS NEPHRITIS

Renal biopsy rarely is necessary for the diagnosis of lupus nephritis, particularly in patients with long-standing extrarenal systemic lupus erythematosus. It may be useful in patients with new onset of systemic inflammatory diseases who have positive antinuclear antibodies but no other manifestations of systemic lupus erythematosus. In this setting, a renal biopsy may provide a diagnosis of lupus nephritis or indicate a completely different diagnosis. Another benefit of a renal biopsy in lupus is the information a biopsy specimen provides regarding the form of lupus nephritis and its level of activity. The World Health Organization has categorized lupus nephritis into five general subsets: class I with no abnormalities; class II with mild mesangial proliferation or mesangial immune deposits; class III with focal and segmental proliferative glomerular injury; class IV with diffuse proliferative glomerulonephritis; and class V with membranous glomerulonephritis. Patients with class I and II lesions have a better prognosis than do patients with class III and IV lesions. Patients with membranous lupus (class V) without proliferative changes have excellent long-term renal survival. Renal biopsy also is used by some pathologists to calculate a disease activity and chronicity score. The usefulness of these scores is controversial. The chronicity score has proved to be more useful than the activity score in assessing long-term renal prognosis ([Table 164.7](#)).

Activity ^a	Chronicity ^b
Glomeruli	Glomerulosclerosis
Hypercellularity	Fibrous crescents
Fibrinoid necrosis/karyorrhexis ^c	Interstitial fibrosis
Cellular crescents ^b	Tubular atrophy
Hyaline thrombi	
Leukocyte infiltration	
Tubule/interstitium	
Mononuclear cell infiltration	

^a Score 0 to 3 for each item.
^b Multiply score by 2.
 (Modified from Austin HA, Muoioz LR, Joyce KM, et al. Prognostic factors in lupus nephritis: contribution of renal histological data. *Am J Med* 1982;75:382.)

TABLE 164.7. LUPUS NEPHRITIS INDICES OF ACTIVITY AND CHRONICITY

The clinical manifestations of lupus nephritis are variable and include mild asymptomatic hematuria, acute nephritis, rapidly progressive nephritis, and chronic nephritis leading to end-stage renal disease (see [Chapter 178](#)). These patterns of injury are typical of any process in which there is a proliferative glomerulonephritis ([Fig. 164.4](#)). The heterogeneity of the clinical and pathologic course in this condition makes therapy more difficult and has caused significant controversy.

FIGURE 164.4. Diagram depicting the serologic analysis of patients with glomerulonephritis. ANCA, anti-neutrophil cytoplasmic antibodies; GN, glomerulonephritis; GBM, glomerular basement membrane. (Modified from Jennette JC, Falk RJ. Diagnosis and management of glomerulonephritis and vasculitis presenting as acute renal failure. *Med Clin North Am* 1990:893.)

EVIDENCE LEVEL: C. Expert Opinion.

What are the indications for therapy? Patients who have acute nephritis or rapidly progressive glomerulonephritis and who have a diffuse proliferative glomerulonephritis with or without necrosis and crescent formation on biopsy should be treated. In general, treatment is initiated with intravenous methylprednisolone (7 to 15 mg per kilogram per day). A reasonable approach to combined cytotoxic and corticosteroid therapy in acute disease is outlined in [Table 164.8](#). Nearly all such patients receive cytotoxic drugs in combination with oral corticosteroids. In patients with severe lupus nephritis, the 5-year renal survival rate is 70% to 80% for those with glucocorticoid treatment alone compared with 30% for those without therapy. This improved survival is attributable to many factors, including earlier diagnosis based on serologic findings, more careful and rational use of glucocorticoid therapy, substitution of antimalarial drugs, and aggressive control of hypertension. The additive effects of cyclophosphamide or cyclophosphamide plus azathioprine have improved appreciably the long-term survival of patients with aggressive lupus nephritis. These agents have significant side effects, however, including life-threatening infection, neoplasia (especially transitional cell carcinoma of the bladder and

lymphoproliferative disorders), gonadal failure, and hemorrhagic cystitis ([Table 164.4](#)).

1. Administer pulse methylprednisolone 7 mg/kg (to a maximum single dose of 1 g) IV over 20 minutes for 3 consecutive days.
2. Within 48 hours after initiation of final dose of pulse therapy, begin oral prednisone, 1 mg/kg/d (not to exceed 80 mg per single dose) for 4 weeks.
3. Within 1 week after start of pulse methylprednisolone therapy, begin giving monthly IV cyclophosphamide (Cytosan) for 6 total monthly doses as follows:
 - a. IV Cytosan is given at an initial dosage of 0.5 g/m² (range 0.5–1.0 g/m²) to induce a leukocyte nadir no lower than 3,000 cells/mm³.
 - b. Each infusion is administered over a period of 1 hour and preceded and accompanied by frequent voiding of dilute urine for 24 hours after drug administration.
 - c. After 4 to 6 weeks, the dosage of oral prednisone should be decreased to 0.5 mg/kg/d for 1 month, then tapered over the next 4 to 6 weeks.

(Adapted from Falk RJ, Jennette JC. Systemic vasculitis. In: Glassock RJ, ed. *Current therapy in nephrology and hypertension*, third ed. St. Louis: Mosby-Year Book, 1992:1371.)

TABLE 164.8. COMBINED PREDNISONE AND INTRAVENOUS CYCLOPHOSPHAMIDE TREATMENT PROTOCOL

Transformation from one morphologic class of lupus nephritis to another (i.e., from milder focal proliferative glomerular disease [class III] to more aggressive diffuse proliferative glomerulonephritis [class IV]) is a well-established phenomenon. Glucocorticoid therapy may transform an aggressive proliferative glomerulonephritis into a pattern of membranous nephropathy. Transformation from one histologic class to another occurs in up to 30% of cases.

Systemic lupus erythematosus is subject to frequent relapses that are extrarenal in manifestation and recurrence of glomerular inflammation. Unless the urinary sediment is typical of a proliferative process, serum complement studies such as the C3 and CH50 decline, and double-stranded DNA titers rebound, a renal biopsy may be considered to restage the lesion and determine whether a relapse of proliferative glomerulonephritis has occurred. From a clinical perspective, it is not always clear whether the transformation and subsequent rise in creatinine level are consequences of relapsing active disease or progressive scarring. Enthusiasm for treating a patient a second time may be tempered by a biopsy specimen that shows globally sclerotic glomeruli with little potential for preserving renal function.

Patients with advanced renal failure and severe chronic changes in lupus nephritis should not be treated further. These patients must be prepared for dialysis or transplantation because continued aggressive immunosuppressive therapy will result in life-threatening complications.

Patients who have membranous lupus nephritis with little proliferative change or chronicity have an excellent long-term prognosis and should be treated conservatively. Although some of these patients respond to corticosteroid therapy with a decrement in proteinuria, most do not. Antimalarial drugs such as hydroxychloroquine (Plaquenil) may be effective in controlling extrarenal manifestations of the disease in patients who have mild symptoms. In such patients, cyclophosphamide is considered primarily for extrarenal manifestations of the disease.

RENAL BIOPSY AND THERAPY IN RAPIDLY PROGRESSIVE GLOMERULONEPHRITIS

USEFULNESS OF SEROLOGIC TESTING IN RAPIDLY PROGRESSIVE GLOMERULONEPHRITIS

Three major types of crescentic glomerulonephritis cause the clinical syndrome of rapidly progressive glomerulonephritis. These can be divided on the basis of renal biopsy findings into immune complex–mediated glomerulonephritis (e.g., lupus nephritis); anti-GBM–mediated glomerulonephritis, including Goodpasture's syndrome; and pauci-immune glomerulonephritis, which usually is associated with ANCA and frequently is a component of a systemic small vessel vasculitis. Serologic studies are useful in differentiating these diseases ([Fig. 164.4](#)). In patients with immune complex glomerulonephritis, there may be evidence of antinuclear antibodies, anti–double-stranded DNA antibodies suggestive of lupus nephritis, or cryoglobulins indicative of cryoglobulinemia or antistreptococcal antibodies such as anti-streptolysin O (ASO) or anti-DNase antibodies. The presence in renal biopsy specimens of linear staining for IgG along GBM is strong evidence for anti-GBM glomerulonephritis, but serologic demonstration of anti-GBM antibodies is useful to confirm this diagnosis.

A close association exists between ANCA and pauci-immune necrotizing glomerulonephritis. This form of glomerulonephritis may occur as a process limited to the kidney or as part of a systemic small vessel vasculitis, such as Wegener's granulomatosis, microscopic polyangiitis, or Churg–Strauss syndrome. ANCA are found in 90% of patients with pauci-immune systemic necrotizing vasculitis. They are detected in serum by indirect immunofluorescence microscopy using alcohol-fixed normal human neutrophils as a substrate. Two patterns of neutrophil staining—perinuclear (P-ANCA) and cytoplasmic (C-ANCA)—discriminate between the two major subtypes of ANCA. The major antigen for P-ANCA is myeloperoxidase, which is located within the primary granule of normal human neutrophils and monocytes. Most C-ANCA are specific for a neutrophil and monocyte proteinase called proteinase 3.

ANTI-GLOMERULAR BASEMENT MEMBRANE DISEASE

Anti-GBM antibodies are found in patients with Goodpasture's syndrome and with anti-GBM antibody–mediated glomerulonephritis. Goodpasture's syndrome initially was defined as the coexistence of pulmonary hemorrhage and glomerulonephritis. This term now is reserved for the coexistence of pulmonary hemorrhage and glomerulonephritis mediated by anti-GBM antibodies. Renal biopsy reveals characteristic linear immunostaining of the GBM with anti-GBM antibodies associated with a necrotizing and crescentic glomerulonephritis. Many rapid immunoassays have been developed for the detection of anti-GBM antibodies because the major antigen, the noncollagenous NCI domain of type IV collagen, appears to be the major reactive moiety of anti-GBM autoantibodies.

Goodpasture's syndrome requires immediate and aggressive therapy. Patients with severe pulmonary hemorrhage need intensive care unit support. Initial therapy is with pulse methylprednisolone (7 to 15 mg per kilogram per day) for 3 days. Corticosteroid treatment is continued using prednisone (1 mg per kilogram of body weight). Plasma exchange is especially beneficial in patients with pulmonary hemorrhage. Total body plasma exchange should be performed daily for 5 days, then on alternate days for 2 weeks. The usual replacement fluid is 5% albumin or normal plasma. To prevent the rebound of autoantibodies after induction therapy is complete, immunosuppressive therapy with cyclophosphamide (2 mg per kilogram) is instituted. The starting dosage is adjusted according to the leukocyte nadir, and the response to therapy is monitored by measurement of anti-GBM titers. Patients with serum creatinine levels of less than 7 mg per deciliter or with fewer than 30% to 50% crescents are more likely to respond to this regimen than are patients with higher creatinine levels or widespread crescentic disease. The latter patients usually progress quickly to end-stage renal disease. Because of the need for rapid therapy, renal biopsy must be performed promptly. Induction therapy with Medrol and plasma exchange need to be instituted even before the biopsy data are available if the patient follows a typical course of rapidly progressive renal failure with pulmonary hemorrhage.

ANCA-ASSOCIATED GLOMERULONEPHRITIS AND SYSTEMIC VASCULITIS

The most common form of aggressive glomerulonephritis is pauci-immune necrotizing glomerulonephritis, which is associated with circulating ANCA in about 90% of patients. By immunohistologic techniques, there is no evidence for immune complex localization or direct antibody binding in the glomerulus. This lesion is associated with systemic vasculitides such as microscopic polyangiitis, Wegener's granulomatosis, and Churg–Strauss syndrome. Pauci-immune necrotizing glomerulonephritis also occurs as a renal-limited process.

Typically, patients with pauci-immune glomerulonephritis have rapidly progressive disease. However, some patients have milder disease with asymptomatic hematuria, and others have acute nephritis. Renal biopsy is essential for the diagnosis of these conditions. Focal necrotizing lesions may be present in few sampled glomeruli, or widespread crescentic disease may be found.

Many extrarenal manifestations of systemic vasculitis are apparent. Most patients have a flulike syndrome heralded by arthralgia and myalgia. The arthralgia typically is migratory, moving from joint to joint. More than 50% of these patients have a pulmonary–renal vasculitic syndrome characterized by pulmonary infiltrates or nodules and cavities. These patients usually have granulomatous inflammation indicative of Wegener's granulomatosis. One third of patients with microscopic polyangiitis or Wegener's granulomatosis have upper respiratory tract symptoms, including otitis media, necrotizing sinusitis, and nasal ulcerations. Gastrointestinal disease is manifest by nonhealing gastric ulcers and the catastrophic development of perforated abdominal viscus. Pancreatitis also may develop. It can be difficult to determine

whether the pancreatitis is the consequence of vasculitis or corticosteroid/immunosuppressive therapy. Other extrarenal manifestations of vasculitis are iritis and uveitis and the neurologic deficit of mononeuritis multiplex.

These systemic vasculitides cause a renal–dermal syndrome. Palpable purpura, necrotizing ulcerative lesions, and even allergic reactions are observed in patients with ANCA-associated systemic vasculitis. The renal–dermal syndrome also is found in patients with cryoglobulinemia, Henoch–Schönlein purpura, and systemic lupus erythematosus. A renal biopsy is most useful in determining which of these conditions is present. For example, a biopsy is necessary to determine whether a patient with palpable purpura and hematuria has Henoch–Schönlein purpura or an ANCA-associated vasculitis and necrotizing glomerulonephritis. Patients with Henoch–Schönlein purpura usually are managed conservatively, whereas those with the renal–dermal vasculitic syndromes associated with lupus or ANCA must be managed with aggressive anti-inflammatory and immunosuppressive therapy.

Pulmonary–renal vasculitic syndromes are caused by ANCA-associated vascular inflammation, anti-GBM disease, and systemic lupus erythematosus. A renal biopsy must be performed in these conditions to prescribe appropriate therapy. These conditions require corticosteroid treatment and, if there is pulmonary hemorrhage, necessitates plasmapheresis in anti-GBM disease and ANCA-associated small vessel vasculitis.

Renal biopsy is useful in evaluating the long-term prognosis of patients with anti-GBM disease and ANCA-associated glomerulonephritis. In patients with Goodpasture's syndrome, a serum creatinine level higher than 7 mg per deciliter and widespread crescents on renal biopsy is associated with almost universal progression to end-stage renal disease and long-term dialysis. In contrast, ANCA-associated necrotizing glomerulonephritis and a creatinine level of 7 mg per deciliter may be associated with recovery of renal function and a prolonged dialysis-free interval. Given equally high initial serum creatinine levels, patients with ANCA-associated crescentic glomerulonephritis have a better prognosis than do those with anti-GBM disease.

High-dose corticosteroids (pulse methylprednisolone) and cytotoxic agents such as cyclophosphamide are used to control the major end-organ damage caused by systemic vasculitis and renal-limited pauci-immune necrotizing and crescentic glomerulonephritis ([Table 164.8](#)). Patients usually are treated with tapering dosages of corticosteroids over 3 months and with oral or intravenous cyclophosphamide. Substantial controversy has surrounded the optimal route of cyclophosphamide administration. Typically, patients with Wegener's granulomatosis have been treated with oral cyclophosphamide for 1 to 2 years. However, intravenous cyclophosphamide appears to be equally efficacious. In inducing a remission, oral cyclophosphamide may be a better modality to decrease the relapse rate. Oral cyclophosphamide is associated with a substantially higher rate of infection and other complications. Its use must be tempered by the consideration of the patient's risks and benefits. The optimal duration of therapy also is controversial. Patients with microscopic polyangiitis may require as little as 6 months of treatment, because 75% never have a relapse. Patients with Wegener's granulomatosis have been treated with intravenous cyclophosphamide with similar results. Because transitional cell carcinoma of the bladder develops in up to 15% of patients who undergo long-term treatment of Wegener's granulomatosis with oral cyclophosphamide, research is underway to determine the shortest effective duration of therapy in patients with systemic vasculitis. Plasmapheresis may be useful in the treatment of massive pulmonary hemorrhage associated with systemic vasculitis, but it has no other indications in this condition.

Up to 25% of patients with these systemic vasculitides have a relapse after the initial therapy is completed. Defining a relapse can be difficult. For example, a patient with a rise in creatinine level of 2 mg per deciliter or more may have relapsing necrotizing glomerulonephritis or progressive glomerulosclerosis. A renal biopsy is essential in this circumstance to document the presence of an active necrotizing glomerulonephritis before anti-inflammatory and immunosuppressive therapy is reinstated.

RENAL BIOPSY AND THE TREATMENT OF THROMBOTIC MICROANGIOPATHY

The renal lesions of thrombotic microangiopathy are glomerular consolidation with expansion of the subendothelial zone, arteriolar fibrinoid necrosis, and edematous intimal expansion in small arteries. These angiopathic lesions also can have superimposed thrombi. The pathologic changes in the kidney are similar in all types of thrombotic microangiopathy ([Table 164.9](#)). The clinical features of these diseases often resemble those of glomerulonephritis and include proteinuria, hematuria, hypertension, and renal insufficiency. Thrombocytopenia and microangiopathic hemolytic anemia distinguish thrombotic microangiopathy from glomerulonephritis, but are not always present. Thrombotic microangiopathy manifests as a variety of clinical syndromes, including childhood and adult hemolytic–uremic syndrome, acute postpartum renal failure, malignant hypertension, thrombotic thrombocytopenic purpura, and systemic sclerosis renal crisis. Childhood hemolytic–uremic syndrome typically presents as acute renal failure, often after a diarrheal enteritis caused by virotoxin-producing *Escherichia coli*. The renal crises of progressive systemic sclerosis should be suspected when there are serologic and clinical manifestations of systemic sclerosis. However, the diagnosis may be detected only on renal biopsy if the patient does not have conspicuous skin changes. Most recently, antibodies to von Willebrand's factor–cleaving protease have been found in patients with thrombotic thrombocytopenic purpura. These antibodies may directly participate in causing the disease and should be removed by plasmapheresis.

Hemolytic-uremic syndrome
Thrombotic thrombocytopenic purpura
Systemic sclerosis
Malignant hypertension
Eclampsia
Toxic drugs
Anticardiolipin antibodies
Cyclosporin A
Mitomycin
Cisplatin

TABLE 164.9. THROMBOTIC MICROANGIOPATHY

The initial treatment of thrombotic microangiopathy is directed at the control of hypertension. This is especially true for systemic sclerosis, in which ACE inhibitors play a prominent role. In postdiarrheal childhood hemolytic–uremic syndrome, the disease process usually abates spontaneously and supportive care is in order. In contrast, plasma exchange with fresh frozen plasma or cryoprecipitate is the appropriate treatment in thrombotic thrombocytopenic purpura. The survival rate is greater than 90% when plasma exchange is used in conjunction with corticosteroid therapy.

RENAL BIOPSY IN ACUTE RENAL FAILURE

Renal biopsy is useful in a patient with acute renal failure when the cause cannot be determined by a careful history, physical examination, and laboratory evaluation. It is particularly helpful when acute renal failure is associated with nephrosis or nephritis, or when it does not resolve after 3 to 4 weeks. In this circumstance, renal biopsy can be used to look for aggressive glomerulonephritis, systemic vasculitis, thrombotic microangiopathy, minimal change disease with acute renal failure, tubulointerstitial nephritis, or acute tubular necrosis. The treatment of acute renal failure is different in the setting of acute tubular necrosis compared with glomerulonephritis or thrombotic microangiopathy.

A small subset of adult patients with minimal change disease have acute renal failure. These patients typically are older and have evidence of systolic hypertension and atherosclerosis. The cause of the acute tubular dysfunction is uncertain, but the condition improves with corticosteroid therapy or diuresis. Affected patients can be identified by their massive proteinuria. Anecdotal data suggest that other forms of nephrotic syndrome in older patients are accompanied by renal insufficiency that resolves with corticosteroid therapy.

CONCLUSION

Renal biopsy is indicated in the diagnosis and management of most forms of glomerular injury. Numerous glomerular diseases produce similar clinicopathologic syndromes but require different types of treatment. The cause and pathogenesis of many forms of glomerular disease are not clearly understood. Until the specific causes of glomerular injury are determined, therapeutic options are limited and often involve anti-inflammatory and immunosuppressive drugs. Because most of these agents carry substantial morbid and even mortal complications, they should be used only after careful consideration of the risks and benefits to the patient. Renal

biopsy is an essential tool in this process because it enables a more definitive diagnosis, helps elucidate the natural history of the disease, and reveals the response to treatment.

CHAPTER 165: RENAL SUBSTITUTION TREATMENT IN ACUTE AND CHRONIC RENAL FAILURE

PAUL SAKIEWICZ AND EMIL PAGANINI

[Renal Substitution Treatment](#)
[Hemodialysis](#)
[Peritoneal Dialysis](#)
[Role of Renal Substitution Treatment in Intoxication](#)

Renal dysfunction has been shown to enhance morbidity and mortality at all levels of patient care. Total renal failure—acute or chronic—is an absolute life-threatening situation, which fortunately can be attenuated somewhat by means of renal substitution treatment, also called renal replacement therapy. Unlike other organ failures, which require transplantation for successful support, the kidneys can also be substituted by artificial mechanical measures that have stood the test of time in both the acute and chronic failure arena.

The functions of the normal kidney are multiple, involving both the well-known aspects of solute and water excretion and balance, participation in acid–base regulation, erythrocyte production through bone marrow erythropoietin stimulation, and the lesser known aspects of hormone and cytokine regulation and bone metabolism. Current methods to “replace” renal function in acute or chronic renal failure aim at achieving fluid and solute balance and azotemic control but do little to replace the more sophisticated renal participation in metabolic balance. Experimental renal substitution treatments are presently being developed, which may address these shortcomings of current dialytic support. Clearly, those techniques that are capable of replacing some of the renal physiologic functions have several limitations and cannot achieve the efficiency of normal renal function. Occasionally, extracorporeal “renal replacement” therapies are used in the treatment of life-threatening intoxications and are frequently undertaken even in the absence of renal dysfunction.

RENAL SUBSTITUTION TREATMENT

The preservation of any residual renal function should be the goal of all renal therapy. Thus, the use of supportive measures for renal replacement should be considered an adjunct to whatever residual function that exists. This concept is of utmost importance because an aggressive therapy outline may compromise residual renal activity. There are indeed indications for aggressive support, especially in the acute renal failure population, but the overall premise to preserve underlying renal function while adding solute and fluid control with dialysis should be standard practice. Thus, a dose-delivery concept of dialysis has become popular in the description and ordering of therapy. This dose considers not only the patient variables such as size, volume, or state of catabolism and diet, but also the renal reserve present and the effect of dialytic management upon its preservation.

In the normal kidney, solute and water clearance occurs by first producing a large volume of plasma ultrafiltrate (approximately 170 to 180 L per day) through application of arteriolar hydrostatic pressure across the glomerular membrane. This primary ultrafiltrate is then altered along its path through the renal tubuli such that ideal water and solute homeostasis in the whole organism results. Glomerular filtration is thus a convective process forcing fluid into Bowman's space. This fluid has the constituents of what was presented to the basement membrane up to the size that is allowed to pass through that membrane.

In standard dialytic treatment, however, solute and water are balanced across a semipermeable membrane with a dialysate solution. The dialysate content can be altered to achieve differing balance characteristics and end points. This process is predominantly a diffusive method. During extracorporeal therapy, the semipermeable membrane is a manufactured substance, such as cellulose acetate or polysulfone. On the other hand, peritoneal dialysis uses the peritoneal membrane as the barrier between blood and dialysate fluid. In a broad sense, the term “dialysis” can be described as a process in which a solute composition of one fluid compartment is changed by exposing it to a second solution in another fluid compartment. Transfer of solutes and water takes place by different physiologic principles: passive diffusion of molecules (diffusive transport) and ultrafiltration through the semipermeable membrane (convective transport). A third process of solute movement can be attributed to adsorption. Although this third process may be minimal in certain diffusive modalities, membrane composition and pressure differentials also play a role in adsorptive properties. Adsorption is also the primary method of solute clearance when applied with resin or activated charcoal during hemoperfusion.

Dialysis efficiency has been centered on the effective removal of small substances such as urea, which are thought to be surrogate indicators for the state of “uremia.” As discussed later in this chapter, dialysis doses have been based on the removal rates of blood urea nitrogen (BUN) or serum creatinine. Although there is ample clinical evidence that this approach is both practical and effective, one must not lose sight of other potential “toxins” that may be important. For example, other “small” molecular substances, such as guanidine and phenolic compounds, aliphatic amines, or ammonia, as well as higher-molecular-weight (1300 to 10,000 daltons) toxins known as “middle molecules,” such as b₂-microglobulin, have been shown to have potential pathologic effects.

DIFFUSIVE TRANSPORT

Defined as the passive transfer of solutes through a membrane in the absence of net solvent transfer, diffusion remains the basis for the most efficient form of dialytic intervention when addressing small molecular substances. The amount of solute crossing a membrane by diffusion depends on (a) the mean concentration gradient of the substance, (b) the effective dialysis surface area (A) exposed to the differing fluids, and (c) the resistance of solute movement through the various layers established by the blood, membrane, and dialysate solution, known as the *dialyzer permeability coefficient* (K_o).

A concentration gradient between compartments is necessary for passage of a given solute from one compartment to the other. Molecular size, protein binding, molecular charge, and membrane pore size and material affect transfer of solutes as well. Small molecules with a molecular weight of less than 200 daltons have a higher transport rate through the membrane than molecules with a molecular size of more than 1,000 daltons. Highly negatively charged molecules such as inorganic phosphate (PO₄⁼) may have more difficulty in moving through a membrane than molecular size might predict. Other influences such as fluid temperature, blood and dialysate flow rates, and artificial kidney design also influence diffusive characteristics.

CONVECTIVE TRANSPORT

Ultrafiltration is the movement of water and permeable solutes through a semipermeable membrane. This process occurs either through the application of hydrostatic pressure (positive or negative respectively) to the blood or dialysate side of the semipermeable membrane (hemodialysis), or through plasma water transfer from one compartment to the other after a high osmotic gradient (peritoneal dialysis). Solvent drag caused by frictional forces between water and solutes leads to convective transfer of small and mid-size molecular substances in the same direction. In hemodialysis, the hydrostatic pressure gradient between the blood and dialysate compartment of the artificial dialyzer causes the plasma water movement from blood to dialysate. The rate of convective movement depends on: (a) the solvent filtration rate that is created by the pressure difference between compartments, (b) the sieving coefficient of the substance directly related to the permeability (porosity) and the surface area of the dialyzer, and (c) the blood concentration of the substance. In peritoneal dialysis, ultrafiltration occurs because of osmotic intraperitoneal pressure.

Solute removal can be achieved through diffusion and/or convection (ultrafiltration), and water removal can be achieved through ultrafiltration. The importance of convection and diffusion varies considerably, depending on the molecular weight of solutes. Diffusive transfer predominates convective transport for small molecules, whereas higher-molecular-weight substances move through the membrane principally by convection. Naturally, in renal replacement therapy both physiologic principles are active in solute balance. Diffusive transport is the primary means of metabolic waste removal in both hemodialysis and peritoneal dialysis. The technique of hemofiltration, defined as a plasma water exchange, relates to the use of high ultrafiltration rates as a means of removing larger-sized solutes, whereas hemodiafiltration is a combination of both aggressive diffusive and high-rate convective treatment, creating the most effective method of large and small solute balance. It is, however, limited by cost and technical challenge.

ADSORPTIVE MECHANISM

An alternative way to remove solutes from the bloodstream is through hemoperfusion, where anticoagulated blood is brought into close contact with an adsorptive substance like activated charcoal or resins. Hemoperfusion relies on the physical process of solute adsorption for its efficiency, and in many instances drug removal in

terms of clearance is far better than what could be done with hemodialysis, peritoneal dialysis, or forced diuresis. Activation of carbon is the formation, induced by chemical or physical processes, of pores within the carbon structure. Hemoperfusion is used mainly in the acute treatment of drug poisoning but has been used in such areas as iron and aluminum intoxication. Some attempts at utilizing the adsorptive properties of some dialysis membrane types for cytokine removal have also found their way into the treatment of the septic patient with acute renal failure, but the data are preliminary.

HEMODIALYSIS

HEMODIALYSIS APPARATUS AND CIRCUIT

Dialysis technology has made great strides not only in the use of equipment and techniques but also in the understanding of the various conditions and issues that are both created and resolved by the dialytic process itself. Dialysis times have varied from a long (8-hour) process in the early years to the short dialysis times (2.5 hours) of the valiant experiments of the late 1980s and the more standard time/clearance ratio of modern prescription dialysis therapy. Although technology has made the process easier to perform, it still consists of a basic dialytic circuit, and principles remain the same.

During hemodialysis, blood is pumped at a fairly high flow rate (300 to 400 mL per minute) from the patient through the dialysis apparatus and then returned to the patient. Basic technical components of hemodialysis include the hemodialysis machine, which consists of pump systems for both blood and dialysate fluid paths and pressure-monitoring devices within those circuits. The artificial kidney is added to the middle of both flow circuits, thus creating an “arterial” or “to” line and a “venous” or “from” line. It is within these lines that the measurements of pressure and the adjustment of anticoagulation occur. Heparin, if used, is usually added to the arterial line, prior to the kidney to ensure that the blood entering the dialyzer does not clot, thus avoiding a lower efficiency of the therapy and reducing the obligatory blood loss of the dialysis session. Nonheparin techniques also are available for use in patients who either cannot tolerate heparin or in whom anticoagulation would be contraindicated.

The dialysate fluid is prepared through a series of proportioning mechanisms, combining dialysate concentrate with a steady supply of purified (treated) water. This highly purified water is then combined with the dialysate concentrate, which contains the solutes required for a balanced dialysis session. It is in this proportioning that the various solute concentrations (sodium, potassium, calcium, bicarbonate) can be altered as dictated by patient need and physician desire. Altering the pressure differences across the semipermeable membrane of the dialyzer will alter the amount of fluid lost (ultrafiltrated) during the session. This difference is set by the machine operator, and volume loss is precisely controlled over time.

The dialyzer is the part of the dialysis circuit in which solute and water transfer actually occur. It consists of a shell containing the semipermeable membrane that separates blood from dialysate fluid. The membrane can consist of a variety of plastic materials (polysulfone, cellulose acetate, polyamide, and others) that have been manufactured to yield a certain fluid porosity and diffusive characteristic. Membrane types differ in several characteristics, such as surface area, porosity, biocompatibility, and charge. The rate of whole blood pumped through the dialyzer is usually between 250 to 500 mL per minute. Dialysate fluid flows at a rate of 500 to 800 mL per minute.

Another prerequisite for hemodialysis is a functioning vascular access that allows for sufficient blood flow. Blood access types may be percutaneous double-lumen venous catheters (mostly tunneled), natural arteriovenous fistulas, or arteriovenous bypass grafts. Percutaneous double-lumen catheters are usually placed in a major vein (internal jugular, femoral vein), because these vessels already support high blood flows. The subclavian vessels were used at one time as a primary site of entry, but recent data showing a strong correlation between subclavian access and subsequent venous stenosis have drastically changed practice. Fistulas and grafts are surgically created arteriovenous malformations that connect an artery and a vein. They increase both venous blood flow and pressure substantially, thereby thickening (arterializing) the venous wall and allowing for a more consistent, stable, and repetitive venous needle entry, while also ensuring an adequate blood flow for dialysis. Most commonly, the radiocephalic natural fistula of the nondominant arm is attempted, followed by the brachiocephalic bypass anastomosis approach. A fistula can take several weeks to months to “mature” from placement to a point at which it can be used for dialysis. Grafts can be used earlier, are usually placed either in the forearm or upper arm, and can have either a straight or loop configuration. For practical purposes, the arteriovenous fistula is the preferred hemodialysis access for chronic hemodialysis because it has a lower complication rate and the longest survival after successful maturation. Grafts are technically easier to place; however, their long-term complications, including stenosis and thrombosis, cause higher morbidity and cost. Potential complications of arteriovenous fistulas or grafts are limb ischemia through a “steal syndrome” that shunts blood away from the limb, venous stenosis and thrombosis, aneurysm formation, and infection. Thrombosis of the hemodialysis access renders it unusable for dialysis and thus should be considered an urgent situation requiring relatively rapid correction. Angioplasty and thrombolysis can be used to attempt recanalization and continued use of the access. Percutaneous double-lumen catheters are the least preferred chronic dialysis access choice, because of lower blood flows and a higher rate of complications caused by catheter-related infections and malfunction. They can be either tunneled or nontunneled and are used mainly in the acute setting. For chronic dialysis, central catheters may be used transiently while awaiting maturation of a fistula or graft. Chronic use of catheters, however, is sometimes seen in dialysis patients only if all other available access sites have been exhausted.

FORMS OF HEMODIALYSIS

Current dialysis techniques are intermittent and continuous hemodialysis. [Table 165.1](#) reflects the current definitions, primary method, and abbreviations commonly used. Intermittent hemodialysis became widely available in 1972 for support of the otherwise fatal condition of end-stage renal disease (ESRD). The usual frequency of intermittent hemodialysis in ESRD is three times weekly, with an average duration of 3 to 5 hours each session. Alternative forms are home hemodialysis, in which the patient dialyzes at home, usually with the help of a relative, and nocturnal hemodialysis, in which longer hemodialysis sessions at slower blood and dialysate flows are used.

Procedure	Definition	Underlying Physical Principle of Operation
Ultrafiltration	Removal of plasma water	Hydrostatic pressure Solvent ultrafiltration During hemodialysis During hemofiltration Directly pressure During peritoneal dialysis using glucose as the ultrafiltration osmotic solute
Dialysis	Movement of solute across a semipermeable dialysis membrane from blood to dialysate or vice versa following gradients. Continuous blood flow and dialysate flow rates determine therapy dosage	Solute diffusion across a membrane. Controlled by temperature, charge, molecular size, and flow characteristics. Membrane is either a plastic variant (hemic) or natural (peritoneal), both “passive” molecule solute movement
Hemofiltration	Movement of solute across a semipermeable dialysis membrane following the flow of fluid during a plasma water exchange. Exchange rate determines therapy dosage	Solute convection following the rapid flow of fluid across a membrane. Solute charge temperature have less influence on to membrane pore size, but “sieve” effect molecule solute movement
Hemodialysis	Combination of dialysis and hemofiltration aspects in a single therapy session	Convection and diffusion flow. Most efficient form of extracorporeal dialysis supports maximum small and middle molecular solute movement
Hemoperfusion	Flow of whole blood or plasma over substances such as charcoal or resin with specific adsorbent surface characteristics	Absorption from perfusate on to surface structure of material contained in the cartridge, system material ultrafiltration (ESRD therapy)

TABLE 165.1. DEFINITIONS AND PHYSIOLOGY BEHIND VARIOUS EXTRACORPOREAL THERAPY INTERVENTIONS

Continuous hemodialysis is a form of renal replacement therapy that is used mainly for acute renal failure support. It applies the principles of hemodialysis in a slow and continuous manner, ideally providing solute and fluid removal 24 hours per day. The gradual solute and fluid removal is thought to be especially beneficial for hemodynamically unstable patients in whom conventional hemodialysis may exacerbate hypotension. The nomenclature and abbreviations applied to continuous dialysis techniques are complex ([Table 165.2](#)). Just as in conventional hemodialysis, vascular access is necessary to provide blood flow in the continuous hemodialysis circuit. Vascular access can be either venovenous (when a double-lumen venous catheter is used, meaning that blood is being drawn from one lumen of the catheter by means of a blood pump and returned through the other lumen of the catheter) or arteriovenous (when one single-lumen catheter is inserted into each femoral artery and femoral vein).

Time Frame	Access Type	Renal Replacement Form
Continuous (C)	Venovenous (VV)	Hemodialysis (HD)
	Arteriovenous (AV)	Hemofiltration (HF) Hemodiafiltration (HDF)

Possible Forms—CVVHD, CAVHD, CVVHE, CAVHE, CVVHDF, CAVHDF
SCUF, Slow continuous ultrafiltration (can be VV- or AV-SCUF)

TABLE 165.2. FORMS OF CONTINUOUS RENAL REPLACEMENT THERAPY

In the arteriovenous form of continuous dialysis, the arterial pump provides blood flow through the dialyzer. The dialytic techniques applied continuously through the mentioned accesses can be either diffusional or convectional in nature, or consist of a combination of both. For example, CVVHD means that the renal replacement is continuous, access is venovenous, and solute clearance is achieved with hemodialysis. CAVHF means that the technique is continuous, arteriovenous access is used, and solute clearance is achieved through purely convective solute transport. Another frequently used term is SCUF, which refers to slow and continuous ultrafiltration (usually 100 to 200 mL per hour); the access can be either venovenous or arteriovenous. No dialysate or replacement fluid is present, and the sole purpose of SCUF is fluid removal without significant solute removal.

GOALS AND MONITORING OF THERAPY

Perhaps one of the most significant advances in the delivery of dialysis therapy to ESRD patients has been the establishment of a dialysis dose. On the basis of both a prospective national cooperative dialysis trial and later on the United States Renal Data System (USRDS) results, there seems to be a close association with patient outcome and amount of dialysis delivered. The surrogate marker used for dosing the session is the control of BUN. This control can be expressed either as a clearance of the therapy delivered using terms that relate to both the patient and the therapy session or as a total amount of marker removed as determined by measurement of a percent change from pre- and postdialysis blood levels of BUN.

The clearance method uses the dialyzer clearance (K) during a dialysis session, the actual length of the session in minutes (t), and the volume of urea present in the body determined from the patient's total fluid content (V). The ratio established (Kt/V) should express a ratio of 1.2 to 1.4. Dialysis ratios of less than 1.2 are associated with a higher mortality. The usual ESRD patient requires three times weekly hemodialysis with a duration of 3 to 5 hours per session to achieve this urea reduction requirement. Wide variations in time on dialysis are due to differing patient size, dietary intake, comorbidities, and access type. Furthermore, the clinician also evaluates nutritional status, calcium and phosphorus balance, weight gains between dialysis sessions, choice of anticoagulation dose on dialysis, hypertension control and medication schedule, and anemia management, including iron and erythropoietin therapy, to arrive at the optimal dialysis dose for each patient.

In acute renal failure support, an optimum dialysis dose has not been established. These patients are varied and present with a myriad of problems that may have much more influence on mortality than does an individually delivered dialysis dose. Both intermittent and continuous hemodialysis techniques are used for support, with the more hemodynamically unstable patient generally being treated with continuous techniques. Controversy exists with respect to the dose of dialysis, such that it is not clear whether adequacy parameters from chronic renal failure support can be extrapolated to acute renal failure support, and to the survival benefit of either intermittent or continuous hemodialysis. It is, however, customary to target a urea reduction of 65% per intermittent dialysis session and to achieve a steady urea concentration of less than 60 mg per deciliter when using continuous hemodialysis. Overall, it appears that daily intermittent hemodialysis may be the optimal technique for most acute renal failure patients, who can hemodynamically tolerate it. Prospective studies to evaluate outcome, modality choice, and dialysis dose in acute renal failure are currently underway.

COMPLICATIONS

The most common hemodialysis complication is hypotension, followed by cramps, nausea and vomiting, headache, chest and back pain, itching, fever, and chills (Table 165.3). These complications can be multifactorial, but in general they relate to the many physiologic and unphysiologic factors that the patient is exposed to during rapid fluid and solute removal. The contact of blood with synthetic material can elicit an inflammatory response, which can be somewhat modulated by choosing so-called biocompatible membranes. Those biocompatible membranes usually elicit the least amount of inflammatory response, and their influence on morbidity and mortality seems positive, although not conclusively proved. Hematologic abnormalities during hemodialysis are transient initial leukopenia, enhanced extracorporeal platelet aggregation, and hemolysis.

Probable Cause	Symptoms
Solute and fluid removal	Hypotension, cramps, nausea, vomiting, headache, chest pain, back pain, dialysis disequilibrium syndrome
Contact of synthetic materials and dialysate fluid with blood	Fever, chills, itching, transient leukopenia, anemia, thrombocyte aggregation, pyrogen reaction, aluminum deposition
Vascular access-related	Infection, thrombosis, stenosis, aneurysm formation, limb ischemia and steal syndrome, high cardiac output heart failure
Dialyzer sterilant use— inadequate rinsing	Formaldehyde/cyanide/hypochlorite: hemodynamic collapse, chest pain, burning sensation
Anticoagulation	Bleeding
Miscellaneous conditions associated with chronic renal failure	Carpal tunnel syndrome, dyslipidemia, hyperhomocysteinemia, anemia, depression, sexual dysfunction, dementia, risk for viral hepatitis infection

TABLE 165.3. POTENTIAL COMPLICATIONS OF HEMODIALYSIS

Frequent long- or short-term access-related complications include infection, thrombosis, limb ischemia through steal syndrome, and malfunction. Chronic complications and associated conditions in chronic renal failure are abnormal lipid profile, anemia, iron loss, β_2 -microglobulin amyloidosis with carpal tunnel syndrome, elevations of homocysteine levels, depression, sexual dysfunction, and a general preponderance for morbidity and mortality from cardiovascular disease. These complications are probably inherent in the pathologic state of renal failure rather than to the dialysis modality alone. Aluminum accumulation in ESRD patients can cause aluminum bone disease and dementia. The source of aluminum can be either the dialysate water supply or the use of aluminum-based phosphate binders, a practice now largely abandoned. Upon initiation of hemodialysis, a dramatic symptom constellation can occasionally be observed, called *dialysis disequilibrium syndrome*. Central nervous system solute and water shifts causing cerebral edema are responsible for this rarely observed syndrome, and prevention of rapid solute and fluid shifts are the mainstay of therapy. Patients can exhibit headache, cramps, nausea, vomiting, mental status changes, seizures, and, in extreme cases, death. Patients who are new to dialysis are particularly at risk, and gradual, slow removal of solutes and fluid should therefore be attempted initially. Anticoagulation is required for efficient dialysis to prevent clotting of the extracorporeal circuit, and patients are obviously exposed to all its inherent risks, like bleeding and anemia. Recombinant erythropoietin therapy has greatly facilitated anemia management in ESRD patients, and the previously observed iron overload from long-term transfusions is now rather rare. Indeed, the opposite effect, iron deficiency, is prevalent among hemodialysis patients and is probably related to the blood loss experienced during the dialysis sessions.

Other inherent risks associated with hemodialysis are exposure to infectious viral hepatitis, and the potential for exposure to dialysate water contaminants such as bacterial pyrogens, chlorines, chloramines, aluminum, and fluorides. The practice of reusing dialyzers can occasionally cause severe reactions like hemodynamic collapse and death when dialyzer rinsing is incomplete and sterilant is flushed into the patient. Diligent attention to dialysate water preparation and reuse practices is

of utmost importance, and those complications have fortunately become rare.

PERITONEAL DIALYSIS

In the adult population, peritoneal dialysis is mostly used as a means to replace renal function in chronic renal failure. It can, however, be used as an alternative to hemodialysis in acute renal failure. Peritoneal dialysis uses the peritoneal membrane as barrier and exchange medium between blood and dialysate fluid. Usually 1 to 3 L of a dialysate solution containing dextrose and solutes in a physiologic concentration are instilled into the peritoneal cavity. The principles of diffusion and convection achieve equilibration between dialysate fluid and blood in mesenteric capillaries and therefore solute and water removal. Fluid removal is achieved osmotically through a high osmotic gradient in the dialysate fluid. After dwelling for a certain period of time (widely different, but usually 4 to 6 hours in continuous ambulatory peritoneal dialysis), the dialysate fluid is then drained and a new cycle is started. Peritoneal dialysis can be performed either continuously, in which dialysate solution is constantly present in the peritoneal cavity, or cycler-assisted, in which usually nocturnal cycles are being performed automatically with a programmable machine.

APPARATUS FOR PERITONEAL DIALYSIS

A peritoneal dialysis catheter must be placed percutaneously through either a midline or, preferably, a lateral abdominal entry site. The ideal internal location is between the anterior abdominal wall and the omentum and bowel loops. The catheter is usually a silicone or polyurethane cuffed catheter, which has to allow for adequate dialysate fluid inflow and outflow. The dialysate fluid is usually a lactate-based dialysate solution with differing solute dextrose levels. Available dextrose concentrations are 1.5%, 2.5%, and 4.25%, which allow for targeted ultrafiltration and solute removal (4.25% providing the highest rate of fluid removal).

Dialysate filling and draining are achieved by using exchange tubing, which is connected to the patient's catheter. Utmost diligence is required when handling the connections because of a high infection risk otherwise. Exchanges of dialysate fluid can be achieved manually or cycler assisted. When performing cycler-assisted peritoneal dialysis, the tubing is attached to a programmable cycler apparatus, which performs instillation, dwell and drain functions, and ultrafiltration measurements automatically.

GOALS AND MONITORING OF THERAPY

The usual peritoneal dialysis prescription (continuous ambulatory peritoneal dialysis) involves exchanging between 1 and 3 L up to four to six times daily. Physiologic differences in peritoneal membrane characteristics of individual patients influence the rate of solute and fluid removal. Occasionally, these individual differences require a change from peritoneal to hemodialysis based on inadequacy of solute or fluid removed. Adequacy of peritoneal dialysis is mostly measured by determining the amount of urea removal and the creatinine clearance provided with dialysis. The ideal dose of peritoneal dialysis is unknown; however, certain adequacy parameters can serve as guides to achieve adequate fluid and uremia control. Peritoneal dialysis can certainly achieve results similar to those of hemodialysis with respect to patient morbidity, mortality, and solute and fluid control. The overall cost on average is significantly less for peritoneal dialysis, and comparative studies with hemodialysis have been controversial but have proved peritoneal dialysis to be comparable to hemodialysis and a viable option as renal replacement therapy for chronic renal failure.

COMPLICATIONS

Infection of the peritoneal dialysis catheter with peritonitis remains the most significant complication of peritoneal dialysis and is frequently the limiting factor in its application. The incidence of catheter-related peritonitis is approximately 1 episode every 18 to 24 months, and the most common causative organisms are *Staphylococcus epidermidis* and *S. aureus*. Depending on the severity of the infection, either intravenous or intraperitoneal antibiotics can be used; occasionally, the catheter must be removed and the patient changed to hemodialysis. Several interventions have been attempted in counteracting catheter infections, and the combination of diligent attention to the catheter exit site and exchange techniques and preventive local antibiotic treatment has decreased the incidence of catheter-related peritonitis.

Catheter malfunction can occur either through fibrinous deposits around the catheter or through obstruction of the catheter holes. Metabolic complications such as hyperglycemia with increased insulin requirements and abdominal wall hernias and pleural leak can occur. Abdominal distention can impair pulmonary function, and gastrointestinal reflux disease can be exacerbated. Loss of protein in the dialysate fluid can be substantial (10 to 15 g per day), requiring adequate oral supplementation. As with all ESRD patients, comprehensive management of lipid and volume status, anemia and hypertension, calcium and phosphorus metabolism, nutrition, and psychological well-being need to be ascertained when managing peritoneal dialysis patients.

GUIDELINES FOR INITIATION OF RENAL SUBSTITUTION THERAPY

Although anyone can start dialysis support, it is much more difficult to know when not to start. There are only vague and general rules on the initiation of dialytic support in the chronic renal failure population, and those rules are even further blurred in patients with acute renal failure.

Absolute indications for initiating renal replacement therapy are the clear presence of signs or symptoms of the uremic syndrome, severe and refractory hyperkalemia, severe acidosis, fluid overload, and severe life-threatening substance intoxications. Another way to remember these is to use the mnemonic AEIOU, standing for **a**cidosis, **e**lectrolyte abnormalities, **i**ntoxications, **o**verload, and **u**remia. An absolute level of BUN or serum creatinine alone is rarely an indication for dialysis in the patient with either acute or chronic renal failure, because symptoms vary from patient to patient. High levels of BUN can be used as a factor in the decision to initiate therapy but should not be used as the only indication for dialysis. Also, small patients with poor nutritional status or small muscle mass may not generate serum creatinine to a level indicative of their degree of renal dysfunction. Indeed, it is not unusual to see serum creatinine levels of 1.5 to 2.0 mg per deciliter in patients with a glomerular filtration rate of less than 10 mL per minute. Thus, the laboratory findings are to be used as aids in the search for an appropriate starting time for dialysis, but must be taken in the context of the whole constellation of signs and symptoms.

The initiation of chronic renal replacement therapy is somewhat controversial but replacement should be started when the patient's glomerular filtration rate drops to less than 10 mL per minute per square meter or, in diabetics, to less than 15 mL per min². This rate should be used as the threshold to avoid major uremic and other complications and to ensure an uncomplicated transition into life with renal replacement therapy. In addition, significant medical and psychological care, most effectively achieved through a multidisciplinary approach involving patient and family, primary and renal physicians, dialysis nurse, social worker, and dietitian, needs to be ascertained. The adequate frequency, duration, and dose of renal replacement therapy is still a matter of intense debate. The usual frequency of maintenance hemodialysis is three times weekly for 3 to 5 hours depending on patient variability, and the frequency and mode of peritoneal dialysis is highly variable but averages about six times per week either as daytime or night-time peritoneal dialysis or a combination of both.

ACUTE RENAL FAILURE

Acute renal failure is still a life-threatening disease with high mortality (on average 50%) despite significant technical advances in the field of renal replacement therapy, including the development of continuous forms of dialysis. Acute renal failure is heterogeneous in nature and invariably complicates patient management by increasing the risk for sepsis, bleeding, mental status changes, and respiratory and cardiac failure. Theoretically, renal replacement therapy should facilitate management of these conditions through solute and fluid control. Renal replacement therapy in acute renal failure can be achieved with either intermittent or continuous forms of hemodialysis. Peritoneal dialysis is used mainly in the pediatric population, but in the adult patient it has the disadvantage of insufficient removal of solutes and volume. Factors and considerations in the choice and frequency of modality are comorbidities and hemodynamic stability. Uncertain factors in the renal replacement treatment of acute renal failure are the time of initiation and the frequency and the dose of dialysis. The mode of hemodialysis is also a matter of debate with respect to patient outcome.

A theoretical advantage of continuous renal replacement therapy is the gradual rate of solute and fluid removal, which minimizes hypotension. Solute and fluid removal is usually greater than in intermittent hemodialysis, and intuitively continuous dialysis is preferred for patients with a greater risk for hemodynamic instability. A specific form of continuous renal replacement therapy, *continuous hemofiltration* (using solely convective solute removal), has been invoked in being able to remove adverse inflammatory cytokines. Because of this theoretical advantage, continuous forms of dialysis intuitively should lead to improved patient outcome. This theoretical advantage, however, has not been corroborated in clinical trials, and currently intermittent and continuous forms of dialysis are equivalent methods for acute renal failure treatment. The approach to renal replacement therapy in acute renal failure should therefore include a proactive approach toward renal replacement therapy, meaning earlier initiation, more frequent (possibly daily) dialysis, usage of biocompatible dialysis membranes and an overall increase in dialysis

dose.

A common error in management of acute renal failure is to underestimate its extent by considering the level of BUN or creatinine, as well as by ignoring the fact that a "normal" urine output of 2 to 3 L per day can be easily achieved with a glomerular filtration rate well below 10 mL per minute per square meter. A prolonged delay in renal replacement therapy in this situation can have devastating consequences by allowing the effects of uremia to continue unabated. At the same time, one must consider that renal replacement therapy can cause hypotension, exacerbate renal damage, and slow renal recovery. Other potential side effects are the risk of bleeding with the use of anticoagulants and infections caused by the placement of temporary dialysis access.

Management of the patient with acute renal failure should involve early nephrologic subspecialty consultation, because the above-mentioned approach is best achieved with the thoughtful judgment of the renal consultant with respect to the application of medical and interventional means that are most likely to benefit the patient.

CHRONIC RENAL FAILURE

Medical care for the chronic renal failure patient on renal replacement therapy (called ESRD by the Health Care Financing Administration) involves several factors: providing sufficient dialysis, special attention to ensuring adequate nutrition, maintaining a healthy dialysis access, correcting hormone deficiencies, treating comorbidities, and practicing an overall excellent general practice of medicine. This approach results in prolonged patient survival, decreased hospitalization, and enhanced patient well-being. In ESRD, there are three choices for chronic renal substitution treatment: standard intermittent hemodialysis, peritoneal dialysis, and renal transplantation. Although peritoneal dialysis is primarily a home dialysis technique, intermittent hemodialysis can be "in-center" (carried on in a dialysis facility), hospital-based (dialysis in the hospital as an outpatient), or home-based method of delivery. Further, home hemodialysis can be performed either nightly or daily or can follow the more traditional thrice-weekly treatment schedule.

The overall life expectancy of patients with ESRD has improved over the last several years, but it is still well below that of the general population. According to the 1999 United States Renal Data System Annual Report, "The expected lifetimes of the ESRD population are between 16 and 38 percent of an age-race-sex matched U.S. population, while lifetimes of all ESRD patients are reported to be 19 to 47% the corresponding US population." Although it is possible for individuals to live with dialytic renal replacement therapy for over 20 years, the average annual mortality rate for all dialysis patients was 23.3% in 1997 (Health Care Financing Administration Annual Facility Survey, 1998).

Survival is best with living-related renal transplantation, whereas overall among dialysis patients mortality increases with age, diagnosis of diabetes, and the addition of other comorbid entities. The main cause of death in dialysis patients is cardiovascular complications. There seems to be no overall survival benefit for either hemodialysis or peritoneal dialysis, even though in general a larger amount of solute clearance can be achieved with hemodialysis. Several current studies have examined patient outcome with respect to dialysis modality and are controversial, but suggest a slight advantage for continuous ambulatory peritoneal dialysis (CAPD) in young nondiabetic patients. With respect to the selection of modality of renal replacement therapy, several patient- and modality-specific variables must be considered. A patient's home situation, preference, practical availability, and convenience are important factors. Considerations in the decision-making process are also large patient size, prior intra-abdominal operations, and presence of intra abdominal infections, which directs therapy away from CAPD.

Once a patient initiates dialytic renal replacement one must ensure further quality medical management, but in addition one must direct attention to healthy maintenance of vascular access (the lifeline of hemodialysis), aggressive treatment of hypertension and anemia (with erythropoietin and iron substitution), and achieving sufficient dialysis.

Dialysis dose is specifically measured by observing the influence of dialysis on blood urea levels (Kt/V_{UREA} , URR_{UREA}), which are used as surrogate markers for the solute control achieved with renal replacement. There are certain minimum treatment goals that the nephrologist attempts to achieve during dialysis therapy, and usually a minimum URR of 68% or a Kt/V of 1.2 is attempted with dialysis. One must be clearly aware of the limitations associated with such practice, knowing that the blood urea level can vary greatly based on nutritional protein intake and other factors. For example, a relatively high blood urea level (60 to 80 mg per deciliter) does not necessarily imply poor patient health or poor dialysis delivery; occasionally, a very low urea and creatinine level can indicate severe malnutrition and underdialysis. Additional clinical signs of dialysis adequacy are calcium and phosphorus metabolism, hypertension control, anemia control, interdialytic weight gain, control of metabolic acidosis, control of hyperkalemia, nutritional status as measured with albumen, transferrin, prealbumin levels, increase in non-water weight, and subjective patient well-being. Hemodialysis factors that may play a role in patient outcome include dialyzer membrane type, the practice of dialyzer reuse, and the so-called high-flux dialysis. It is abundantly clear that inadequate dialysis, late referral to the nephrologist, and the presence of malnutrition at initiation of dialysis lead to poorer survival independent of the modality of renal replacement therapy. Currently it is recommended to refer patients for renal consultation when the serum creatinine level reaches 2 mg/dl for men and 1.5 mg/dl for women recognizing that serum creatinine is a relatively inaccurate indicator of glomerular filtration rate. These thresholds however are attempting to recognize significant renal failure in otherwise asymptomatic patients, in order to assure proper preparation for the possibility of renal replacement therapy and also optimized chronic renal failure management. The recent improvement in patient survival in the United States is encouraging and it suggests that improved dialysis is being delivered and that several of the important management factors mentioned above are being adequately applied.

ROLE OF RENAL SUBSTITUTION TREATMENT IN INTOXICATION

Renal replacement therapy in the form of hemodialysis or hemoperfusion can be used as adjunctive treatment to enhance poison elimination even in the absence of renal failure. Hemoperfusion is an extracorporeal technique by which toxins are adsorbed to either a charcoal or resin hemofilter in a circuit setup similar to hemodialysis. Toxin properties affecting dialytic clearance are molecular weight, protein binding, volume of distribution, lipid solubility, membrane binding and charge. Extracorporeal removal of toxins is necessary when conservative poisoning management cannot adequately assure the patient's well-being. Significant benefit from renal replacement therapy is most frequently achieved in overdoses of lithium, ethylene glycol, methanol, salicylates, and theophylline.

CHAPTER 166: RENAL TRANSPLANTATION

CHRISTOPHER Y. LU, MIGUEL A. VAZQUEZ, MARIUSZ KIELAR, D. ROHAN JEYARAJAH AND XIN J. ZHOU

[Evaluation of the Potential Transplant Recipient](#)
[Immunologic Evaluation of the Patient and Potential Recipient](#)
[Management Early After Transplantation](#)
[Management of Late Post-Transplantation Complications](#)
[Interpretation of the Transplant Biopsy](#)
[Immunosuppressive Agents](#)
[Kidney Transplant Donors](#)

A successful kidney transplantation may completely reverse the uremic state in a patient with end-stage renal disease (ESRD). Advances in basic and clinical research have progressively improved the results. One-year renal allograft survival rates are 84% for first cadaveric renal transplants and 96% for two-haplotype-identical transplants from a sibling. The corresponding 1-year patient survival rates are 94.6% and 98%. This chapter takes the perspective of a general practitioner caring for a transplant recipient in concert with a transplant center.

The care of a patient undergoing renal transplantation may be divided into phases: evaluation of the potential transplant recipient, the immunologic evaluation of the patient and potential donor, management of the early post-transplantation course, and management and prevention of late complications. Although the problems of one phase can overlap those of another, we discuss each phase separately and then address related topics: the interpretation of the allograft biopsy, the immunosuppressive agents used to treat and prevent rejection, and the donor (living *versus* cadaveric) of the renal allograft.

EVALUATION OF THE POTENTIAL TRANSPLANT RECIPIENT

The major objectives of the evaluation phase are to determine whether the risk of complications from transplantation surgery and immunosuppression is acceptable; to identify and, if possible, correct any underlying diseases; and to educate the patient about transplantation.

The physician and patient must determine whether transplantation or dialysis is the best treatment for ESRD for that individual patient. For some patients, coexisting illnesses, such as cardiovascular disease, cause an excessive risk of morbidity or mortality from the transplantation surgery or the immunosuppressive regimen. Transplantation is a treatment but not a cure for ESRD; a few patients will not accept the risks of the transplantation surgery and the complications of the immunosuppressive medications that must be taken for the life of the transplant. However, for many patients, transplantation is the optimal treatment for ESRD and markedly improves their quality of life.

Many centers exclude patients with recent or disseminated cancer or with severe, untreatable cardiac, pulmonary, or vascular disease. However, patients with diabetes mellitus or inactive systemic lupus erythematosus may receive a transplant if they are in good general physical condition. Infections, peptic ulcers, and active gallbladder and diverticular disease should be identified and treated before transplantation. Patients with symptomatic heart disease, older patients, those with diabetes mellitus, and others with significant risk factors for atherosclerosis require a cardiac evaluation. The specific tests vary among transplant centers. The possible adverse effects of long-term immunosuppression on chronic viral hepatitis remain unsettled. Many centers perform a liver biopsy and discourage transplantation if severe chronic active hepatitis is found. Some patients may benefit from treatment with interferon before transplantation. Such treatment after transplantation may precipitate rejection. Functional integrity of the urinary tract may need to be confirmed, particularly in patients with histories of recurrent urinary tract infection, reflux, or kidney stones. Patients should be intellectually and emotionally capable of managing the stresses that accompany many of the post-transplantation complications and should be willing to comply with the medical regimen.

Many types of primary glomerulopathy and secondary renal disease recur in the allograft. However, rejection remains the major cause of allograft loss. Recurrent disease rarely results in allograft failure. An exception is focal segmental glomerulosclerosis, which has a high rate of recurrence in the allograft and can lead to transplant failure. Diabetic nephropathy, type II membranoproliferative glomerulonephritis, IgA nephropathy, and Henoch–Schönlein purpura recur frequently in the allograft, but the long-term prognosis for allograft function remains good. Some centers perform simultaneous kidney and pancreas transplantations to ameliorate the complications of type I diabetes mellitus.

In choosing between dialysis and transplantation, patients and their physicians must understand the risks associated with the surgery and the long-term immunosuppression. Despite the progress made in this field, many problems remain unsolved. Although the 1-year survival of transplanted organs is excellent, only 50% of all first-time recipients of a kidney from a cadaver donor have a functioning transplant after 9 years. There are many late complications (discussed under Management of Late Post-Transplantation Complications). Compared with patients receiving dialysis, transplant recipients have a higher risk of mortality and morbidity during the first months after transplantation. Only after 3 years is the cost-effectiveness of transplantation over dialysis demonstrable.

IMMUNOLOGIC EVALUATION OF THE PATIENT AND POTENTIAL RECIPIENT

About 75% of transplant recipients in the United States obtain their kidneys from cadavers. The donors are brain dead from trauma or acute illness but have functioning kidneys. The legal criteria for brain death are rigorous and indicate irreversible absence of brain function. Prospective studies, before the era of cadaveric transplantation and in countries where there is no legal definition of brain death, indicate that people who satisfied these criteria also inevitably suffered a cardiovascular death as well, despite continued aggressive intensive care. Although the number of patients waiting for transplant has tripled from 1985 to 1995, the number of transplantations performed annually has remained constant and is severely limited by the shortage of cadaver organs. Misconceptions about brain death prevent many families from allowing recovery of kidneys from the brain dead. Because of the shortage of cadaver organs, it is not uncommon for a patient to wait years for a transplant. Therefore, patients should be encouraged to explore the possibility of receiving a kidney from a living donor—a blood relative or a spouse—as discussed at the end of this chapter.

When their pretransplantation evaluations are complete, all patients awaiting cadaver kidneys are placed on a national waiting list maintained by the United Network for Organ Sharing (UNOS). UNOS is authorized by the federal government to distribute all cadaveric organs in the United States according to a computerized algorithm. This algorithm allows transplantations only between donors and recipients with compatible blood groups. It attempts to maximize the match between the human leukocyte antigen (HLA) genotype of the donor and recipient. However, these gene loci are extremely polymorphic, and the average match between donor and recipient in the United States is only two out of a possible six HLA antigens. A kidney with no HLA mismatches with a recipient will be shipped anywhere in the United States to that recipient; kidneys with lesser mismatches are used locally because the damage suffered by the kidney during the “cold ischemia” time required for the long-distance shipment outweighs the benefits of better HLA matching.

Approximately 10% to 20% of patients waiting for transplant have antibodies against 80% or more of a panel of all possible HLA genotypes. These patients have a “high panel reactivity” or PRA. These antibodies arise in patients who have previously rejected kidney transplants within 1 year of transplantation, received numerous blood transfusions, or borne several children. If a patient has antibodies against the HLA antigens of the donor kidney, the transplant will be destroyed shortly after transplantation. Thus, patients with a high PRA cannot receive transplants from 80% of the population and often wait many years longer than the average patient before obtaining a transplant. The UNOS algorithm gives these patients an advantage when an appropriate cadaver kidney does become available. Even when laboratory testing indicates that patients with a high PRA do not have antibodies against a cadaver kidney (negative cross-match), there is still an increased likelihood of rejection. Many transplant centers prefer a better HLA match and perform special cross-match tests (such as flow cytometry or B-cell cross-matches) for these high-risk patients to improve outcomes.

The UNOS algorithm also takes other factors into account. For example, patients with uncommon HLA genotypes would be disadvantaged by an algorithm that placed too great an emphasis on matching HLA genotypes of the donor and recipient. Therefore, the algorithm gives some consideration to patients solely based on the time they have waited for a transplant.

Although patients are waiting for their cadaver transplant, they may develop new, active medical problems, such as severe infection, myocardial disease, or gastrointestinal bleeding. There is no evidence that earlier transplantation prevents these complications. The primary physician should keep the transplant center informed about any new medical problems and resolve any treatable illnesses so that the patient is ready for transplantation when the organ finally becomes

available.

MANAGEMENT EARLY AFTER TRANSPLANTATION

During the first 2 months after transplantation, the most common complications center around dysfunction of the renal allograft, the recent surgery, and medications. Most infections involve conventional pathogens at this phase after transplantation.

Several electrolyte abnormalities are common early after transplantation. Hyperkalemia is associated with cyclosporin A or tacrolimus and can occur in patients with excellent serum creatinine and therapeutic serum levels of drug. Dangerous hyperkalemia can occur with dietary indiscretion and the use of nonsteroidal anti-inflammatory agents, b-blockers, and angiotensin-converting enzyme (ACE) inhibitors. Hypophosphatemia may require treatment with phosphate supplements. Hypercalcemia can result from hyperparathyroidism associated with the uremic state before transplantation; it is usually mild and remits spontaneously. Some patients with type I diabetes mellitus receive combined kidney–pancreas transplants. If the exocrine pancreas is drained into the bladder, these patients may develop profound hypovolemia and acidosis owing to the losses of bicarbonate and sodium in the exocrine pancreatic secretions into the bladder. These losses should be prevented by ingestion of sodium and bicarbonate.

Although immunosuppressive protocols vary among transplant centers, most patients receive a regimen of prednisone, cyclosporin A, and mycophenolate mofetil. To reduce the adverse effects of these agents, their dosages are tapered gradually, which may allow the development of acute rejection. Rejection occurs in about 20% to 30% of transplant recipients, and the highest incidence is during the first several weeks after transplantation. Successful treatment depends on expeditious diagnosis, often by renal biopsy. This invasive diagnostic procedure should be performed only after the diagnoses in [Table 166.1](#) have been excluded by following the approach shown in [Figure 166.1](#).

Decreased effective arterial blood volume
Inadequate volume replacement
Congestive heart failure
Myocardial ischemia
Excessive antihypertensive medications
Postoperative hemorrhage
Anatomical problems
Bladder dysfunction, particularly in diabetics
Obstructive lymphocele or hematoma
Ureteral obstruction
Urine leak
Vascular embolism/thrombosis
Drug nephrotoxicity
Cyclosporin A
Antibiotics
Nonsteroidal anti-inflammatory drugs
Angiotensin-converting enzyme inhibitors
Other
Infection
Urinary tract infection
Sepsis
Cytomegalovirus
Acute tubular necrosis
Acute rejection
Recurrent or de novo renal disease

TABLE 166.1. COMMON CAUSES OF EARLY TRANSPLANT DYSFUNCTION

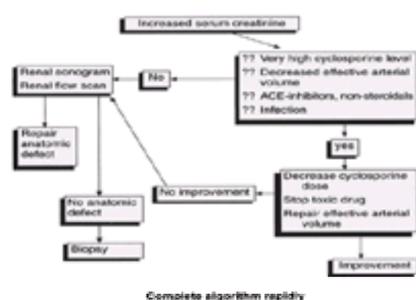

FIGURE 166.1. A simplified approach for renal allograft dysfunction during the early phase after transplantation. ACE, angiotensin-converting enzyme.

Inadequate salt and fluid intake is a common cause of allograft dysfunction because transplant recipients are trained to limit their salt and fluid intake during dialysis. In addition, after the ischemic insult of transplantation, the kidney is unable to conserve salt and water optimally. After diarrhea, vomiting, or sweating, hypovolemia may occur. The serum creatinine level improves quickly after salt and water are replenished by the oral or intravenous route.

Anatomical problems can be detected by ultrasonography or renal flow scans of the allograft. Lymphoceles may occur because the lymphatic system is disrupted during the transplantation surgery. A diagnostic tap may be necessary to exclude the more uncommon diagnoses of urinoma (the creatinine level of the fluid should be high), hemorrhage, or abscess. In addition to routine bacteriologic cultures, the specimen should be cultured for fungi, *Mycobacterium tuberculosis*, and atypical mycobacteria. Lymphoceles frequently reaccumulate after a diagnostic tap. If the lymphocele does not compromise allograft function by obstructing the ureter or blood vessels, it usually resolves spontaneously over months without treatment. If the lymphocele does obstruct the allograft ureter or blood vessels, chronic catheter drainage or surgical drainage into the peritoneal cavity may be necessary. These invasive procedures may be performed best at the transplant center by experienced surgeons and radiologists. Bladder dysfunction is another common cause of allograft dysfunction, particularly in patients with diabetes, who may develop neurogenic distention of the bladder. Other, less common, anatomical problems are listed in [Table 166.1](#).

The renal allograft often is sensitive to nonsteroidal anti-inflammatory agents and ACE inhibitors during the first weeks after transplantation. The serum creatinine level should return to baseline rapidly after these agents are withdrawn. The use of a combination of trimethoprim and sulfamethoxazole (Bactrim) is recommended by many transplant centers to prevent *Pneumocystis* and urinary tract infections. These agents may cause a rise in creatinine but not in blood urea nitrogen.

After these conditions have been excluded, three other complications must be considered: acute tubular necrosis in the allograft, nephrotoxicity due to either cyclosporin A or tacrolimus, and acute rejection. A biopsy may be necessary to differentiate these conditions. The allograft may fail to achieve a normal serum creatinine level because of acute tubular necrosis. This injury results from ischemia occurring in the donor kidney during organ procurement and storage and during the surgery.

Cyclosporin A is the mainstay of most immunosuppressive regimens. However, cyclosporin A itself causes renal dysfunction. It can be difficult to distinguish allograft dysfunction caused by cyclosporin A nephrotoxicity from that caused by rejection. Although high blood or serum levels of cyclosporin A often are associated with nephrotoxicity, rejection occasionally occurs in patients with high levels, and toxicity sometimes occurs in patients with low levels. Oliguria, fever, graft tenderness, or more than 50% elevation of the serum creatinine level suggest rejection. If the cyclosporin A level is markedly elevated and none of these findings is present, it may be appropriate to decrease the cyclosporin A dosage and observe the patient for 24 to 48 hours. If a favorable response does not occur, biopsy may be necessary. Rarely, cyclosporin A and tacrolimus are associated with a hemolytic uremic syndrome that may respond to decreasing or discontinuing these agents.

Several points deserve emphasis. Successful treatment of acute rejection requires early diagnosis. The diagnostic and therapeutic maneuvers outlined herein are usually completed within 24 to 48 hours. In patients receiving cyclosporin A, rejection generally occurs without fever and allograft tenderness. Most often, the only finding is an elevated serum creatinine level detected during a routine clinic visit. The presence of fever may indicate infection or rejection, particularly if localized findings of pneumonia, urinary tract infection, or sore throat are absent. Finally, reducing the cyclosporin A or tacrolimus dosage to treat nephrotoxicity may result in drug levels that are too low to prevent rejection. Careful follow-up is necessary whenever the immunosuppressive regimen is changed.

The diagnosis of acute rejection is made by allograft biopsy in the setting of deteriorating allograft function. The biopsy, treatment, and prognosis of the different types

of acute rejection are discussed in the section on the allograft biopsy.

MANAGEMENT OF LATE POST-TRANSPLANTATION COMPLICATIONS

RENAL ALLOGRAFT FUNCTION

Late deterioration in renal function may result from factors unique to transplantation or from diseases common to all kidneys. Acute transplant rejection is rare in the late post-transplantation period unless the immunosuppressive regimen has been recently tapered to reduce side effects or the patient has been noncompliant. The most common cause of late allograft loss is chronic allograft nephropathy. This manifests as a slow, progressive rise in the serum creatinine. The precise mechanisms responsible for chronic allograft nephropathy are unknown. Many authors divide its causes into alloantigen-dependent and alloantigen-independent causes. Alloantigen-dependent causes include chronic rejection; however, chronic rejection is not known to respond to currently available immunosuppressive agents. Previous episodes of acute rejection increase the risk for subsequent chronic rejection. Alloantigen-independent causes include chronic cyclosporin A toxicity, the maladaptive response to nephrons lost during the transplantation procedure or previous rejections, insufficient nephron mass due to transplanting small or aged kidneys into large recipients, hypertension, and hyperlipidemia. Anatomical problems such as renal artery stenosis or obstruction also can appear long after transplantation.

Treatment of chronic allograft nephropathy is problematic because its cause is not understood. However, the patient and allograft may benefit from aggressive treatment of hyperlipidemia and blood pressure, as discussed in the text that follows, and from optimal doses of cyclosporin A or tacrolimus.

CARDIOVASCULAR DISEASE

Cardiovascular disease is the leading cause of death among renal transplant recipients. Risk factors are pretransplantation ischemic heart disease, diabetes, male gender, hypertension, smoking, hypercholesterolemia, older age, and high cumulative doses of corticosteroids. Disease of the native kidneys, suboptimal allograft function, preexisting hypertension, cyclosporin A, and corticosteroids all can contribute to hypertension. Allograft artery stenosis is rare given the use of modern surgical techniques. Calcium channel blockers may offer some protection against cyclosporin A–induced afferent arteriolar vasoconstriction. Diuretics are effective, but volume contraction should be avoided. ACE inhibitors may be effective but may cause an acute deterioration of the glomerular filtration rate, particularly if renal allograft artery stenosis is present. These agents also are associated with hyperkalemia and are avoided early after transplantation in some centers. Impaired renal function, the nephrotic syndrome, diabetes, obesity, and both cyclosporin A and corticosteroids increase the risk for hyperlipidemia. Treatment of hypercholesterolemia may require HMG-CoA reductase inhibitors (statin drugs). Patients should be observed closely after the initiation of HMG-CoA reductase inhibitors because rhabdomyolysis can occur when they are given in combination with cyclosporin A. Resin binders such as cholestyramine may prevent the absorption of cyclosporin A and should be given more than 2 hours after the cyclosporin A dose, if at all.

INFECTION

Recipients of renal transplants are susceptible to more infections than affect the general population. Furthermore, they differ from other persons in their increased susceptibility to opportunistic infections and in the greater severity and more subtle physical findings of their illnesses. During the early post-transplantation period, conventional pathogens cause pneumonia, urinary tract infections, and catheter and wound infections. Most opportunistic infections occur following the first month after transplantation. Pathogens include herpesviruses, *Candida* and other fungi, *M. tuberculosis*, atypical mycobacteria, and parasites. Dysphagia can indicate a fungal or viral esophagitis, and endoscopy may be indicated.

Candida growth limited to the oral pharynx is common and responds to oral nystatin. Persistent diarrhea should prompt an investigation for parasites or invasive cytomegalovirus (CMV) colitis. Headache may indicate the presence of *Listeria*, cryptococcal meningitis, or lymphoma. “Cold” swelling of the joints or skin should prompt a consideration of fungal or atypical mycobacterial infection. Immunosuppression plus preexisting peripheral vascular disease and neuropathy predispose patients with diabetes to osteomyelitis and amputation of their extremities. These patients must be instructed carefully in the proper care of their feet and hands to prevent this complication.

CMV infection is common, and many transplant recipients who are not ill shed virus into their urine and other secretions. Occasionally, CMV causes disease. Patients with CMV infection may present with a mild illness with fever, leukopenia, thrombocytopenia, and small elevations in liver function test results, or they may have a severe disease with pneumonitis, gastrointestinal ulcerations, and a high mortality rate. Rapid diagnosis involves the use of polymerase chain reaction or monoclonal antibodies against viral proteins expressed on the surfaces of infected cells. CMV disease predisposes to superinfection with other pathogens and has been associated with graft dysfunction and, possibly, rejection. Transmission of CMV by the donor kidney into a recipient not previously immunized against CMV may predispose the recipient to severe disease. Patients receiving antilymphocyte antibodies to treat rejection also are at high risk. Some studies indicate that severe CMV disease can be prevented in high-risk patients by high-dose acyclovir, ganciclovir, or CMV hyperimmune immunoglobulin. Established CMV disease is treated with ganciclovir or foscarnet.

Pneumonia is the leading cause of death secondary to infection in transplant recipients. In addition to conventional pathogens, organisms such as *Pneumocystis carinii*, *Nocardia*, and *M. tuberculosis* must be considered. An aggressive diagnostic approach is necessary to guide therapy effectively. Many transplant centers recommend prophylactic therapy with a combination of trimethoprim and sulfamethoxazole to prevent *P. carinii* pneumonia.

MALIGNANCY

Renal transplant recipients are at higher risk than the general population for some malignancies. The most common are skin cancers; these are common in white patients with significant sun exposure. Squamous cell carcinomas are more common than basal cell carcinomas and may be aggressive and metastasize earlier than in immunocompetent persons. Post-transplantation lymphoproliferative disease can occur after intensive immunosuppressive therapy. It usually involves B lymphocytes and is extranodal. The most common locations are the central nervous system, the renal allograft, and the gastrointestinal tract. Epstein–Barr virus often is found in the abnormal B lymphocytes. Kaposi’s sarcoma is more common in transplant recipients, can manifest as mucocutaneous lesions, and may progress to visceral involvement. Hepatobiliary tumors and anogenital cancers also are more common.

LIVER DISEASE

Chronic infections with hepatitis B or C virus are a leading cause of long-term morbidity and mortality in the transplant population. Transplant recipients who have evidence of active hepatitis B viral replication at the time of transplantation are at high risk for cirrhosis and ESRD. Patients with chronic hepatitis may have mild elevations in their transaminase levels and progress silently to cirrhosis. Reduction of immunosuppressive therapy and administration of interferon- α have been used to treat chronic hepatitis, with variable results.

BONE DISEASE

Patients with ESRD have renal osteodystrophy and osteomalacia. Patients with successful renal transplants also experience significant morbidity secondary to bone disease. Progressive osteopenia is a common problem in many renal transplant recipients who are taking corticosteroids. Osteonecrosis usually affects the femoral head in adults and can lead to significant pain and impaired mobility. Magnetic resonance imaging aids in the early diagnosis of hip osteonecrosis. Total hip arthroplasty is occasionally required. Hypercalcemia due to hyperparathyroidism may complicate administration of calcium and vitamin D supplements. Some patients may benefit from oral bicarbonate to treat any metabolic acidosis caused by cyclosporin A or tacrolimus or by any renal insufficiency.

POST-TRANSPLANTATION ERYTHROCYTOSIS

Post-transplantation erythrocytosis is self-limited, occasionally requires phlebotomy, and generally responds to the inclusion of ACE inhibitors in the hypotensive regimen. Affected patients should be screened for other causes of erythrocytosis, such as pulmonary disease and polycythemia vera. In addition, the native kidneys should be imaged. Patients with ESRD develop acquired cystic disease of the kidneys, which may undergo malignant transformation to renal cell carcinoma.

INTERPRETATION OF THE TRANSPLANT BIOPSY

The interpretation of the renal allograft biopsy has been standardized by the Banff 97 working classification. This classification results from a multicenter collaborative effort and multiple revisions since 1991. Parts of this classification are summarized in [Table 166.2](#).

Banff 97 Classification	Prognosis After Treatment
Antibody-mediated rejection	
Immediate (hyperacute)	Very poor
Delayed (accelerated acute)	
Acute rejection	
Type I: interstitial inflammation, tubulitis, no arteritis	Good
Type II: intimal arteritis	Fair
Type III: transmural arteritis	Poor
Chronic/sclerosing allograft nephropathy	Long-term, poor

TABLE 166.2. COMMON BIOPSY FINDINGS IN PATIENTS WITH RENAL ALLOGRAFT DYSFUNCTION

Two types of acute allograft rejection are mediated predominantly by antibodies. Immediate or hyperacute rejection occurs shortly after the blood supply to the allograft is established. The kidney becomes dusky and cyanotic immediately, and there is no urine output. By light microscopy, neutrophils and platelets are found in the glomeruli, arterioles, small arteries, and peritubular capillaries. These lesions often result in cortical necrosis. Preformed antibodies in the recipient against the donor HLA molecules are responsible for this form of rejection. Hyperacute rejection is rare because modern cross-match techniques usually detect these antibodies in the recipient before transplantation, and the kidney is not allocated to that patient. Immediate nephrectomy is necessary when this form of rejection occurs. Delayed antibody-mediated (or accelerated acute) rejections occur in the first weeks after transplantation. Often, the patient had a high PRA before transplantation. Rejection mediated predominantly by antibodies has a very poor prognosis. By light microscopy, antibody-mediated rejection is differentiated from acute rejection by the type of inflammatory cells (neutrophils and platelets *versus* mononuclear cells).

Acute rejection is divided by Banff 97 into three major types. In type I, there is a mononuclear inflammation of the interstitium and tubules. The prognosis after therapy with high-dose corticosteroids is good. In type II acute rejection, there is also mononuclear inflammation involving the arterial intima. The prognosis after therapy with high-dose corticosteroids or polyclonal or monoclonal anti-T-cell antibodies is fair. (Agents used to treat rejection are discussed in the following text). In type III rejection, the endarteritis of mononuclear cells is more severe and involves not only the intima but the entire arterial wall, which may be necrotic. The prognosis of this lesion is poor.

CYCLOSPORIN A NEPHROTOXICITY

Acute cyclosporin A or tacrolimus nephrotoxicity usually has no definitive pathologic findings and is associated with an improvement in allograft function after the doses of these drugs are decreased. Previous reports indicate that isometric tubular vacuoles occurred with much higher doses of cyclosporin A than are commonly used today. Rarely, there may be glomerular thrombi, which are associated with a hemolytic uremic syndrome. Chronic cyclosporin A toxicity is associated with characteristic apoptosis of the medial smooth muscle cells of arterioles and small arteries; these cells are replaced by nodular protein deposits. In addition, there may be interstitial fibrosis, glomerular sclerosis, and tubular atrophy common to chronic allograft nephropathy.

IMMUNOSUPPRESSIVE AGENTS

Different immunosuppressive agents, detailed below, are used at different times after transplantation:

- To prevent rejection, many protocols use low-dose corticosteroids and either cyclosporin A or tacrolimus. In addition, these protocols may include either azathioprine or mycophenolate mofetil.
- To treat rejection, high-dose corticosteroids, polyclonal antilymphocyte antibodies, or monoclonal antibodies to the CD3 e molecule on T cells are used.
- In addition, during the days immediately after transplantation, some centers use agents that are otherwise used to treat rejections, or monoclonal antibodies against the interleukin-2 receptor a chain.

Several immunosuppressive regimens are available. In general, the primary physician should follow the transplant center's protocol and consult the center if adjustments are necessary.

CYCLOSPORIN A AND TACROLIMUS

Cyclosporin A and tacrolimus (FK506) are generally used to prevent rejection. They have many similarities in their actions and side effects. The active intracellular forms are the drug bound to intracellular proteins called *immunophilins*. The drug-immunophilin complex prevents the dephosphorylation of the nuclear factor of activated T cells and its translocation into the nucleus, where it would activate lymphokine gene transcription. Many drugs affect the pharmacokinetics of cyclosporin A. For example, the antifungal agents, fluconazole and ketoconazole, can increase cyclosporin A levels sufficiently to cause acute renal failure if appropriate dosage adjustments are not made. Rifampin, dilantin, and phenobarbital dramatically decrease cyclosporin A levels such that rejection can occur unless the cyclosporin A dosage is adjusted appropriately. Common side effects of cyclosporin A and tacrolimus are hepatotoxicity, neurotoxicity, hyperlipidemia, hirsutism, and gingival hyperplasia. Tacrolimus and cyclosporin A have similar nephrotoxicity. Tacrolimus causes more hyperglycemia and neurotoxicity, but less hirsutism, gingival hyperplasia, and hyperlipidemia. The different preparations of cyclosporin A have different pharmacokinetics, and patients must be observed carefully for rejection and toxicity if they are switched from one preparation to another.

CORTICOSTEROIDS

Corticosteroids continue to play an important role in many immunosuppressive regimens. They are used in combination with cyclosporin A or azathioprine to prevent allograft rejection. High doses of corticosteroids may reverse acute rejection and are also used immediately after transplantation. Corticosteroids inhibit inflammation by inhibiting the production of tumor necrosis factor- α , interleukin-1, eicosanoids, and adhesion molecules. Finally, some data suggest a role for corticosteroids in preventing transcription of interleukin-2.

Corticosteroids have many side effects, including infections, hypertension, glucose intolerance, obesity, cosmetic changes, bone loss, growth retardation in children, cataracts, gastrointestinal disturbances (pancreatitis, ulcers), and psychiatric disturbances. Dosages should be minimized.

AZATHIOPRINE

Azathioprine is used to prevent rejection. It is converted in red blood cells to 6-mercaptopurine, which is metabolized into thioinosinic acid. This molecule interferes with the synthesis of purines, especially adenosine nucleotides. The side effects of azathioprine are bone marrow suppression, infection, malignancy, and hepatotoxicity. Although gout is common in transplant recipients, allopurinol should not be used in patients receiving azathioprine. Allopurinol interferes with the metabolism of azathioprine, and severe leukopenia may result.

MYCOPHENOLATE MOFETIL

Mycophenolate mofetil is metabolized to mycophenolic acid. Like azathioprine, mycophenolate mofetil inhibits purine synthesis. However, it inhibits the enzyme inosine monophosphate dehydrogenase. This enzyme is required for the de novo synthesis of guanosine nucleotides, which are important for the proliferation of lymphocytes and the production of adhesion molecules. The main side effects of this agent are nausea, vomiting, diarrhea, and bone marrow suppression.

POLYCLONAL ANTIBODIES

Polyclonal antilymphocyte antibodies are an effective treatment for acute rejection and are also used by some transplant centers immediately after transplantation surgery, particularly when there is post-transplant acute tubular necrosis and the allograft is susceptible to cyclosporin A nephrotoxicity. There are major differences in the recommended doses of the various approved preparations. Common side effects are fever, leukopenia, and thrombocytopenia. Serum sickness and anaphylaxis can occur. An increased incidence of infection and lymphoma has been observed in some patients.

MUROMONOAB-CD3 (OKT3)

Muromonoab-CD3 (OKT3) is a mouse monoclonal antibody against the ϵ chain of the CD3 complex of the T-cell receptor. It is more effective than corticosteroids in the treatment of first rejection episodes and is also effective in cases of corticosteroid-resistant rejection. In addition, muromonoab-CD3 can be used immediately after transplantation as induction therapy to delay the introduction of cyclosporin A and avoid an additional nephrotoxic insult in the early post-transplantation period. The administration of muromonoab-CD3 may precipitate a first-dose reaction. This ranges from fever, headache, and diarrhea to life-threatening pulmonary edema secondary to increased capillary permeability. To ameliorate the latter, patients should be at their "dry weight" before administering the first dose. Aseptic meningitis can occur early in the course. An increased risk of infection and lymphoma has been observed in some patients after therapy with muromonoab-CD3. Because it is a murine product, some patients form antimouse antibodies, which may interfere with the action of the drug.

BASILIXIMAB AND DACLIZUMAB

Basiliximab and daclizumab (anti-interleukin-2 receptor) are monoclonal antibodies that are genetically engineered to contain the antigen-binding sites of murine antibodies placed into the framework of human immunoglobulin. Thus, the first-dose response seen with muromonoab-CD3 is ameliorated, and the patient does not make antibodies against these agents. Basiliximab and daclizumab both bind to the α chain of the interleukin-2 receptor. The α chain is found only on activated T cells. Blocking this receptor decreases further activation of these cells and thus decreases the likelihood of rejection. These antibodies should be started before the transplantation surgery. At this time, they are not used for treatment of rejection.

KIDNEY TRANSPLANT DONORS

In the United States, about one fourth of all kidney transplantations involve living donors, both blood relatives and spouses. The main benefit of living related donor kidney transplantation is better short- and long-term allograft survival. Donors should have two normal kidneys as confirmed by anatomical and functional studies. They should be free of any medical problems and emotionally and intellectually able to understand the preoperative evaluation and kidney donation process. The perioperative mortality risk to the carefully selected donor is extremely low (0.03% to 0.6%), and significant perioperative morbidity is seen in less than 2% of cases. Long-term follow-up of kidney donors has revealed no evidence of progressive loss of renal function when compared with control patients. Hypertension also is no more common than in control patients. A higher incidence of proteinuria has been reported in some series. Life expectancy is not affected by kidney donation.

Cadaveric renal transplantation is the only option available for most transplant candidates with ESRD. Cadaver donors used in transplantation have suffered brain death most frequently secondary to head injuries, central nervous system vascular events, localized brain tumors, or severe cerebral anoxia. As the number of patients awaiting renal transplantation continues to increase (more than 40,000), the criteria for donor acceptability have been revised. Nevertheless, certain conditions, such as extremes of age, most infections and malignancies, underlying advanced medical illnesses, and renal diseases or dysfunction, preclude the use of cadavers as donors. A history of behavior in the donor that may result in a high risk for AIDS or hepatitis and technical or logistical aspects that result in prolonged ischemia time for the kidney also are considered relative contraindications.

CHAPTER 167: ADJUSTMENT OF DRUG DOSAGE IN PATIENTS WITH RENAL INSUFFICIENCY

SUZANNE K. SWAN

[Pharmacokinetics](#)
[Dosing Regimens](#)
[Narcotic Pain Management](#)
[Guidelines for Drug Dosage in Renal Failure](#)

Normal renal function is required for the metabolism and elimination of many pharmacologic agents from the body. Likewise, pharmacologically active metabolites of many drugs depend on the kidney for removal from the body. Many compounds, whether excreted by renal or nonrenal means, exert toxic effects in the setting of reduced renal function. Renal function often declines with advanced age, and the increase in adverse drug reactions in geriatric populations is attributable, in part, to drug accumulation by the kidney. In this chapter, basic pharmacologic principles are reviewed and applied to the clinical setting of renal insufficiency. Guidelines for dosage adjustments appear in tabular form. However, clinicians should not rely heavily on dosing tables or nomograms when treating patients with impaired renal function. Rather, they should maintain a heightened awareness of the pharmacologic alterations that occur in this setting while closely monitoring their patients' clinical courses to help guide dosimetry.

PHARMACOKINETICS

Pharmacokinetic factors can be altered by renal insufficiency ([Table 167.1](#)). Drug absorption can be affected by gastrointestinal dysfunction and the concurrent medications often used in the setting of renal failure. For example, uremia-induced vomiting, delayed gastric emptying, and decreased intestinal motility may contribute to decreased drug absorption. In addition, the concurrent ingestion of phosphate binders, both aluminum- and calcium-containing, can lead to the formation of insoluble compounds with drugs such as ferrous sulfate or tetracycline, blocking absorption. Bowel wall edema, often encountered in congestive heart failure and hypoalbuminemic states such as nephrosis or cirrhosis, also can slow drug absorption.

Absorption

Volume of distribution

Protein binding

Biotransformation (metabolism)

TABLE 167.1. PHARMACOKINETIC FACTORS AFFECTED BY RENAL INSUFFICIENCY

The volume of distribution can be altered in the setting of renal failure, but not in a predictable manner. The volume of distribution for a specific drug is derived by dividing the total amount of drug in the body by its plasma concentration. It does not refer to a specific anatomical compartment; instead, it is used mathematically to determine the dose of a drug necessary to achieve a desired concentration. Volume contraction tends to decrease and ascites and edematous states tend to increase the volume of distribution for hydrophilic compounds such as aminoglycosides. As a general rule, serum or plasma concentrations of a drug correlate inversely with its volume of distribution.

Changes in the protein binding of various pharmacologic agents can be expected with significant renal impairment. The organic acids and bases that accumulate in azotemic patients can displace acidic and basic drugs, respectively, from their binding proteins. This, in turn, results in a greater proportion of unbound or "active" drug being available at tissue sites.

Finally, the biotransformation or metabolism of pharmacologic agents can be altered in patients with renal insufficiency. Although renal impairment usually has little effect on drug metabolism by hepatic mechanisms, exceptions do exist. For example, more rapid oxidation of phenytoin, digitoxin, and propranolol has been reported. This may be attributable to the observation that a larger proportion of a given compound can exist in its unbound or free form in uremic serum. Conversely, quinidine is oxidized more slowly in patients with renal insufficiency. Acetylation, hydrolysis, and reduction also may be impaired in such patients. In addition, agents with active metabolites that are dependent on renal excretion may require dosage adjustment even when parent compound pharmacokinetics are unaffected by the presence of renal impairment.

DOSING REGIMENS

When the glomerular filtration rate (GFR) is reduced, the elimination of many compounds and pharmacologically active metabolites falls proportionately. In other words, the prolongation of a drug's elimination half-life (the time required for the plasma drug concentration to be reduced by half) is proportional to the reduction in the GFR. Although drug accumulation can occur at any level of renal insufficiency, such adverse events are relatively uncommon when the GFR remains greater than 40 to 50 mL per minute. If dosage restrictions are excessive because of fears of toxicity, inadequate therapy may result. This is particularly important when prescribing anticonvulsants, antiarrhythmics, and antibiotics. Patients with impaired renal function must be maintained within a narrow therapeutic window, avoiding drug accumulation and toxicity on one hand and subtherapeutic dosing on the other. A stepwise process can aid clinicians in establishing drug dosage regimens for patients with renal insufficiency ([Table 167.2](#)).

1. Perform initial assessment
2. Calculate creatinine clearance
3. Choose a loading dose
4. Choose a maintenance dose
5. Monitor therapy

TABLE 167.2. APPROACH TO DOSING REGIMENS IN RENAL INSUFFICIENCY

INITIAL ASSESSMENT

A history and physical examination constitute the first step in assessing dosimetry in a patient with renal impairment. Previous drug toxicity or intolerance should be ascertained if possible. The patient's current medication list (both prescription and nonprescription formulations) must be reviewed to identify potential drug interactions and nephrotoxins. Physical findings indicate the patient's volume status, provide the height and weight data used in calculating ideal body mass, and reveal whether extrarenal disease states such as hepatic dysfunction exist, which require additional dosage adjustment.

CALCULATING CREATININE CLEARANCE

An estimate of renal function is necessary because the elimination rate of most drugs is related to the GFR. Because blood urea nitrogen and serum creatinine (SCr) values themselves are insensitive measures of renal function, creatinine clearance (C_{cr}) conventionally is used to estimate the GFR. The Cockcroft-Gault formula for calculating C_{cr} is convenient and appropriate for clinical use because age and lean body mass correlate with C_{cr} :

$$C_{cr} = \frac{[140 - \text{age}][\text{lean body weight in kg}]}{[72][\text{SCr in mg/dL}]}$$

In women, 85% of this calculated value should be used. The lean body weight in men is about 50 kg plus 2.3 kg per inch of height over 5 feet, whereas in women it is 45.5 kg plus the same height adjustment factor. These calculations assume that renal function is stable. In the setting of oliguric acute renal failure, SCr values should be ignored and a C_{cr} of less than 10 mL per minute used for drug dosing adjustment. Likewise, an SCr value that falls within the "normal" range cannot be presumed to reflect normal renal function. Particularly in elderly or debilitated patients with reduced muscle mass, this erroneous assumption frequently results in overdose and adverse drug reactions.

CHOOSING A LOADING DOSE

In general, rapid achievement of therapeutic, steady-state drug concentrations is sought. A standard loading dose should be administered to patients with renal insufficiency to achieve therapeutic drug levels rapidly. The loading dose can be calculated by the following formula:

$$\text{Loading dose} = V_d \times \text{IBW} \times C_p$$

where V_d is the volume of distribution (in liters per kilogram), IBW is the ideal body weight (in kilograms), and C_p is the desired plasma concentration (in milligrams per liter).

If a drug with a particularly narrow therapeutic window is being used, such as digoxin or an aminoglycoside, and its volume of distribution is predictably low in uremic or volume-contracted patients, reducing the loading dose by 25% to 30% may be prudent.

CHOOSING A MAINTENANCE DOSE

After a loading dose has been administered, a maintenance regimen in patients with renal insufficiency can be determined by one of two methods. One approach involves lengthening the dosing interval as follows:

$$\frac{\text{Dosing interval} = \text{normal } C_{cr}}{\text{patient's } C_{cr} \times \text{normal interval}}$$

Alternatively, the dose can be reduced but administered at the standard interval:

$$\frac{\text{Dose} = \text{patient's } C_{cr}}{\text{normal } C_{cr} \times \text{normal dose}}$$

The varying interval method can lead to periods of inadequate drug concentrations, whereas the varying dose method allows for more constant drug levels but risks toxicity resulting from higher trough levels. The interval method is preferred for aminoglycosides, which demonstrate concentration-dependent bactericidal properties, whereas the dosage method is more appropriate for anticonvulsant or antiarrhythmic agents. A combination of these methods also can be used to individualize pharmacotherapy.

MONITORING DRUG LEVELS

Measurement of plasma drug concentrations is helpful in assessing the success of a dosing regimen, especially in patients with multiple problems. It is imperative that the relations among the measured level, efficacy, and toxicity of the drug are known and that attention is paid to the details of sample collections. For example, an aminoglycoside drug level within the therapeutic range would indicate major drug accumulation and toxicity if the sample were obtained 48 hours after the last dose. In general, blood levels should be determined after three or four doses to ensure steady-state conditions. For some drugs, maximum and minimum concentrations are useful. Peak levels obtained after the rapid distribution phase are helpful in ensuring that an adequate concentration to provide efficacy has been reached. The trough concentration measured before the next dose is an index of drug elimination during the dosing interval; it measures drug accumulation in the setting of renal failure. Because therapeutic drug monitoring is expensive, it should be limited to pharmacologic agents with narrow therapeutic windows and those with pharmacologic actions that are difficult to assess clinically.

For patients receiving hemodialysis, peritoneal dialysis, or continuous renal replacement therapy, attention must be paid to dose scheduling and the need for supplemental doses to replace lost body stores. Dialysis clearance of a drug depends primarily on its molecular weight, degree of protein binding, and water solubility. As protein binding increases, dialysis clearance decreases. The smaller and more hydrophilic the compound, the more drug is removed during a dialysis treatment. In general, scheduled doses should be given after dialysis if possible. In addition, if a drug undergoes significant dialyzer clearance, supplemental doses should be given after each dialysis treatment or, in the case of continuous therapy, dosage reductions may need to be limited given the continuous clearance provided.

NARCOTIC PAIN MANAGEMENT

The number of options are limited for narcotic pain management in patients with renal impairment because of an increase in adverse reactions to this class of compounds as well as excessive sedation and respiratory depression. This is due in part to active metabolites of the parent compound as well as to prolonged elimination half-lives of both parent drug and metabolite. In addition, many narcotic agents are not readily removed from the body by dialysis, thus compounding the problem of prolonged or increased sedation. Unfortunately, little data regarding the use of narcotics in patients with reduced renal function exist in the literature.

One approach is to categorize narcotic use in renal failure on the basis of relative safety recommendations ([Fig. 167.1](#)). For example, meperidine is a narcotic that should be avoided in patients with renal failure. Meperidine is metabolized to normeperidine, which has little analgesic effect but has an excitatory effect on the central nervous system. Normeperidine is also eliminated from the body by the kidneys. Thus, in patients with renal failure, seizure activity may result because of the accumulation of normeperidine. Despite the relative safety categorizations of different compounds in [Figure 167.1](#), *no narcotic agent is truly considered safe in the presence of renal failure*. Thus, close monitoring of this patient population during narcotic analgesic therapy to detect the earliest sign of drug accumulation in addition to minimizing drug exposure to this class of compounds is imperative.

FIGURE 167.1. Flow chart showing the relative safety of narcotic therapy for pain management in patients with end-stage renal disease. (Adapted from Lewis MJ, Swan SK. A potpourri of drug idiosyncrasies in ESRD. *Semin Dial*. 1997;10:278–281.)

GUIDELINES FOR DRUG DOSAGE IN RENAL FAILURE

The preceding text has presented the theoretical aspects of dosimetry adjustments that may be required in the presence of renal insufficiency. [Table 167.3](#) provides rough guidelines and recommendations on which to base therapy for drugs commonly used in clinical practice. The prescribing physician is responsible for assessing individual patient factors; the data presented are simply starting points. Individualization of therapy is mandatory, and adjustments in these guidelines should be made as frequently as clinically necessary. More complete compilations are available but are beyond the scope of this book (see [Bibliography](#)).

therapy. Treatment that is not directed at the initial cause of a condition addresses only its symptoms. The clinical problem is likely to persist or recur. For example, treating a primary mechanical joint problem such as osteoarthritis with nonsteroidal anti-inflammatory drugs may provide symptomatic relief but will not positively affect the progression of the condition. Treating gout with nonsteroidal anti-inflammatory drugs will not change the persistent abnormality in uric acid metabolism, which will continue to cause the problem. Treating a knee joint that is deformed from rheumatoid involvement with realignment by osteotomy has no good rationale, because the underlying problem is inflammatory and will erode the surgical result.

Before causative therapy can be prescribed, it must be determined whether the cause of the patient's complaints is primarily mechanical, metabolic, or inflammatory. This can usually be accomplished mainly by obtaining and analyzing the history of the problem. By way of illustration of this, metabolic processes usually involve the whole body and are symmetric, chronic, and long-standing. Metabolic conditions commonly are hereditary, and a family history may be significant. The symptom constellation itself may be diagnosable. For example, Paget's disease of bone should be suspected from a history of localized, unremitting pain with slow progression, unrelated to position or activity.

To distinguish between inflammatory and mechanical pain, it is important to discover what aggravates the pain and what relieves it. Pain from both inflammatory and mechanical aberrations worsens with use. Mechanically generated pain improves at rest, whereas pain from inflammation tends to persist. The physician should inquire whether certain positions, movements, or activities reliably alleviate or aggravate the symptoms. Severe, chronic immunologic and inflammatory responses, such as rheumatoid arthritis, are global enough that a patient's activities may have little effect on the symptoms. Such joints are usually most comfortable when held in a position that maximizes the volume of the joint, reducing the tension in the joint's capsule and synovial membrane.

Pains from inflammatory conditions persist at rest and frequently are associated with joint stiffness after immobilization as a result of the associated edema that collects around the joint during rest. In contrast, pain from mechanically caused problems usually is relieved by rest, is better in bed, and often is least noticeable first thing in the morning. On physical examination, inflamed joints are swollen and diffusely tender. Mechanically damaged tissues usually are focally tender and not very warm.

Chronic inflammatory musculoskeletal problems that are not obviously infectious or metabolic usually involve immunopathologic pathways. Chronic inflammation can follow an injury that is slow to heal. Persistent inflammation of soft tissues that are in constant use, such as tendons and bursae, eventually can cause self-sustaining chronic inflammation and a proliferation of fibroblasts and macrophages that can lead to secondary mechanical problems, such as rupture of a tendon or a calcific deposit in a bursa.

The ability to move an injured part of the body after significant trauma does not exclude the possibility of fracture. Pain may not increase on use with an undisplaced impacted fracture. Radiographs are required to make this diagnosis, which should be suspected from the nature of the force involved and localized tenderness. Tendinitis and bursitis resulting from accumulated microtrauma are usually limited to a single structure.

The possibility of neoplasm must be included in the differential diagnosis, particularly when the patient's symptoms are localized and the physical signs do not fit the usual pattern for a musculoskeletal abnormality of mechanical or inflammatory origin. A history of symptom onset in association with trivial trauma is common in nontraumatic conditions. About 30% of patients with osteogenic sarcoma, a rapidly growing malignant bone tumor, report the onset of symptoms after trivial trauma. Fractures can result from trivial trauma to pathologically weakened bone; from infectious, congenital, or metabolic problems; or from metastatic cancer. If the trauma is inconsistent with the symptoms, the examiner must be suspicious of pathologically involved structural tissues and cognizant that infection mimics tumorous or metabolic involvement of bone. Infection of bones and joints does not require a break in the skin.

LOCALIZATION OF THE PROBLEM TO A PARTICULAR ORGAN

Next, the physician must identify the structure (organ) involved. Locating the source of the problem is critical to the use of causative therapy. Pain of musculoskeletal origin actually may be generated in organs distal to the pathology. Pain can be referred to more distant regions because of the sensory distribution of the nerves that innervate the pathologically involved part. Failure to recognize referred pain is a major cause of misdiagnosis.

The physician should be able to isolate the structures involved through physical examination of the musculoskeletal system. A knowledge of surface anatomy is crucial, and an anatomy text is a useful adjunct in the examining room. For example, direct tenderness over the lateral malleolus of the ankle suggests a fracture, whereas tenderness just distal, anterior, or posterior to the lateral malleolus suggests a ligamentous sprain. Combined palpation and range-of-motion testing often are useful to differentiate tendon and ligamentous injuries. Pathologic condition of the hip with referred pain to the knee can be identified by putting the hip and knee, separately, through a full range of motion to determine which joint motion provokes the symptoms. Osteomyelitis of bone near a joint can be differentiated from pyarthrosis (infection in a joint) by precisely locating the tenderness and determining whether gentle motion of the joint aggravates the pain.

With an appropriate physical examination, differentiation of the pain's origin—from joints, bones, or soft tissues and muscles—should be possible. Imaging studies are helpful to confirm the diagnostic conclusions of the history and physical examination but should not be used as the primary means of diagnosis.

ORIGINS OF MUSCULOSKELETAL PAIN

Physicians often are inclined to use radiographs, computed tomography, magnetic resonance imaging, bone scanning, and other imaging procedures to screen patients with musculoskeletal complaints. They assume that the diagnosis can be made on the basis of these studies. Individual structures show up well. Harried practitioners often believe that such technology is a superb substitute for the history and physical examination. This philosophy has led to many therapeutic disasters.

Artifacts of normal aging are common and are difficult or impossible to visually differentiate from pathologic conditions. The pathophysiology of most musculoskeletal pain cannot be demonstrated by imaging. Musculoskeletal pain is caused by inflammation or swelling of periarticular soft tissues, by muscle spasm, or by increased interosseous venous pressure. None of this is visible on imaging studies. It takes 10 to 14 days for bone infection to become visible on radiographs. Joints with arthritis or arthrosis can appear normal on radiographs for years. Increased fluid in the joint (effusion) from synovitis can be seen on radiographs, but it is identified better in most joints by a careful physical examination. The correlation between musculoskeletal pain and radiographic images is poor.

Natural tissue remodeling occurs with aging. Some manifestations are bulging, thinning, and rupture of intervertebral disks; softening and fibrillation of articular cartilage; attrition of knee meniscal cartilages, soft tissue, and fat; and osteopenia and bony remodeling. These processes affect everyone and usually do not cause symptoms. Other changes seen on imaging may have caused symptoms at one time but are no longer painful; a previous pathologic condition leaves anatomical artifacts that are not associated with the patient's present symptoms. A diagnosis based solely on imaging studies can lead to misdirected therapy.

Similar difficulties are common when joint arthroscopy, particularly of the knee, is performed in the absence of an adequate history and physical examination, routine radiographs, and laboratory studies. Considerable arthroscopic surgery of the knee may be inappropriate, focusing on artifactual and age-related changes of articular cartilage and menisci that never have been or no longer are symptomatic. In some cases, arthroscopic surgical procedures work to the detriment of the patient, accelerating osteoarthrotic change.

To avoid diagnostic and therapeutic pitfalls, the findings from radiographic imaging and interventional procedures must be interpreted in context with the patient's complaints and physical examination. Before therapeutic intervention is attempted, all the data must be collected and must fit together pathophysiologically.

ARTHRITIS VERSUS ARTHROSIS

In evaluating joint complaints, arthritis and arthrosis must be differentiated if causative therapy is to be recommended. Arthritis is caused by inflammation of the synovium, the lining of the joint cavity. A general list of such problems appears in [Table 168.1](#) and includes conditions resulting from infections, chronic immunologic responses, and metabolic abnormalities causing chemical irritations. Arthrosis is created by a mechanical problem of the joint, such as traumatic injury or cumulative microdamage. Inflammation of the synovium in arthrosis always results from intra-articular sulfated proteoglycan and articular cartilage and bony debris.

In early arthritis and arthrosis, no radiographic changes can be seen, and "baseline" radiography probably is of little benefit. Later in the inflammatory or degenerative process, radiography is associated with loss of cartilage space (joint-space narrowing) as the articular cartilage disappears. In arthritis, the bone surrounding a joint is osteopenic, and bony erosions associated with synovial inflammation are common. In arthrosis, the bones tend to be normal or more dense than normal. Subchondral

bony sclerosis is evident, and osteophytes almost always are present.

In recommending causative therapy, arthrosis must not be thought of as a primarily inflammatory condition, even though its symptoms (pain and joint stiffness) frequently result from the secondary synovial inflammation. The unfortunate term for this condition, *osteoarthritis*, suggests an inflammatory cause. For the purposes of causative therapy, it is best to think of the condition as *osteoarthrosis*.

A SYSTEMATIC APPROACH TO LOW BACK PAIN

The treatment of low back pain is a persistent problem in medical practice and is discussed in detail in [Chapter 171](#). Low back pain can be acute and self-limiting or chronic and refractory. Causative therapy is difficult to apply because the diagnosis is so challenging. Psychogenic overlay is common, and entire professional groups have been organized to treat the symptoms without addressing the underlying cause. The results of the physical examination in such patients can be nonspecific and can change from day to day.

Healers of low back pain by manipulation usually can relieve the patient's symptoms temporarily. Spinal manipulation interrupts paraspinal muscle spasm, a common reason for pain. No data suggest that spinal manipulation "rearranges" any tissue. Spinal manipulation can effect a cure only when the problem is strictly muscle spasm. If there is a persistent underlying pathologic condition, such as spondylosis, osteoarthrosis, spinal instability, disk herniation, or neurapraxia, symptoms usually recur. Occasionally, spinal manipulation aggravates symptoms.

In evaluating patients with low back pain, two important determinations should be made. The first is whether the pain is primarily muscular in origin. Muscular pain results from muscle spasm and can be caused by a partially torn muscle, bone or joint pathologic lesion, or neurapraxia of the spinal roots. Ninety-five percent of all cases of acute low back pain are the result of pulled muscles. The muscles of the back are torn when they are contracted and the patient moves suddenly, stretching them. The symptoms of a spinal muscle tear can be acute and incapacitating. It is useful to think of the condition as a "charley horse" of the paraspinal muscles. It doesn't last more than a few days.

The diagnosis of a torn paraspinal muscle or muscles is made by a history and physical examination. Lifting of a heavy object usually is not the inciting factor. Rather, the most common onset is from reaching or bending to pick up a smaller object or a sudden motion in another direction, as when trying to keep a carried object from falling. The entire back goes into spasm. There is no localizing tenderness; the whole back is tender and the pain is incapacitating. These muscle tears are self-limited and improve within 1 or 2 weeks. Rest is not mandatory for healing.

After the possibility of a torn paraspinal muscle (i.e., acute low back strain) is ruled out, the physician must determine whether the back pain is mechanical or neurogenic in origin. Mechanical problems such as vertebral fracture can occur, particularly in postmenopausal women. The pain associated with this is acute, well localized, and associated with characteristic radiographic findings. In the case of a pathologic fracture (e.g., a vertebral body fracture with a metastasis from a lung tumor or a fracture in a thin malnourished woman with a long-standing malabsorption syndrome), the trauma may have been as mild as putting on underwear. In contrast, damage to intervertebral ligaments or dislocation of the spine requires high-velocity trauma, such as being thrown out of a car or off a horse.

Mechanically caused low back pain, from spondylosis or arthrosis of the intervertebral facet joints, is common in middle-aged and older persons. It is the most common cause of chronic low back pain with radiation to the lower extremities in males in these age groups. Sometimes there is no low back component to the pain. Spinal instability can result from congenital and developmental problems. Symptoms of claudication (pain and cramping in the buttocks or below that occurs during walking and is relieved by rest) imply stenosis of the spinal canal and frequently are arthrotic in cause. In such cases, arterial claudication of the lower extremities must be ruled out.

Neurogenic pain is associated with the clinical signs of neurapraxia: motor weakness, sensory loss, and reflex diminution. It is not appropriate to make a diagnosis of neurogenic pain on the basis of pain alone without these physical findings. Neither the nature of the pain (e.g., sharp, dull) nor its pattern of radiation differentiates reliably between mechanical and neurogenic causes. Acute ruptured disks are rare, but chronic ruptured disks are common and frequently asymptomatic. Bulging intervertebral disks are normal with aging. Magnetic resonance imaging evidence of an old ruptured disk in a patient with low back pain radiating to the lower extremities may be a false-positive finding. Treatment of persistent low back pain with surgical excision of previously ruptured disks in the absence of objective signs of neurapraxia usually is ineffective.

The cause of low back pain remains an enigma because the spine is buried within muscle, making it impossible to palpate each spinal component individually. It is difficult to determine which structure of the spinal complex is involved through physical examination. All that can be done is to isolate the spinal segment that is the source of the symptoms by localized tenderness. The history and physical examination should indicate whether the pain is mechanical or neurogenic in origin. Magnetic resonance imaging and computed tomography are capable of demonstrating the entire spinal and neurologic anatomy, but these findings must be consistent with the history and physical examination before a causative diagnosis can be made. Advanced imaging studies should be performed only after a presumptive diagnosis has been made, based on the history, physical examination, and x-rays.

Psychogenic overlay may potentiate musculoskeletal symptoms, especially because physical disability has become a socially acceptable way to hide from harsh reality. In the case of psychogenic musculoskeletal problems, complaints are vague and generalized, are unrelated to activity or time of day, and wax and wane unpredictably. The diagnosis is made by history in the absence of objective physical signs. It is unfortunate that costly advanced imaging techniques frequently are used to ensure that nothing has been overlooked. Instead, careful social histories should be obtained to elicit those factors in patients' lives that can precipitate such pain, often without their awareness. Primary care physicians see many such patients. The diagnosis should not be one of exclusion, but should be made on the basis of a consistent history and physical examination.

CHAPTER 169: APPROACH TO PATIENT WITH PAIN IN ONE OR A FEW JOINTS

ALISA E. KOCH

[Approach to the Patient and Presentation](#)
[Laboratory Studies and Diagnostic Tests](#)
[Differential Diagnosis](#)
[Strategies for Optimal Care](#)

APPROACH TO THE PATIENT AND PRESENTATION

Most patients with joint disorders present with symptoms of monoarticular arthritis (pain and swelling of a single joint), which creates a diagnostic challenge for clinicians. Some of these disorders, such as septic arthritis, require immediate attention and possible hospitalization. The clinician is initially faced with the problem of localizing the pain to the joint itself or surrounding structures.

In contrast to what happens with arthritis in which pain can be elicited on active motion of the joint, patients with tendinitis or bursitis often present with local tenderness with active motion on one side of the joint. Pain of the biceps tendon, for instance, can be elicited by direct palpation of the tendon itself. Identification of a septic bursitis is particularly important, because it is critical not to introduce microorganisms into the joint by performing an arthrocentesis through the infected area.

Soft tissue infections can masquerade as arthritis. For instance, perirectal abscesses may be referred to the sacroiliac joint. Psoas abscesses may manifest as hip pain. Fever and the acute onset of symptoms with normal synovial fluid findings suggest nonarthritic processes. Computed tomography or magnetic resonance imaging may be helpful in diagnosing these conditions.

Bone pain results from involvement of the periosteum or marrow, which contains sensory nerves. Bone pain may result from fractures, malignancy, infiltrative processes, or new bone formation. Typically, bone pain is elicited by tenderness to palpation of the involved periosteum or pain on weight-bearing. Often, minimal pain is elicited while performing active range-of-motion exercises of a nearby joint. Radiographs of the involved areas may be helpful if the process is long-standing.

Neuropathic pain is due to irritation of a peripheral nerve and may radiate to a joint. Carpal tunnel syndrome, or compression of the median nerve, may radiate to the wrist or even to the elbow. Neuropathic pain often occurs at night and follows the distribution of the involved nerve. Percussion over the median nerve at the wrist may result in tingling in the nerve distribution (first four digits) in patients with carpal tunnel syndrome (Tinel's sign). Generally, the distribution of the pain is not localized to the nearby joint. Nerve conduction velocities may be useful in distinguishing this type of pain.

Compartment syndromes can occur when locally increased pressure occurs in a closed muscle compartment and compromises vascular and neuromuscular function. These syndromes may arise with limb trauma, ischemia, and physical exertion. Typically, patients with compartment syndrome present with severe pain (particularly on stretch of the muscles in the compartment), muscle weakness, and altered sensation in the distribution of the nerves coursing through the compartment. These syndromes can occur in the thigh, buttocks, hand, forearm, and arm. Treatment is aimed at minimizing neurologic deficits and often involves surgical intervention.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

After a thorough history and physical examination to determine the presence of monoarticular arthritis, initial laboratory evaluation should include a complete blood with differential count, urinalysis, hepatic and renal function tests, and serum uric acid. If infection is likely and the patient is febrile, blood cultures should be obtained. The white count is often elevated, and a left shift is seen in the differential count in cases of septic arthritis. If the clinician suspects gonococcal arthritis, then genital, oral, anal, and blood cultures should be obtained because synovial fluid cultures for *Neisseria gonorrhoeae* are positive in less than 25% of cases. Hyperuricemia is suggestive of gout, but does not establish it. Similarly, normouricemia does not rule out gout. It is important for the patient to have normal or near-normal renal function if a nonsteroidal anti-inflammatory medication is prescribed, as in the case of pseudogout.

Perhaps the most useful test for a patient with joint pain is *synovial fluid aspiration*, with culture and crystal analysis. In nongonococcal bacterial arthritis, the synovial fluid cultures are positive in 95% of cases. These tests can generally be performed using a few drops of synovial fluid. If enough fluid is available, a white cell count should be obtained. Synovial fluid findings in some common causes of monoarticular arthritis are found in [Table 169.1](#). In addition to the white cell count, the percentage of neutrophils is high in those with acute inflammatory and septic forms of arthritis, but low in those with noninflammatory forms of arthritis. Synovial fluid glucose values are low in patients with inflammatory and septic forms of arthritis, but not in those with noninflammatory forms of arthritis. The more the sample resembles pus, the greater the urgency to determine whether infectious or crystalline disease is the cause of the effusion.

Condition	Color/Characteristics	Viscosity	WBC/mm ³	PMNs (%)	Glucose Concentration	Crystals
Noninflammatory arthritis						
Trauma	Clear to turbid, straw to red	High	<1000, many RBC	<25	Normal	Negative
Osteoarthritis	Clear yellow	High	0-2000	<25	Normal	Negative
Inflammatory arthritis						
Rheumatoid	Cloudy yellow	Low	10,000-150,000	>50	Low	Positively birefringent crystals
Gout	Cloudy yellow to milky white	Low	10,000-150,000	60-70	Low	Negatively birefringent crystals
Recurrent arthritis	Cloudy yellow	Low	1,000-50,000	60-70	Low	Negative
Richter's syndrome	Cloudy yellow	Low	1,000-50,000	60	Low	Negative
Septic arthritis						
Tuberculous arthritis	Turbid, purulent	Low	10,000-50,000	50-60	Very low	Negative
Bacterial arthritis	Turbid, purulent	Low	10,000-150,000	70	Very low	Negative

*Septic fluid cultures are positive in gonococcal arthritis, 20% to 25% of the culture are positive. PMNs, polymorphonuclear leukocytes; WBC, white blood cells; RBC, red blood cells; BSC, white blood cells.

TABLE 169.1. SYNOVIAL FLUID FINDINGS IN SOME COMMON CAUSES OF MONOARTICULAR ARTHRITIS

Radiographs are useful in helping establish the diagnosis of the cause of joint pain. Even if the radiographs are normal, the initial studies serve as a baseline for future examinations. Linear cartilage calcification can be seen in chondrocalcinosis, suggesting that pseudogout may be the diagnosis. Medial joint space narrowing of the knee is often seen in patients with osteoarthritis. Patients with osteochondritis dissecans may present with sclerotic lesions separated from the surrounding bone by a radiolucent line. Periarticular osteopenia, joint space narrowing, and marginal bony erosions may suggest an inflammatory process such as rheumatoid arthritis. Destructive bony changes may indicate a chronic infectious arthritis such as that seen with tuberculosis or fungal disease. Alternatively, tumors may result in bony destruction.

Radionuclide scans may be used to search for a hidden site of infection. In some instances, computed tomography or magnetic resonance imaging may be useful. In compartment syndromes, these tests may help establish the diagnosis. In mechanical injury, such as a meniscal tear of the knee, the latter examinations can indicate the site of damage, thus helping make the diagnosis.

If chronic destructive changes are present on x-ray or if the patient continues to have a recurrent hemarthrosis or undiagnosed condition, a synovial biopsy may be indicated. This biopsy may be performed blind, during an open surgical procedure, or through an arthroscope. Recently, office-based arthroscopy often replaces the need for an open surgical procedure. The synovial sample should be examined for routine histology and also sent for culture. A biopsy is often useful in diagnosing tumors as well as chronic fungal or tuberculous arthritis.

DIFFERENTIAL DIAGNOSIS

After the clinician has determined that the patient does not have a nonarticular process, he or she should ask several key questions.

Is the arthritis chronic or acute? Pain that occurs over minutes suggests an internal derangement, trauma, or fracture. *Is the arthritis truly monarticular?* It is important to rule out additional joint involvement, such as may occur in migratory polyarthralgias, since this may signal a noninfectious cause such as rheumatoid arthritis.

Once the clinician has determined that the condition is indeed a monarticular arthritis, it is important to determine whether the arthritis is inflammatory or noninflammatory (Fig. 169.1). The American College of Rheumatology has recently proposed guidelines for the workup and therapy of monarticular arthritis. Often, the best way to determine this is to perform an arthrocentesis and synovial fluid analysis.

FIGURE 169.1. The flowchart shows the steps in determining whether monarticular arthritis is inflammatory or noninflammatory.

EVIDENCE LEVEL: A. Reference: Guidelines for the initial evaluation of the adult patient with acute musculoskeletal symptoms. American College of Rheumatology Ad Hoc Committee on Clinical Guidelines. *Arthritis Rheum* 1996;39:1–8.

If the synovial white blood cell count is over 5,000 cells per cubic millimeter, one should suspect an inflammatory arthritis. Synovial fluid Gram stain and culture should be performed to rule out infection. Joint sepsis can lead to rapid destruction of cartilage and bone and can be the harbinger of a severe systemic infection. An infected joint is often red, swollen, and extremely tender upon active motion. Large joints, particularly the knees, are more likely to be infected than are small joints. Often, the patient experiences fever, rigors, and leukocytosis. Patients at risk for joint sepsis include those on systemic immunosuppressive agents, such as glucocorticoids. Also at risk are patients with immunodeficiency syndromes and those who are drug abusers. Inflammatory arthritis, such as rheumatoid arthritis, particularly in sites of joint prostheses, can predispose patients to septic arthritis. Patients with penetrating joint trauma also may develop joint infections. Staphylococcal and streptococcal infections are among the most common causes of bacterial monarticular joint infections in otherwise healthy adults. Synovial fluid Gram stains are positive in approximately 50% to 75% of cases of nongonococcal arthritis. Gram-negative microorganisms, such as *Escherichia coli*, are found in patients with underlying medical conditions such as sickle cell anemia, drug abuse, or immunosuppressed states.

The most common infectious arthritis of sexually active adults is due to *N. gonorrhoeae*, which produces septic arthritis of the small joints of the hands, wrists, elbows, knees and ankles, and rarely the axial skeletal joints. This form of arthritis is often accompanied by a rash, tenosynovitis, and sterile synovial fluid cultures. Tuberculous and fungal arthritis often present with a more indolent course.

If the patient gives a history of recurrent, self-limited attacks in the same joint, a crystal-induced arthritis is likely. Monosodium urate crystals are found in those with acute gout. These intracellular, needle-shaped, negatively birefringent crystals can be visualized by polarized microscopy in 95% of gouty joint effusions and even in some asymptomatic joints by polarized microscopy. Patients with acute gout generally present with pain so severe that “even the bed sheets hurt my joints.” Approximately 75% of patients with acute gout have inflammation of the great toe, *podagra*, during the course of their disease. Often, the joints of the lower extremities are involved. Typically, patients are middle-aged and may have recent predisposing factors such as alcohol intake, diuretic use, vigorous exercise, or recent surgery.

Calcium pyrophosphate dihydrate deposition disease may manifest as acute monarticular arthritis (*pseudogout*). This form of crystalline arthritis often is associated with osteoarthritis. The knee joint is the most commonly affected joint. Attacks, although self-limited, tend to last longer than gout attacks, often resolving within 1 week after initial symptoms. The diagnosis is made by visualizing positively birefringent, rhomboid-shaped crystals within white blood cells under polarizing microscopy.

Hydroxyapatite deposition disease, due to the deposition of basic calcium phosphate crystals, presents a particular diagnostic problem. Affected patients often are on dialysis and present with shoulder pain and immobility, called the *Milwaukee shoulder*. These calcium phosphate crystals cannot be seen by polarized microscopy, but must be visualized with an electron microscope or under light microscopy using Alizarin red stain.

If the synovial fluid culture and crystal examination are both negative, a physician should consider other disorders. Patients with rheumatoid arthritis present with an acute monarticular arthritis in approximately 20% of patients. This disease generally becomes polyarticular with time. Seronegative spondyloarthropathies, which include ankylosing spondylitis, psoriatic arthritis, enteric-associated arthritis, and Reiter's disease can manifest as monarticular arthritis. Patients with rheumatoid arthritis as well as those with seronegative spondyloarthritis complain of morning joint stiffness.

If the synovial fluid white blood cell count is under 2,000 cells per cubic millimeter, the patient probably has a noninflammatory monarthritis. If the synovial effusion is bloody, the physician should consider joint trauma, villonodular synovitis or other tumors, and coagulopathies.

Joint trauma is a major cause of acute joint pain and swelling. The synovial effusion can be bloody. The physician must be certain to rule out fracture. If a patient presents with hemarthrosis, the clinician should consider tumors, particularly pigmented villonodular synovitis. Patients with coagulopathies, such as hemophilia and von Willebrand's disease, also present with hemarthroses.

If the synovial effusion is nonbloody with a white blood cell count under 2,000 cells per cubic millimeter, osteoarthritis should be considered in patients over 40 years of age. These patients may also present with monarticular pain without joint effusion. In younger patients, internal derangements and mechanical lesions, particularly of the knee, may occur and result in a joint effusion. Torn menisci or ligaments or loose bodies may result in clicking, locking, or “giving out” of the knee. Symptoms are often elicited by testing the knee joint for stability. Osteochondritis dissecans occurs in children and in young adults when a fragment of articular cartilage and subchondral bone demarcates, often separating from the surrounding bone and cartilage. These patients may present with decreased joint motion, an effusion, and a limp.

STRATEGIES FOR OPTIMAL CARE

If the physician's suspicion for bacterial infection is high, a course of antibiotic therapy is warranted immediately. The antibiotic regimen should be adjusted, since the culture and sensitivity results are available in about 2 days. Patients with gonococcal arthritis generally respond well to parenteral antibiotics such as penicillin. Usually, a 1- to 2-week course of intravenous antibiotics is administered, with the likelihood of a clinical response in days. Oral antibiotics are generally administered for a week after intravenous antibiotics. If gram-positive cocci are identified, a penicillinase-resistant antibiotic should be given parenterally for 2 to 4 weeks. Most forms of infectious arthritis require daily drainage of the purulent synovial effusions.

If uric acid crystals are found on synovial aspiration, either colchicine or a nonsteroidal anti-inflammatory agent can be given acutely. Nonsteroidal anti-inflammatory agents are also helpful in the treatment of pseudogout and osteoarthritis. If the physician's suspicion for infection is high, a nonsteroidal anti-inflammatory agent should not be used initially because it may mask the patient's febrile response.

Therapeutic surgical approaches may be warranted in some cases of joint pain. If closed drainage of an infected joint cannot be accomplished, open drainage is

necessary. Arthroscopic surgery can aid in the repair of mechanical joint problems, such as knee meniscal tears and ligamentous injuries.

[History and Physical Examination](#)
[Laboratory Studies and Diagnostic Tests](#)
[Differential Diagnosis](#)
[Diagnosis of Inflammatory Rheumatic Diseases](#)

Musculoskeletal symptoms are among the most common bases for patients to consult a physician. Up to 20% of visits to a doctor are for musculoskeletal complaints. Most patients who present with a musculoskeletal complaint have a self-limited condition, such as a transient tendinitis or bursitis, or a limited chronic noninflammatory condition, such as fibromyalgia or osteoarthritis, leaving a sense that musculoskeletal problems are not life-threatening or do not require an urgent intervention. However, a minority of patients have connective tissue inflammatory rheumatic diseases, such as systemic lupus erythematosus, scleroderma, polymyositis, vasculitis, and may have a poorer prognosis than that of patients with stage IV Hodgkin's disease and other lymphomas or with three-vessel coronary artery disease. Accurate identification of progressive inflammatory rheumatic diseases may be difficult, particularly because laboratory tests and imaging procedures often are not definitive. Therefore, the approach to a patient with generalized musculoskeletal pain is governed by the following principles:

1. The definitive diagnosis in most patients generally emerges primarily from the history and physical examination. Laboratory tests, radiographs, and other imaging procedures are generally used to confirm the diagnosis, and only a limited number are needed.
2. The most common cause of generalized musculoskeletal pain is fibromyalgia, found in 5% of women over the age of 50. Patients with fibromyalgia are often easily recognized, and elaborate evaluations to rule out specific diseases are generally unproductive and are often harmful to a patient's reassurance that there is no life-threatening disease.
3. At least 50% of patients who present with an inflammatory arthritis, even those who meet criteria for rheumatoid arthritis, have a self-limited process rather than a progressive disease. The distinction between self-limited or progressive generally is accomplished primarily by observation of the patient's clinical course rather than by extensive laboratory or other tests.
4. Blood tests in patients with rheumatic diseases are often not precise guides to a diagnosis, unlike those tests for many diseases, such as a blood glucose in diabetes or a serum creatinine in renal failure. Blood tests identify higher probabilities of certain diagnoses, such as rheumatoid arthritis or systemic lupus erythematosus, but usually are not definitive. For an individual patient, probabilities are often only marginally useful, because of a high rate of false-positive and false-negative results.
5. False-positive results, in which blood tests are abnormal in people who do not have a disease, are common in tests for rheumatic diseases. For example, more than 5% of people in the population have a positive antinuclear antibody (ANA) test, elevated uric acid level, or *Borrelia burgdorferi* antibodies found in Lyme disease, and most who have a positive test do not have systemic lupus erythematosus, gout, or Lyme disease, respectively. This phenomenon would not be a clinical problem if blood tests were performed only in patients who had clinical evidence of these diseases. However, because musculoskeletal symptoms are so common and evoke considerable uncertainty in many physicians, blood tests are performed on a large number of persons whose clinical picture is uncertain, but does not suggest a specific rheumatic disease. Many, if not most, people who are given labels of systemic lupus erythematosus, gout, or Lyme disease do not have these diseases, but merely a positive laboratory test.
6. The problem of false-negative laboratory test results, in which patients have a certain disease but a normal laboratory test, is less common, but nonetheless leads to important errors in diagnosis. For example, 20% of patients with rheumatoid arthritis do not ever have rheumatoid factor in their serum, and 50% of patients whose sera eventually become positive for rheumatoid factor have negative results during the first 6 months of disease. Therefore, a test for rheumatoid factor is least useful when it is clinically needed most—in early disease—when the patient may have either a self-limited inflammatory polyarthritis or progressive rheumatoid arthritis. Most positive rheumatoid factor tests are performed in patients known to have rheumatoid arthritis, resulting in an unnecessary or inappropriate medical expense.
7. Abnormal findings on radiographs, bone scans, or magnetic imaging resonance scans are common, particularly in most people over age 40. However, these findings often do not explain the patient's musculoskeletal symptoms. Symptoms of fibromyalgia, soft tissue rheumatism, back pain, and other conditions are frequently incorrectly attributed to osteoarthritis, often on the basis of common radiographic abnormalities. By contrast, radiographs may be minimally abnormal in early rheumatoid arthritis at a time when aggressive intervention might provide optimal therapeutic benefit.
8. The importance of establishing a precise diagnosis to direct treatment usually is not as urgent for patients with subacute and chronic musculoskeletal pain as for those with acute diseases. In patients with generalized musculoskeletal pain, it is usually possible to easily recognize fibromyalgia, soft tissue rheumatism, osteoarthritis, or other noninflammatory conditions and thereby be reasonably certain that a patient does not have progressive inflammatory connective tissue disease, such as rheumatoid arthritis, systemic lupus erythematosus, vasculitis, subacute bacterial endocarditis, or polymyositis, which are seen in a very small minority of patients with generalized musculoskeletal pain.
9. A rheumatology consultation is often the most cost-effective test for diagnosis of a person with musculoskeletal pain, provided that it does not include irrelevant extensive laboratory and imaging data.

HISTORY AND PHYSICAL EXAMINATION

A systematic, careful history and physical examination can effectively be used to determine whether patients have a noninflammatory condition such as soft tissue rheumatism, osteoarthritis, or fibromyalgia, or an inflammatory condition such as a self-limited inflammatory polyarthritis, progressive inflammatory articular or nonarticular condition, or connective tissue disease ([Table 170.1](#)). Diffuse connective tissue diseases, such as systemic lupus erythematosus, scleroderma, polymyositis, and vasculitis, are rare, defined as occurring in fewer than 1 in 2,000 persons. A physician in general practice may expect to see only two or three cases of some of these diseases during a 40-year career. Affected patients should generate an appropriate sense of urgency, but an expert rheumatologist is often more helpful than extensive testing.

TABLE 170.1. CLASSIFICATION OF RHEUMATIC DISEASES BASED ON THE LIKELIHOOD OF BEING SEEN IN A GENERAL PRACTICE SITUATION

LABORATORY STUDIES AND DIAGNOSTIC TESTS

A diagnosis at the first visit may be difficult in some patients, even for the experienced rheumatologist, and it may be reasonable to observe a patient over two or more visits to establish a diagnosis. Laboratory tests should be used sparingly. A screening complete blood count and erythrocyte sedimentation rate may provide clues to the presence of inflammatory diseases, although all tests may be normal in the presence of inflammatory disease, as discussed in the text that follows.

DIFFERENTIAL DIAGNOSIS

NONINFLAMMATORY CAUSES OF GENERALIZED MUSCULOSKELETAL PAIN

A classification of patients with musculoskeletal symptoms ([Table 170.1](#)) is based primarily on information elicited from the history and physical examination.

Localized Musculoskeletal Soft Tissue Conditions

The most common cause of acute musculoskeletal symptoms is soft tissue rheumatism, including tendinitis, bursitis, and back pain, which tends to be localized. In some patients, soft tissue rheumatism may progress to a chronic, significant, but localized, long-term problem.

Osteoarthritis

Osteoarthritis is probably the most common form of structural damage manifested as arthritis. Osteoarthritis is usually localized to one or a few joints, but it may be generalized. A diagnosis of osteoarthritis should include radiographic evidence of joint space narrowing and joint destruction.

Fibromyalgia

Fibromyalgia is the most common basis for generalized musculoskeletal pain. Although referred to as a diagnosis of exclusion by most textbooks, if the physician has solid reasons for making the diagnosis ([Table 170.2](#)), it is not necessary nor desirable to perform exhaustive laboratory tests to rule out possible diagnoses with a lower probability of being the problem.

History
Widespread pain not limited to joints; may be "all over"
Frequent report of other somatization problems, such as headaches, gastrointestinal distress, chest pain, dyspnea
Dysfunctional sleep
Physical Examination
Muscle spasm
Tender points
No joint swelling or limited motion
Radiographs
Osteoarthritis seen, but nonelective, especially for the cervical spine
Laboratory Tests
Generally normal, but 5% may have positive results for antinuclear antibody and elevated uric acid levels
Treatment
Frank discussion
Pain is real
Exercise program
Better sleep
Drugs: tricyclic antidepressants, nonsteroidal antiinflammatory drugs, avoid narcotics

TABLE 170.2. DIAGNOSIS AND TREATMENT OF FIBROMYALGIA

Two important problems are associated with the "rule-out" approach. First, common abnormalities such as radiographic osteoarthritis of the cervical spine, found in most people between the ages of 30 and 60 years, or a positive ANA or Lyme disease test (i.e., antibodies to *B. burgdorferi*), found in 5% of the population, may lead to an erroneous diagnosis. Second, the process of extensive testing often renders it difficult to reassure a patient that there is no progressive or life-threatening disease.

The differential diagnosis of fibromyalgia may be difficult, in part because this condition may mimic early rheumatoid arthritis. The absence of specific signs of rheumatoid arthritis can be used to exclude this diagnosis, although for some patients, it is unclear whether the primary problem is early rheumatoid arthritis or fibromyalgia, in which case an "n of 1" clinical trial of treatment for one disease sequentially with the second is sometimes helpful in establishing a diagnosis and helping the patient.

Other Noninflammatory Articular Conditions

Localized myofascial syndromes are similar to fibromyalgia but may be seen in specific joint areas, such as the shoulder, knee, and hip. These conditions are manifested by pain without a recognized structural source of the pain.

Reflex sympathetic dystrophy syndrome manifests as diffuse and burning pain involving a single extremity, although this condition may be bilateral. Patients generally have a history of trauma preceding development of this syndrome.

Amyloidosis is a relatively unusual infiltrative rheumatic disease in which infiltration involving the hands, wrists, elbows, and shoulders may mimic the swelling of synovitis.

Hypertrophic pulmonary osteoarthropathy presents with diffuse musculoskeletal pain in persons with pulmonary neoplastic or infectious disease. The pain is generally pronounced in the distal bones of the limbs near the wrists and ankles. The digits may or may not be clubbed. Radiographs reveal periosteal separation. A search for pulmonary disease is indicated in patients with this clinical or radiographic finding.

Sickle cell crises may lead to joint effusions, most commonly involving the knees and elbows with a noninflammatory synovial fluid.

INFLAMMATORY MUSCULOSKELETAL CONDITIONS

The term "inflammatory" refers to conditions characterized by a host response that involves release of cytokine mediators from polymorphonuclear leukocytes. The presence of an inflammatory condition is established by clinical evidence of a systemic disease, including the presence of widespread symmetric polyarthritis and morning stiffness, often accompanied by constitutional symptoms of fatigue and malaise. The physical examination indicates joint tenderness, swelling, or other signs of inflammation.

Self-Limited Inflammatory Arthritis

Classification criteria established by the American College of Rheumatology for rheumatoid arthritis are useful to identify relatively homogeneous patients for research studies. However, many persons who manifest an inflammatory arthritis and meet these criteria do not have a progressive disease. In population surveys, only about 25% of persons who meet criteria for rheumatoid arthritis have evidence of disease 3 to 5 years later. Most self-limited inflammatory polyarthritis is resolved within 6 months of onset.

Acute-phase reactants such as the erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP) determinations may be elevated in both self-limited and early progressive inflammatory arthritis. The presence of rheumatoid factor suggests a higher likelihood of a progressive disease, but the absence of rheumatoid factor does not exclude rheumatoid arthritis, because rheumatoid factor is not found in more than 50% of persons with rheumatoid arthritis during the first 6 months of their disease. Radiographs are usually normal or show minimal soft tissue swelling and osteopenia for patients with both self-limited or progressive inflammatory arthritis.

Patients with self-limited inflammatory arthritis may have a variety of diagnoses, such as postinfectious arthritis, reactive arthritis, inflammatory polyarthritis, or benign polyarthritis of the elderly. Note that patients who meet criteria for rheumatoid arthritis may have a self-limited process rather than a progressive disease. Often, the exact cause remains unknown. One of the primary reasons to establish a viral cause is to assess the strong probability of a self-limited course. Patients who are

improving significantly when first seen are likely to have a self-limited form of inflammatory arthritis.

If a polyarticular arthritis persists longer than 30 or 60 days, it is likely that some form of progressive arthritis such as rheumatoid arthritis is present, rather than a reactive or postinfectious inflammatory polyarthropathy. Observation over 30 to 90 days is usually the most effective and most cost-effective approach to differentiate self-limited from progressive inflammatory arthritis.

Progressive Inflammatory Arthritis

Rheumatoid Arthritis

The prototypical form of inflammatory arthritis is rheumatoid arthritis, characterized by symmetric polyarthritis, morning stiffness, and systemic symptoms of fatigue, malaise, and weight loss. The physical examination in early-stage disease indicates tenderness, swelling, and limited motion of joints, most commonly the metacarpophalangeal and proximal interphalangeal joints of the hand, wrists, and feet. Other signs of inflammation such as erythema and warmth are uncommon.

Early rheumatoid arthritis is characterized by disease activity, seen as tenderness and swelling, which leads to long-term tissue damage, seen as joint deformity and radiographic malalignment, and poor long-term outcomes, such as work disability and premature death. Inflammatory activity is reversible and amenable to drug therapies, whereas long-term damage is generally irreversible and not affected by drug therapy. Unfortunately, inflammation may persist indefinitely, and therefore treatment to reduce inflammation is needed even after damage is present.

Crystal-induced arthritis such as gout is described as the great masquerader because it can mimic any rheumatic disease, including rheumatoid arthritis. The classic podagra of acute gout affects the great toe, although gout may affect the ankle or any joint. A search for tophi in the ear and urate nodules, which may mimic rheumatoid nodules, is valuable. The definitive test for the diagnosis of gout is identification of negatively birefringent uric acid crystals in the synovial fluid, but this test often is not done or is done poorly. Gout tends to be overdiagnosed in persons with elevated uric acid levels and musculoskeletal symptoms on the basis of other rheumatic conditions. The diagnosis of gout also is missed in some persons who have normal uric acid levels.

Calcium pyrophosphate deposition disease, also called *pseudogout*, is often seen in the knee or ankle, commonly in a hospitalized patient with recent surgery for an acute illness. This disease is also diagnosed definitively on the basis of positively birefringent crystals in synovial fluid.

Seronegative Spondyloarthropathies

Seronegative spondyloarthropathies include ankylosing spondylitis, Reiter's syndrome, the arthritis of inflammatory bowel disease, and some forms of psoriatic arthritis. These conditions are characterized by inflammation involving the entheses (i.e., structure that connects a tendon to bone), in contrast to the synovitis seen in rheumatoid arthritis, which involves a generalized synovial inflammation. This distinction is important in at least two respects. First, patients with enthesitis generally do not experience constitutional symptoms at a level as high as patients with synovitis, as seen in rheumatoid arthritis. Second, patients with enthesitis are more likely to respond to indomethacin than to other nonsteroidal anti-inflammatory drugs (NSAIDs), but patients with synovitis are more likely to respond to salicylates than to other NSAIDs.

Patients with seronegative spondyloarthropathies are likely to have the HLA-B27 antigen on the surface of their lymphocytes. Although this phenomenon is considerably helpful in understanding pathophysiology, it is of little clinical usefulness because 6% of normal persons are HLA-B27-positive. In fact, only one of three persons who have back pain and are HLA-B27-positive have ankylosing spondylitis.

Ankylosing spondylitis is manifested primarily by involvement of the spine, with limited motion detected on physical examination. The radiograph may indicate syndesmophytes of the spine, culminating in the appearance of a "bamboo spine." In more severe cases of ankylosing spondylitis, hip, knee, shoulder, and other large joints may become involved, often before a person reaches the age of 20 years.

Reiter's syndrome classically includes the triad of arthritis, urethritis, and conjunctivitis. Various manifestations of "incomplete" Reiter's syndrome have been described, including an oligoarthritis involving several large joints, such as one or both ankles, wrists, or knees. Reactive arthritis has been associated with several enteric bacterial entities, including *Yersinia*, *Helicobacter*, *Shigella*, and *Salmonella*. Reiter's syndrome and reactive arthritis may occur as a single episode, as infrequently recurring episodes, or as a chronic arthritis.

Psoriatic arthritis is probably second to rheumatoid arthritis in prevalence among the progressive inflammatory rheumatic diseases. It may be seen in several forms, including a symmetric polyarthritis, which appears almost identical with rheumatoid arthritis; an asymmetric oligoarthritis, which appears similar to Reiter's syndrome; and a severe deforming type called *arthritis mutilans*.

The *arthritis associated with inflammatory bowel disease* tends to be nondestructive, involving large joints of the knees and ankles.

Rheumatic fever is a relatively unusual condition that was thought to be disappearing, but it has reappeared in some small epidemics.

Lyme disease is an important new rheumatic disease described over the last two decades. It begins with a rash known as *erythema chronicum migrans*, and the disease may progress to produce arthritis, carditis, and neurologic inflammation. The diagnostic test involves identification of antibodies to *B. burgdorferi* in the serum. As is the case in most rheumatic diseases, this diagnostic test is overused, if not abused. Fewer than 1 of 100 individuals with a positive Lyme antibody titer actually have evidence of Lyme disease.

The *arthritis of sarcoidosis* often produces a characteristic picture of swelling in the ankles. In classic cases, erythema nodosum, hilar adenopathy, and fever may be manifestations of sarcoidosis, but arthritis may occasionally be the primary manifestation of sarcoid. Although sarcoid arthritis usually is self-limited, in some cases, it may be relapsing and may lead to cystic destructive lesions of bone.

Polyarthritis and Fever

Theoretically, all forms of inflammatory arthritis may include fever. However, fever is unusual in rheumatoid arthritis and most forms of polyarthritis and raises a concern about infection. Fever is seen in several forms of arthritides: juvenile rheumatoid arthritis (Still's disease), subacute bacterial endocarditis, septic arthritis involving a bacterial, mycobacterial, or fungal cause. Fever may accompany a postinfectious or reactive arthritis, vasculitis, systemic lupus erythematosus, and several unusual diseases, including familial Mediterranean fever, Behcet's disease, Kawasaki's disease, and pyoderma gangrenosum. Familial Mediterranean fever generally appears in childhood with brief episodes of fever, arthritis, and abdominal and pleuritic pain.

Vasculitis may present as a polyarticular arthritis that appears similar to rheumatoid arthritis. Other manifestations of vasculitis are generally seen, including palpable purpura, postprandial abdominal pain, and mononeuritis multiplex.

Diffuse Connective Tissue Diseases

Diffuse connective tissue diseases are rare diseases seen in fewer than 1 in 2,000 patients. They can be life threatening and are associated with as high a 5-year mortality rate as in many types of cardiovascular or neoplastic diseases.

Systemic lupus erythematosus is a multisystem disease, which may include a rash, serositis, Raynaud's phenomenon, oral ulcers, pleuritis, pericarditis, anemia, leukopenia, thrombocytopenia, and possible evidence of pulmonary, cardiac, gastrointestinal, renal, or central nervous system involvement. More than 90% of these patients have arthritis. The arthritis tends to mimic that of rheumatoid arthritis but is not as destructive. The natural history of systemic lupus erythematosus with renal, cardiac, or central nervous system involvement includes mortality rates of 50% over 5 years. Considerable evidence suggests preservation of renal function and longer survival with use of cytotoxic therapy, rendering a sense of urgency in making a correct diagnosis.

The diagnosis is established through a positive ANA test, but, as previously noted, many persons have positive high-titer ANA tests and no evidence of a multisystem

disease. A positive ANA test result may be considered analogous to an enlarged lymph node. In most persons, this finding is not of any pathologic significance (e.g., benign hyperplasia), although it may indicate a relatively urgent problem (e.g., lymphoma) in a few. A biopsy is required to establish the pathologic significance of an enlarged lymph node. By contrast, the pathologic significance of a positive ANA test result is established by a careful history and physical examination.

In most cases, a physical examination generally reveals evidence of multisystem disease. Antineutrophil cytoplasmic antibodies (ANCA) may be detected in patients with Wegener's granulomatosis and other forms of vasculitis, but clinical evidence from the history and physical examination remains the primary guide to diagnosis and therapy.

Polymyositis and dermatomyositis are diseases that present with muscle weakness. A useful finding is evidence that a patient cannot arise from a chair without help, which indicates a problem affecting joints, muscles, or nerve structures. The diagnosis can be made on the basis of a triad of elevated muscle enzymes (creatinine phosphokinase and aldolase), a muscle biopsy, and electromyographic results. Polyarthritis is unusual but may be a component of the initial presentation, although muscle weakness emerges as the primary symptom.

Scleroderma may manifest as generalized musculoskeletal pain. Patients occasionally have diffusely puffy hands, but may have pain associated with skin thickening and contractures. Scleroderma is diagnosed on the basis of a physical examination by an experienced physician. A skin biopsy is rarely needed to make the diagnosis.

Generalized Inflammatory Musculoskeletal Syndromes Without Arthritis

Polymyalgia rheumatica is seen almost exclusively in persons older than 50 years of age who have discomfort of the hip and shoulder girdles. Constitutional symptoms of malaise, fatigue, and weight loss are often seen, similar to findings in patients with early rheumatoid arthritis. The diagnosis is established by the finding of a substantially elevated ESR, usually at least 50 mm per minute.

DIAGNOSIS OF INFLAMMATORY RHEUMATIC DISEASES

Figure 170.1 summarizes information used to establish a diagnosis for a patient with musculoskeletal pain. It outlines the four major sources of data, including the history and physical examination, laboratory tests, radiographs and imaging procedures, and synovial fluid analysis. A box surrounds the most important information required to establish a diagnosis.

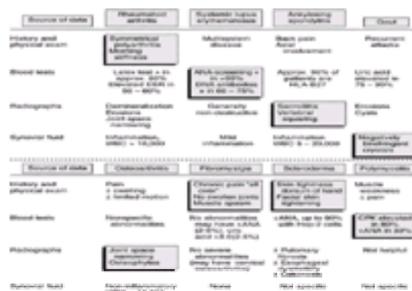

FIGURE 170.1. Diagnosis of rheumatic diseases. Clinical data from different sources, with the source of the most valuable data boxed. ANA, antinuclear antibodies; WBC, white blood cell count.

EVIDENCE LEVEL: C. Expert Opinion.

The top half of Figure 170.1 includes the four most prominent inflammatory rheumatic diseases—rheumatoid arthritis, systemic lupus erythematosus, gout, and ankylosing spondylitis. Critical data for a diagnosis of rheumatoid arthritis is derived from the history and physical examination; for systemic lupus erythematosus, from a laboratory test, the ANA, although with a requirement for multisystem disease; for gout, from a synovial fluid examination; and for ankylosing spondylitis, from a radiograph. Figure 170.1 may clarify why the practice of ordering a battery of blood tests and radiographs is rarely definitive in establishing a diagnosis of an inflammatory rheumatic disease or other inflammatory condition.

The bottom half of Figure 170.1 includes two other common conditions seen in usual practice, osteoarthritis and fibromyalgia, and two unusual diseases, scleroderma and polymyositis. As noted previously, a diagnosis of osteoarthritis should require a radiograph to document joint space narrowing and other changes. Fibromyalgia is seen in about 3% of the population. In certain cases, even experienced rheumatologists have difficulty differentiating fibromyalgia from inflammatory musculoskeletal disease, but distinguishing these problems is generally not resolved through laboratory tests. Patients with fibromyalgia often have more extensive testing than patients with rheumatoid arthritis, systemic lupus erythematosus, or other potentially life-threatening rheumatic diseases.

The diagnosis of scleroderma can generally be established from a physical examination. Similarly, polymyositis includes a test of creatine phosphokinase and muscle biopsy, but, again, patients in whom this diagnosis is considered should be seen by a rheumatologist. The clinician might consider an early referral to a specialist in patients in whom a problem appears complex. The author suggests that the primary basis for referral to a rheumatologist should involve symptoms that remain unexplained or with poor response to therapy, rather than laboratory tests or radiographs.

A COST-EFFECTIVE APPROACH TO DIAGNOSIS

The clinician seeing a patient with musculoskeletal symptoms seeks to identify an accurate diagnosis. In view of the likelihood that laboratory and radiographic data will not be helpful in many, if not most cases, a cost-effective approach is outlined here.

The history provides most of the important information. A thorough review is not possible, and a simple set of questions generally suffices:

1. Is there pain, stiffness, swelling, limited motion, or weakness in any joint, bone, muscle, or supporting structure, or unusual fatigue? (If the answer is “no,” no further musculoskeletal history is needed.)
2. Where is the pain (localized or widespread)?
3. How severe is the pain, stiffness, or swelling?
4. When is the discomfort most difficult (early morning, after activities, late in the day)?
5. How did the pain, stiffness, or swelling begin (acute or chronic)?

Widespread pain and report of morning stiffness suggest fibromyalgia or an inflammatory disease. Inflammatory arthritis is suggested by polyarthritis, pain localized to joints, and the absence of diffuse symptoms. Fibromyalgia is suggested by poor sleep, generalized pain with absence of localization to joints, and a history of somatization in other organ systems, such as irritable bowel syndrome, headaches, and floppy mitral valve.

A brief physical examination can identify most problems of the musculoskeletal system. Examination of affected areas should involve palpation for tenderness and swelling and a check of range of motion; generally, the examiner can serve as a “control.” Arthritis is suggested by pain in all motions of a joint. Tendinitis or bursitis is suggested by point tenderness and pain in only one plane of motion. Fibromyalgia is suggested by diffuse muscle spasm and tender points. A brief, gentle “squeeze” of each proximal interphalangeal (PIP) and metacarpophalangeal (MCP) joint requires no more than 30 seconds and can detect subtle inflammation, as seen in early rheumatoid arthritis.

The patient can be asked to squeeze the finger of the examiner to assess hand strength and then move his or her arms above the head, behind the back, and in a

wing-span position to test for shoulder flexion, abduction, and internal and external rotation. The trapezius muscle should be palpated for spasm and tender points characteristic of fibromyalgia. Clinicians may not recognize that a patient cannot walk when the patient is evaluated only on an examining table or a bed; therefore, it is worthwhile to include asking the patient to arise from a chair without holding on to anything and walk to a wall. A patient who cannot arise from a chair without holding on to a support has an abnormality, which may exist in the joints, muscles, or nerves. It is more important to recognize an abnormality than to characterize it precisely.

Laboratory tests should be ordered sparingly. A complete blood count is often as helpful as any specific "rheumatology" test. If evidence points to rheumatoid arthritis, a test for an acute-phase protein, such as an ESR or a C-reactive protein, and a test for rheumatoid factor may be ordered. If systemic lupus erythematosus is suggested on the basis of multisystem disease, an ANA should be ordered; an ANA with no multisystem disease will yield 5% or more false-positive results. If the patient is acutely ill, a urinalysis, chemistry profile, anti-DNA test, and a test for complement, C3 and C4, or CH50 (but only one of the three) should be ordered.

If the patient is weak and might have polymyositis, testing of creatine phosphokinase and aldolase is indicated. In cases of suspected vasculitis, an ANCA may be ordered, although diagnosis and treatment are determined by clinical criteria. In case of recurrent miscarriages or clotting tendencies, an anticardiolipin antibody is appropriate. Ordering additional subsets of ANAs or rheumatology screens is discouraged.

In general, the radiographic investigation of most patients with arthritis requires only an anteroposterior view of joints. The lateral and oblique views are included routinely in radiologic evaluation and are appropriate for possible fractures, but are rarely useful in screening joints for arthritis other than the knee. Radiographs should be limited to affected areas, although an elderly patient with hip or knee pain should have two radiographs, an anteroposterior view of the pelvis and an anteroposterior view of both knees standing, to screen for severe osteoarthritis, which may be more effectively treated by means of total joint replacement surgery than with any medication.

If a radiographic explanation for widespread musculoskeletal pain is sought, a set of four radiographs may include (a) an anteroposterior view of the hands and wrists, (b) an anteroposterior view of the pelvis, (c) an anteroposterior view of both knees standing, and (d) an anteroposterior view of both feet. If these radiographs do not point to a specific diagnosis, such as rheumatoid arthritis or gout, it is most unlikely that extensive imaging procedures will prove helpful. In most situations, even this radiographic evaluation is beyond what is needed; this is especially true in the diagnosis of back pain.

CHAPTER 171: APPROACH TO THE PATIENT WITH BACK PAIN

GLEN S. O'SULLIVAN

[History](#)
[Age](#)
[Medical Review](#)
[Pain](#)
[Occupational and Social Factors](#)
[Physical Examination](#)
[Diagnostic Studies](#)
[Clinical Conditions](#)

Lower back pain is one of the most common reasons for medical visits. Two of every three people have suffered from lower back pain at some time in their lives; the annual incidence is 2% to 5%. Lower back pain is becoming a growing problem in industrialized countries, accounting for up to \$50 billion spent per year in the United States alone. Ninety percent of that budget is spent on 10% of those patients, who have persistent chronic pain lasting longer than 3 months. In 85% of cases, an underlying cause for lower back pain is not established.

A detailed history and examination will help determine the presence or threat of neurologic compromise. The clinical conditions of herniated disc with sciatica and spinal stenosis have a clearly different set of initial signs and symptoms, natural history, and treatment course compared with backache alone. Infections, tumors, or fractures must be ruled out before settling on a diagnosis related to aging or degenerative processes. As physicians, we must diagnose and treat our patients with lower back pain in a cost-effective manner without adding to morbidity. This chapter focuses on the key elements of the history and physical examination, when and what type of imaging studies are appropriate, and specific common clinical conditions, such as backache (sprain/strain), herniated discs, cauda equina syndrome, spinal stenosis, and spondylolisthesis.

HISTORY

The initial encounter with a patient with lower back problems may be the most important factor affecting his or her outcome. The patient should be observed for any nonorganic signs suggestive of psychological problems or underlying psychosocial disorders. Care must be taken to prevent the patient from falling into the sick role or becoming dependent on the medical system for medications, excessive tests, permission not to perform work, and continual therapy. It is important to instill confidence and foster attitudes of independence from the outset. The cause for lower back pain is rarely known; a precise symptom-related diagnosis might be made only 10% to 15% of the time. The patient may become confused by conflicting diagnoses and different terms used by various caregivers, including chiropractors, osteopaths, medical doctors, and physiotherapists.

AGE

The age of the patient at the onset of lower back symptoms is critical. When adults complain of back pain, the diagnosis and management may be difficult and frustrating because of subjective complaints, the coexistence of degenerative diseases, and the frequent involvement of psychological, medical, and legal compensation issues. In contrast, children and adolescents complain of back pain infrequently. When they do complain, the history and clinical examination usually show objective findings, a differential diagnosis becomes clear, and therapeutic interventions are often effective. The diagnosis and treatment of back pain in young patients is generally a much more rewarding experience for the physician. Typically, one-third of children with back pain have spondylolysis or spondylolisthesis, one-third have Scheuermann's disease, and about 20% of patients have either tumors or spinal infections. Older patients are more likely to have underlying neuropathy, degenerative disease, metabolic disorders, or malignancy. Adolescents with back pain frequently fall midway between adults and children, reflecting socioeconomic and cultural factors.

MEDICAL REVIEW

A thorough general medical review is particularly important in older patients. Metabolic and systemic conditions that might play a role include infection, tumors, diabetes mellitus, osteoporosis, pancreatitis, and hyperthyroidism. It is imperative to rule out any neurologic deficit, particularly changes in bowel or bladder habits, such as urinary retention with overflow incontinence. Perianal paresthesia or pain is a clue to the symptoms of possible cauda equina syndrome. A history of trauma or transient paresis is important, particularly in elderly patients with underlying osteoporosis.

PAIN

The onset, duration, quality, severity, and location of the pain are all important in a detailed history. One should distinguish between the ubiquitous human experience of acute lower back pain lasting up to 6 weeks, from which 80% of patients usually recover, and chronic pain, which persists beyond 3 months and evades specific diagnosis in most cases. It is essential to differentiate mechanical lower back pain from nonmechanical pain that is present at rest. The red flags that may indicate a serious problem warranting a more thorough diagnostic evaluation include pain at rest, no positional relief, night pain, fever, weight loss, history of malignancy, and morning stiffness lasting more than 30 minutes. The nonmechanical serious causes of lower back pain are very rare, accounting for only 1% of cases; they comprise infection, tumors, and fractures. When they are suspected, a comprehensive workup is necessary, including erythrocyte sedimentation rate, serum protein electrophoresis, radiographs, bone scan, and, possibly, further imaging with magnetic resonance imaging (MRI) or computed tomography (CT).

Chronic pain lasting longer than 3 months should alert the treating physician to reconsider the initial diagnosis. Workers' compensation, job dissatisfaction, previous lower back disorders, and personal problems, including psychosocial issues and narcotic addiction, all contribute to the disability of lower back pain. Other causes for mechanical back pain include degenerative disc disease with a collapsing spine, resulting in an instability pattern, such as scoliosis or spondylolisthesis. Systemic causes include seronegative spondyloarthritis, metabolic bone disease, osteoporosis, osteomalacia, fibromyalgia, and polymyalgia rheumatica.

Besides quantifying the intensity of the pain and the accompanying degree of disability, it is important to determine the location and the relative ratio of back pain to leg pain. A pain diagram and visual analog scale can be helpful. Patients often describe a dull, deep pain radiating into the posterior buttock and thigh. This is typically referred pain and occurs in structures with the same mesodermal origin. Neurocompressive pain can be felt as sharp, lancinating pain radiating below the knee into the foot. This radicular pain can be associated with radiculopathy, weakness, and reflex changes in the distribution of a specific nerve root due to mechanical compression or inflammation of the nerve root itself. True sciatica or radicular pain develops in a small percentage (~1%) of patients with lower back pain. Extrinsic nerve compression stemming from intrapelvic tumor or aneurysms, trochanteric bursitis, pathologic conditions of the hip, neuralgia paresthetica, diabetes, and piriformis syndrome, in addition to disc herniation, should all be considered in the differential diagnosis of sciatica. Claudication pain can take the form of diffuse fatigue or heaviness in the legs developing in the context of ambulation, relieved by rest, and accompanied by a forward flexed stooped change in position of the lumbar spine (see [Table 171.1](#)).

Symptoms	Possible Cause
Sharp, narrow band of pain radiating below the knee	Herniated disc
"Stepping stone" numbness	Referred pain, nonorganic pain
Night pain unrelieved by positional change	Tumor
Swing, chills, sweats	Infection
Long-standing back pain unrelieved by activity	Discospondylitis
Pain increased by sitting	Discogenic disease
Long pain unrelieved by walking, unaffected by standing, best relieved by sitting	Neurologic claudication
Chronic spinal pain in patient with unrelieved job or home life	Stress
Global pain	Nonorganic pain
Referred stiffness that improves as day goes on	Inflammatory arthritis
Unrelieved, throbbing lumbar pain	Arterioartery
Mediocranal pain radiating to buttock	Pancreatitis, gastrointestinal reflux disease, peptic ulcer disease
Back pain in athletic teenager	Epilepsy, pyelitis, discogenic disease, spondylolysis, or spondylolisthesis
Back pain starting to a specific injury	Strain or sprain

TABLE 171.1. LOWER BACK PAIN: SYMPTOMS AND CAUSES

Efforts should be made to distinguish between vascular and neurogenic provocation and to assess the possibility of peripheral neuropathy due to other disease processes (Table 171.1 and Table 171.2). Typically, the difference between neurogenic claudication symptoms and vascular claudication symptoms is that neurogenic pain is severe in the leg after walking a short distance. The patient is forced to stop and bend forward or sit. Pain due to vascular compromise, on the other hand, may occur at rest or in the standing position; this pain usually dissipates quickly. A noninvasive vascular workup may be necessary.

Diagnosis	Symptoms	Signs
Degenerative spinal stenosis	Diffuse leg(s) pain aggravated by standing and walking downhill	Limited lumbar range of motion, weakness only after exercise
Hip disease (degenerative)	Groin or buttock anterior thigh pain	Limited hip rotation range, especially loss of internal rotation
Peripheral vascular disease	Distal leg pain relieved by standing	Check for bruits and diminished pulses
Diabetic neuropathy	Glove and stocking diffuse distal bilateral burning pain	Reflexes diminished or absent
Tumor or infection	Constant pain at rest, location of pain varying	Weight loss, increased ESR, positive bone scan

From Murray, LH. Lumbosacral spine. In: Southwestern Orthopaedic Review Course, 1989 (52, with permission.)

TABLE 171.2. SPECIFIC DIAGNOSES ASSOCIATED WITH BACK PAIN

OCCUPATIONAL AND SOCIAL FACTORS

It is important to establish whether the patient was injured on the job. A detailed account should be made of the tasks performed and the mode of injury. The patient may be unhappy with the work environment. The accident process may provide a solution, especially when injury compensation can provide income. These patients may have a poor prognosis for recovery. Social factors that should be taken into consideration include excessive alcohol intake, use of drugs, and cigarette smoking, which can all adversely affect the prognosis.

PHYSICAL EXAMINATION

GENERAL EXAMINATION

The patient's vital signs should be assessed, to rule out fever indicating infection. Skin involvement may suggest an underlying systemic illness, such as psoriasis, inflammatory bowel disease, or sarcoidosis. Pathologic lesions of the eye include conjunctivitis (Reiter's syndrome) or iriditis (ankylosing spondylitis). Lymphadenopathy or thyroid dysfunction may be evident from the neck examination. Costovertebral inflammation or cardiac disease can induce back pain. Limitation of chest expansion to less than 2 inches in women and 3 inches in men suggests ankylosing spondylitis. A detailed abdominal examination is important, to rule out visceral causes for back pain, including gallbladder disease, abdominal masses, and the presence of aneurysms. A rectal exam and a fecal Hemoccult test should be performed on all men over the age of 50, to rule out prostatic and bowel disease. A detailed neurologic assessment for perianal function, including rectal tone, also must be made.

EXAMINATION OF THE SPINE

One should examine the patient from a distance to see how easily the patient moves and whether he or she requires assistive devices, such as walking canes, lumbosacral orthoses, or corsets. Patients should be examined standing, kneeling, and sitting as well as bending forward. With the patient standing, abnormalities in posture should be noted, including the presence of scoliosis and asymmetry in the shoulder and pelvic height as well as spinal range of motion. The spinous processes, sacroiliac joints, and paraspinal musculature should be palpated to look for signs of muscle spasm or atrophy. The patient should be examined walking on toes, walking on heels, and tandem walking (sequential heel to toe walking as by a tightrope walker). To test for sacroiliac joint movement, place one thumb on the posterior superior iliac spine and the other on the sacrum, and ask the patient to flex the ipsilateral hip. If the iliac spine moves up, the sacroiliac joint is fixed.

The character of motion is as important as the range of motion of the lumbosacral spine. An increase in pain while bending to the ipsilateral side (lateral flexion) suggests facet articular disease or a herniated disc lateral to the nerve root. The same symptoms on the contralateral side suggest a herniated disc medial to the nerve root. The tender points of fibromyalgia should be assessed quickly. The amount of pressure applied is the amount that begins to induce a pain sensation on one's own ulnar styloid process, usually about 4 kg (10 lb of force). One should look for control points (the lateral forehead and dorsal surface of the lower midforearm). If the patient overreacts to these control points, one should suspect psychogenic pain. If these control points are not painful, proceed to palpate the fibromyalgia tender points. Coccydynia frequently can arise in association with lower back pain felt to be due to pain in a sacral coccygeal joint.

POSITIONAL EXAMINATIONS

Kneeling

Ask the patient to kneel on a chair facing the backrest, to test for the S1 ankle (Achilles tendon) reflex. An absent ankle reflex is not necessarily a pathologic sign; it must be compared with the contralateral limb. To test for malingering, have the patient kneel on a chair, grasp the chair back with one hand, and reach forward and down to the floor with the outside hand. Acute flexion of the knee and hip does not aggravate spinal disease. If the pain is exacerbated, malingering might be considered. Other findings related to nonorganic causes for lower back pain include increased lower back pain with light pressure on the vertex of the skull, exacerbated lower back pain with motion of the lumbosacral spine and pelvis in unison (holding the patient's torso and pelvis and rotating both together), and diffuse nondermatomal global glove and stocking pain or numbness involving one or more extremities.

Sitting

Have the patient sit on a chair with feet on the floor and apply steady downward pressure on the dorsum of the foot. Genuine weakness of the muscles supplied by the L5 nerve root is felt as uniform resistance to pressure that is gradually and smoothly overcome. The patient who feigns weakness will often resist the pressure briefly and then suddenly let go. This is described as *collapsing strength*. With the patient seated, begin manual muscle testing for motor strength and control, first of the upper extremities and then of the lower extremities, including hip flexion, extension, abduction and adduction; knee flexion and extension; and ankle dorsiflexion, plantar flexion, inversion, and eversion. Examine radicular and cortical dermatomal function and responses and deep tendon reflexes.

Bending Forward

With the patient flexed at the waist over the examination table, one should inspect the spine for asymmetry and palpate the sacroiliac joint, ischiatic tuberosities, and sciatic notch. Look for tenderness, masses, and defects. When patients with radiculopathy lie supine, certain maneuvers tighten the sciatic nerve and further compress an inflamed lumbar root against a herniated disc or bony spur. These maneuvers are generally termed "tension signs" or a straight-leg-raising test. The examiner slowly elevates the supine patient's leg by the heel with the knee straight. The test result is considered positive if leg pain occurs below the knee, not just in the back and buttocks. The pain is aggravated by dorsiflexion of the foot. The reliability of this test may be age dependent. With the patient in a supine position, test hip range of motion—the straight-leg-raise test. Look for hamstring tightness by measuring the popliteal angle with the leg elevated and palpate the pelvis. Hip

abduction and extension and the femoral nerve stretch test (L3 and L4 nerve root irritation) are best done with the patient in a lateral position.

DIAGNOSTIC STUDIES

A challenge to the physician in the assessment of lower back pain is to select tests that can lead to the correct diagnosis at the lowest cost and morbidity. Because of the high potential for false-positive results, these tests are not performed for screening purposes and should not be used in an isolated context for making management decisions, particularly surgery. Treatment options must be based on a careful assessment of the history and clinical findings and interpretation of imaging studies.

ROENTGENOGRAPHY

Plain x-ray films are useful for surveying the bony structures of the spine, particularly such instability patterns as spondylolisthesis, scoliosis, fractures, tumors, and infections. They do not display the soft tissues, including the neuroelements and discs. The presence of degenerative changes, such as disc space narrowing with vacuum phenomenon, traction osteophytes, and end-plate sclerosis, though common, do not correlate well with clinical symptoms. Radiographs should be performed early in patients younger than 20 or older than 50 who are experiencing pain. When spondylolysis is suspected, oblique views are helpful. To follow the progression of spondylolisthesis, a spot lateral view of the area in question, usually the L5-S1 segment, may be better than lateral views of the entire lumbar sacral spine. An anteroposterior view of the pelvis should incorporate both hips, to rule out pathologic hip conditions.

COMPUTED TOMOGRAPHY AND MYELOGRAPHY

CT scans provide the greatest information about osseous lesions and less specific information about periosseous soft-tissue swelling. They can be particularly helpful in evaluating spondylolysis, infection, or tumor associated with bony destruction. Using myelography in conjunction with CT allows for more precise viewing of pathologic anatomy and enhances diagnostic accuracy.

MAGNETIC RESONANCE IMAGING

MRI is an excellent noninvasive imaging method for the lumbar spine. MRI best evaluates soft tissue, such as the disc, nerve roots, thecal sac, and paraspinous soft tissues. It is especially helpful when spine infection or soft-tissue tumors are suspected. Gadolinium contrast enhancement helps distinguish recurrent disc herniations from scar tissue.

NUCLEAR MEDICINE STUDIES

The technetium Tc 99m bone scan can be very helpful in elucidating any underlying sinister cause for back pain, including occult spondylolysis, primary and metastatic tumors, discitis, and vertebral osteomyelitis as well as some visceral causes for back pain. The single-photon-emission CT scan has been particularly helpful in detecting occult spondylolysis.

ELECTRODIAGNOSTIC TESTING

Electromyography is performed by placing needles into muscles to determine the integrity of the nerve supply. Results can establish impaired nerve transmission to a specific muscle and can isolate the involved nerve root. Fibrillation potentials confirm the presence of denervation. This study can help distinguish radiculopathy from other neuropathic conditions that cause leg pain, such as diabetes. Both electromyography and nerve conduction studies are helpful when the correlation between clinical signs and imaging is equivocal.

CLINICAL CONDITIONS

Several conditions can show initial symptoms of lower back pain. The following are the most common and important conditions that are seen in primary practice settings.

BACK SPRAIN/STRAIN

The vast majority of people with lower back pain without radiation into the lower extremities have what is described as a back strain, or lumbago. Following an acute back injury, 70% of patients are significantly improved after 2 weeks, and 90% recover within 2 to 3 months. Typically, the patient has no findings of nerve root compression (sciatica). Physical examination may pinpoint both lumbar tenderness and muscle spasms, with restricted range of motion of the lumbosacral spine. These attacks can vary in intensity. Radiographic findings are usually normal; these tests should be obtained only if the patient does not improve over a course of 2 to 3 months or if the patient is younger than 20 or older than 50 and has history or physical examination findings that suggest a nonmechanical, serious cause for lower back pain.

The Agency for Health Care Quality and Research convened a 23-member multidisciplinary panel to establish basic guidelines for treatment of acute back pain in adults. They defined an acute lower back problem as limitation of activity stemming from symptoms in the lower back and/or back-related leg symptoms of less than 3 months' duration. The guideline provided numerous conclusions about the safety and efficacy of current options for treating acute lower back pain in adults ([Table 171.3](#)).

Bed rest for more than 4 days may lead to debilitation and is not recommended.
Low-stress aerobic exercise can prevent debilitation due to inactivity during the first month of symptoms. Thereafter it may help return patients to the highest level of functioning.
Acetaminophen, NSAIDs, muscle relaxants, and opioid analgesics are all options.
Lumbar corsets and belts beneficial only when used prophylactically.
Manipulation can be helpful in patients without radiculopathy, but only within the first month of symptoms.
Epidural injections are an option only for short-term relief of radicular pain after conservative therapy.
Back schools in the workplace that offer worksite-specific education may be effective adjuncts.
Oral steroids and antidepressants are not recommended.
Transcutaneous electrical nerve stimulation is not recommended.
Spinal traction is not recommended.
Trigger point and facet joint injections are not recommended.

NSAIDs, nonsteroidal anti-inflammatory drugs.

TABLE 171.3. GUIDELINES OF THE AGENCY FOR HEALTH CARE QUALITY AND RESEARCH

A comprehensive treatment plan is important for these patients, not just in terms of addressing the acute situation but also for incorporating preventive measures. Initial treatment includes supportive measures to control pain, with the goal of early return to maximum function. The patient should not stay at bed rest for longer than 3 days, to avoid deconditioning. Medication used to treat lower back pain includes analgesics, anti-inflammatory drugs (occasionally for chronic pain), and such mood-altering medications as antidepressants. Short-term use of opiates is appropriate and is unlikely to lead to habituation or abuse. It is important to involve the patient in as active a program as possible in the early phases of management. The patient should start in a physical therapy program and be instructed in posture techniques ([Table 171.4](#)). In the early phases of acute pain, such passive treatments as heat, ultrasonography, manual manipulation, and mobilization techniques may be helpful, but ultimately the patient should be instructed in a stretching and conditioning program that can be performed at home as well as with the therapist ([Table 171.5](#)). The most common techniques are dynamic stabilization and the use of muscle-strengthening exercise equipment. All require instruction by trained therapists for maximal benefit. Each has a specific rationale, and a combination of these techniques may be beneficial ([Table 171.6](#)).

Standing
 Maintain good abdominal tone; keep abdomen flattened while standing.
 When prolonged standing is necessary, place one foot on a step for a few minutes.
 Wear cushion-soled shoes for prolonged standing.

Bending, lifting, carrying
 Bend at the knees not at the waist.
 Lift with the thighs (keep heavy objects centered close to abdomen).
 Flex knees while bending.
 When carrying heavy objects, turn with the feet, not by twisting the trunk.

Sitting and lying
 Sit on straight-backed, firm, supportive chair.
 Sit only for short periods.
 Sleep on back, with knees bent, or on side on a firm mattress.

^a Avoid prolonged standing, prolonged sitting, and improper lifting.

TABLE 171.4. POSTURE TECHNIQUES THAT HELP AVOID LOWER BACK PAIN^a

Most patients with back pain improve. If a back problem cannot be cured, function should at least be optimized.
 Imaging abnormalities are common in persons with and without back problems.
 Explain to the patient that "hurt" does not equal "harm." Back pain is common and does not necessarily signify a permanently impaired life.
 The key decision point in treatment is 6 weeks after injury. Back pain should spontaneously improve in this time. If improvement has not occurred, reassess the patient and refer him or her to an active physical therapy program, emphasizing functional restoration rather than pain relief.
 Reserve expensive imaging studies for those patients not responding to an active rehabilitation program or at risk of progressive neurologic compromise.
 Surgery is a last resort for most patients, considered only for one who has failed a good, active, functional restoration program or shows signs of progressive neurologic injury.

TABLE 171.5. GUIDELINES FOR TREATMENT OF A PATIENT WITH LUMBER SPINE COMPLAINTS

	Definition	Technique	Outcome
Witness program	With upright spine treatment, the patient reports benefits to muscular tone applied to the spine.	Careful analysis of the patient's symptoms, diagnosis, structural problems, in the vertebral column phenomena, pain source, toward the center of the spine is abolished with repeated exchange spinal movements. Consideration is a predictor of herniate condition with mechanical therapy and rehab. Determine the appropriate direction of the treatment.	Patent self-treatment program with diagnosis or general instructions and the present recurrent episode of back pain.
Dynamic stabilization	Develops adequate neuromuscular control of the lumbar spine to limit repetitive movements by generating muscular coordination, endurance, and aerobic fitness.	Spine based and functional training instruction in dynamic strength, flexibility, balance, proprioception, and trunk control.	Learned technique because voluntary and ingrained, leading to independence of the patient.
Collaboration with surgeon	Strength training improves neuromuscular control. Functional exercise equipment makes and facilitates unique target work for muscle groups (lumbar extension).	With the patient in a sitting position use all general equipment previously used. Patient and guest maintain standardized exercises that isolate the lumbar extension.	Treatment is complete when scientific strength testing confirms muscle function and strength has returned to normal or has reached a plateau.

TABLE 171.6. STRATEGIES TO IMPROVE BACK PAIN

If the symptoms do not resolve over a 12-week period, the treating physician should reconsider the diagnosis. Psychosocial issues, including narcotic addiction and workers' compensation, should be considered as possible causes of persistent back pain. After other causes of mechanical pain have been eliminated, such as degenerative disc disease, scoliosis, and spondylolisthesis, one must consider systemic causes in the differential diagnosis, such as seronegative spondylarthropathy, metabolic bone disease (osteoporosis, osteomalacia), fibromyalgia, and polymyalgia rheumatica. If the workup at this point generates negative results, it is important to keep in mind that a specific anatomic source is clearly identifiable in only 10% to 20% of patients with chronic lower back pain. The advice of a spine specialist should be sought if the patient suffers chronic lower back pain ([Fig. 171.1](#)).

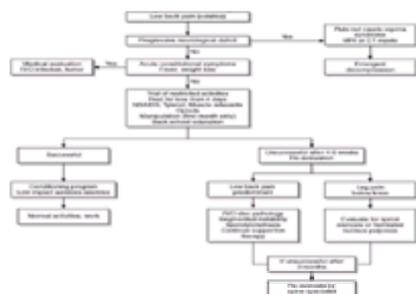

FIGURE 171.1. Algorithm for assessment of low back pain.
EVIDENCE LEVEL: B. Reference: Mooney V. Treating low back pain with exercise. *J Musculoskeletal Med* 1995;12:24–36.

HERNIATED DISC

True sciatica or radicular pain related to nerve root compression occurs in a small percentage of patients with lower back pain, roughly 1%. A herniated disc is defined as a herniation of the nucleus pulposus through the torn fibers of the annulus fibrosis. This takes place most often in the third and fourth decades of life. Eighty percent of cases arise at the L4-5 and L5-S1 levels, compressing the fifth lumbar and first sacral nerve roots, respectively. Typically, the patient has localized pain radiating down the leg in the distribution of the affected nerve root. The symptoms may be severe enough to prevent the patient from standing and walking and may be associated with loss of range of motion of the spine. A dynamic list away from the affected side is noticeable as the patient bends forward. The patient may avoid bearing weight on the extremity in an attempt to avoid stretching the sciatic nerve. A neurologic examination may detect findings of nerve root compression, including sensory, motor, and reflex changes ([Table 171.7](#)). The straight-leg-raise test is very important in eliciting nerve root irritation.

Disc space	L3-4	L4-5	L5-S1
Root compressed	L4	L5	S1
Reflex diminished	Knee jerk	No reflex	Ankle jerk
Motor weakness	Knee extension	Great toe dorsiflexion	Ankle plantiflexion
Sensory deficit	Medial ankle and foot	Dorsal foot at the first web space	Lateral foot
Pain	Anterior thigh	Posterior leg	Posterior leg

TABLE 171.7. RADICULAR SYMPTOMS AND SIGNS

MRI is the study of choice to determine the extent of disc herniation and the level affected. CT can be used alone or with myelography. The herniation may be either contained or extruded, with nuclear pulposus contents passing beyond the posterior longitudinal ligament or even sequestered completely free in the spinal canal. Ninety percent of patients respond to conservative efforts, usually an exercise program. Occasionally, a spinal epidural injection or selective nerve root block can help diminish the pain and allow further exercises to be performed. If radiculopathy persists, as occurs in 10% to 25% of cases, or if there is progressive neurologic compromise with increasing weakness, the patient may become a candidate for a surgical decompressive procedure. The surgical treatment of choice is microdiscectomy, involving a minimal incision and the use of a microscope to enhance visibility of the neurological tissues. The surgical success rate with this procedure is about 92%. There is a 10% incidence of recurrent herniation and a 10% to 15% incidence of ongoing disabling back pain.

CAUDA EQUINA SYNDROME

Only a small percentage of patients with lower back pain have cauda equina syndrome; the incidence is one in 10,000. One should inquire about changes in bowel or bladder habits. A large midline disc herniation may compress several roots of the cauda equina, resulting in lower back pain, bilateral motor weakness of the lower extremities, bilateral sciatica, saddle anesthesia, and even frank paraplegia with bowel and bladder incontinence. Patients with suspected cauda equina syndrome require immediate imaging, such as MRI or myelography. A missed diagnosis can have disastrous consequences. This is a surgical emergency. Spontaneous neurologic recovery has not been observed. Only surgery undertaken promptly can offer any hope of neurologic recovery.

SPINAL STENOSIS

Spinal stenosis is defined as a narrowing of the spinal canal. The mechanical pressure on the structures within depends on the rate and degree of narrowing. Typically, patients experience lower back pain or lower extremity symptoms in middle age or at older ages. Patients may describe a long history of nonincapacitating lower back pain. The onset of radicular symptoms or claudication often leads the patient to seek medical attention. Some patients describe a feeling of fatigue or weakness in the lower extremities with activities, particularly ambulation. The symptoms are relieved usually by sitting, squatting, or bending forward, maneuvers that optimize the lumbar spinal canal dimensions. Symptoms frequently are vague, and these elderly patients often have several systemic diseases. It is important not to overlook other coexisting causes, including vascular disease, peripheral neuropathy, and the presence of an occult neoplasm.

On physical examination, the patient may have minimal findings, which can change if the patient is stressed during the examination by engaging in repetitive push-ups or walking for a certain distance or period of time. The patient may also show signs of profound neurologic abnormalities. As stenosis progresses, symptoms occur even at rest and can be accompanied by muscle weakness, atrophy, and asymmetric reflex changes. If the symptoms are aggravated only dynamically, however, neurologic changes may not develop until after the patient is stressed. In clinical terms, this means that after the initial neurologic examination has been completed, the patient should walk in the hallway until he or she feels symptomatic. Repeating the neurologic examination at this point can help identify a focal deficit. Plain roentgenograms are often helpful in assessing spinal stenosis, pinpointing degenerative changes that can show intervertebral disc degeneration and facet degeneration. In addition to these films, MRI and CT scans can locate and quantify the degree of neurologic compression. If patients do not improve with conservative efforts, a surgical decompressive procedure might be considered. Usually the success rate is approximately 70%.

SPONDYLOLISTHESIS

Spondylolisthesis is defined as slippage forward of one vertebral body onto another (Fig. 171.2). The amount of displacement varies and has been graded from 1 (minimal) to 5 (severe). There are five types of spondylolisthesis, which can be differentiated with proper imaging techniques. A lateral radiograph of the lumbar spine can show the degree of forward displacement (percentage of slip) and the angular relationships between the lower lumbar vertebrae and the sacral vertebrae (angle of slip). The oblique views disclose the actual pars defect.

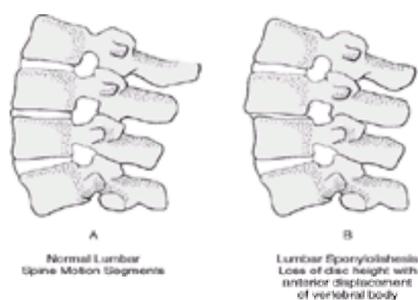

FIGURE 171.2. The most common form of symptomatic spondylolisthesis.

A child typically has symptoms of lower back pain, tight hamstrings, and exaggeration of lumbar lordosis, with a palpable step-off at the level of the slippage. A growing child may be at risk of progressive slippage and should be carefully monitored. A surgical spinal fusion and instrumentation procedure may be necessary if there is neurologic involvement or persistent pain or if progressive slippage occurs. Degenerative spondylolisthesis usually occurs in patients over the age of 60. These patients frequently have back pain or leg symptoms or symptoms suggesting spinal stenosis or neurogenic claudication. Plain radiographs show the degenerative process, with the loss of disc height and degenerative changes in the facet joints leading to the forward slippage (Fig. 171.2). An MRI study or CT myelogram will confirm the degree of spinal canal compromise. Most patients can improve with conservative efforts; depending on the symptoms and findings, however, surgery may be necessary. In that case, posterior spinal decompression is performed, with a concomitant stabilization, instrumentation, and fusion procedure across the affected level. The surgical success rate is about 70%.

CHAPTER 172: APPROACH TO THE PATIENT WITH ANERGY

ABBA I. TERR

[T-Cell Anergy](#)
[B-Cell Anergy](#)
[Testing Methods](#)
[Causes of Global T-Cell Anergy](#)
[Causes of Antigen-Specific Anergy](#)
[Therapeutic Induction of Anergy](#)

Anergy is the inability of the T or B lymphocyte to respond immunologically to an antigen or a bacterial superantigen, such as *Streptococcus pyogenes* erythrogenic toxin A or *Staphylococcus aureus* enterotoxins. In the normal immune response, the antigen is phagocytized and processed by the monocyte/macrophage, known as the antigen-presenting cell (APC). Antigen processing generates peptide fragments that are presented to the CD4⁺ T-cell receptor (TCR) in association with products of the major histocompatibility complex expressed on the APC surface. T-cell activation and clonal expansion also requires co-stimulating signals from the APC to the CD4⁺ T cell. The activated T cell then synthesizes and releases cytokines and expresses interleukin-2 receptors. The profile of the released cytokines determines the nature of the immune response. For example, a predominant interleukin-4 response that characterizes the helper T-cell subtype 2 cytokine profile favors IgE antibody production by B cells, which, in turn, leads to an allergic response to the antigen.

T-CELL ANERGY

T lymphocytes are rendered anergic in vivo by exposure of an antigen or an antigenic peptide fragment to the TCR without the co-stimulatory signals from the APC necessary for activation of the T cell. The resulting T-cell anergy is both peptide specific and major histocompatibility complex restricted. The anergic T cell, however, retains the ability to respond to mitogen and to interleukin-2. CD4⁺ and CD8⁺ T cells made specifically anergic to an antigenic peptide or to a bacterial superantigen fail to proliferate when stimulated with antigen or bacterial superantigen, do not produce interleukin-2 or interferon- α , and do not express interleukin-2 receptors.

B-CELL ANERGY

When occupied by an antigenic molecule, the B-cell receptor for antigen, like the TCR, activates the cell to cause differentiation and proliferation with ultimate production and secretion of specific antibody by the plasma cell, or it induces a state of specific tolerance to the antigen. The former scenario is the probable outcome for foreign antigens, and the latter is the preferred pathway for self-antigens. T cell–B cell interactions and the secreted cytokine profile of the activated T cell are important determinants of B-cell immunity versus anergy. Antigen-specific B-cell anergy is an important feature of theories that explain the normal tolerance to self-antigens. In vitro experiments show that immature cells in the B-lymphocyte lineage are the most susceptible to this phenomenon, and susceptibility is related to the preferential use of particular V_b gene families.

TESTING METHODS

Skin testing for the absence of delayed hypersensitivity to a standard panel of recall antigens is the procedure for detecting a state of global T-cell anergy (lack of T-cell immunity). The test antigens are selected on the basis of an expected high prevalence delayed skin hypersensitivity because of frequent natural exposure in the general healthy population. These usually include streptococcal, fungal, tuberculous, and vaccine antigens. The absence of delayed hypersensitivity in an adult to all antigens in such a panel would be presumptive evidence of T-cell immunosuppression.

The skin tests are applied to the volar surface of the forearm and read in 48 hours. There are two accepted procedures for performing these tests. The standard one is the intradermal injection of 0.1 mL of each antigen at separate skin sites at least 3 cm apart. This is the procedure known as the Mantoux test for tuberculosis. For large-scale epidemiologic studies, a prick test method often is used. In this case, a plastic device delivers eight superficial skin pricks for individual antigens simultaneously, according to a preset pattern.

CAUSES OF GLOBAL T-CELL ANERGY

CONGENITAL CELLULAR IMMUNODEFICIENCIES

There are three categories of congenital immunodeficiencies: B-cell (antibody) deficiencies, T-cell (cellular) deficiencies, and combined immunodeficiencies. Representative examples are shown in [Table 172.1](#).

B-cell immunodeficiency
Common variable immunodeficiency
Selective IgA deficiency
Selective IgG subclass deficiencies
X-linked hypogammaglobulinemia
Immunodeficiency with hyper-IgM
T-cell immunodeficiency
DiGeorge syndrome (congenital thymic aplasia)
T-cell deficiency with purine nucleoside phosphorylase deficiency
Chronic mucocutaneous candidiasis
Combined T-cell and B-cell immunodeficiency
Severe combined immunodeficiency disease
Wiskott–Aldrich syndrome (T-cell deficiency, eczema, and thrombocytopenia)
Nizelof syndrome (T-cell deficiency with abnormal immunoglobulin synthesis)
Immunodeficiency with ataxia–telangiectasia
Immunodeficiency with thymoma
Immunodeficiency with adenosine deaminase deficiency

TABLE 172.1. SELECTED CONGENITAL IMMUNODEFICIENCY DISORDERS

INFECTIONS

The anergy that occurs in patients infected with the human immunodeficiency virus is the best-known example of acquired arrest of immune system function caused by a viral infection. Skin testing with the panel of recall antigens described earlier in this chapter correlates inversely with the clinical status of the disease but even more closely with the peripheral blood CD4 cell count. Transient T-cell anergy may develop during the course of acute infectious mononucleosis. Cellular immunity is depressed significantly, but transiently, during acute measles infection. Both skin test reactivity and in vitro lymphocyte activation by antigens and mitogens reflect this state and should suggest the possibility of reactivation of dormant tuberculosis or other infections.

MALNUTRITION

Protein-calorie malnutrition of dietary origin or from chronic debilitating disease reduces the number of CD4 cells and the activity of CD8 cells. Patients with this form of malnutrition are functionally anergic with respect to their cell-mediated immunity.

TRAUMA

Severe physical trauma causes transient suppression of delayed skin tests for cell-mediated immunity. In children there also is a temporary depletion of circulating B

cells.

OTHERS

Jaundice from liver disease is associated with anergy, regardless of whether the underlying pathologic condition is benign or malignant. Advanced age itself does not cause anergy, though the intensity of the skin test reaction is lessened, suggesting waning of the inflammatory phase of immunity. Splenectomy attenuates the IgM antibody response, and patients who have had their spleens removed are especially susceptible to pneumococcal infections. Acquired immunodeficiency also has been associated with cancer, chronic infection, chronic renal disease with azotemia, primary biliary cirrhosis, drug abuse, and many transfusions.

Sarcoidosis is a disease with active local immune responsiveness at sites of disease activity, hypergammaglobulinemia, and tissue granulomas but paradoxically diminished cellular responses in vitro to antigens and mitogens, peripheral blood lymphopenia, and delayed skin test anergy. The cause of this disease remains unknown. In terms of immunologic features, it bears some resemblance to asbestosis, a noninfectious disease of known origin that also exhibits skin anergy, lymphopenia, and evidence of diminished lymphocyte activity measured in vitro.

CAUSES OF ANTIGEN-SPECIFIC ANERGY

About 10% of patients with pulmonary tuberculosis have anergy, as shown by the absence of delayed skin test reactivity to tuberculin. Compared with infected patients who have positive skin test results, they tend to be older and to have more extensive pulmonary disease, especially miliary tuberculosis, but they do not necessarily have a higher prevalence of extrapulmonary disease. Furthermore, they tend to be less symptomatic, which probably reflects lessening of inflammation in the anergic state. The skin test result may revert to positive with effective antituberculosis therapy. A similar state of antigen-specific T-cell unresponsiveness occurs in certain clinical manifestations of parasitic diseases, such as filariasis and leishmaniasis.

THERAPEUTIC INDUCTION OF ANERGY

Immunosuppressant regimens to prevent transplant rejection and to treat certain connective tissue or autoimmune disorders are nonspecific and, therefore, subject the patient to opportunistic infections. A potential new approach to immunotherapy for autoimmune or allergic diseases, involving an attempt to induce antigen-specific anergy, is being pursued actively in several diseases. The challenge to the use of this method in autoimmune disease is the identification of the pathogenetic autoantigen. Patients with multiple sclerosis have autoantibodies to myelin basic protein, and oral administration of this antigen has been used in therapeutic trials.

CHAPTER 173: APPROACH TO THE PATIENT WITH ALLERGY

ABBA I. TERR

[Principles of Allergy Diagnosis](#)
[Laboratory Tests for Allergy](#)
[Principles of Allergy Treatment](#)
[Allergic Diseases](#)

Allergy refers to both a pathogenetic mechanism and the resulting diseases. In these diseases, immunologically induced inflammation is triggered by environmental antigens, referred to as *allergens*. In most cases, the allergens themselves are innocuous. Allergy is common and can be local or systemic, depending, in part, on the mode of exposure to the allergen. Allergic rhinitis, asthma, and allergic contact dermatitis are the most prevalent manifestations and are responsible for significant morbidity. Accurate diagnosis and appropriate treatment can significantly curtail the pathologic manifestations and disability of the disease. Because of the variety of pathways by which the immune response can generate inflammation, allergic diseases are classified by their underlying immunologic pathogenesis. A commonly used scheme is the Gell and Coombs classification shown in [Table 173.1](#).

Type	Immunologic Mechanism of Action	Representative Diseases
I	IgE antibody–mast cell mediator release	Atopy (allergic rhinitis, asthma, atopic dermatitis)
II	IgG antibody–complement activation–cytolysis	Anaphylaxis Drug-caused immune-mediated hemolytic anemia, neutropenia, thrombocytopenia
III	Immune complex–mediated, complement–dependent inflammation	Serum sickness
IV	T cell–mediated inflammation	Allergic contact dermatitis

TABLE 173.1. GELL AND COOMBS CLASSIFICATION OF ALLERGIC DISEASES

PRINCIPLES OF ALLERGY DIAGNOSIS

The diagnosis of any allergic disease is dependent on an accurate and thorough history and physical examination. Laboratory tests and specific allergy testing should be selective and based on the clinical history. The important elements in the history are a detailed description of the patient's symptoms and the time and place of their occurrence, to establish the relationship between symptoms and specific environmental exposures. Respiratory symptoms suggest the role of airborne allergens, such as pollens, dusts, fungi, animal dander, and materials and substances found in the workplace. Allergic contact dermatitis often is caused by plants, perfumes, cosmetics, clothing, topical medications, and substances encountered on the job and in association with hobbies. Other cutaneous reactions may implicate ingested allergens in foods or drugs. Finally, a complete medical history is necessary to rule out nonallergic diseases in the differential diagnosis.

Physical signs of active tissue inflammation, such as rhinitis, asthma, or dermatitis, will be detected if the patient is examined during a period of disease activity. These signs may be absent between active episodes, so a normal physical examination does not preclude a diagnosis of allergy. Depending on the results of the history and physical examination, tests for target organ dysfunction, such as pulmonary function testing, imaging of the paranasal sinuses, and stool examination for eosinophils, may be indicated.

LABORATORY TESTS FOR ALLERGY ([TABLE 173.2](#))

Allergy tests detect the presence of a response through a particular immune pathway to a specific allergen. The type of test must be selected to be consistent with the patient's disease. The allergens selected for testing must be consistent with those to which the patient might have been exposed at the appropriate time interval in relation to symptoms. The existence of a specific immune response, as detected by a positive allergy test result, is not in itself sufficient to cause an allergic reaction on exposure to that allergen. A positive allergy test result may indicate past, present, or future disease. There are varying degrees of diagnostic sensitivity and specificity. Allergy test results are diagnostically useful only in relation to the clinical examination.

TABLE 173.2. PRINCIPLES OF ALLERGY TESTING

SKIN TESTS FOR IGE ALLERGY

Atopy, anaphylaxis, and urticaria are mediated by IgE antibodies, which respond to the allergen by prompt local release of vasoactive and inflammatory mediators. Challenge of the skin vasculature to the allergen results in an immediate wheal-and-flare reaction, which has been well validated as an accurate test for diagnosis. The epicutaneous test involves pricking the skin with a needle through a drop of aqueous allergen extract applied to the skin site. In a patient with IgE antibodies to the test allergen, a cutaneous wheal-and-flare reaction appears in 15 to 20 minutes and is pruritic. Intracutaneous testing gives the same response to the injection of 0.005 to 0.020 mL of a properly diluted sterilized allergen extract. It is used selectively to supplement prick testing for atopy.

IN VITRO TESTS FOR IGE ALLERGY

The detection of circulating IgE antibodies uses such techniques as the radioallergosorbent test or the enzyme-linked immunosorbent assay, which are sensitive enough to detect and measure allergen-specific antibody levels in picograms per milliliter. Nevertheless, their diagnostic sensitivity is lower than that of skin testing. Measurement of total serum IgE concentration does not determine allergen specificity and has only limited value for diagnosis. Compared with nonallergic controls, levels are higher, on average, in patients with atopy, especially those with atopic dermatitis and asthma, but many patients have normal levels. Total serum IgE is markedly elevated in allergic bronchopulmonary aspergillosis, especially during exacerbations.

SKIN PATCH TEST

In testing for allergic contact dermatitis, a predetermined concentration of allergen is taped on a patch of skin for 48 hours. A positive test result consists of localized erythema, papules, and vesicles, which usually are present at the skin test site when the patch is removed; in some cases, the result may not be seen for up to 96 hours.

PRINCIPLES OF ALLERGY TREATMENT

The three cardinal principles of allergy treatment are avoidance of the allergen, medications to control symptoms, and immunotherapy with specific allergens. Although it may not be necessary to implement all three treatments in every case, effective therapy requires accurate diagnosis and follow-up monitoring of the recommended regimen.

AVOIDANCE

Avoiding inhaled aeroallergens requires various environmental control maneuvers. Exposure to outdoor pollens and fungal spores usually can be minimized by staying indoors but at the sacrifice of a lifestyle change that may be undesirable. Indoor mold exposure can be partly abated through cleaning and dehumidification. Animal dander from household pets can be avoided only by removing the animals from the house. Treatment of the animals, such as frequent washing, is of unproven benefit. House dust control is directed toward elimination of the dust mite from its principal habitat: mattresses, pillows, and bedroom carpets. Food and drug allergens must be avoided.

MEDICATIONS

Drug therapy for allergic diseases is aimed at reversing or preventing target organ inflammation and its effects on organ function. These drugs do not alter allergic sensitivity itself. Glucocorticoids are especially powerful in suppressing every known form of allergic inflammation. Their usefulness is limited by side effects and long-term toxicity, but these effects can be significantly lessened by using one or more of the many topical forms available for skin, nasal, and bronchial application.

The H₁ histamine receptor-blocking drugs (antihistamines) often are effective in minimizing or eliminating the symptoms of allergic rhinitis and may relieve the pruritus of atopic dermatitis and urticaria. They are not helpful for asthma, but they are not contraindicated if needed for other purposes. Nonsedating H₁ histamine receptor antagonists lack the major adverse effect of older antihistamines. Nevertheless, they retain the undesirable drying effect on mucous membranes, and patients must be cautioned against overdose because of reports of cardiac arrhythmias associated with some of these agents.

Drugs that modify the inflammatory effect of leukotrienes are effective for asthma, but to date they have not been shown to be useful for other allergic diseases. Both 5-lipoxygenase inhibitors and leukotriene receptor antagonists are available. Other drugs with proven efficacy include inhaled or systemic β₂-adrenergic agonists and anticholinergic drugs, α-adrenergic agonists, theophylline (because of its bronchodilator action), and cromolyn and nedocromil, which have a poorly defined mast cell-stabilizing property.

ALLERGY IMMUNOTHERAPY

Immunization to induce clinical tolerance to the effects of environmental allergens is accomplished by repeated subcutaneous injections of the allergen at frequent intervals in increasing dosage. The treatment is tailored to each patient, to ensure that the amount of allergen administered each time is small enough to avoid initiating an allergic reaction but sufficient to stimulate ongoing protective immunity. Patients with multiple atopic allergies can be treated with a mixture of all relevant allergens simultaneously. Numerous controlled clinical trials over the past 30 years prove that this form of therapy is effective, without long-term toxicity in most patients with allergic rhinitis to the major inhaled allergens. Effectiveness of immunotherapy for allergic asthma is less well established. There is no documented role for this form of treatment in improving atopic dermatitis.

Immunization of patients with *Hymenoptera* venom anaphylaxis is highly successful. Short-term desensitization of penicillin allergy has been established, but the effect may be transient and therefore unreliable for a future course of the drug. Oral desensitization for cutaneous reactions to other drugs, especially sulfonamides, is frequently efficacious, but it should not be attempted in patients with an exfoliative reaction to the drug. There is no role for its use in the context of food allergy.

ALLERGIC DISEASES

ALLERGIC RHINITIS

Atopy is the term used to denote an inherited tendency toward the development of IgE antibodies to a variety of inhaled and ingested organic substances commonly encountered in everyday life. Allergic rhinitis is the most common manifestation of atopy (see [Chapter 366](#)). The other atopic diseases are allergic asthma and atopic dermatitis. Overall, 10% to 20% of the US population is affected. The onset of symptomatic disease can occur at any age, but most cases begin in childhood. The illness persists for many years, though it may remit spontaneously. Both sexes are affected equally.

A typical attack of allergic rhinitis consists of paroxysmal sneezing; clear, watery rhinorrhea; nasal congestion; red, watery eyes; itching of the eyes, nose, and palate; and postnasal drainage. Malaise is common when symptoms are severe. Headache accompanies sinus congestion, and pain in the neck may ensue from sneezing spasms. Symptoms are triggered on exposure to allergen, so the illness follows a seasonal pattern in patients with pollen allergy. Allergy to indoor dust mites, dander, and fungi can cause year-round symptoms. Although the problem is not life-threatening, morbidity and disability can be significant. Complications are otitis media, especially in children, and sinusitis at any age.

Physical findings during symptomatic periods are red, swollen conjunctivae; pale blue, swollen nasal mucosa with excessive clear secretions; and edema of the mucosa of the soft palate and posterior oral pharynx. The diagnosis is made by history, physical examination, and specific allergy skin testing. The differential diagnosis includes infectious rhinitis (usually viral), chronic nonallergic (vasomotor) rhinitis, rhinitis medicamentosa, sinusitis, and, rarely, a cerebrospinal fluid leak from fracture of the cribriform plate. Routine laboratory studies are not necessary in uncomplicated cases, but the presence of eosinophilia in blood and nasal secretions is helpful in differentiating this disease from nonallergic forms of rhinitis.

Every effort should be made to avoid those allergens that are avoidable, especially indoor allergens. Antihistamines long have been helpful in minimizing or alleviating symptoms, and the development of nonsedating antihistamines (fexofenadine, astemizole, loratadine, cetirizine) makes this therapeutic option more attractive than previously. The addition of oral sympathomimetic decongestants occasionally is warranted, but topical nasal decongestants should not be used. Topical nasal corticosteroids are beneficial and safe. Cromolyn sodium by nasal spray is an effective prophylactic medication for some patients, and it has the advantage of producing no side effects or long-term toxicity.

Allergic conjunctivitis almost always accompanies allergic rhinitis, and the same allergens are responsible for both conditions. In addition to avoidance of allergens, treatment consists of oral antihistamines, conjunctival antihistamines or cromolyn, and immunotherapy. Glucocorticoid eyedrops may provide temporary relief, but the potential for glaucoma, corneal ulcers, or other complications must be monitored.

ASTHMA

The pathophysiologic characteristics and treatment of asthma are discussed in detail in [Chapter 363](#). Some patients with asthma have atopy, and their attacks can be triggered by environmental allergens. The immunologic mechanism of action is the same as that described for allergic rhinitis. Allergic asthma can accompany allergic rhinitis, especially in patients with symptomatic pollen allergy. Certain allergens, such as the house dust mite, airborne fungi, and animal dander, can cause asthma preferentially, without significant nasal symptoms. Childhood asthma may remit during adolescence and then recur later in life. A search for the presence of immune responses to specific inhaled allergens, preferably by prick or intradermal skin testing, is important when the history points to an allergic component of asthma. Seasonal or diurnal variations in disease activity, worsening in certain physical locations, and the presence of pets in the home are examples of factors that warrant an allergy evaluation.

The treatment of asthma requires special attention to the elimination of environmental allergens because of the considerable morbidity associated with respiratory obstruction and the potential for a fatal outcome in a severe asthma attack. Environmental avoidance measures also must include protection against nonallergic respiratory irritants, including a variety of dusts, fumes, and vapors to which all patients with asthma are susceptible because of the nonspecific bronchial hyperirritability that characterizes the disease. Immunotherapy is indicated for patients who experience significant exacerbation of the disease by airborne allergens

that cannot be avoided effectively.

ATOPIC DERMATITIS

Atopic dermatitis is a chronic skin disease with the primary features of pruritus and an eczematous eruption that occurs on scratching of the skin (see [Chapter 196](#)). The term *eczema* refers to any inflammatory skin disease, including atopic dermatitis, that is characterized by erythema, papules, and scaling. Because of repeated scratching, the lesions undergo lichenification, and scarring results. As signified by its name, atopic dermatitis is the cutaneous manifestation of atopy. It affects less than 1% of the population and can coexist with allergic rhinitis and asthma in the same patient or in other family members.

ANAPHYLAXIS

Anaphylaxis is a systemic allergic reaction that begins rapidly on exposure to an allergen and can be fatal because of irreversible shock, bronchospasm, and laryngeal angioedema. The interaction of allergen and IgE antibody triggers mediator release, which affects several target organs almost simultaneously. Anaphylactic shock is caused by vasodilatation and vascular leakage, resulting from enhanced permeability of the postcapillary venules in the vascular beds of visceral organs, skin, and mucous membranes. Bronchial and gastrointestinal muscle spasms produce acute airway obstruction and colicky abdominal pain. Increased vascular permeability in the skin results in pruritus, urticaria, and angioedema. Uterine muscle contractions and various effects on the intrinsic coagulation pathway are less common manifestations.

Anaphylaxis is not common, but prevalence and incidence figures are unavailable because it is not a reportable disease. The diagnosis must be made on the basis of clinical findings and treatment initiated with the greatest urgency, because the mortality rate approaches 10% in patients with anaphylactic shock. The first sign or symptom typically occurs within a few minutes to an hour of contact with the allergen. A latent period of more than 2 hours is unusual. The list of reported allergens causing anaphylaxis is extensive, but the most common ones are foods, drugs, and *Hymenoptera* insect venom. The most frequently encountered food triggers are seafoods, nuts, legumes (especially peanuts), berries, buckwheat, and seeds. Penicillin, other b-lactam antibiotics, and injected protein drugs, such as antisera, enzymes, and vaccines, lead the list of medication triggers. Among health care workers, exposure to latex in gloves and other medical devices is becoming a growing cause of anaphylaxis and a range of other allergic diseases.

The term *anaphylactoid* is used to designate reactions that are indistinguishable from anaphylaxis but lack a demonstrable IgE allergic element. Some anaphylactoid reactions are triggered by an identifiable agent, such as a drug that possesses the pharmacologic property of causing nonimmunologic release of mast cell mediators. Aspirin and nonsteroidal anti-inflammatory drugs, opiates, and iodinated contrast media used in radiography are the most common agents with this property. In other cases, the reaction is triggered by a physical activity, such as exercise, and a few patients have recurrent idiopathic "anaphylaxis." Details concerning the treatment of acute attacks can be found in [Chapter 60](#).

Permanent desensitization can be achieved in virtually all cases of *Hymenoptera* venom anaphylaxis through the subcutaneous injection of 100 mg of venom at monthly intervals, after a build-up period of increasing amounts starting at a dose lower than that capable of causing a local or systemic allergic response. After 5 years of such treatment, most patients are permanently protected from future reactions to natural stings, whereas the untreated disease carries a 50% risk of systemic reaction to subsequent stings. A temporary state of tolerance to penicillin can be achieved in some patients with anaphylaxis to the drug by "rush" desensitization, permitting therapeutic use of the drug. In this case, the allergic sensitivity returns at the termination of treatment.

URTICARIA AND ANGIOEDEMA

Urticaria is a common disease that occurs most often as a single episode recognized easily as an allergic reaction. The disease is provoked by the same types of allergens that are responsible for systemic anaphylaxis (drugs, foods, and insect stings). As in the case of anaphylaxis, some drugs, such as aspirin and the nonsteroidal anti-inflammatory agents, and some foods, most notably mollusks, crustaceans, and berries, contain certain chemicals that trigger nonimmunologic mast cell mediator release. In some individuals urticaria also can result from physical triggers, such as exercise, cold, heat, or local skin pressure. In addition, emotional stress is a fairly common initiator. Angioedema is a variant of urticaria in which the target blood vessels that undergo enhanced permeability are located subcutaneously.

The typical lesions of urticaria are intensely pruritic and evanescent. The individual lesions clear completely within hours without side effects, though recurrences can be frequent or even continuous. The chronic form of urticaria (continuously recurring lesions over many weeks or months) is a nonallergic, idiopathic disease in most cases. Angioedema consists of localized, nondependent, and usually nonpruritic, areas of edema with a particular predilection for the eyelids, lips, and buccal mucosa, but they may appear anywhere. Urticaria-like lesions that persist for days and are characterized by skin discoloration, purpura, or tenderness are likely to be caused by cutaneous vasculitis. This may be a manifestation of a systemic disorder, such as infection (especially hepatitis B) or autoimmune disease.

SERUM SICKNESS

Serum sickness is a systemic immune complex-mediated allergic disease. High-dose administration of a potent allergen, such as foreign serum, elicits a brisk IgM and IgG antibody response, resulting in the formation of circulating antigen-antibody complexes that deposit in various target organs. The immune complexes induce local and systemic inflammation through the action of various complement-derived proinflammatory mediators. Although it was a much more common disease in the past, serum sickness is now encountered rarely, because the therapeutic use of foreign serum protein is limited to antilymphocyte or antithymocyte globulin and a few antivenoms. The exceptions to this rule are some of the recombinant products (anti-tumor necrosis factor α). A mild form of serum sickness occurs occasionally with injected nonprotein drugs, especially penicillin. There is a latent period of several days to weeks after drug administration because of the time required for specific antibody production and immune complex formation. Dermatitis, fever, lymphadenopathy, and arthritis are the cardinal manifestations. The rash can be erythematous, morbilliform, or urticarial. Peripheral neuritis and central nervous system involvement are rare. The disease remits spontaneously and usually without permanent tissue damage. Treatment can be directed toward alleviation of symptoms. The diagnosis is made on the basis of clinical findings, because there are no pathognomonic laboratory tests and because evidence of circulating immune complexes and complement consumption may come and go before symptoms and signs appear.

ALLERGIC BRONCHOPULMONARY ASPERGILLOSIS

Allergic bronchopulmonary aspergillosis is a unique allergic disease caused by *Aspergillus fumigatus* (see [Chapter 369](#)). It develops in patients who produce IgE antibodies to an allergen from the spore and IgG antibodies to a different allergen of the organism's mycelial phase. Patients typically are young adults with atopic allergy or children with cystic fibrosis. The IgE antibody causes asthma, which usually is chronic, because airborne allergens from *Aspergillus* spores are ubiquitous in the environment. Organisms persisting in the mucus of proximal airways stimulate the production of IgG antibodies, which then form localized immune complexes that activate complement and induce focal immune-mediated inflammation. This accounts for the acute episodes interspersed in ongoing chronic asthma. Repeated bouts lead to bronchiectasis and pulmonary fibrosis.

Allergic bronchopulmonary aspergillosis should be suspected in a patient with asthma who has repeated episodes of fever, productive sputum, and pulmonary infiltrates on chest radiography. The diagnosis requires appropriate laboratory confirmation. The result of an immediate wheal or erythema skin prick test to *A. fumigatus* almost always is positive. IgG antibodies often can be detected by the precipitin test. Total serum IgE levels typically are elevated during acute episodes and fall after the attack subsides. Blood eosinophilia is present, as it is in any case of symptomatic asthma.

HYPERSENSITIVITY PNEUMONITIS

An uncommon form of allergic pulmonary disease in which acute high-dose inhalation of an airborne allergen produces a specific immune inflammatory response in the lung parenchyma is known as hypersensitivity pneumonitis. Numerous allergens and their environmental sources have been identified, though many have been discovered as single cases or in only a few patients. Some of the more common causes are listed in [Table 173.3](#). In most cases, the allergen is a protein, inhaled in the form of fumes, vapors, dusts, or intact microorganisms.

Bacteria
 Thermophilic actinomycetes
Bacillus subtilis
Streptomyces albus
 Fungi
Aspergillus species
Aureobasidium species
Graphium species
Cryptosporium corticale
Penicillium species
Alternaria species
 Insects
Sitophilus granarius
 Miscellaneous
 Animal fur proteins
 Bat urine proteins
 Pituitary snuff
 Coffee bean protein

TABLE 173.3. ALLERGENS THAT CAUSE HYPERSENSITIVITY PNEUMONITIS

The immunopathogenesis of hypersensitivity pneumonitis, as confirmed by extensive clinicopathologic studies and experimental disease models in animals, is complex, but the disease principally is a T cell–mediated response to the allergen causing localized alveolar inflammation on contact with the inhaled allergen. Repeated acute or long-term exposure leads to chronic granulomatous inflammation and fibrosis. Reaction of allergen with precipitating antibody is involved in the acute form of the disease, analogous to the Arthus reaction. Genetic predisposition and immunoregulatory effects of the allergens themselves are additional factors in pathogenesis.

The diagnosis is made on the basis of clinical findings and evidence of host immune response to the suspected allergen. This requires that the clinician be acutely aware and vigilant and that a searching environmental history be taken, with particular emphasis on occupational exposures. Although specific serum precipitins correlate with exposure to the organic allergens causing hypersensitivity pneumonitis, the test lacks disease-related specificity. Therefore, a positive test result cannot diagnose the disease without clinical confirmation. The differential diagnosis and treatment of acute hypersensitivity pneumonitis are discussed in [Chapter 372](#).

ALLERGIC CONTACT DERMATITIS

Allergic contact dermatitis is a T cell–mediated allergic disease expressed on the skin at the area of contact with the allergen. It is a common form of allergy and is reviewed in [Chapter 196](#). Both sensitization and elicitation of the reaction result from skin contact. Once sensitized, later contact with the allergen anywhere on the skin surface will produce the eruption, which consists of erythema, swelling, papules, and vesicles at the site of exposure. Because this is a nonantibody cellular immune inflammatory reaction, there is a delay of 24 to 48 hours or even longer for mild reactions before the lesions are apparent. Sensitivity usually is permanent.

DRUG ALLERGY

Allergy is one of several adverse drug effects ([Table 173.4](#)). The clinical manifestations of drug allergy reflect the inflammation induced by the patient's immune response to an antigenic determinant from the drug. The determinant can be the drug itself, a drug metabolite, a product of a drug (or one of its metabolites) conjugated with a host protein, or an autoantigen elicited by the drug. The immune response can be mediated through the IgE–mast cell route, the IgG complement–immune complex pathway, or the T cells. Cytotoxic reactions from complement activation by IgG or IgM antibodies to drugs also can be considered a form of drug allergy. Cutaneous drug reactions are discussed in detail in [Chapter 199](#).

Allergy
 Side effects
 Toxicity
 Idiosyncrasy

TABLE 173.4. ADVERSE DRUG REACTIONS

Because almost all therapeutic agents are “foreign” to the body, an immune response after exposure to any drug is an expected event and usually has no clinical consequence. Allergy to a drug requires additional factors, such as dose, route of administration, genetic predisposition, nature of the underlying disease, and probably others. The manifestations of drug allergy are consistent with the immune pathway involved. IgE responses and T cell–mediated allergic contact dermatitis are the most common. IgE responses usually take the form of anaphylaxis, urticaria, or angioedema. Asthma and rhinitis are rare and restricted to protein drugs given by inhalation or nasal insufflation.

An erythematous or maculopapular rash from a drug, usually an antibiotic, is a particularly common problem, which is encountered by most physicians. This condition presumably is an allergic one when the intensity of the skin eruption is greater and the latency period shorter with each succeeding course of the drug. In most such cases, there is no validated skin or in vitro test to identify the relevant immune response. In some cases, an empiric course of “desensitization” has permitted the patient to tolerate therapeutic doses of the drug, at least transiently, further supporting an allergic cause.

The basic immunologic concepts of allergen determinant specificity and cross-reactivity are clinically relevant in drug allergy. For example, the immunologic specificity in penicillin allergy usually is to the b-lactam heterocyclic ring structure and not to its side chain. An individual with allergy to penicillin G usually reacts similarly to all b-lactam penicillin derivatives and occasionally to a cephalosporin, but not to a monolactam, such as aztreonam.

The diagnosis of drug allergy requires a history to explore the symptoms, timing, previous experience with the drug and potentially cross-reacting drugs, other drug use, other allergies, and the nature of the patient's disease. In spite of continuing research efforts to devise specific diagnostic tests for any drug and for each type of allergic reaction, reliable tests are few. Immediate wheal-and-flare skin testing with protein drugs usually is diagnostic for cases of suspected IgE reactions. The patch test is appropriate for drug-caused allergic contact dermatitis. Because most drugs used today in clinical practice are low-molecular-weight organic molecules, the drug or one of its metabolites functions as a hapten in drug allergy. In the case of penicillin, penicilloic acid is the major determinant of most nonanaphylactic IgE reactions. Penicilloyl-polylysine is a polyvalent skin test reagent that predicts future IgE-mediated penicillin reactions with a high degree of sensitivity and specificity, except for systemic anaphylaxis. Skin testing with a mixture of penicillin, penicilloic acid, and penicillamine, the so-called minor determinant mixture, is predictive of penicillin anaphylaxis, though this product is not marketed for general clinical use. Similar testing reagents for allergy to other drugs are not available.

The treatment of drug allergy is avoidance of the drug and all cross-reacting compounds. When there is no alternative therapy, desensitization can be attempted. This is performed by administering increasing doses of the drug at about 30-minute intervals, beginning with an appropriately low initial dose. Desensitization has been used successfully in many cases of penicillin allergy. It lowers the level of circulating IgE and increases the level of IgG antibodies to the drug, but these changes and clinical tolerance to the drug eventually disappear, and the procedure may have to be repeated for a later course of the drug.

CHAPTER 174: RHEUMATOID ARTHRITIS

GARY S. FIRESTEIN

[Incidence and Epidemiology](#)
[Etiology](#)
[Pathogenesis](#)
[Clinical Findings](#)
[Laboratory Findings](#)
[Therapy](#)

Rheumatoid arthritis (RA) is a chronic symmetrical polyarthritis of the small joints of the hands and feet as well as the larger appendicular joints. In addition to articular manifestations, patients with RA can suffer from a variety of extra-articular complications, such as nodule formation and vasculitis.

INCIDENCE AND EPIDEMIOLOGY

RA is the most common form of inflammatory arthritis, affecting about 1% of people worldwide. This incidence is surprisingly constant regardless of ethnic or racial origin, with a few notable exceptions. For example, RA develops in 3% to 6% of the Yakima Indians. Females are affected two to three times more often than males. The disease can begin at any age, but the peak onset is in the fifth decade of life. Susceptibility to RA has a genetic component, and the risk is approximately doubled (2% to 4%) if an individual has a first-degree relative with the disease, including a fraternal twin. The rate of concordance for monozygotic twins is considerably higher, approaching 30% to 50%. The fact that the concordance is not 100% implicates as yet undefined environmental factors.

Of the several genes that likely contribute to RA susceptibility (probably six or more), the class II major histocompatibility complex (MHC) plays a particularly prominent role. These cell-surface molecules bind to antigenic peptides and present the antigens to CD4⁺ helper T cells. Early studies confirmed a higher prevalence of HLA-DR4 in patients with RA compared with controls. After a variety of DR4 subtypes were identified, however, it became clear that only selected ones were associated with RA. Furthermore, in some ethnic and racial populations there were different associations. The discrepancies were resolved in part using molecular biology techniques to sequence the respective HLA-DR genes. These studies showed that susceptibility to RA is associated with a specific sequence of amino acids (amino acids 70-74: Glu-Lys-Arg-Ala-Ala, sometimes called QKRAA) in the third hypervariable region of the b chain of HLA-DR. However, it is important to appreciate that the association is still weak or nonexistent in many ethnic and racial groups, even when this sequence is considered. In addition, some data suggest that the DR associations define the severity of RA rather than susceptibility to disease.

QKRAA is strategically located near the antigen-binding site in HLA-DR that is responsible for initiating immune responses by T cells, suggesting that the association between RA and HLA-DR is somehow related to the ability of a putative “rheumatoid antigen” to bind specific MHC proteins. This could result in an immune response by the appropriate antigen-specific T cells. There are also several alternative explanations for the HLA-DR associations. For instance, it is possible that this specific sequence results in a “hole” in the immune response that permits an arthrotrophic pathogen to proliferate and cause arthritis in the absence of an appropriate T-cell response. Also, the effect on T cells could be due to the fact that class II MHC genes help shape the repertoire of T-cell receptors in the thymus, thereby indirectly altering T-cell responses. Finally, the sequence of MHC genes can alter trafficking of DR proteins in the cell cytoplasm and alter antigen presentation.

ETIOLOGY

Despite an intensive search for transmissible agents that might cause RA, an infectious source has yet to be proved. Occasional associations with nonbacterial pathogens, such as chlamydia or mycoplasma, are intriguing but far from conclusive. Sensitive reverse transcriptase–polymerase chain reaction studies of synovial tissue have detected bacterial DNA in RA as well as other inflammatory types of arthritis. The types of bacteria identified are nonspecific and could merely reflect the phagocytic capacity of synovial macrophages as they clear live or dead organisms from the blood. It is also possible that nonbiodegradable bacterial cell walls play a key role in the disease. This is amply illustrated in a model of inflammatory arthritis in which purified streptococcal cell walls induce an RA-like disease in rats; similar antigens have not been detected in human articular samples. Inflammatory arthritis in animals also can be caused by live microorganisms. For instance, in caprine arthritis/encephalitis disease, a lentivirus infects macrophage precursors in the bone marrow that subsequently migrate to the joint and cause synovitis. Mycoplasma can produce arthritis in a variety of species.

In humans, various viruses are known to cause arthritis. Rubella virus can lead to a rheumatoid-like syndrome after either wild-type rubella infection or vaccination with attenuated virus. In some cases, the virus can be cultured from synovial tissue or synovial fluid. However, rubella arthritis is generally self-limited, and viral cultures in RA are usually negative. Parvovirus B19 has also been associated with inflammatory arthritis; B19 proteins and infective virus have been reported in RA synovial tissue. Serologic studies in RA suggest that some individuals with new-onset RA have experienced recent B19 infection, but this represents a small fraction of patients.

Epstein–Barr virus (EBV) has also been implicated in RA. Patients with RA have higher serum antibody titers for EBV proteins, and rheumatoid peripheral blood lymphocytes have a specific defect in the immune response to EBV. Moreover, one of the EBV coat proteins contains the QKRAA sequence that is found in HLA-DR4, suggesting that molecular mimicry might link EBV and RA (see later discussion). There is also a suspicion that patients with RA have increased EBV shedding in their saliva. Despite these tantalizing data, there is no compelling evidence that EBV can initiate RA, and its role in chronic disease is uncertain at best.

An immune response against autoantigens is another mechanism for initiating arthritis. Several self-antigens can potentially serve as autoimmune targets. Type II collagen (which is a major component of hyaline cartilage), heat-shock proteins, the cartilage protein gp39, cartilage link protein, proteoglycans, or even class II MHC proteins could serve as autoantigens. Several of these autoantigens, such as gp39 and type II collagen, can induce inflammatory arthritis when particular strains of mice are immunized with them. The basis for the claims regarding the etiologic role of such antigens in RA is serologic (anti-type II collagen or anti-proteoglycan antibodies in the serum of some RA patients) or related to cell-mediated responses (increased proliferative responses of synovial fluid T cells to heat-shock proteins). Evidence of the direct role of these antigens as initiators of RA is circumstantial, however, and the immune responses could be epiphenomena related only to the destruction of articular tissue with the release of neo-antigens.

While it is not known exactly how one initiates immunity to these articular antigens, one possibility is molecular mimicry. In this paradigm, an immune response can be mounted against an exogenous antigen bearing structural homology to a normal human antigen. The normal tissue, though it is an innocent bystander, could ultimately be the target of an immune attack and be damaged. Adjuvant arthritis in the rat is one example of molecular mimicry in an animal model of inflammatory arthritis. In this model, animals are immunized against nonviable mycobacteria and mount a brisk immune response directed against mycobacterial proteins (especially heat-shock proteins). Nevertheless, some T cells that respond to mycobacteria also recognize an epitope on proteoglycans and might serve as a link between the robust response to mycobacteria and destruction of cartilage in this model.

PATHOGENESIS

The synovium serves two major functions in the joint: to provide oxygen and nutrients to cartilage, which lacks its own blood supply; and to produce lubricants that permit the articular surfaces to glide smoothly across one another. The normal synovium in diarthrodial joints is a delicate tissue made up of a synovial intimal lining and a sublining region supported by an underlying fibrous capsule. The intimal lining, which is in direct contact with synovial fluid, is typically a discontinuous structure one to two cell layers deep containing macrophage-like and fibroblast-like cells (referred to as type A and type B synoviocytes, respectively). The sublining contains bland fibrous tissue with scattered mononuclear cells or fibroblasts, a few blood vessels, and fat cells.

In RA the synovium is transformed into a hyperplastic, chronically inflamed tissue. The intimal lining dramatically increases in size and is sometimes more than a dozen cell layers deep. This change is due to local proliferation of fibroblast-like cells and an even greater increase in the number of macrophage-like synoviocytes. Macrophage-like cell accumulation is mainly due to migration of new cells from the bone marrow via the bloodstream. The sublining is marked by a prominent

mononuclear cell infiltrate that is composed mainly of T cells, B cells, and macrophages. The T cells, which are primarily CD4⁺ helper cells, can accumulate diffusely through the synovium or collect into lymphoid aggregates. These aggregates are occasionally so prominent that the synovium looks like a lymph node. Local proliferation appears to account for only a very small fraction of T-cell accumulation; most T cells migrate into the joint under the nonspecific stimulus of local adhesion molecule and cytokines. Macrophages, B cells, and plasma cells are scattered throughout the sublining.

The degree of mononuclear cell infiltration varies considerably between patients and even between different regions of the same joint. Some biopsy specimens have only a minor inflammatory infiltrate despite significant symptoms, and even asymptomatic joints in patients can have synovial-lining hyperplasia and characteristic infiltration with lymphocytes. While neutrophils are abundant in synovial fluid, they are conspicuously absent in synovium in the context of RA. Angiogenesis is prominent in RA, because the number of blood vessels is greater than normal; careful capillary morphometry suggests, however, that the increase in the number of blood vessels is not commensurate with the increase in tissue mass, resulting in local ischemia. Surprisingly, the histopathologic characteristics of the synovium in early RA (within a few weeks after symptoms begin) can be very similar to chronic disease, including abundant cytokines and metalloproteinase expression.

Various aspects of humoral immunity dominated early paradigms of RA, beginning in the 1940s with the initial descriptions of rheumatoid factor in the serum of patients with RA. Rheumatoid factors are antibodies that bind to the C_γ2 and C_γ3 regions of the Fc portion of IgG and can lead to the formation of immune complexes in the joint or in the blood. Standard clinical tests for rheumatoid factors mainly detect IgM antibodies, though other types (especially IgG) are also produced and can be more phlogistic. Rheumatoid factors found in patients with RA are distinct from those detected in other diseases, such as cryoglobulinemia and Waldenstrom's macroglobulinemia. For instance, distinct germ line genes are used in constructing the RA rheumatoid factors. In addition, the autoantibodies have higher affinity for IgG in RA and have distinct mutations in the hypervariable regions, suggesting that their production is driven by a specific antigen(s).

In addition to being present in blood, rheumatoid factors are synthesized in the synovium and can be detected in synovial fluid. Rheumatoid factor-containing immune complexes are found in synovial fluid as well as in synovial tissue and cartilage. These complexes activate complement with the subsequent generation of a variety of chemotactic factors, including C5a, that serve to recruit additional inflammatory cells to the joint. Neutrophils, in particular, are summoned by this mechanism and, upon arrival in the joint, they can ingest the immune complexes and disgorge their full panoply of degradative enzymes to act upon the cartilage and extracellular matrix. Other chemotactic mediators in synovial fluid, like interleukin-8 (IL-8), also draw inflammatory cells into the articular cavity.

The types of T cells in synovial fluid differ from those of synovial tissue: there is a greater number of CD8⁺ lymphocytes in synovial fluid. In light of the preponderance of neutrophils and the differences in T-cell subsets in synovial fluid, it is clear that effusions do not simply mirror the synovium but are, in fact, a distinct compartment. Synovial fluid also contains many cytokines, small molecule mediators of inflammation (prostaglandins and leukotrienes), and proteolytic enzymes. The synovium itself appears to be the source of many of these factors in synovial effusions. In contrast to the synovium (see later discussion), the cytokine milieu of synovial fluid seems to favor cytokine antagonists, with very substantial concentrations of IL-1Ra, soluble tumor necrosis factor (TNF) receptors (which can bind and neutralize synovial fluid TNF-α), and suppressive cytokines like IL-10 and transforming growth factor β.

While synovial fluid was the focus of early studies, the synovium itself, with its own distinct mechanisms of inflammation, has garnered increasing scrutiny in recent years. Many studies strongly implicate cell-mediated immune responses in rheumatoid synovium rather than the acute inflammatory processes that predominate in the intra-articular cavity. The prominent helper T-cell synovial infiltrate and class II MHC associations in RA have suggested to many that RA is an antigen-specific T cell-mediated response in the joint. In this model, an arthrotrophic agent in the joint activates local T cells, causing *in situ* proliferation and release of soluble mediators known as cytokines that subsequently induce adhesion molecules and activate other cell types in the vicinity. Some studies examining T-cell receptor gene rearrangement in rheumatoid joints support this hypothesis owing to the suggestion of T-cell oligoclonal expansion. Other studies, however, have not confirmed a T-cell receptor bias, so this is by no means established. In fact, depending on the techniques used and the population of patients studied, highly conflicting results have been reported.

How, then, does one account for the accumulation of T cells within the synovium? As was mentioned earlier, local proliferation does not seem to be the answer. Instead, the local cytokine milieu induces adhesion molecules on synovial endothelium. Molecules like ICAM (intercellular adhesion molecule) and VCAM-1 (vascular cell adhesion molecule) are overexpressed on endothelial cells in the RA joint. These bind to counterreceptors known as integrins on circulating leukocytes, especially the β2 and α4 integrin families (e.g., VLA-4). The combination of increased adhesion molecule expression in the joint and local chemokine production serves as a siren song to summon cells into the synovium, where they can take up residence. Hence, the populations of T cells that accumulate in the joint are probably determined by antigen-independent forces.

While the abundance of T cells in the joint is striking, a variety of antigen-independent forms of arthritis evidence a similar histologic picture, and T cells accumulate at sites of chronic inflammation regardless of the cause. Another perplexing aspect is the relative lack of cytokines typically associated with T-cell activation in the joint. In normal immune responses, T cell-derived factors like IL-2, IL-3, IL-4, TNF-β, or immune interferon (IFN-γ) orchestrate the inflammatory response. These cytokines are readily detected at the site of disease in T cell-mediated diseases like tuberculous pleuritis or asthma. The levels of T-cell cytokines are conspicuously low in the rheumatoid joint, however.

Helper T cells have been divided into specific subsets based on their cytokine profile; T_H1 cells produce IFN-γ and IL-2 but not IL-4, IL-5, or IL-10, whereas T_H2 cells express the opposite profile. While levels of most T-cell cytokines are rather low in the joint, the profile of those that have been detected using very sensitive techniques suggest a T_H1 bias in the synovium. This is similar to the situation in animal models of autoimmunity, where T_H1 cells are responsible for disease initiation, whereas T_H2-cell activation correlates with disease regression.

In contrast to T-cell cytokines, macrophage and fibroblast cytokines are abundant. These include cytokines IL-1, IL-6, TNF-α, granulocyte-macrophage colony stimulating factor, macrophage colony stimulating factor, and a family of chemoattractants known as chemokines as well as prostaglandins, complement proteins, and proteolytic enzymes. The plethora of macrophage/fibroblast products in the rheumatoid joint suggests that they might play a key role in disease perpetuation. Moreover, a complex network of factors that stimulates macrophages and fibroblasts in an autocrine or paracrine fashion could contribute to the pathogenesis of RA. It is not certain how the cytokine cascade is initiated, nor is it clear whether it requires intermittent stimulation from an outside source, such as infectious agents, or low levels of T-cell activation. Current models of RA suggest that the initiation phase of the disease might result from an antigen-specific T-cell response, but the late chronic phase is quite complex and might involve T cell-independent processes in addition to T-cell responses.

In the synovium, degradative enzymes are mainly produced by intimal lining fibroblasts and are responsible for much of the tissue destruction associated with long-standing RA. *In situ* hybridization studies of RA synovial tissue show massive amounts of messenger RNA (mRNA) for such metalloproteinases as collagenase and stromelysin in the intimal lining, along with smaller amounts of the natural inhibitors of metalloproteinases known as TIMPs (tissue inhibitors of metalloproteinases). Protease gene induction takes place very early in the disease, with significant mRNA detected in synovial biopsy specimens obtained a few weeks to months after onset. The production of metalloproteinases is regulated by the cytokine network, with macrophage-derived factors like IL-1 and TNF-α acting as the major inducers. One major determinant of net extracellular matrix destruction is related to the ratio of natural inhibitors like TIMP to the active enzymes. Studies of synovial gene expression indicate that relatively subtle imbalances between these inhibitors can lead to net tissue damage over long periods of time. In addition, cysteine proteases called cathepsins are also expressed in RA synovium. Cathepsin K, in particular, has been associated with bone resorption and is produced by synovial cells near sites of bone destruction.

New evidence suggests that chronic erosive RA might be perpetuated by partial transformation of synoviocytes in the joint. The proliferative tissue in the synovial intimal lining contains pleomorphic mesenchymal cells that express genes typically associated with transformation, such as the oncogenes *c-jun* and *c-fos*. Furthermore, cultured synovial tissue fibroblasts, under some circumstances, can proliferate under anchorage-independent conditions, a phenotype that is characteristic of transformed cells. Finally, somatic mutations in key regulatory genes, like *H-ras* and the p53 tumor suppressor gene, can occur in RA synovium and synoviocytes. The mutations do not cause arthritis but might be the result of long-standing exposure to genotoxic oxygen and nitrogen radicals in the inflamed joint. The altered cells can then behave more aggressively by proliferating and invading cartilage.

CLINICAL FINDINGS

The American College of Rheumatology revised 1987 criteria are shown in [Table 174.1](#). These guidelines can be useful in some situations, though patients with the classic symptoms are usually not difficult to distinguish from those with other forms of arthritis. A scale to grade the clinical severity of RA also has been established to guide clinical evaluation, determine prognosis, and provide guidelines for quantifying treatment responses ([Table 174.2](#)).

Morning stiffness (>1 hr before maximal improvement)
 Arthritis of three or more joint areas (e.g., MCPs, wrists, knees)^a
 Arthritis of the hands
 Symmetrical arthritis
 Rheumatoid nodules
 Serum rheumatoid factor
 Radiographic changes typical of RA (e.g., marginal erosions, periarticular osteopenia)

MCP, metacarpal phalangeal joints.

^a Four or more criteria must be satisfied for at least 6 weeks to diagnose RA.

^b Must be observed by a physician.

TABLE 174.1. 1987 AMERICAN COLLEGE OF RHEUMATOLOGY REVISED CRITERIA FOR RHEUMATOID ARTHRITIS^a

Class I: No restriction of ability to perform normal activities
 Class II: Moderate restriction, but adequate for normal activities
 Class III: Marked restriction, inability to perform most duties related to occupation or self-care
 Class IV: Incapacitation or confinement to wheelchair or bed

TABLE 174.2. CLASSIFICATION OF DISEASE SEVERITY IN RHEUMATOID ARTHRITIS

MODE OF ONSET AND GENERAL FINDINGS

The onset of RA varies greatly. Typically, it begins insidiously, in the form of symmetric polyarticular arthritis involving the small joints of the hands and feet. This picture is by no means universal, and patients can show initial signs of monoarthritis or oligoarthritis that persists for weeks or months before disseminating to a more characteristic pattern. Signs and symptoms may wax and wane during the early stages of the disease, making the diagnosis difficult to establish owing to a paucity of physical findings. The average time from the onset of symptoms to diagnosis is about 6 months to 1 year. In some cases, the onset can be explosive, with an abrupt onset of polyarthritis associated with constitutional signs such as fever and weight loss. In addition to joint pain, patients with RA experience generalized fatigue and often require naps in the afternoon. Morning stiffness lasting longer than 30 minutes is particularly prominent and can persist for several hours or even all day during disease exacerbations. A similar “gelling” phenomenon occurs when patients remain in a single position for a prolonged period of time, such as on an airplane or simply sitting in a chair to read a book. Once established, the course of RA varies considerably. About 70% of patients have a chronic remitting course, while 10% to 20% express a very aggressive and destructive form of disease with few clinical remissions. The remaining patients have spontaneous, long-lasting remissions after the initial diagnosis; patients experiencing an abrupt onset of symptoms might be more likely to fall into this group.

ARTICULAR MANIFESTATIONS

The distribution of arthritis in RA is usually symmetrical and diffuse. The small diarthrodial joints of the hands are classically involved early in the course. The proximal interphalangeal joints (PIPs) and metacarpal phalangeal joints (MCPs) are usually tender and swollen. Physical examination shows loss of the usual contours across the MCPs, with palpable synovium between and over the bony prominences. Distal interphalangeal joint (DIP) disease can arise, but it is usually very mild. If it is prominent, alternative diagnoses should be considered, especially psoriatic arthritis or osteoarthritis. Wrist disease is quite common in RA, with resultant pain, tenderness, and decreased range of motion. Deformities of the hands and wrists are prevalent and can develop relatively early in the disease. One of the earliest deformities is radial deviation at the wrist, where the normal obtuse angle formed by the fifth metacarpal bone and the ulna increases to 180°. This deformity causes torque across the MCPs and contributes to the ulnar deviation at the MCPs, which is the most characteristic and obvious deformity of RA (Fig. 174.1). Swan neck deformities (hyperextension of the PIP and flexion of the DIP) and boutonniere deformities (flexion of the PIP and hyperextension of the DIP) are also very common after years of unabated synovitis. Similar pathologic manifestations can develop in the small joints of the feet, with synovitis of the metatarsal phalangeal joints as well as the PIPs of the toes. Common deformities of the feet include cock-up toes, loss of arches due to chronic midfoot disease, and hallux valgus.

FIGURE 174.1. Typical hand radiographic findings in RA. This 34-year-old female patient had had RA for 2 years and was being treated only with NSAIDs. In addition to soft-tissue swelling and periarticular osteopenia, there is also evidence of cartilage damage with joint space narrowing (➤) and destruction of bone with marginal erosions (➤). Note the bilateral destruction of the ulnar styloid, which is a common location for early erosive disease.

The larger proximal joints are also affected in RA. Chronic elbow synovitis frequently leads to mild flexion contractures. Arthritis in the shoulder joint can cause pain, decreased range of motion, and chronic rotator cuff tears. Abduction is especially restricted in long-standing RA, and marked atrophy of the shoulder girdle muscles is a frequent accompaniment. Difficulty in sleeping due to pain is a very common complaint in patients with significant shoulder arthritis. In the lower extremities, disease of the knees and hips can be quite debilitating. Because of the weight-bearing responsibilities of the cartilage and ligaments, progressive cartilage destruction and ligamentous laxity can lead to difficulty in walking, pain, and, ultimately, joint replacement surgery. In the most severe cases, the femoral head migrates medially and superiorly and, with tissue remodeling, can protrude through the acetabulum into the pelvis (“petrusio acetabulum”).

Cervical spine disease, with neck pain and decreased range of motion due to synovitis of the facet joints, is a prevalent complication of RA. One insidious and dangerous complication is myelopathy due to subluxation of the atlantoaxial joint. Atlantoaxial disease is especially important to note in patients undergoing surgical procedures, since forced flexion during intubation can be complicated by a neurologic catastrophe if the anesthesiologist is not appropriately forewarned. The presence of myelopathy due to cervical spine disease is a clear indication for surgical intervention and stabilization. In long-standing disease, the odontoid process can be eroded so severely that it is reduced to a mere spicule of bone, thereby increasing the risk of subluxation. The thoracic and lumbar spine is relatively spared in RA, although back pain from vertebral compression fractures can occur after years of inactivity and chronic glucocorticoid use in postmenopausal women. Other joints can be affected in RA and present special problems, including the temporomandibular joint and the cricoarytenoid joint. With RA of the temporomandibular joint,

chewing food can be painful and lead to weight loss from malnutrition, while RA of the cricoarytenoid joint can cause throat pain or hoarseness.

EXTRA-ARTICULAR MANIFESTATIONS

Articular symptoms are the primary clinical manifestations of RA in the majority of patients. Extra-articular complications also occur with some regularity. Rheumatoid nodules are especially common and are caused by the formation of extra-articular granulation tissue. They are found in about 20% of patients, almost all of whom are seropositive for rheumatoid factor and have erosive disease. Nodules can appear anywhere, but they are most prevalent on bony prominences, pressure points, and tendon sheaths. They are rubbery or granular in texture and can be indistinguishable from gouty tophi. In some cases, such as in the olecranon bursa, rheumatoid nodules can be large and highly mobile; they also can be fixed to the surface of the bone (such as the ulna) or to tendons. On histologic examination, nodules have a central area of fibrinoid necrosis, a middle zone of palisading histiocytes, and an outer layer of dense fibrous tissue with a mononuclear cell infiltrate. While they are usually of only cosmetic significance, rheumatoid nodules can sometimes arise in the vocal cords, nervous system, lungs, or heart (particularly the conduction system). Nodules tend to wax and wane over time, with new nodule formation sometimes paralleling exacerbations of disease. Treatment is usually conservative, since surgical removal can be followed promptly by formation of new nodules in the same location.

Compression neuropathy is also a typical extra-articular manifestation of RA. Carpal tunnel syndrome is the most common, with proliferative synovitis compressing the median nerve as it passes through the wrist. Numbness or paresthesias of the thumb, index, and middle finger are suggestive symptoms; weakness and muscular atrophy occur late. The tarsal tunnel of the ankle also can be affected by compression neuropathy, though this is less common.

Synovial cysts or herniation also form with some regularity. Particularly troublesome are popliteal cysts, known as Baker's cysts. They can sometimes rupture and lead to extravasation of synovial fluid into the calf, causing signs and symptoms resembling deep venous thrombosis. Cysts also can appear as periarticular masses in the elbow (particularly in the forearm), shoulder, or the small joints of the hand.

Pleuropulmonary disease is a relatively typical accompaniment of RA. Asymptomatic effusions are frequently noted on routine chest roentgenograms and can vary in size from a minor radiographic curiosity to a massive effusion. On occasion, effusions can cause shortness of breath or pleuritic chest pain. Aspiration of the pleural space yields exudative fluid, typically with a mildly elevated leukocyte count (less than 5,000 cells per cubic millimeter), low glucose level, and low complement levels. Pleural biopsies can show nonspecific chronic inflammation or rheumatoid nodules. Pulmonary parenchymal disease in RA ranges from mild fibrosis to progressive interstitial lung disease that is indistinguishable from idiopathic pulmonary fibrosis. Rheumatoid nodules also can form in lung parenchyma. They are usually of little functional significance, but because of their resemblance to solitary metastases, they present a diagnostic dilemma.

Other major organ systems also can be involved in RA. For instance, symptomatic cardiac disease is uncommon, though pericardial thickening has been found in 40% of patients at autopsy. Asymptomatic pericardial effusions occur with even greater frequency. In rare cases, pericardial effusions can be quite large and result in pericardial tamponade. Conduction system abnormalities from rheumatoid nodules in or about the atrioventricular node can cause heart block with syncope. Rarely, dilatation of the aortic root due to local inflammation or nodule formation can lead to aortic regurgitation. Ocular disease has also been noted in RA. Episcleritis is a common inflammatory eye condition in RA that causes mild discomfort and can be treated conservatively. Scleritis, however, is more serious and can be accompanied by severe eye pain; if left untreated, it can cause scleral perforation. The sicca syndrome (dry eyes and dry mouth) can result from lymphocytic infiltration into lacrimal and salivary glands (as in primary Sjögren's syndrome). Severe cases can lead to corneal erosion or ulceration in the eye, dental carries, and oral thrush.

Among the most feared complications of RA is systemic rheumatoid vasculitis. This syndrome is very similar to idiopathic polyarteritis nodosa and appears to result from immune complex-mediated inflammation in small and medium-size arteries. As with polyarteritis, the signs and symptoms depend on the location and caliber of the involved vessels. Mononeuritis multiplex with prominent motor dysfunction (such as wrist- or footdrop) as well as sensory deficits are present, as is evidence of cutaneous vasculitis with palpable purpura. Systemic rheumatoid vasculitis is a life-threatening disease that is associated with elevated circulating immune complexes in the blood and hypocomplementemia. Its presence does not correlate with activity of RA, since it is characteristically found in older men with relatively inactive arthritis. Patients are almost invariably seropositive for rheumatoid factor and have rheumatoid nodules. Small nail-fold infarcts are also evident and sometimes can be a harbinger of impending systemic vasculitis. Nail-fold infarcts, due to small vessel vasculitis, can also be found in the absence of systemic rheumatoid vasculitis. Treatment of fulminant vasculitis typically consists of high-dose glucocorticoids with or without such cytotoxic drugs as cyclophosphamide.

A variety of other diseases are associated with RA. For instance, the incidence of bacterial infections in rheumatoid joints is higher than normal. Establishing the diagnosis can sometimes be difficult if patients have very active disease or several septic joints. Diagnostic clues favoring infection include a relatively abrupt onset (though it can be insidious in patients taking immunosuppressive drugs or corticosteroids) and a synovial fluid analysis with a positive gram stain result and a low level of synovial fluid glucose. Nevertheless, the gram stain often gives negative results in septic arthritis. Other complications of RA or its treatment (particularly corticosteroids) include osteoporosis, vertebral compression fractures, and avascular necrosis, primarily in the femoral head. Tendon rupture, especially of the extensor tendons of the wrist and finger, can also occur as the result of overgrowth of synovium and might be forestalled by wrist synovectomy.

The overall mortality rate of patients with RA is modestly higher than that of the normal population. For the most part, people with RA die of the same causes as the general public, albeit earlier. In severely disabled patients with stage IV disease, however, mortality is equivalent to stage IV Hodgkin's disease. Such statistics dispel the myth that advanced RA is a benign disease and leads one to the conclusion that aggressive management is warranted. When RA patients are taken as a group, cardiovascular diseases are responsible for about 40% to 45% of deaths, followed by cancer (about 15%) and infection (about 10%). Lymphoproliferative diseases are somewhat more prevalent in the context of RA; non-Hodgkin's lymphoma, leukemia, multiple myeloma, and Hodgkin's disease account for most excess malignancies. A slight increase in renal deaths is caused by amyloidosis, which is an uncommon side effect of long-standing RA. It is often difficult to single out RA itself as the cause of death, rather than to assign the blame to complications of treatment.

LABORATORY FINDINGS

There are no specific tests to confirm the diagnosis of RA (Table 174.3). Hematologic parameters are usually notable for mild normochromic, normocytic anemia and an elevated platelet count. In fact, the degree of thrombocytosis is useful as a clinical manifestation and is often an indicator of disease activity. The leukocyte count is generally normal, though neutropenia occurs in association with splenomegaly in Felty's syndrome. Neutropenia may stem from a number of factors and appears to be related to antineutrophil antibodies, splenic sequestration, and/or cell-mediated damage to bone marrow precursors. Some cases of Felty's syndrome are associated with oligoclonal or monoclonal expansion of large granular lymphocytes in the blood and represent a form of chronic leukemia. The erythrocyte sedimentation rate and C-reactive protein level are usually elevated in active RA and can be used to monitor disease activity and response to disease-modifying drugs. Results of serum chemistry studies are normal, though liver enzymes can be elevated either by nonsteroidal anti-inflammatory drugs (NSAIDs) or, more commonly, by methotrexate or leflunomide.

Test	Typical Finding
Complete blood count	Normochromic, normocytic anemia
Platelet count	Elevated (usually 350,000–500,000 platelets/mm ³)
Erythrocyte sedimentation rate	Elevated (usually 30–60 mm/hr)
C-reactive protein	Elevated
Chemistry panel	Normal
Uric acid	Normal
Synovial fluid	2,000–25,000 leukocytes/mm ³ , predominantly polymorphonuclear leukocytes Normal glucose No crystals
Rheumatoid factor	Positive
Antinuclear antibody	Negative
Anti-double-stranded DNA antibody	Negative
Serum complement	Normal
Hand and foot radiographs	Soft tissue swelling Periarticular osteopenia Marginal erosions Joint space narrowing
Synovial tissue biopsy	Synovial lining hyperplasia Mononuclear cell infiltration Lymphoid aggregates Negative cultures

TABLE 174.3. LABORATORY TESTS IN ACTIVE RA

While there is no specific diagnostic test, a variety of serologic tests have some usefulness in RA. By far the most useful is the rheumatoid factor test. As noted, rheumatoid factors are antibodies that bind to the Fc portion of immunoglobulins. This propensity for aggregation is used to perform the latex or sheep red blood cell

agglutination test. Latex particle or red cells coated with IgG are incubated with various dilutions of patient's serum, and the degree of agglutination is assessed. The results are most often reported as the greatest dilution of serum that still causes agglutination. About 85% of patients with RA are "seropositive" for rheumatoid factor, usually at a dilution of $1:80$. New quantitative assays are also available, though determination of seropositivity depends on the standards established by an individual clinical laboratory. The presence of rheumatoid factor in the blood portends more aggressive disease, and its absence might identify a subset of patients with milder disease or with a syndrome similar to polymyalgia rheumatica. The test result can be positive for many years before arthritis develops, but only a relatively small percentage of individuals with a positive rheumatoid factor test result ultimately develop RA. Seropositivity, if it is going to develop in a patient with RA, usually does so before the end of the first year of disease.

In spite of its name ("rheumatoid" factor), this test is relatively nonspecific. In fact, 1% to 5% of normal individuals show positive latex agglutination test results, the higher percentage found in the elderly. Many other chronic inflammatory conditions are also associated with a positive result on a rheumatoid factor test, though the titers are usually somewhat lower than those observed in seropositive nodular RA. Patients with subacute bacterial endocarditis, tuberculosis, other connective tissue diseases (such as systemic lupus erythematosus), and noninflammatory diseases (like cirrhosis of the liver and sarcoidosis) can have positive test outcomes.

Other serologic tests that are used often to diagnose various connective tissue diseases are of limited value in RA. Tests for antinuclear antibodies usually show negative results, or else antibodies are present at low titers (though some patients have high titers of antinuclear antibodies). If anti-DNA antibodies are detected, they are almost always directed against single-stranded DNA rather than native double-stranded DNA. Other specialized serology tests, such as those for anti-Sm and anti-RNP antibodies, typically generate negative results. SSA and SSB antibodies are variably positive, and serum complement levels are normal in uncomplicated RA. Serologic tests for other viruses can be helpful in the differential diagnosis and can aid in distinguishing post-rubella arthritis or parvovirus B19 from RA. Hepatitis B and C serology tests can also furnish useful information, since these infections can cause a self-limited symmetrical polyarthritis. The usefulness of EBV serology is limited.

Analysis of synovial fluid can provide supportive data but is rarely, if ever, diagnostic. Synovial fluid is most frequently aspirated from the knee, though virtually any diarthrodial joint can contain an increased volume of fluid in RA. On gross examination, synovial fluid in RA is generally straw-colored and mildly turbid. If a wide-bore needle is used to aspirate fluid, gelatinous particles called "rice bodies" can also be withdrawn. These particles are composed of fibrin, collagen, and, occasionally, small fronds of synovium. White counts in synovial fluid are moderately elevated (between 2,000 and 20,000 cells per cubic millimeter), with varying differential counts. Usually, 50% to 75% of cells are neutrophils. The balance of cells are lymphocytes (mainly T cells) and monocytes.

In some cases, synovial fluid leukocyte counts exceed 100,000 cells per cubic millimeter with more than 90% neutrophils, which causes difficulty in ruling out pyogenic infection or crystal-induced arthropathy. A normal synovial fluid glucose level helps distinguish RA from acute infections. Complement levels are usually low in inflamed rheumatoid joints despite abundant production of complement proteins by synovium. A variety of other studies are frequently ordered on synovial fluid, but they are rarely useful. Rheumatoid factors are often present in RA synovial fluid, but they might not be detected by standard assays because they can be of the IgG isotype. Rheumatoid factor tests on synovial fluid are rarely indicated. Other traditional studies, such as the mucin clot test, do not provide significant additional clinical information.

Despite the well-documented MHC associations in RA and other forms of inflammatory arthritis, tests to determine the HLA phenotype of patients are not indicated, owing in part to the high prevalence of HLA-DR4 and other susceptibility markers in the normal population. Rarely, tests to determine the presence of HLA-B27 might be useful, if there is concern that polyarticular seronegative arthritis could be a form of seronegative spondyloarthritis, such as psoriatic arthritis or Reiter's syndrome, rather than RA.

There is considerable overlap in the synovial histologic features of various forms of inflammatory arthritis. Hence, synovial biopsies provide little useful information. They occasionally can be used to rule out mycobacterial or fungal infections. Surrogate markers for disease activity or for prognosis, in general, have been disappointing. The degree of macrophage infiltration in early arthritis might be a predictor of radiographic progression.

Bone radiographs in RA can help with diagnosis and can be used to follow the progression of erosions and the response to therapy. Hand and wrist radiographs (as well as radiographs of other areas disproportionately affected) should be obtained early in the course of disease as a baseline determination. The presence of erosions at this time would be a clear indication to advance therapy rapidly to a second-line agent. Typically, the first changes in the hand are periarticular osteopenia and soft-tissue swelling, especially of the PIPs and MCPs. The source of osteopenia is not certain; it could be due to immobilization or disuse. Alternatively, the local cytokine milieu might favor increased osteoclast activity. Synovial effusions sometimes can be detected in joint radiographs, owing to subtle changes in fat pads. As RA progresses, cartilage loss causes joint space narrowing, particularly at the second and third MCPs, the PIPs, and between the carpal bones in the wrist. Bone erosions often first appear at the "bare areas" located in the recesses of joints, where bone is not protected by cartilage and is in direct contact with synovium or synovial fluid (Fig. 174.1). It is here that pannus forms and begins to erode into the extracellular matrix. Pannus, which is unique to RA, is the aggressive leading edge of synovium and is composed of pleomorphic mesenchymal cells that express oncogenes and proteases. In the later stages of disease, the erosions and joint space narrowing become more prominent, and a variety of nonreducible deformities can be seen on radiographs, such as ulnar deviation of the fingers. Intra-osseous cysts can also develop, especially in the wrist. Ultimately, the carpal bones can fuse, causing ankylosis.

Radiographs of the lower extremities show a similar progression from osteoporosis to erosions/joint space narrowing to deformity. In the knees, tricompartmental narrowing and cartilage loss are evident. This picture differs from that of osteoarthritis, where medial joint space narrowing is the most prominent. The hip also shows symmetric joint space narrowing in RA, with medial and superior migration of the femoral head, whereas superior joint space narrowing predominates in osteoarthritis. Radiographs of the cervical spine can be used to identify and quantify atlantoaxial subluxation, erosions of the odontoid process, and erosive disease of the facet joints.

There are no established criteria for determining the frequency of radiography in RA. Most of the erosions occur during the first 5 years of disease, but it is unusual to see significant progression at intervals of less than 6 months. If the radiographs will help guide therapy, it is reasonable, at least during the earliest phases of RA, to obtain films of significantly affected joints or of the hands every 1 to 2 years, to assess progression.

THERAPY

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

The treatment of RA in large part addresses the symptoms; few drugs alter the natural history of the disease. For decades the mainstays of therapy have been NSAIDs, including aspirin and newer selective and nonselective cyclo-oxygenase inhibitors. Sufficient aspirin must be given in order to achieve anti-inflammatory blood levels (10 to 20 mg per deciliter). At lower concentrations, patients can experience analgesia, albeit without significant anti-inflammatory effects. The typical daily dose of aspirin in patients with RA ranges from 2 to 6 g of aspirin in divided doses. At the higher doses, clearance mechanisms can be saturated, and a relatively small increase in dose can be accompanied by a marked increase in blood levels. Because of gastrointestinal toxicity (including dyspepsia, erosive gastritis, and peptic ulcer disease), the large number of pills required, and skillful marketing, aspirin use has declined in recent years in favor of newer NSAIDs. Nonselective NSAIDs like ibuprofen or indomethacin provide little additional benefit besides improved pharmacokinetics, however, and exhibit a similar toxicity profile. Because aspirin inhibits platelet function and prolongs bleeding time, some physicians prescribe nonacetylated salicylates or salicylsalicylate instead. These are generally tolerated better than aspirin.

Production of prostaglandins in the rheumatoid synovium is dependent on two distinct cyclooxygenase enzymes, known as COX-1 and COX-2. The former is constitutively expressed and is responsible for normal endogenous production of prostaglandins in many tissues, including cytoprotective prostaglandins in the stomach. COX-2, on the other hand, is induced by such inflammatory cytokines as IL-1 and TNF- α and regulates increased prostaglandin synthesis in RA synovium. Most NSAIDs, including indomethacin, naproxen, and ibuprofen, inhibit both COX-1 and COX-2. It appears that most of the anti-inflammatory activity and analgesia result from inhibition of the latter. Selective COX-2 inhibitors, such as celecoxib and rofecoxib, are as effective as the nonselective inhibitors in RA, suggesting that COX-1 inhibition does not add appreciably to the therapeutic benefit.

A vast array of newer NSAIDs are now available, some of which can be purchased without prescription in the United States (ibuprofen and naproxen). No single drug can be recommended as clearly superior, and patients frequently try a number of agents to determine the most effective. For unclear reasons, some patients seem to respond better to one NSAID compared with the others. To avoid an unending cycle of NSAID experimentation, a physician should become familiar with a limited number of these agents and individualize therapy. The role of the selective COX-2 inhibitors in the treatment of RA is still evolving. In general, they probably should be used by patients with contraindications to standard NSAIDs, including bleeding diatheses, a history of peptic ulcer disease, or gastrointestinal intolerance.

Because COX-2 is not expressed in platelets, the selective COX-2 inhibitors potentially can be used in patients with platelet dysfunction. If patients respond well to generic NSAIDs, however, and do not experience adverse effects, there is no specific indication for switching to the more expensive agents. It is hoped that pharmaco-economic studies evaluating the relative costs of nonselective NSAID toxicity and selective COX-2 inhibitors will provide additional guidance.

There are few reasons to favor one drug over another. Because of the long half-life of piroxicam, it should be used with care in the elderly, in whom clearance might be diminished. Sulindac is said to have less kidney toxicity in patients with mild renal insufficiency, though the clinical relevance of this observation remains unclear. None of the nonselective NSAIDs have a clear-cut benefit over others with regard to gastrointestinal toxicity. Some gastrointestinal side effects can be minimized if pills are taken with food. Antacids, sucralfate, H₂ blockers, or proton pump inhibitors can also be symptomatically helpful, though they may not protect against drug-induced gastric erosions or ulcers. Prostaglandin analogues (e.g., misoprostol) appear to limit mucosal damage, but they need to be taken three to four times a day and can cause diarrhea. The selective COX-2 agents may have a lower incidence of asymptomatic gastric erosions and ulcers associated with their use.

Doses of NSAIDs in RA can be advanced quickly to the maximum recommended dose (500 mg naproxen taken orally twice a day or 600 to 800 mg ibuprofen taken orally four times a day), which frequently exceeds analgesic doses or doses used in osteoarthritis. Celecoxib, a selective COX-2 inhibitor, is given at 100 to 200 mg in oral doses twice a day and rofecoxib is administered at doses of 12.5 to 25 mg once a day. While some improvement might be noted within days after starting a new drug, a fair therapeutic trial should be 2 to 4 weeks before switching to another compound. If pain relief is not achieved with NSAIDs, judicious use of narcotics, such as codeine, can be appropriate on occasion, but they should be used with caution, owing to the obvious problems of tolerance and addiction that can arise in patients with chronic pain.

SECOND-LINE AGENTS

In traditional paradigms of RA treatment, advancement from NSAIDs to second-line agents is recommended if a patient does not have sufficient symptomatic improvement after an adequate therapeutic trial of NSAIDs; if a patient has aggressive seropositive disease, especially with rheumatoid nodules; or if there is radiographic evidence of erosions or joint destruction. The second-line agents are sometimes called DMARDs, or disease-modifying antirheumatic drugs, though their ability to slow progression of RA is not fully established. An alternative name for this class of drugs is SAARDs, or slow-acting antirheumatic drugs. There are many available SAARDs, and each has advantages and disadvantages. As a group, they tend to have relatively low response rates (usually about 30%), comparatively high toxicity levels, and a significant delay before onset of action (3 to 6 months). Some of the newer agents have more favorable profiles. A typical paradigm for treating patients whose pain is not adequately controlled by NSAIDs is shown in [Fig. 174.2](#).

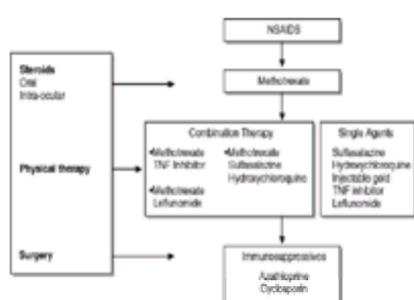

FIGURE 174.2. Suggested schema for RA treatment. In the past, patients whose disease was not adequately controlled by NSAIDs were treated with SAARDs (slow-acting antirheumatic drugs), such as gold. Many rheumatologists today bypass these drugs in favor of methotrexate as the initial second-line treatment. Superimposed on this paradigm is the judicious use of various glucocorticoid preparations, physical therapy, and surgery.

The most commonly used second-line drug is the folic acid antagonist methotrexate. Originally designed to inhibit dihydrofolate reductase, low-dose weekly methotrexate has unique efficacy in RA. Unlike the results with other second-line drugs, the majority of patients benefit, with a response rate of 70% to 80%. Moreover, the benefit occurs relatively rapidly compared with the other drugs, and improvement is sometimes observed after only 4 to 8 weeks of therapy. Treatment is usually initiated at 7.5 mg taken orally as a single dose 1 day a week. The dose is usually advanced (increasing by 2.5 to 5 mg per week each month) to 15 mg per week or until clinical benefit is achieved. Occasionally, higher doses (20 to 25 mg per week) or parenteral therapy (intramuscular or intravenous injections) are required for clinical improvement. When a sufficient clinical response is achieved, the dose sometimes can be modestly diminished without loss of benefit. The majority of patients have less morning stiffness, fewer signs of synovitis (swelling, warmth, erythema), less pain, and improved energy levels while taking methotrexate. Complete remissions are uncommon, and discontinuation of the drug usually leads to a flare-up within a few weeks. Methotrexate is very well tolerated, and about 50% of patients continue to take the medicine for at least 5 years. It is difficult to be certain whether methotrexate has true disease-modifying action or simply improves symptoms and quality of life. Radiographic studies suggest that erosions heal in a subset of patients, perhaps owing to a selective decrease in synovial collagenase gene expression.

The mechanism of action of methotrexate is still a matter of conjecture. At the doses used in RA, there are at most only very modest immunosuppressive effects. In adjuvant arthritis in the rat, methotrexate inhibits IL-1 production by macrophages. In addition, some acute anti-inflammatory activities appear to be mediated by increasing endogenous adenosine production. It is not clear whether the anti-inflammatory activities are in any way related to inhibition of dihydrofolate reductase, since coadministration of methotrexate with folic acid or folinic acid decreases gastrointestinal toxicity (especially oral ulcers) without affecting efficacy.

The primary safety concern with methotrexate is hepatotoxicity. Prolonged use of methotrexate can cause hepatic fibrosis and, rarely, cirrhosis with portal hypertension. This problem was particularly prominent in the 1950s and 1960s, when methotrexate was administered daily to treat patients with psoriasis. The advent of pulse methotrexate therapy (once a week) appears to have alleviated many of these problems. Several studies of liver biopsies from RA patients taking weekly methotrexate suggest that significant hepatic fibrosis is very uncommon. For this reason, it is no longer standard practice to perform serial liver biopsies (formerly recommended after every 1 to 2 g of total dose) unless specific risk factors dictate, such as preexisting liver disease or a history of excessive alcohol intake.

A complete blood count and liver enzyme profile should be obtained before initiating therapy and every 4 to 6 weeks thereafter to monitor toxicity. Renal insufficiency is a relative contraindication, since it can delay excretion and exacerbate the potential for bone marrow toxicity, leading to leukopenia or thrombocytopenia. Concomitant use of other folic acid antagonists, such as trimethoprim or trimethoprim-sulfamethoxazole is contraindicated, owing to possible synergistic marrow and mucosal toxicity. A mild increase in liver enzymes (usually the transaminases) in patients taking methotrexate is often rapidly reversed by temporarily discontinuing the drug and restarting it at a lower dose after the blood test results normalize. The relationship between serum transaminase elevation and hepatic fibrosis is tenuous at best. Nevertheless, it seems prudent to maintain liver enzymes within the normal range. The best-known risk factor for liver toxicity is the use of alcohol; it should be avoided. Methotrexate can also cause allergic pneumonitis marked by dyspnea and a eosinophilic infiltrate. In addition, it is a potent teratogen and abortifacient. Women of childbearing years must be advised of the reproductive consequences and should take appropriate precautions to avoid becoming pregnant. In men, methotrexate can cause mild azospermia.

If patients fail to have an adequate response to methotrexate, one can either add therapeutic agents (combination therapy) or switch to another single agent. Injectable gold, sulfasalazine, or antimalarial agents have been widely used individually as SAARDs. For many years, injectable gold was the first line of therapy after the failure of NSAIDs. Its effectiveness was established in prospective double-blind studies, and it is one of the few drugs with documented disease-modifying properties (albeit mild). Gold is available in two forms, an aqueous formulation (gold sodium thiomalate) and an oil-based preparation (aurothioglucose). The aqueous form is used preferentially, and the oil-based form is given to patients who experience "nitritoid" reactions with gold sodium thiomalate (episodes of flushing, diaphoresis, and hypotension shortly after injection).

To initiate gold therapy, a test dose of 10 mg gold sodium thiomalate is usually given intramuscularly, followed 1 week later by 25 mg. If it is well tolerated, the intramuscular dose is increased to 50 mg per week until a total dose of 1 g is reached. Before each dose, a urinalysis should be performed and a complete blood count taken (including a platelet count). Patients should be questioned about side effects, particularly oral ulcers and skin rash, which can occur in up to 30% of patients. The skin rash of injectable gold is usually intensely pruritic and can develop virtually anywhere on the body. If the rash resolves quickly upon cessation of

therapy, injectable gold can sometimes be restarted at a lower dose and gradually increased without recurrence. Other adverse effects, such as thrombocytopenia, leukopenia, or proteinuria from membranous glomerulonephritis, are indications to discontinue gold permanently. Severe glomerulonephritis or thrombocytopenia might respond to high-dose corticosteroids.

Antimalarial drugs are second-line agents that, like gold, require 3 to 6 months of continuous therapy to determine efficacy. As with many other slow-acting drugs, any clinical response observed before about 1 to 2 months of therapy must be considered coincidental rather than evidence of response. The most commonly used antimalarial agent in RA is hydroxychloroquine (200 mg administered orally twice a day). The response rate is similar to that observed with injectable gold; its primary advantage over gold is relative safety and ease of administration. The general tendency has been to administer injectable gold to patients with more aggressive disease and to use hydroxychloroquine in patients with milder RA. The major toxicity of antimalarial agents is ocular; retinal deposits develop after administration of high doses for years. Visual problems that can ultimately lead to blindness, such as loss of fine color distinction, can be monitored easily at home by patients, and periodic funduscopic examination can be used to confirm the lack of toxicity. Retinal disease due to the interaction of the drug with melanin in the pigmented epithelial layer and damage to the rods and cones should be distinguished from benign corneal deposits that can produce a halo effect around bright lights; the latter condition is not an indication to discontinue the drug. At the therapeutic doses used today, hydroxychloroquine is very safe, and discontinuation for retinal toxicity is rare. Other potential side effects include dyspepsia, increased skin pigmentation, and myopathy.

Sulfasalazine is used by many physicians to treat RA, especially in Great Britain; it is probably as effective as antimalarial drugs. Sulfasalazine is usually started at low doses (500 mg orally twice a day), and the dose is increased over several weeks to a maximum of 3 g per day, taken in divided doses. Gastrointestinal intolerance and lack of efficacy are the major reasons for discontinuing therapy. The active moiety in arthritis appears to be the sulfapyridine portion of the molecule. The mechanism of action is not known, but it might be inhibition of leukotriene B₄ production by neutrophils, scavenging of reactive oxygen species, blocking activation of the transcription factor NF- κ B, or increasing production of the anti-inflammatory autacoid adenosine.

Instead of using a series of individual agents to treat refractory RA, some clinicians use combination therapy. One possible approach is to add sulfasalazine and hydroxychloroquine to methotrexate (triple therapy), and there are data that suggest that this treatment is more effective than any of these agents used alone.

Specific anticytokine approaches have been successfully tested in RA. TNF inhibitors, in particular, have shown striking efficacy. Both an anti-TNF- α antibody (infliximab) and a soluble TNF receptor/Fc fusion protein (etanercept) have been confirmed to be effective in clinical studies and both are approved for use in the United States. Although both can be used as single agents, considerable success has also been achieved in combining them with methotrexate. Etanercept has been approved for use in RA as a subcutaneous injection twice a week (250 mg per dose). The response rate is 50% to 70%, and clinical improvement can occur within weeks of initiating therapy. Toxicity seems limited to local irritation at injection sites. In addition, acute phase reactants, such as the erythrocyte sedimentation rate and C-reactive protein, also decrease rapidly. Infliximab is administered intravenously at a dose of 30 mg/kg every 1 weeks. It is generally used in combination with oral methotrexate since this appears to diminish production of human antimouse antibodies. TNF- α inhibition does not cure RA; symptoms quickly return if the inhibitors are discontinued. It appears that they delay progression of RA, as evidenced on radiography, perhaps through the capacity of TNF- α to induce metalloproteinase production. Long-term safety of TNF inhibition remains uncertain, especially with regard to infections, and there is concern about antibody development to components of the compounds, particularly IgG, and tumor immunology. Studies with etanercept suggest safety comparable to methotrexate after at least 3 years of continuous treatment. Nevertheless, this therapy represents a truly effective alternative to the SAARDs.

IMMUNOSUPPRESSIVE AGENTS

Patients that fail treatment with standard second-line agents can advance to immunosuppressive drugs. Some are approved for use in RA in the United States, though they are used somewhat sparingly. Azathioprine, which is metabolized to the active metabolite 6-mercaptopurine, is modestly effective at doses from 1 to 2 mg per kilogram per day. Alkylating agents (such as chlorambucil and cyclophosphamide) are efficacious, but they are rarely used because of the potential for toxicity (especially the increased risk of malignancy). Cyclosporin (2.5 to 5 mg per kilogram per day) appears to provide modest benefit for a subset of patients, often at the expense of renal toxicity. Combinations of antimetabolites, like azathioprine and methotrexate, seem to have marginal additional benefit and a higher risk of side effects. Leflunomide is an inhibitor of *de novo* pyrimidine synthesis recently approved for use in RA. Because of its long half-life, a loading dose usually is required (100 mg/dx5), followed by 20 mg/d. Leflunomide also appears to block radiographic progression. Its major target for toxicity is the liver, although preliminary studies suggest that it can be given safely with methotrexate.

GLUCOCORTICOIDS

Superimposed on this strategy for treating RA are a variety of other treatment methods. The most prominent is the judicious use of oral prednisone. In general, the dose should not exceed 10 mg per day. Alternate-day treatment, with a view to limiting side effects, is generally not successful, owing to worsening of symptoms during the "off" day. Steroid therapy should be started with some trepidation, because it can be difficult to wean patients once it has been initiated. Glucocorticoids are indicated for patients who are unable (or unwilling) to wait for the benefit of a second-line drug or whose disease is so severe that it jeopardizes their livelihood or their ability to care for themselves or others (especially their children). The clinical response is usually gratifyingly rapid (within a few days). Once the decision has been made to begin tapering prednisone, patience is a key virtue. One should be satisfied with very small decreases in the dose at intervals of 2 to 4 weeks, particularly when the dose is less than 5 mg per day.

Corticosteroids should be used with particular care in postmenopausal women because of the increased risk of osteoporosis. It is often advisable to initiate preventive therapy for osteoporosis, such as estrogen replacement or bisphosphonates. In men, low-dose steroids can be used with somewhat greater assurance, though care should still be taken to monitor patients periodically for evidence of declining bone density, such as vertebral compression fractures. In particular, bone densitometry should be performed on postmenopausal women to determine whether they are candidates for hormone replacement therapy or bisphosphonates. At the doses used in RA, diabetes, mood changes, sleep disturbances and other serious side effects are not common. Cataracts and skin atrophy, with easy bruising, do occur with some frequency.

Intra-articular steroids represent an effective alternative in treating RA of the individual joints that flares up out of proportion to the rest of the disease. Care must be taken, of course, to rule out an infectious source for a monoarticular flare-up. The amount of corticosteroid injected depends on the size of the joint. A useful guideline is 40 mg or the equivalent of an insoluble salt of triamcinolone (triamcinolone hexacetonide) in large joints (hips, shoulders, knees), 20 mg in medium-size joints (elbows and ankles), 10 mg in small joints (wrists), and 5 mg in the joints of the fingers and toes. If a soluble steroid preparation is injected instead of an insoluble form, the response is generally more limited and transient. Many physicians recommend immobilizing the injected joint for 1 to 2 days to enhance and prolong the response. Improvement after injection is usually relatively rapid, with a significant response in less than a week (usually after a day or two).

Occasionally, short-term flare-ups develop within a few hours after injection, perhaps because of the phlogistic properties of the steroid crystals themselves. The duration of the response varies, but it averages about 6 months. Sometimes joints remain quiescent for well over a year. Improvement occasionally can be observed in other joints, possibly due to small amounts of the active compound leaking into the circulation or activated immune cells trafficking through the injected joint and being suppressed by the local glucocorticoid effect before recirculating to other active joints. Repeated injections into the same joint have few demonstrable adverse effects, though it is probably inadvisable to inject an individual joint more than two or three times in a year.

PHYSICAL THERAPY AND SURGERY

Physical therapy and other nonpharmacologic treatments are often prescribed but rarely are shown to be effective in well-controlled studies. Most physical measures, like whirlpool baths, heated wax treatments, ultrasonography, and diathermy, certainly make patients feel better during the procedure and perhaps for a short time afterward. This, in and of itself, is a worthy outcome. Nevertheless, such methods have not been shown to provide significant long-term functional, anti-inflammatory, or disease-modifying benefit. Many patients become disillusioned with these treatments after varying degrees of experimentation. It is important for patients to maintain an active life, and guidance from physical therapists with range-of-motion exercises and aerobic training is probably beneficial. Swimming or other water exercises are especially valuable for patients with significant pain in weight-bearing joints. Exercise programs might help delay or prevent joint contractures and muscular atrophy. Too much activity can exacerbate arthritis; a good balance must be struck. Temporary immobilization of some joints by splinting can provide significant relief in these cases. In fact, in years past, bed rest was an effective anti-inflammatory regimen for generalized RA flare-ups. Splinting might also lessen the progression of nonreducible deformities, especially in the hands and wrists.

Surgical treatment has become an important therapeutic option. Improvement in surgical techniques, antibiotic prophylaxis, and the development of new polymers have revolutionized the care of surgical patients, particularly those with total knee and total hip replacements. These procedures can transform a patient from

wheelchair bound to ambulatory. With increased activity after surgery, new problems can arise, and previously unrecognized foot disease or other problems can suddenly become limiting. Long-term complications include loosening of the prostheses and bacterial infection. Despite such problems, joint replacement surgery has had a major impact on the quality of life for RA patients.

The indications for surgical interventions vary from patient to patient. A primary reason is amelioration of intractable pain, especially for joint replacement surgery. The relief achieved by total joint replacement or even less radical approaches is nothing short of remarkable. A second indication for surgery is severely impaired function. Completely eroded cartilage (resulting in bone-on-bone articulation), ruptured ligaments, and progressive destruction of bone matrix can lead to severe functional derangement that is amenable only to surgical correction. In addition to weight-bearing joints, impairment due to severe deformities in the hands also can be helped by surgery. For instance, dislocation and subluxation of the MCPs can render the hands useless, while implantation of artificial joints or merely arthrodesis (joint fusion) can improve grip and lead to dramatic functional improvement. Synovectomy in aggressive wrist disease may delay rupture of the extensor tendons of the hand. Arthroscopic synovectomy is also useful if symptoms in one joint, especially the knee, are particularly disabling in the absence of structural abnormality. This is a temporizing procedure, however, since the synovium can grow back over a period of a few years. Occasionally, surgery is indicated for cosmetic reasons, either to correct a deformity or to remove strategically located rheumatoid nodules.

Conclusion

Future therapeutic interventions in RA are being guided by increased understanding of the mechanisms of disease. In addition to the TNF inhibitors, IL-1 inhibitors are also being developed. For instance, IL-1Ra, which is a naturally occurring antagonist of IL-1, has been evaluated as a therapeutic agent. Preliminary data suggest that modest anti-inflammatory activity is accompanied by decreased bone destruction. Small-molecule inhibitors of signal transduction pathways involved in cytokine gene expression, such as the mitogen-activated protein (MAP) kinases, could lead to novel oral agents to block cytokine production. Treatment with immunosuppressive T_H2 cytokines, such as IL-10 and IL-4, might have usefulness in RA. Attempts to inhibit cellular trafficking through the synovium by interfering with adhesion molecule function are also under investigation, including specific inhibitors and integrins. While antibodies directed at specific T-cell subsets (including anti-CD4 and anti-CD5) have generally been a disappointment in clinical trials, newer, more specific reagents designed to remove cells expressing specific combinations of a and b T-cell receptor genes might have greater success. Moreover, it is hoped that such rationally designed agents will be able to achieve something that empirical treatment has not: arresting the progression of RA as well as providing symptomatic relief.

CHAPTER 175: OSTEOARTHRITIS AND POLYCHONDROITIS

MARC C. HOCHBERG

[Osteoarthritis](#)
[Relapsing Polychondritis](#)

OSTEOARTHRITIS

Osteoarthritis, formerly referred to as degenerative joint disease, is the most common form of arthritis. In 1986, a comprehensive definition of osteoarthritis was published in the proceedings of a conference on the etiopathogenesis of osteoarthritis, sponsored by the National Institutes of Health; this definition summarized the clinical, pathophysiologic, biochemical, and biomechanical changes that characterize osteoarthritis:

Clinically, the disease is characterized by joint pain, tenderness, limitation of movement, crepitus, occasional effusion, and variable degrees of local inflammation, but without systemic effects. Pathologically, the disease is characterized by irregularly distributed loss of cartilage more frequently in areas of increased load, sclerosis of subchondral bone, subchondral cysts, marginal osteophytes, increased metaphyseal blood flow, and variable synovial inflammation. Histologically, the disease is characterized early by fragmentation of the cartilage surface, cloning of chondrocytes, vertical clefts in the cartilage, variable crystal deposition, remodeling, and eventual violation of the tidemark by blood vessels. It is also characterized by evidence of repair, particularly in osteophytes, and later by total loss of cartilage, sclerosis, and focal osteonecrosis of the subchondral bone. Biomechanically, the disease is characterized by alteration of the tensile, compressive, and shear properties and hydraulic permeability of the cartilage, increased water, and excessive swelling. These cartilage changes are accompanied by increased stiffness of the subchondral bone. Biochemically, the disease is characterized by reduction in the proteoglycan concentration, possible alterations in the size and aggregation of proteoglycans, alteration in collagen fibril size and weave, and increased synthesis and degradation of matrix macromolecules.

In 1994, a revised definition of osteoarthritis was proposed at a conference sponsored by the American Academy of Orthopaedic Surgeons and National Institutes of Health:

Osteoarthritis (OA) is the result of both mechanical and biologic events that destabilize the normal coupling of degradation and synthesis of articular cartilage and subchondral bone. Although it may be initiated by multiple factors including genetic, developmental, metabolic and traumatic; OA involves all of the tissues of the diarthrodial joint. Ultimately, OA is manifested by morphologic, biochemical, molecular and biomechanical changes of both cells and matrix which lead to a softening, fibrillation, ulceration and loss of articular cartilage, sclerosis and eburnation of subchondral bone, osteophytes and subchondral cysts. When clinically evident, OA is characterized by joint pain, tenderness, limitation of movement, crepitus, occasional effusion, and variable degrees of local inflammation.

EPIDEMIOLOGY

Osteoarthritis is the most common form of arthritis, with a worldwide distribution; indeed, age-specific prevalence rates of osteoarthritis by groups of joints are strikingly similar in all populations studied. Most epidemiologic studies of osteoarthritis have used the presence of radiographic changes as illustrated in the *Atlas of Standard Radiographs* for the purpose of case definition. Population-based studies in the United States, reviewed by the National Arthritis Data Workgroup in 1998, show that approximately one-third of US adults aged 25 to 74 had radiographic evidence of osteoarthritis involving at least one joint group; the prevalence was greatest in the hands and then the feet, knees, and hips in declining order of frequency. The prevalence rises with increasing age in all joint groups and is generally higher in women than men. Gender-specific rates vary by age and site, especially at the knee and hip.

Factors associated with the development of osteoarthritis are listed in [Table 175.1](#). Age is the strongest determinant of osteoarthritis; indeed, radiographic changes of osteoarthritis are almost universal in at least one joint group in persons older than 75. Gender is also associated with variations in the rate of development of osteoarthritis; the disorder is more common in men younger than 45 and in women older than 55. Furthermore, the clinical subset of nodal generalized osteoarthritis (see "[Classification](#)" below) is seen almost exclusively in middle-aged and elderly women. In the United States, osteoarthritis of the knee is both more common and more severe in African-American women than in white women, even after adjustment for other known risk factors.

TABLE 175.1. RISK FACTORS FOR OSTEOARTHRITIS

Heredity

Hereditary factors have been recognized as important in the development of Heberden's nodes for more than 40 years. New studies have presented significant evidence of familial aggregation of polyarticular osteoarthritis, and twin studies have established significant heritability for the radiographic features of osteoarthritis, including osteophytes and joint space narrowing. In several families, a single base mutation at position 419 in the *COL2A1* gene, resulting in a single amino acid change from cysteine to arginine, has been found to be linked to a syndrome of mild chondrodysplasia with polyarticular osteoarthritis. Other mutations in the *COL2A1* gene as well as in genes for type IX and XI collagen and the aggrecan protein also have been associated with osteoarthritis.

Obesity

Data from prospective epidemiologic studies show a causal association between obesity and the development of osteoarthritis of the knees. This association is most likely explained on a biomechanical basis, though the role of an underlying metabolic disturbance cannot be completely excluded. The association of obesity with knee osteoarthritis is stronger than that with osteoarthritis of the hip; furthermore, obesity is more strongly associated with bilateral than unilateral disease at both the hip and knee.

Mechanical Stress

Biomechanical stresses, as reflected by repetitive occupational joint use or a history of significant joint trauma, are also associated with the development of osteoarthritis. Persons with jobs that require frequent knee bending and greater strength demands are at higher risk of knee osteoarthritis, while those with jobs that require heavy bending and lifting are at increased risk of hip osteoarthritis. Persons with a history of unilateral knee or hip trauma are at increased risk of ipsilateral but not contralateral knee or hip osteoarthritis, respectively. The role of avocational exercise, including running, as a risk factor for osteoarthritis, in the absence of

injury, remains the subject of controversy.

Other Factors

Other risk factors for osteoarthritis include congenital and developmental disease of bones and cartilage (congenital hip subluxation, slipped capital femoral epiphysis), previous inflammatory joint disease (rheumatoid arthritis), selected metabolic and endocrine disorders (ochronosis, hemochromatosis, acromegaly), and calcium pyrophosphate deposition disease.

CLASSIFICATION

Based on the occurrence of osteoarthritis in various populations and the risk factors that have been identified from epidemiologic studies, several classification schema have been developed. One such schema, modified from the one proposed by the American College of Rheumatology, is shown in [Table 175.2](#). Idiopathic osteoarthritis manifests either in a localized form, affecting one or two joint groups (usually the distal interphalangeal, proximal interphalangeal, and first carpometacarpal joints of the hands; the cervical or lumbar spine, or the first metatarsophalangeal joints of the feet, knees, and hips), or in a generalized form, involving three or more joint groups. This generalized form is frequently associated with Heberden's nodes; in this instance, it most often affects middle-aged or elderly women and is inherited in an autosomal dominant fashion. In patients with osteoarthritis of atypical joints (metacarpophalangeal joints of the hands, wrists, elbows, shoulders, and ankles), the physician should search for an underlying disorder (e.g., hemochromatosis) as a cause of secondary osteoarthritis.

Idiopathic
Localized (hands, feet, knee, hip, spine, and other single sites)
Generalized (includes three or more areas listed above)
Secondary
Posttraumatic
Congenital or developmental diseases
Localized (hip disease)
Generalized (bone dysplasia and metabolic diseases, such as ochronosis, hemochromatosis)
Calcium deposition disease
Other bone and joint disorders (avascular necrosis, rheumatoid arthritis, Paget's disease)
Other diseases
Endocrine diseases (acromegaly, hyperparathyroidism)
Neuropathic arthropathy
Miscellaneous

(From Altman RD, Asch E, Bloch D, et al. Development of criteria for the classification and reporting of osteoarthritis. *Arthritis Rheum* 1986;29:1038-1049, modified and reproduced with permission.)

TABLE 175.2. CLASSIFICATION OF OSTEOARTHRITIS

ETIOLOGY AND PATHOGENESIS

Osteoarthritis is thought to be primarily a disease of the articular cartilage and subchondral bone, with mild secondary inflammation of the synovial membrane. In idiopathic osteoarthritis, it is not known whether the primary abnormality occurs in the articular cartilage or the subchondral bone; in most cases of secondary osteoarthritis, however, it appears that the primary defect is in the articular cartilage.

The articular cartilage has two major functions in health: minimizing contact stress by deforming under conditions of mechanical load and providing a smooth load-bearing surface to permit motion of the joint with minimal friction and wear. Articular cartilage is composed of chondrocytes imbedded in an extracellular matrix of collagen and proteoglycans. The major structural protein in articular cartilage is type II collagen, other minor collagens include types IX and XI. It is believed that these minor collagens are involved in cross-linking of adjacent bundles of type II collagen and interactions between proteoglycan molecules and type II collagen. Proteoglycan molecules are composed of hyaluronic acid and an aggrecan molecule attached by link protein; the aggrecan molecule is composed of a core protein to which are attached glycosaminoglycans, including keratan sulfate, chondroitin-4-sulfate, and chondroitin-6-sulfate.

The earliest biochemical changes in articular cartilage are an increase in water content, presumably due to weakening of the type II collagen network, and accompanying decreases in proteoglycan concentration, aggregation, and size. These changes result in other changes in the biomechanical properties of the cartilage, with increased hydraulic permeability and decreased ability to bear load. Remodeling of the subchondral bone leads to advancement of the tidemark region of calcified cartilage and a decline in the volume of articular cartilage. Proliferation of cartilage at the margins of the joint, followed by endochondral ossification, leads to the formation of the osteophyte, the radiologic hallmark of osteoarthritis.

As noted earlier, osteoarthritis reflects a disturbance in the homeostasis of synthesis and degradation of articular cartilage. The chondrocyte, under stimulation by interleukin-1 and other cytokines as well as by mechanical deformation, increases synthesis of degradative enzymes, including matrix metalloproteases (collagenase, gelatinase, stromelysin) and aggrecanase; these enzymes degrade the structural components of articular cartilage, hastening its biomechanical failure. Although synthesis of normal cartilage extracellular components remains intact and is even increased early in the course of disease, in later stages synthesis declines, and the cartilage cannot be repaired. Data from numerous laboratories suggest that inhibitors of interleukin-1 and inhibitors of the synthesis of matrix metalloproteases may alter the development and progression of osteoarthritis in animal models of this disease. Trials of these agents in humans are in progress.

CLINICAL FINDINGS

Typically, the patient with osteoarthritis is middle-aged or elderly and experiences gradual onset of pain and stiffness accompanied by loss of function. This gradual or insidious pain is usually moderate in intensity, worsened by use of the involved joints, and improved or relieved with rest. While pain at rest or nocturnal pain are felt to be features of severe disease, they also may be markers of local inflammation. The onset of pain in patients with osteoarthritis stems from several possible factors; pain may result from periostitis at sites of bony remodeling, subchondral microfractures, capsular irritation from osteophytes, periarticular muscle spasm, bone angina due to decreased blood flow and elevated intraosseous pressure, and synovial inflammation accompanied by the release of prostaglandins, leukotrienes, and various cytokines, including interleukin-1. Articular cartilage itself has no nerves.

Morning stiffness is common in patients with osteoarthritis. The duration of morning stiffness, however, is significantly shorter (often less than 30 minutes) than in patients with active rheumatoid arthritis. A gelling phenomenon, or stiffness after periods of inactivity, is also common and resolves within several minutes. Both pain and stiffness are modified by weather changes in the majority of patients; symptoms worsen in damp, cool, and rainy weather and improve when the weather improves. Patients with osteoarthritis of the knees also may complain of a sense of instability or buckling, especially when descending stairs or curbs.

On physical examination, evidence of disease usually is found to be localized to symptomatic joints. Bony enlargement is common, with tenderness at the joint margins and attachments of the joint capsule and periarticular tendons. Limitation of motion of the affected joint frequently is related to osteophyte formation and/or severe cartilage loss. Signs of local inflammation may be present, including warmth and soft-tissue swelling due to joint effusion. The presence of a hot, erythematous, markedly swollen joint should suggest either a superimposed microcrystalline process, such as gout or pseudogout, or septic arthritis. Instability can be detected by excess joint motion; locking of a joint during range-of-motion testing is likely due to loose bodies. Crepitus, which can be felt on passive range of joint motion and is due to irregularity of the opposing cartilage surfaces, is present in more than 90% of patients with osteoarthritis of the knee. Malalignment is evident in almost 50% of patients with osteoarthritis of the knee; a varus deformity (e.g., bowlegs) due to loss of articular cartilage in the medial compartment is more common than a valgus deformity.

LABORATORY FINDINGS

The clinical diagnosis of osteoarthritis is usually confirmed with radiographs. The radiographic features of osteoarthritis are illustrated in [Fig. 175.1](#). The classic radiographic finding is marginal osteophyte formation. Subchondral bone sclerosis and asymmetric joint space narrowing due to loss of articular cartilage develop with progression of disease. Joint space narrowing may be due to actual degradation of articular cartilage and/or progression of the tidemark region of calcified cartilage toward the surface during bone remodeling. Later changes include the formation of subchondral cysts with sclerotic walls and bone remodeling with alteration in the shape of the bone ends. Bone demineralization (periarticular osteoporosis) and marginal erosions are not a radiographic feature of osteoarthritis; their presence

should strongly suggest the diagnosis of a form of inflammatory arthritis, such as rheumatoid arthritis.

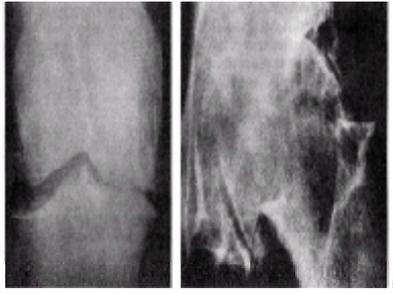

FIGURE 175.1. A: Radiograph of the knee showing osteoarthritis. Note the marked narrowing of the joint space in the medial compartment, osteophyte formation, sclerosis of subchondral bone, and attrition of bone in the medial tibial plateau. **B:** Radiograph of the hip showing osteoarthritis. Note the marked loss of joint space, osteophyte formation, subchondral sclerosis, subchondral cyst formation, and deformity of the femoral head.

Routine laboratory tests, including complete blood count, erythrocyte sedimentation rate, chemistry panels, and urinalysis, generally show normal results in patients with osteoarthritis. These studies, especially the complete blood count and chemistry panel, should be obtained at the time of baseline evaluation of patients with osteoarthritis—before instituting therapy with nonsteroidal anti-inflammatory drugs (NSAIDs)—and at 3- to 6-month intervals during therapy. Tests for rheumatoid factor, commonly performed in the evaluation of patients with arthritis, may show positive results in low titer in up to 20% of elderly individuals; therefore, the presence of rheumatoid factor does not exclude a diagnosis of osteoarthritis if the clinical picture and radiographic changes are most suggestive of this disorder. Synovial fluid analysis usually reveals type I, noninflammatory fluid. The finding of inflammatory fluid with an elevated white cell count suggests either a superimposed microcrystalline process (gout, pseudogout, or basic calcium apatite crystals) or septic arthritis.

Optimal Management

The principles of the treatment of patients with osteoarthritis are listed in [Table 175.3](#). Treatment should be individualized based on the distribution and severity of joint involvement as well as the presence of comorbid conditions. Educational materials, including pamphlets published by the Arthritis Foundation, provide basic information that allows the patient to understand and cope with his or her disease. Patients should be encouraged to participate in the Arthritis Self-Help Course, administered by local chapters of the Arthritis Foundation; this course includes educational sessions supervised by a lay coordinator with professional speakers.

Nonpharmacologic therapy
Education of the patient
Self-management program
Social support
Physical and occupational therapy
Range-of-motion and muscle-strengthening exercises
Aerobic conditioning
Weight loss
Pharmacologic therapy
Simple analgesics (acetaminophen)
Topical analgesics (capsaicin cream)
Nonsteroidal anti-inflammatory drugs
COX-2-specific inhibitors
Intra-articular corticosteroid injections
Intra-articular hyaluronate injections
Closed tidal joint irrigation
Narcotic analgesics
Surgical therapy
Arthroscopic debridement and joint irrigation
Osteotomy
Total joint arthroplasty

TABLE 175.3. APPROACH TO THE TREATMENT OF PATIENTS WITH OSTEOARTHRITIS

Patients with osteoarthritis are likely to suffer from physical disability characterized by difficulty in performing activities of daily living, including bathing, dressing, eating, grooming, and toileting, and limitation in mobility. The occupational therapist will evaluate the patient's ability to perform activities of daily living, provide assistive devices as needed, and teach joint protection techniques and energy conservation skills. In addition, splints can be designed either to stabilize or to reduce inflammation in finger joints, especially the thumb base. The physical therapist also will teach the patient the therapeutic use of heat and massage and devise an individualized exercise program. This exercise program will stress muscle strengthening to provide stability to weight-bearing joints. In addition, braces, canes, and other ambulation aids and devices can be furnished, if needed. Physical therapy also plays a key role in the pre- and postoperative care of patients who undergo reconstructive orthopaedic surgery, including total joint arthroplasty.

Overweight patients should be encouraged to lose weight; referral for dietary instruction and enrollment in an aerobic exercise program, either supervised fitness walking or aquatic swimming, may be helpful. Studies have verified that weight loss is associated with improvement in both pain and disability. The main indication for drug therapy in patients with osteoarthritis is pain relief. Simple analgesics, such as acetaminophen, are the drug of choice for initial therapy in patients with mild to moderate pain. Patients who fail to achieve adequate pain relief with acetaminophen should be treated with an NSAID; these drugs are approximately equally effective, and the choice of a specific NSAID is largely influenced by differences in toxicity profiles and costs. It is preferable for patients who are at high risk of adverse upper-gastrointestinal-tract effects to receive a COX-2-specific inhibitor, such as celecoxib or rofecoxib, rather than an NSAID that inhibits both isoforms of the cyclooxygenase enzyme. COX-2-specific inhibitors have an incidence of adverse upper-gastrointestinal-tract effects similar to that of placebo and significantly less than that of nonselective NSAIDs.

Intra-articular corticosteroid injections have a role in the treatment of patients whose symptoms are limited to one or a few joints that have effusions and signs of local inflammation. Local injections are beneficial as an adjunct to NSAID therapy or for the patient who is unable either to take or to tolerate NSAIDs. Care should be taken to use aseptic technique when injecting joints; in addition, fluid aspirated at the time of injection always should be sent for appropriate bacteriologic culture. Other medical treatments include topical analgesic creams (capsaicin) and intra-articular preparations of hyaluronic acid in patients with osteoarthritis of the knee who have failed to respond to or who are intolerant of other therapies.

Patients whose symptoms are not adequately controlled with medical therapy and who have severe pain and functional impairment are candidates for reconstructive joint surgery. Total joint arthroplasty has markedly altered the quality of life of patients with osteoarthritis of the knees and hips and is thought to be the major advance in the treatment of patients with osteoarthritis over the past 30 years. Short-term outcomes include moderate to marked pain relief; in the long-term, the majority of patients experience significant improvement in function. The perioperative mortality rate is generally below 1%, and short-term complications, including thromboembolic disease and infection, occur in less than 5% of patients. A major concern is the long-term development of loosening due to deterioration of the bone–cement interface; the development of porous coated prostheses, which allow fixation by bone ingrowth, and newer techniques for cementing of noncoated prostheses may lead to a reduction in the rate of revision surgery due to loosening.

RELAPSING POLYCHONDRITIS

Relapsing polychondritis is a rare multisystem disease characterized by episodic inflammation of cartilaginous structures, resulting in tissue destruction. Little is known of the epidemiology of relapsing polychondritis; no reliable data are available on incidence and prevalence. Proposed diagnostic criteria for relapsing polychondritis are based on the clinical manifestations (see [Clinical Findings](#)).

ETIOLOGY AND PATHOGENESIS

The cause of relapsing polychondritis remains unknown. Tissue destruction results from release of degradative enzymes, including matrix metalloproteases, from chondrocytes and other cells. The release of these enzymes likely stems from immune-mediated activation of the chondrocytes and inflammatory cells; data supporting the role of the immune system include the association of relapsing polychondritis with autoimmune diseases—among them, rheumatoid arthritis, systemic lupus erythematosus, and systemic vasculitis—the presence of antibodies to type II collagen in the serum samples of patients with relapsing polychondritis, and the finding of immunoglobulins suggestive of immune complexes in tissue lesions from patients with relapsing polychondritis.

CLINICAL FINDINGS

Relapsing polychondritis can develop at any age, though the majority of cases are diagnosed in patients between ages 40 and 59. The sex distribution is equal; the disorder, however, has been reported mainly among whites. Clinical features are listed in [Table 175.4](#). The most common feature of this disease is bilateral auricular chondritis, with redness, swelling, and tenderness in the acute phase and development of so-called cauliflower ears in the later phase. Hearing impairment, due to closure of the external auditory meatus, serous otitis media, eustachian tube obstruction, inflammation of the middle ear and a neurosensory hearing loss, and vestibular dysfunction, may accompany the ear symptoms. Involvement of the nasal cartilage is typical, with redness, swelling, and tenderness in the early phase and a “saddle nose” deformity in the later phase. Ocular inflammation manifests as episcleritis, scleritis, iritis, and keratitis in the majority of patients. Joint symptoms include peripheral inflammatory, nonerosive, and nondeforming polyarthritis and costochondritis. Involvement of the larynx and tracheobronchial tree is accompanied by complaints of hoarseness, dyspnea, wheezing, and stridor. Airway collapse is a major cause of death in these patients. Cardiovascular symptoms include aortic insufficiency, usually due to aortitis with dilatation of the aortic ring rather than valvular changes; aneurysms of the ascending and descending aorta have also been described. Renal symptoms are rare. Small-vessel vasculitis may produce palpable purpura.

Ears
Bilateral auricular chondritis
Auditory and/or vestibular dysfunction
Nose
Nasal chondritis
Eyes
Episcleritis, scleritis
Nongranulomatous uveitis
Keratitis with corneal perforation
Joints
Parascleritis
Peripheral nondeforming, nonerosive polyarthritis
Respiratory tract
Laryngeal chondritis
Tracheobronchial chondritis
Airway collapse
Cardiovascular
Aortic insufficiency
Aortic aneurysms
Small-, medium-, and large-vessel vasculitis
Arterial and venous thrombosis
Kidney
Crescentic glomerulonephritis
Skin
Cutaneous vasculitis

TABLE 175.4. CLINICAL MANIFESTATION OF RELAPSING POLYCHONDritis

LABORATORY FINDINGS

Results of laboratory tests generally show nonspecific changes suggestive of chronic inflammation, including elevation of the erythrocyte sedimentation rate, mild normochromic/normocytic anemia, leukocytosis, thrombocytosis, and polyclonal hyperglobulinemia. Tests for antinuclear antibodies and rheumatoid factor usually generate positive results in patients with coexistent connective tissue diseases. Positive test results for antinuclear cytoplasmic antibodies and antiphospholipid antibodies have been reported in a minority of patients. Antibodies to both native and denatured type II collagen and a cell-mediated immune response to type II collagen and cartilage proteoglycans have been found in some patients. On biopsy of tissue lesions, the cartilage shows loss of basophilic staining of matrix, suggesting proteoglycan depletion, focal or diffuse infiltration by mononuclear inflammatory cells (predominantly CD4⁺ lymphocytes), and replacement of normal cartilage structure by fibrous granulation tissue. Focal calcification may be present.

OPTIMAL MANAGEMENT

There is no standard therapy for relapsing polychondritis. Generally, patients with signs of acute inflammation are treated with prednisone, in doses equivalent to 0.75 to 1 mg per kilogram per day. When the acute inflammation subsides, doses are tapered to a maintenance level, as tolerated; alternate-day therapy is not recommended. Diaminodiphenyl sulfone (Dapsone), in doses of 50 to 200 mg per day, has also been used for patients without respiratory or cardiovascular involvement. In patients who are unresponsive to or intolerant of corticosteroids or who require higher than acceptable maintenance doses of corticosteroids, such immunosuppressive agents as azathioprine, cyclophosphamide, cyclosporine, and methotrexate may be useful. Patients with upper-airway involvement may require tracheostomy for relief of symptoms of airway collapse; those with laryngeal symptoms may need endotracheal intubation or surgical stabilization of the trachea. Patients with aortic insufficiency should be considered for valve replacement in conjunction with replacement of the aortic root.

CHAPTER 176: SPONDYLOARTHROPATHIES

FRANK C. ARNETT

[Etiology and Pathogenesis](#)
[Prevalence and Epidemiology](#)
[Clinical Features](#)
[Laboratory Findings](#)
[Optimal Management](#)

The spondyloarthropathies encompass a family of chronic inflammatory disorders primarily affecting peripheral and axial joints. Although they have been considered variants of rheumatoid arthritis, these diseases now are classified as distinct entities based on clinical, epidemiologic, and immunogenetic differences. Unifying features include the following:

- A tendency for the disease to affect sacroiliac and other spinal joints (sacroiliitis and spondylitis)
- Peripheral arthritis, typically asymmetrical and oligoarticular
- Inflammatory lesions of tendon and fascial insertions (enthesopathy) at peripheral and axial sites
- Extra-articular complications affecting the eye (anterior uveitis) or heart (aortitis and conduction disturbance)
- Disease onset in young adults, especially men
- Absence of rheumatoid factor and other autoantibodies
- Strong associations with the class I histocompatibility antigen HLA-B27

Despite these common characteristics, each spondyloarthropathy manifests unique clinical and immunogenetic features, suggesting etiologic diversity. In clinical features, these differences usually permit precise diagnosis, which is important for management and prognosis. At times, overlapping clinical manifestations or incomplete expression make diagnosis difficult. Members of the spondyloarthropathy family include the following:

- Ankylosing spondylitis, a predominantly axial form of arthritis that usually begins in the sacroiliac joints and slowly progresses to spinal fusion
- Reiter's syndrome, or reactive arthritis, an acute peripheral type of arthritis associated with nongonococcal urethritis, conjunctivitis, or other mucocutaneous features, which typically occurs after enteric or genitourinary infections
- Psoriatic arthritis, a slowly progressive peripheral variety of arthritis, with or without axial disease, that occurs in the context of cutaneous psoriasis
- Enteropathic arthritis, a type of peripheral or axial arthropathy accompanying the idiopathic inflammatory bowel diseases, ulcerative colitis, and Crohn's disease

ETIOLOGY AND PATHOGENESIS

An atypical immune response to certain specific bacteria, mediated by HLA-B27, other major histocompatibility complex genes (HLA-B60, -DR1, and -DR8 and tumor necrosis factor α), and additional unidentified genetic loci, is believed to underlie the pathogenesis of most of the spondyloarthropathies ([Table 176.1](#)). The strongest evidence for this model is provided by Reiter's syndrome, or reactive arthritis, in which genitourinary infections caused by *Chlamydia trachomatis* and, possibly, *Ureaplasma urealyticum* and gastroenteritis caused by *Shigella flexneri*, many *Salmonella* species, *Yersinia enterocolitica* and *Yersinia pseudotuberculosis*, and *Campylobacter jejuni* have been shown in epidemiologic studies to incite the disease, primarily in individuals with HLA-B27. Accumulating data suggest that there is bacterial persistence at the primary sites of infection and dissemination of living microbes or their products to the joints and other extra-articular structures.

Infections
Enteric pathogens
Shigella flexneri
Salmonella species
Yersinia enterocolitica
Campylobacter jejuni
Genitourinary pathogens
Chlamydia trachomatis
Ureaplasma urealyticum
Other pathogens
Yersinia pseudotuberculosis
Yersinia enterocolitica
Bacterial antigens (T helper organisms) in synovial fluid/tissue
Specific granulocyte response of synovial fluid T cells
Serum IgA antibodies to causative bacteria
Asymptomatic bowel inflammation (T site of bacteria)
Clinical response to specific antibiotic treatment
Animal model of spondyloarthropathy (B27 transgenic rats)
Shows that disease develops in germ-free environment
Genetics
Strong association of disease across ethnic lines with class I HLA-B27
Transgenic rats with human HLA-B27 spontaneously develop reactive spondyloarthropathy
High concordance rate of ankylosing spondylitis in monozygotic versus dizygotic twins
Genetic mapping in families shows ankylosing spondylitis to be predominantly genetic in origin
Genetic mapping in families shows linkage to HLA-B27 as well as several other chromosomal regions

TABLE 176.1. ETIOLOGIC AND PATHOGENETIC FACTORS IN REACTIVE ARTHRITIS AND POSSIBLY OTHER SPONDYLOARTHROPATHIES

Bacterial antigens, especially lipopolysaccharides, from most of these intracellular pathogens have been found in synovial fluid phagocytes or synovial cells from patients with reactive arthritis using electron microscopy or fluorescent monoclonal antibodies. Although attempts to culture living bacteria from the joints have been unsuccessful, studies using the polymerase chain reaction have detected chlamydial RNA or DNA in synovial tissue, suggesting the presence of viable microorganisms. In addition, synovial fluid T lymphocytes from patients with reactive arthritis proliferate specifically when challenged with bacterial antigens from the causative agent, whereas peripheral blood mononuclear cells show this response less often. Moreover, serum IgA antibodies to the triggering microbe often are found for many months or even years in patients with reactive arthritis, suggesting ongoing mucosal immunity to a chronic infection. Asymptomatic bowel inflammation has been verified by ileocolonoscopy in most patients with postenteric reactive arthritis and ankylosing spondylitis, but it is not known whether these bowel lesions represent sites of persisting bacterial infection. Finally, several controlled clinical trials suggest that reactive arthritis and other spondyloarthropathies are responsive to certain antibiotics, especially tetracycline or sulfasalazine.

The exact role of HLA-B27 in the pathogenesis of the spondyloarthropathies is not known ([Table 176.1](#)). A direct effect of the HLA-B27 molecule seems certain, because diarrhea with inflammatory bowel lesions, peripheral and axial arthritis, and psoriasiform skin and nail lesions resembling human disease develop spontaneously in transgenic rats that express high copy numbers of the human B27 and b₂-microglobulin genes. Underscoring the requirement for bacteria, the bowel and joint lesions do not develop when these animals are reared in a germ-free environment. Additional studies in HLA-B27 transgenic animals have shown that T lymphocytes are required for spondyloarthropathy, that the disease can be transferred to nontransgenic animals by bone marrow–derived cells from affected transgenes, and that experimental *Yersinia* infection is more severe and persistent in these HLA-B27–positive animals.

Three major hypotheses concerning the possible role of HLA-B27 in human spondyloarthropathies are being explored. The first is that the HLA-B27 class I molecule fails to mount an effective immune response, presumably cytotoxic T cells, to certain bacteria, permitting microbial persistence and dissemination. The second hypothesis states that HLA-B27 presents an arthritigenic bacterial or self-peptide (presumably cross-reactive) to cytotoxic T cells that then incites an autoimmune response in the joints and other tissues. In each of these models, the normal function of HLA-B27 (peptide presentation) might or might not have a role. Molecular mimicry between HLA-B27 and bacteria, in theory, could result in either possibility, and HLA-B27 has been shown to share sequence homology with *Klebsiella pneumoniae*, an *S. flexneri* plasmid, and other enteric bacteria. The third hypothesis, which is supported by experimental evidence, is that the HLA-B27 molecule might promote bacterial invasiveness and/or persistence in cells.

Studies of the immunology of synovial fluid in reactive arthritis show predominantly helper T cells, especially those with the T_H2 cytokine profile, reacting to bacterial products and restricted by HLA class II molecules. HLA-B27 (class I)–restricted, cytotoxic T-cell responses to triggering bacteria also have been found, but it is unclear whether they are relevant to the underlying cause of the disease. A causative agent for ankylosing spondylitis has not been identified, though *K. pneumoniae* has been proposed as a possibility. Some cases definitely evolve from reactive arthritis. Whether bacterial antigens or viable organisms are present in sacroiliac and other spinal joints is unknown; this question awaits further study. Similarly, modern bacteriologic investigations of psoriasis and enteropathic arthritis have not been reported. New genomic mapping studies of twins and multiplex families with ankylosing spondylitis have established a strong polygenic mode of inheritance, and

several non-HLA regions that may correspond to those regions linked to inflammatory bowel disease and psoriasis have been linked tentatively to the disease.

The inflammatory lesions of joints and entheses in the spondyloarthropathies are made up primarily of mononuclear cells, including T cells and macrophages, and cytokines, including tumor necrosis factor α and transforming growth factor β , which invade the synovium, cartilage, subchondral bone, joint capsule, or bony periosteum. There is a striking tendency for fibrosis and ossification leading to bony and periarticular fusion around peripheral and axial joint structures, resulting in the characteristic roentgenographic findings.

PREVALENCE AND EPIDEMIOLOGY

The prevalence of spondyloarthropathies, especially ankylosing spondylitis and reactive arthritis, generally parallels the prevalence of HLA-B27 in different populations. Ankylosing spondylitis affects about 0.1% to 0.2% of American and European whites, or about 2% of such HLA-B27–positive individuals. HLA-B27 occurs in about 6% to 14% of whites, depending on the ethnic background. American blacks have an HLA-B27 prevalence of only 2% to 3% and are affected less often by the disease. Ankylosing spondylitis and HLA-B27 are rare in African blacks and Japanese but common among certain Native American tribes. Men appear to be affected more often than women (3:1), and the disease usually begins in young adulthood.

Family studies indicate that about 15% of patients with ankylosing spondylitis will have at least one affected relative with both the disease and HLA-B27. It appears that HLA-B27–negative relatives are at no risk of this disease. However, HLA-B27–positive relatives of a patient with ankylosing spondylitis have a 25% to 45% risk of disease development, in contrast to the only 2% risk of HLA-B27–positive individuals with a negative family history. Concordance rates for ankylosing spondylitis are 63% in monozygotic twins and 13% in dizygotic twins.

The prevalence of Reiter's syndrome in most populations is unknown, primarily because of its sporadic occurrence and usually self-limited course. A high prevalence has been reported in Navajo Native Americans and both Alaskan and Greenland Inuits, who have high prevalence rates of HLA-B27 and who reside in areas endemic for shigellosis or venereal infections. Reiter's syndrome appears to be the most common cause of inflammatory peripheral arthritis in young adult men in the military; however, its frequency has fallen significantly since the introduction of safer sexual practices dictated by the AIDS epidemic. Women acquire the disease less frequently than men, usually after an enteric infection. The risk that reactive arthritis will develop after exposure to each of the causative bacterial infections has been estimated at 1% to 2% overall for whites and 20% for HLA-B27–positive individuals. Reiter's syndrome has been reported often in men infected with the human immunodeficiency virus, especially those with AIDS, in whom it appears to pursue a more severe course.

Cutaneous psoriasis affects nearly 2% of whites, but psoriatic arthritis develops in only 5% to 7% of patients with psoriasis. Men and women, usually young adults, are affected equally. Streptococcal infections, trauma, and stress have been implicated as triggers for psoriasis. Several HLA class I antigens are associated with susceptibility to psoriasis but the strongest is HLA-Cw6, which also shows genetic linkage in families. Other non-HLA genes also appear to be necessary. Peripheral arthritis occurs in 20% and spondylitis in 10% of patients with ulcerative colitis or Crohn's disease. Men and women are affected equally.

CLINICAL FEATURES

The clinical features of the spondyloarthropathies are summarized in [Table 176.2](#).

Feature	Ankylosing Spondylitis	Reiter's Syndrome Reactive Arthritis	Psoriatic Arthritis	Enteropathic Arthritis
Male-to-female ratio	3:1	3:1	3:1	3:1
Onset of onset	Medial, usually lower	Acute, variable, symmetric, distal	Medial, acute	Acute, variable or symmetric
Pattern of peripheral arthritis	Asymmetric, oligoarthral	70% asymmetric or oligoarthral; 30% symmetric	70% asymmetric or oligoarthral; 30% symmetric	20% oligoarthral; 80% symmetric
Spinal involvement	90%	0%	0%	0%
Enthesopathy	90%	0%	0%	0%
Extra-articular features	None	Uveitis, conjunctivitis, oral ulcers, skin lesions	None	None
HLA-B27	90%	0%	0%	0%
Associated diseases	None	None	None	None
Response to HLA-B27	90%	0%	0%	0%

*Based on 1000 population prevalence rates of 0% to 10%.

TABLE 176.2. CONTRASTING CLINICAL AND IMMUNOGENETIC FEATURES AMONG THE SPONDYLOARTHROPATHIES

ANKYLOSING SPONDYLITIS

Ankylosing spondylitis typically shows initial features of chronic lower back pain or stiffness in an adolescent or young adult. The discomfort usually localizes to the sacroiliac regions of the buttocks; however, a more generalized lumbar or thoracic stiffness may dominate. Typically, symptoms are worse during periods of rest and improve with increasing physical activity. Sciatica-like pains may occur but are not associated with neurologic deficits. As the disease progresses, normal lumbar lordosis is lost, and spinal mobility in all planes is restricted. The thoracic spine may assume an accentuated kyphosis, and fusion of costovertebral joints results in diminished chest expansion. Cervical motion may become severely restricted, with eventual head fixation in a flexed position. Although the disease usually progresses slowly over many years, spinal deformity, at times of a grotesque degree, occasionally develops rapidly. Peripheral joints are involved infrequently, except for the shoulders or hips.

Atypical forms of the disease, with peripheral arthritis, occur commonly in children, usually boys who have oligoarthritis of the lower-extremity joints and enthesopathy. Later, spinal symptoms emerge and pursue the usual course. Similarly, women often have a predominantly peripheral or cervical pattern of involvement, with few or no lower spinal symptoms. Extra-articular complications include episodes of acute anterior uveitis in 25% of patients, which occur independently of arthritis activity. Aortic regurgitation or varying degrees of atrioventricular conduction disturbance eventually develop in 5% of patients from inflammatory involvement of aortic valve cusps, proximal aortic root, and adjacent atrioventricular nodal tissue. Apical pulmonary fibrosis, often mimicking tuberculosis, is rare, as are amyloidosis and cauda equina syndrome. IgA nephropathy may develop.

The diagnosis is based on clinical features, supporting physical findings, and, most specifically, pelvic radiographs showing sclerosis, erosions, or fusion of sacroiliac joints (sacroiliitis) ([Fig. 176.1](#)). Computed tomography and magnetic resonance imaging of sacroiliac joints are more sensitive than conventional radiographs in the early stages of disease, but rarely are they necessary. In advanced cases, spinal radiographs show inflammatory erosions of vertebrae, resulting in a squared appearance; ossified ligamentous structures originating at vertebra; and bridging intervertebral discs (syndesmophytes), bony fusion of apophyseal joints, and spinal osteopenia ([Fig. 176.1](#)). Distinguishing ankylosing spondylitis from diffuse idiopathic skeletal hyperostosis can be difficult, though sacroiliitis is not present in the latter condition. Determination of HLA-B27 sometimes is diagnostically useful in disease that is not evident on radiography and in the atypical forms commonly seen in children and women.

FIGURE 176.1. Roentgenogram of the pelvis in advanced ankylosing spondylitis. Both sacroiliac joints have undergone bony fusion, and previous sacroiliac sclerosis and erosions are now gone. Bilateral syndesmophytes bridge intervertebral disks at multiple lumbar levels, and there is marked osteopenia.

REITER'S SYNDROME (REACTIVE ARTHRITIS)

Reiter's syndrome typically begins 2 to 4 weeks after a diarrheal illness or venereal exposure. Mild dysuria and a mucopurulent urethral discharge, along with conjunctivitis, usually herald by several days the development of acute arthritis, enthesitis, fever, and other mucocutaneous features. The knees, ankles, and small joints of the feet are affected most often in an asymmetrical and oligoarticular pattern. Diffuse swelling of the digits, especially the toes, results in a "sausage" appearance. Enthesopathy produces pain over nonarticular bony areas; heel pain (Achilles or plantar tendonitis) is a common and disabling symptom. Back pain is common, but sacroiliitis eventually develops in only 20% of patients. In addition, more than half of all patients have one or more mucocutaneous lesions, such as keratoderma blennorrhagicum, a papulosquamous eruption indistinguishable from pustular psoriasis usually over the soles or palms; painless oral ulcers on the tongue or palate; circinate balanitis on the penile glans or shaft; or dystrophic nails.

Incomplete forms of Reiter's syndrome are common—urethritis and conjunctivitis often are absent. Nevertheless, the distinctive pattern of arthritis, enthesopathy, and mucocutaneous involvement should strongly suggest the diagnosis. Exclusion of septic arthritis is mandatory, and typing for HLA-B27 may prove useful. Even more limited clinical syndromes of HLA-B27 diathesis have been reported, including uveitis, pustular psoriasis (keratoderma), circinate balanitis, "sausage" digits, chronic heel pain, monoarthritis, and heart block, all of which have been associated with HLA-B27. Reiter's syndrome, or reactive arthritis, is a self-limited disease that lasts 3 to 12 months in most patients. Relapses occur in up to one-third of patients. Persistent and progressive joint or skin disease ensues in about 15% to 20% of patients. Distinctive radiographic features are found most often in the latter group of patients, including joint destruction, bony fusion across joints, and periosteal reactions at sites of enthesopathy, especially the calcaneus.

PSORIATIC ARTHRITIS

Psoriatic arthritis typically emerges long after or concurrently with cutaneous psoriasis, though arthritis may appear first, especially in children. Several forms have been described, including a type with distal interphalangeal involvement; arthritis with an asymmetrical, oligoarticular pattern; symmetrical polyarthritis; arthritis mutilans (similar to serious cases of rheumatoid arthritis); and sacroiliitis and spondylitis. Overlap among these patterns is the norm, and "sausage" of digits and pitting of nails occur frequently. The disease usually is indolent and progresses slowly. Radiographic changes include "pencil-in-cup" deformities and bony fusion similar to that of chronic Reiter's syndrome.

Acne arthritis, or the SAPHO syndrome (synovitis, acne, pustulosis, hyperostosis, osteitis), is a rare disorder with features of reactive and psoriatic arthritis. It typically takes the form of oligoarthritis with or without bony lesions or palmoplantar pustulosis (resembling psoriasis) in patients with severe types of acne (acne fulminans, acne conglobata, hidradenitis suppurativa, and dissecting cellulitis of the scalp). Sacroiliitis and syndesmophytes have been described, but there appears to be no association with HLA-B27. Microbiologic studies have failed to identify a causative bacterium, and antibiotic therapy usually is ineffective. Low-dose corticosteroids, along with vigorous local treatment of the acne, are the best approach in most cases.

ENTEROPATHIC ARTHRITIS

Peripheral arthritis and the extra-articular features ([Table 176.1](#)) of inflammatory bowel disease reflect active gut involvement. Asymmetric arthritis of the knees, ankles, feet, and wrists is the typical pattern and results in no radiographic changes or permanent deformities. Sacroiliitis and spondylitis occur independently of active bowel inflammation. Although it resolves peripheral arthritis, colectomy for ulcerative colitis does not alter the progression of axial disease. The radiographic changes in this type of spondylitis are indistinguishable from those of idiopathic ankylosing spondylitis, in contradistinction to Reiter's syndrome and psoriatic arthritis, in which sacroiliitis and syndesmophytes are more asymmetrical.

Whipple's disease is a rare systemic condition that most often affects middle-aged white men and is characterized by diarrhea with malabsorption, weight loss, fever, lymphadenopathy (especially mesenteric), skin hyperpigmentation, and, occasionally, cardiac or nervous system involvement. Peripheral arthritis, usually symmetrically affecting the knees, ankles, or wrists, occurs in about 60% of cases and may precede the other symptoms by many years. Sacroiliitis and spondylitis have been documented, and about one-third of patients have been reported to possess HLA-B27 regardless of spinal involvement. The disease appears to be caused by widespread dissemination of a bacillus that is positive on periodic acid–Schiff staining and is found in biopsy samples of most affected tissues, including synovium but especially the small bowel. The bacterium has not been cultured, but it has been identified in tissue samples and peripheral blood by polymerase chain reaction as a gram-positive actinomycete and has been named *Tropheryma whippelii*. Long-term treatment with tetracycline or sulfonamide antibiotics seems to be curative.

LABORATORY FINDINGS

Laboratory abnormalities are few in the spondyloarthropathies. Mild normocytic, normochromic anemia and elevation of the erythrocyte sedimentation rate and total serum IgA level are common. Modest leukocytosis and thrombocytosis are seen most often in acute Reiter's syndrome and enteropathic arthritis. Tests for serum rheumatoid factors and antinuclear antibodies render uniformly negative results. The incidence rates of class I HLA are shown in [Table 176.2](#); HLA-B27 may serve as a useful test in early-stage or atypical ankylosing spondylitis or Reiter's syndrome, but not when there is either a high or very low probability that one of these conditions is present. Synovial fluid findings include leukocyte counts ranging from 5,000 to 50,000 per microliter, with the highest counts found in Reiter's syndrome; elevated protein levels; normal glucose levels; and an absence of organisms on Gram stain and culture.

OPTIMAL MANAGEMENT

Therapy for the spondyloarthropathies involves pharmacologic suppression of joint inflammation in conjunction with physical therapy to preserve axial and peripheral joint function and prevent deformity. Unlike rheumatoid arthritis, these arthritides usually do not respond to salicylates, proprionic acids, corticosteroids, or long-acting drugs, such as gold salts, D-penicillamine, or hydroxychloroquine. Instead, the nonsteroidal anti-inflammatory agents indomethacin, tolmetin, piroxicam, and others are more effective in suppressing symptoms of pain and stiffness, and signs of inflammation. A rational basis for the concomitant use of certain antibiotics has been established (see Etiology and Pathogenesis). Sulfasalazine (2 to 3 g per day) has been shown to be effective in relieving joint symptoms and signs and improving acute phase reactants in all the spondyloarthropathies. Tetracycline therapy may shorten the duration of *Chlamydia*-induced reactive arthritis and may prevent recurrences when used early to treat venereal infections. In all patients with reactive arthritis, an attempt should be made to identify the causative microorganism so that the most appropriate antibiotic trial can be initiated ([Fig. 176.2](#)). Quinolone antibiotics do not appear to be effective in acute or chronic reactive arthritis caused by enteric pathogens.

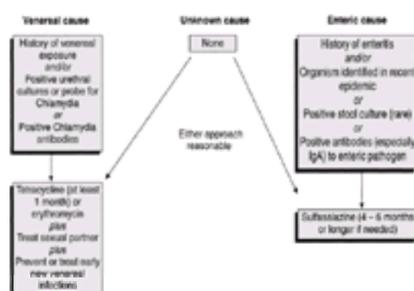

FIGURE 176.2. Rational approach to an antibiotic treatment of reactive arthritis.

Immunosuppressants, such as methotrexate or azathioprine, are needed occasionally, but they should be used sparingly in patients with reactive arthritis in view of the possibility of promoting further bacterial persistence, and they should not be used at all in those with human immunodeficiency virus infection. Methotrexate is a more useful agent for psoriatic arthritis. The presence of peripheral arthritis in inflammatory bowel disease indicates active bowel inflammation, and treatment of the bowel with corticosteroids or other drugs (or colectomy in the case of ulcerative colitis) usually results in resolution of the peripheral, but not axial, joint disease. Physical therapy exercises to preserve range of motion in affected spinal and peripheral joints and habits that promote good posture are important in preventing contractures and spinal deformities. Swimming is an excellent recreational exercise. With these measures, less than 20% of patients have permanent disability. Death occurs in less than 5% of patients and results primarily from spinal (especially cervical) fractures, cardiac complications, and amyloidosis.

CHAPTER 177: CRYSTAL-INDUCED SYNOVITIS

MICHAEL M. WARD

[Gout](#)
[Calcium Pyrophosphate Dihydrate Deposition Disease](#)
[Basic Calcium Phosphate Crystal Deposition Diseases](#)

Crystal-induced synovitis refers to a group of conditions characterized by acute or chronic arthritis due to the deposition of crystals in and around joints. The deposition of monosodium urate crystals leads to acute gout and chronic tophaceous gout; deposition of calcium pyrophosphate dihydrate crystals leads to chondrocalcinosis, acute pseudogout, and several types of chronic arthritis; and deposition of apatite-like crystals leads to calcific tendinitis, periarthritis, acute arthritis, and chronic destructive arthritis. These conditions are among the most common causes of inflammatory arthritis. Identification of crystals in synovial fluid is the key to the correct diagnosis.

GOUT

DEFINITION

Gout is a chronic metabolic disease with several features: an elevated serum urate concentration (hyperuricemia), intermittent episodes of acute arthritis induced by monosodium urate monohydrate crystals, extracellular deposition of masses of urate crystals in and around joints or in soft tissues (tophi), uric acid nephrolithiasis, and renal disease due to the deposition of urate or uric acid crystals in the renal interstitium, tubules, or collecting system. Hyperuricemia is a necessary precursor of each of the clinical features. Individual patients may experience one or more of the clinical features.

INCIDENCE AND EPIDEMIOLOGY

Hyperuricemia, defined as a serum urate concentration of more than 7 mg per deciliter in men and more than 6 mg per deciliter in women, is found in 2% to 10% of adults. Serum urate concentrations increase with age, body size, blood pressure, decreased renal function, and alcohol intake and are higher in men and in persons of Pacific Islander ethnicity. Fewer than 20% of all persons with hyperuricemia experience clinical consequences.

Acute gouty arthritis primarily affects middle-aged and elderly men and, less often, elderly women. The incidence of acute gouty arthritis in the general population ranges from 0.20 to 0.35 per 1,000 person-years. Among adult men, the incidence is about 10 times higher (two to three per 1,000 person-years). The incidence of gouty arthritis rises with age and with serum urate concentration, from one per 1,000 person-years at serum urate concentrations of less than 7 mg per deciliter to 49 per 1,000 person-years at serum urate concentrations of 9 mg per deciliter or more. It is the most common type of inflammatory arthritis in adult men, with a prevalence of 1.4% to 5%. Tophaceous gout develops in up to 25% of patients with recurrent attacks of acute gouty arthritis who are not treated with hypouricemic medications.

ETIOLOGY

Hyperuricemia can result from either overproduction or underexcretion of uric acid ([Table 177.1](#)). Uric acid is the end product of purine metabolism ([Fig. 177.1](#)). The purine pool is derived from dietary sources, the breakdown of tissue nucleic acids, the formation of purine nucleotides (such as adenylic acid [AMP] and guanylic acid [GMP]) from pre-formed purines by the salvage pathway, and de novo synthesis from phosphoribosyl pyrophosphate (PRPP). The rate-limiting step in *de novo* purine synthesis is the conversion of PRPP and glutamine to 5-phosphoribosyl-1-amine by the enzyme amidophosphoribosyltransferase. This reaction is accelerated by the substrate PRPP and inhibited by AMP, GMP, and inosinic acid.

Hyperuricemia can be produced by
Purine
Overproduction: hyperuricemia associated with gouty arthritis
Underexcretion: hyperuricemia associated with gouty arthritis
Dietary: hyperuricemia associated with gouty arthritis
Renal: hyperuricemia associated with gouty arthritis
Drugs: hyperuricemia associated with gouty arthritis
Chronic kidney disease: hyperuricemia associated with gouty arthritis
Hypertension: hyperuricemia associated with gouty arthritis
Diabetes mellitus: hyperuricemia associated with gouty arthritis
Obesity: hyperuricemia associated with gouty arthritis
Alcohol: hyperuricemia associated with gouty arthritis
Hypothyroidism: hyperuricemia associated with gouty arthritis
Hemolytic anemia: hyperuricemia associated with gouty arthritis
Leukemia: hyperuricemia associated with gouty arthritis
Lymphoma: hyperuricemia associated with gouty arthritis
Epilepsy: hyperuricemia associated with gouty arthritis
Hypertension: hyperuricemia associated with gouty arthritis
Diabetes mellitus: hyperuricemia associated with gouty arthritis
Obesity: hyperuricemia associated with gouty arthritis
Alcohol: hyperuricemia associated with gouty arthritis
Hypothyroidism: hyperuricemia associated with gouty arthritis
Hemolytic anemia: hyperuricemia associated with gouty arthritis
Leukemia: hyperuricemia associated with gouty arthritis
Lymphoma: hyperuricemia associated with gouty arthritis
Epilepsy: hyperuricemia associated with gouty arthritis

TABLE 177.1. CAUSES OF HYPERURICEMIA

FIGURE 177.1. Human purine metabolism. Inosinic acid is synthesized by the pathway of purine biosynthesis *de novo*. This purine nucleotide can be converted to adenylic acid or guanylic acid. Purine nucleotides may be degraded to uric acid following initial dephosphorylation to adenosine, inosine, or guanosine. Inosine or guanosine is then converted to hypoxanthine or guanine, respectively. These compounds are further degraded to xanthine and uric acid. Purine bases may be salvaged to purine nucleotides by the reutilization pathways. Hypoxanthine and guanine are converted to inosinic acid and guanylic acid, respectively, while adenine can be converted to adenylic acid. Reaction 1, amidophosphoribosyltransferase; reaction 2, hypoxanthine-guanine phosphoribosyltransferase; reaction 3, phosphoribosylpyrophosphate synthetase; reaction 4, adenine phosphoribosyltransferase; reaction 5, adenosine deaminase; reaction 6, purine nucleoside phosphorylase; reaction 7, 5'-nucleotidase; reaction 8, xanthine oxidase. PRPP, phosphoribosylpyrophosphate; ATP, adenosine triphosphate. (From Palella TD, Kelley WN. Purine and deoxypurine metabolism. In: Kelley WN, Harris ED Jr, Ruddy S, et al., eds. *Textbook of Rheumatology*. Philadelphia: WB Saunders, 1985:337, with permission.)

Rare mutations in the enzymes that regulate the concentration of PRPP are among the primary causes of hyperuricemia and gout. PRPP synthetase overactivity increases the concentration of PRPP and therefore promotes *de novo* purine synthesis. Deficiencies in the enzyme hypoxanthine-guanine phosphoribosyltransferase (HGPRT) in the purine salvage pathway promote increased *de novo* purine synthesis by the accumulation of PRPP and the decreased production of GMP, AMP, and

inosinic acid, which are inhibitors of amidophosphoribosyltransferase. Mutations leading to PRPP synthetase overactivity and partial or complete HGPRT deficiency are X linked, and patients with these mutations have severe and premature gout. Patients with complete HGPRT deficiency (Lesch–Nyhan syndrome) also have neurologic signs of growth and mental retardation, spasticity, choreoathetosis, and self-mutilation. Among the secondary causes of increased urate production are conditions that increase the catabolism of ATP or cell turnover and high dietary purine intake ([Table 177.1](#)).

Urate excretion occurs mainly via the kidney (up to 75%); the remainder is excreted in the intestines and metabolized by gut bacteria. In the kidney, urate undergoes glomerular filtration (100%), proximal tubular reabsorption (98%), tubular secretion (50%), and postsecretory tubular reabsorption (40%), so that about 10% of filtered urate is excreted in the urine. Conditions that affect any of these processes can lead to hyperuricemia ([Table 177.1](#)). For example, renal insufficiency may diminish urate filtration, dehydration increases proximal tubular reabsorption of urate (and may decrease glomerular filtration), and elevated levels of organic acids compete with urate for tubular secretion. In the vast majority of patients, however, diminished urate excretion results from primary undefined defects in tubular secretion. In these patients, urate excretion is 40% lower than that of normal individuals at any given plasma urate concentration.

Alcohol may cause hyperuricemia by both increased urate production through accelerated catabolism of ATP in the liver and decreased urate excretion by competition from lactate. Beer is also rich in purines. Diuretics raise serum urate concentrations by increasing its proximal tubular reabsorption and possibly by lessening glomerular filtration. Up to 80% of transplant patients treated with cyclosporine have hyperuricemia, owing in part to impaired fractional urate clearance and irreversible tubular damage; coexisting renal insufficiency and hypertension may also be contributory.

In 90% of patients, hyperuricemia is due to diminished urate excretion, and in 10% it is due to urate overproduction. Those patients with hyperuricemia due to urate overproduction can be identified by quantitation of the urinary excretion of uric acid. Excretion of more than 600 mg of uric acid per 24 hours while consuming a purine-free diet or excretion of more than 800 to 1,000 mg per 24 hours on an unrestricted diet is an indication of urate overproduction. Collections should not be obtained during acute attacks. The sensitivity of this test is lower in the context of renal insufficiency or incomplete collections, and its specificity is lessened by the use of medications that increase urate excretion. Results may be used to guide the initial choice of long-term hypouricemic therapy (allopurinol for overproducers; uricosuric drugs for underexcretors), but this test is often not performed, and initial treatment is based on the presumption that most patients are underexcretors. Other clinical features may also have an impact on this choice.

PATHOGENESIS

Formation of monosodium urate crystals occurs when solutions become supersaturated with urate. In plasma and synovial fluid, saturation takes place at a concentration near 7.0 mg per deciliter. Higher concentrations favor crystal formation. Urate solubility also varies with temperature and is diminished at cooler peripheral joints. Solubilizing factors likely inhibit crystal formation in plasma and may play a role in limiting crystal formation in supersaturated synovial fluids. In most cases, 20 to 30 years of sustained hyperuricemia is required before sufficient urate becomes deposited in joint tissues, leading to acute gout.

Acute gouty arthritis develops when monosodium urate monohydrate crystals are shed from the synovium or cartilage into the joint space, where they produce local inflammation, or when crystals form in supersaturated synovial fluid. Shedding may be promoted by local trauma or abrupt declines in serum urate levels. Crystal precipitation may occur with abrupt increases in urate levels (either systemically or within joints as a result of preferential resorption of free water) or with changes in temperature, pH, or the concentration of local inhibitory factors.

The inflammatory response to crystals depends on their size and surface character, including the types of proteins bound to them. Urate crystals have a strong affinity for immunoglobulin. Immunoglobulin-coated crystals are highly phlogistic. They attract and activate neutrophils, which perpetuate inflammation by activating the complement, kinin, prostaglandin, and leukotriene pathways and generating reactive oxygen species. Phagocytosis of crystals by neutrophils can cause rupture of these cells and their lysosomes, releasing intracellular enzymes. Urate crystals also stimulate synovial lining cells to produce interleukin-1, interleukin-6, interleukin-8, tumor necrosis factor α , prostaglandin E_2 , leukotriene B_4 , and reactive oxygen species, further increasing local inflammation. The natural processes that terminate acute attacks or prevent inflammation on occasions when urate crystals are shed into joints are not well understood.

Tophi are compact extracellular collections of monosodium urate crystals surrounded by a chronic inflammatory cell infiltrate and foreign-body granuloma. They incite a low-grade local inflammatory reaction mediated by interleukins, tumor necrosis factor α , and prostaglandins derived from macrophages or adjacent synovial fibroblasts, which causes bone and cartilage damage.

CLINICAL FINDINGS

Acute Gout

Acute gouty arthritis typically affects one joint, though 10% of attacks may be polyarticular. Podagra, or inflammation at the first metatarsophalangeal joint, is the initial sign of gout in 50% of patients and occurs at some time in 90% of patients. Other commonly affected joints are the midfoot, ankle, knee, wrist, finger joints, and elbow. Olecranon or prepatellar bursitis may also occur. The affected joint is intensely painful, swollen, erythematous, and warm. Fever and chills may ensue, raising concern about the possibility of septic arthritis. Attacks often happen at night. Patients may report that the weight of the bedsheet causes severe pain, or they may become aware of symptoms only on rising from bed in the morning. Attacks can be precipitated by local trauma, dehydration, surgery, severe illness, alcohol intake, dietary indiscretion, or certain medications (most often diuretics). Symptoms usually peak within 24 hours. With treatment, attacks can last 2 to 7 days, but untreated attacks may last several weeks.

Intercritical Gout

Patients are asymptomatic, and joints appear normal between attacks. This period is called interval, or intercritical, gout. Recurrence of acute gouty arthritis is common: two-thirds of patients experience a second attack within 1 year, 75% within 2 years, and 90% within 5 years. A second attack usually marks someone as being at risk of frequent recurrences, which may be reduced or eliminated with hypouricemic treatment. Without treatment, the interval between attacks often declines over time.

Tophaceous Gout

Tophaceous gout develops more often in persons with persistent severe hyperuricemia. Tophaceous gout can affect either joints or primarily soft tissues ([Fig. 177.2](#)). Chronic gouty arthritis develops in patients with tophaceous deposits of urate in synovium, cartilage, and bone. These deposits cause low-grade inflammatory synovitis in many joints, often in the hands and feet, that is slowly progressive and leads to severe deformity and disability. Rarely, patients have chronic gouty arthritis in the absence of a recalled history of acute attacks. Tophi in soft tissue and skin typically develop over the first metatarsophalangeal joint, the ulnar forearm, olecranon, finger pads, or external ear. Tophi over finger joints are common in elderly women treated with diuretics. Tophi are painless firm masses that distend the skin and show mottled hypopigmentation. Overlying skin may occasionally ulcerate and drain urate chalk. Tophi may resorb with treatment, but residual joint damage is not repaired.

FIGURE 177.2. Chronic tophaceous gout. Deformities of the hands are related to tophaceous deposits.

Nephrolithiasis

Uric acid nephrolithiasis develops in 10% to 25% of patients with gout. The annual incidence is 0.27% in those with asymptomatic hyperuricemia and 1.0% in those with a history of acute gouty arthritis. The risk increases with the level of hyperuricemia and urinary uric acid excretion. Acute uric acid nephropathy is acute renal failure due to the precipitation of uric acid crystals in the distal tubules and collecting system. It occurs most commonly in patients with very high serum urate levels, those with leukemia or lymphoma with high cell turnover, after chemotherapy (acute tumor lysis syndrome), and with the initiation of uricosuric medications. Urate nephropathy, the deposition of urate crystals in the kidney interstitium, is rarely thought to cause clinically significant renal disease.

LABORATORY FINDINGS

The diagnosis of acute gouty arthritis depends on the identification of monosodium urate monohydrate crystals in leukocytes in synovial fluid from an inflamed joint. Urate crystals are needle-shaped. Under polarizing microscopy, they are highly birefringent (bright) and evidence negative elongation (they appear yellow when aligned parallel to the orientation of the red compensator). Crystals are most numerous early in an attack. Extracellular crystals can be seen in synovial fluid obtained during intercritical periods. Sheets of urate crystals also may be seen on aspirates of tophi.

Synovial fluid leukocyte counts during episodes of acute gouty arthritis range from 5,000 to 100,000 per cubic millimeter; these cells are mostly neutrophils. Peripheral leukocytosis and elevation of acute phase reactants are common, making the distinction from septic arthritis more difficult. Septic arthritis and acute gout can coexist. During episodes of acute gouty arthritis, serum urate levels can be spuriously normal or low and are unreliable for diagnosis. Mildly inflammatory synovial fluid may be present in patients with chronic gouty arthritis, but evidence of systemic inflammation is absent. Radiographs in acute gouty arthritis usually show only soft-tissue swelling or joint effusions. Radiographs in tophaceous gout often show large cystic erosions of bone near affected joints, with sclerotic margins and overhanging edges.

OPTIMAL MANAGEMENT

Hyperuricemia without associated clinical features of gouty arthritis or uric acid nephrolithiasis does not require treatment. Prophylaxis with allopurinol is indicated before chemotherapy for patients at risk of acute uric acid nephropathy due to tumor lysis syndrome. Acute gouty arthritis is treated by resting the affected joint (using splints or crutches) and taking anti-inflammatory medications, including nonsteroidal anti-inflammatory drugs (NSAIDs), glucocorticoids, or colchicine. NSAIDs are the optimal choice for most patients. Although indomethacin is often used, any NSAID at a sufficiently high dose will likely be effective. Salicylates should be avoided because they decrease urate excretion. Treatment should be stopped when the acute episode resolves. Glucocorticoids (GCs) may be used when NSAIDs are contraindicated. Intra-articular injections of GCs are preferred when one or two joints are affected. Parenteral GCs may be used for severe polyarticular attacks. Oral colchicine can be given hourly until symptoms abate, side effects occur, or a maximum of 6 mg is consumed. Because this treatment often causes diarrhea, abdominal pain, and vomiting, NSAIDs are preferred. Intravenous colchicine is not recommended, owing to the risk of serious morbidity and mortality. It should be noted that a clinical response to colchicine is not specific to acute gouty arthritis.

Long-term treatment to lower serum urate concentrations is indicated for patients who have had two or more attacks of acute gouty arthritis, both to lessen the frequency of recurrences and to prevent chronic tophaceous gout. Uricosuric medications, such as probenecid or sulfapyrazone, which lower serum urate levels by blocking renal tubular reabsorption and therefore increasing excretion, should be used in patients when hyperuricemia is known or suspected to be due to defects in renal urate excretion. This group includes 90% of patients with idiopathic hyperuricemia.

Allopurinol is a competitive inhibitor of xanthine oxidase, the enzyme that catalyzes the two terminal steps in uric acid production ([Fig. 177.1](#)). Inhibition of this enzyme by allopurinol and its metabolite oxypurinol decreases the conversion of hypoxanthine to xanthine and of xanthine to uric acid. Hypoxanthine and xanthine are excreted readily in the urine, and uric acid production is diminished. Treatment with allopurinol is indicated for patients who are known overproducers of urate, for those who fail treatment with uricosurics, for those with renal insufficiency (creatinine clearance of less than 60 ml per minute), and for those with uric acid nephrolithiasis. Initiation of treatment with either uricosurics or allopurinol may precipitate acute gouty arthritis, the risk of which may be lessened by delaying the start of treatment 4 to 6 weeks after an attack and by using NSAIDs or daily oral colchicine concomitantly. The goal of treatment is to maintain serum urate concentrations at less than 6.8 mg per deciliter. Lifelong treatment is usually necessary. Symptoms of chronic gouty arthritis can be treated with analgesics or NSAIDs. Tophi often resolve faster with the use of allopurinol than with uricosurics and when serum urate concentrations are less than 5 mg per deciliter.

CALCIUM PYROPHOSPHATE DIHYDRATE DEPOSITION DISEASE

DEFINITION

Calcium pyrophosphate dihydrate (CPPD) deposition disease is a chronic metabolic disease that results from the local overproduction of pyrophosphate (PP_i) in cartilage, which causes the deposition of crystals of CPPD (Ca₂P₂O₇·2H₂O) and a group of associated joint conditions. CPPD deposition disease has several manifestations, including asymptomatic chondrocalcinosis, episodes of acute arthritis (pseudogout), and chronic arthritis.

INCIDENCE AND EPIDEMIOLOGY

CPPD deposition disease is a disease of aging. The prevalence of chondrocalcinosis in radiographic surveys of the general population is less than 1%, but the rate increases to 10% in those aged 60 to 75 and to 30% or more in those age 80 or older. Premature disease may develop in rare familial forms. Men and women are equally affected. Symptomatic acute or chronic arthritis develops in more than 75% of cases. In the general population, acute pseudogout has a prevalence of 0.1%.

The prevalence of CPPD deposition disease is higher in patients with hyperparathyroidism (20% to 30%), hemochromatosis (20% to 50%), hypophosphatasia, hypomagnesemia, and several other conditions ([Table 177.2](#)). Screening for these conditions is indicated when CPPD deposition disease occurs before age 60. Severe myxedema also may be associated with CPPD deposition disease, but mild hypothyroidism is not. Chondrocalcinosis is associated with osteoarthritis, but its presence does not predict the later development of osteoarthritis, suggesting that chondrocalcinosis may be a consequence of osteoarthritic changes in cartilage.

Hyperparathyroidism
Familial hypocalciuric hypercalcemia
Hemochromatosis
Hemosiderosis
Hypomagnesemia
Hypophosphatasia
Osteoarthritis
Gout
Amyloidosis
Bartter's syndrome
Neuropathic joints
Osteochondrodysplasias

TABLE 177.2. CONDITIONS ASSOCIATED WITH CALCIUM PYROPHOSPHATE DIHYDRATE DEPOSITION DISEASE

ETIOLOGY

CPPD crystals form in cartilage as a result of excess production by chondrocytes of PP_i. PP_i is produced in the metabolism of most major macromolecules; nucleoside

triphosphates are the major source. Nucleoside triphosphates (such as ATP) are metabolized to nucleoside monophosphates (such as AMP) and PP_i . In chondrocytes, this reversible reaction is catalyzed by a group of enzymes, the nucleoside triphosphate pyrophosphohydrolases (NTPPPHase), present on the external surface of the cell membrane. The activity of these enzymes, which is enhanced by transforming growth factor β and inhibited by interleukin-1, results in the extracellular accumulation of PP_i . Calcium salts of PP_i develop in areas of focal high concentrations. Systemic levels of PP_i are normal in patients with CPPD crystal deposition disease.

Formation of CPPD crystals is favored by conditions that increase the extracellular concentration of PP_i , including high concentrations or overactivity of NTPPPHases, high local concentrations of ATP (the enzyme substrate) or transforming growth factor β , or decreased activity of enzymes that metabolize PP_i , such as inorganic pyrophosphatases and alkaline phosphatases. The activity of NTPPPHases is high in cartilage affected by CPPD crystal deposition disease. Elevated levels of calcium and iron and low levels of magnesium inhibit inorganic pyrophosphatases and may account for the accumulation of PP_i and the development of CPPD crystal deposition disease in patients with hyperparathyroidism, hemochromatosis, and hypomagnesemia. In hypophosphatasia, deficiency of alkaline phosphatase may also lead to the accumulation of PP_i .

PATHOGENESIS

Episodes of acute pseudogout occur when CPPD crystals are shed from the articular cartilage, a process that can stem from a decrease in the concentration of either calcium or phosphate in synovial fluid (as after surgery), from direct trauma to the joint, or from joint inflammation. The inflammatory response to crystal shedding is similar to that which occurs in acute gout. CPPD crystals also stimulate synovial cells to produce and release metalloproteinases, including collagenase, stromelysin, and gelatinase, which degrade cartilage and periarticular tissues. Ongoing exposure to these degradative enzymes may contribute to the chronic form of arthritis associated with CPPD crystal deposition disease.

CLINICAL FINDINGS

Chondrocalcinosis is evident on radiographs as fine, stippled calcifications in fibrocartilage (knee menisci, triangular cartilage of the wrist, symphysis pubis, glenoid and acetabular labra) and, less often, in hyaline cartilage of joints. Acute pseudogout develops in 25% of patients with CPPD deposition disease and may be present in joints without radiographic evidence of chondrocalcinosis. Acute pseudogout usually appears as the sudden onset of swelling, warmth, and pain in one joint, typically the knee (in 50% of attacks), wrist, or ankle. The degree of joint inflammation may be less than that seen in gout. Polyarticular attacks may occur. This condition may be accompanied by fever, particularly in the elderly. Episodes can be precipitated by trauma, surgery, or severe illness. Joint inflammation peaks on day 2 or 3 and can last from 7 to 14 days, with subsequent complete resolution. Recurrent attacks are more common in patients with more extensive chondrocalcinosis.

A chronic form of arthritis that mimics osteoarthritis, with pain and deformity, develops in 50% of patients with CPPD deposition disease. The knees are affected most often, but joints that are not usually affected by idiopathic osteoarthritis, such as the wrists, elbows, shoulders, ankles, and metacarpophalangeal joints, may also be involved. Chronic arthritis may develop in patients who have not experienced previous episodes of acute pseudogout. A chronic type of symmetrical inflammatory polyarthritis that mimics rheumatoid arthritis develops in 5% of patients.

LABORATORY FINDINGS

Synovial fluid in acute pseudogout can evince intracellular and extracellular CPPD crystals, which are rod-shaped or rhomboid crystals. Under polarizing microscopy, the crystals are weakly birefringent (dull), show positive elongation (they appear blue when aligned parallel to the orientation of the red compensator), and may be sparse and difficult to locate. Synovial fluid leukocyte counts are elevated, but they are usually less than 50,000 per cubic millimeter; these cells are mainly neutrophils. Peripheral leukocytosis and elevation of acute phase reactants may be seen. CPPD crystals also may be found in synovial fluids of joints affected by chronic CPPD-associated arthritis. Serum chemistry tests give normal results in patients with idiopathic CPPD deposition disease.

OPTIMAL MANAGEMENT

Chondrocalcinosis requires no treatment. Episodes of acute pseudogout are treated in the same manner as episodes of acute gout. If episodes are frequent, daily oral colchicine may help limit their number. Aspiration of the affected joint often provides relief, even without additional therapy. Chronic arthritis is treated symptomatically with analgesics, NSAIDs, and colchicine and is generally slowly progressive.

BASIC CALCIUM PHOSPHATE CRYSTAL DEPOSITION DISEASES

Basic calcium phosphate (BCP) crystals include crystals of carbonate-substituted apatite, octacalcium phosphate, tricalcium phosphate, and other rare types. Shedding of crystals from deposits in cartilage, tendons, bursae, and soft tissues surrounding joints leads to acute inflammation. Clumps of apatite crystals, the most common crystal of this group, appear on microscopic examination of synovial fluids as shiny but non-birefringent globules that stain with alizarin red S stain. Individual apatite crystals are too small to be distinguished by light microscopy, and specific identification requires electron microscopy or x-ray diffraction. Because of the difficulty of precise identification of these crystals, the diagnosis of BCP crystal deposition diseases often rests on the recognition of typical clinical and radiographic features.

BCP crystal deposition diseases include calcific tendinitis and bursitis, acute arthritis, and a type of chronic destructive noninflammatory arthritis. Calcific tendinitis is an acute, painful tendinitis, most often of the rotator cuff tendons, associated with periarticular calcifications on radiographs. It occurs most often in young adults and in diabetics. Calcific bursitis or periartthritis is an acute inflammatory reaction in a bursa or near a joint, associated with local calcific deposits on radiographs. Typical sites include the areas around the first toe, shoulder, greater trochanter, elbow, wrist, and knee. Affected areas are painful, swollen, and erythematous, mimicking acute gout or cellulitis. Acute inflammatory arthritis due to BCP crystals may develop in joints affected by osteoarthritis or in patients with chronic renal failure. The treatment for each of these conditions includes NSAIDs, local glucocorticoid injection, and colchicine.

Rarely, destructive arthritis associated with apatite crystals develops in the shoulder (Milwaukee shoulder) or knee. Elderly women are affected most often. Large, cool effusions with abundant apatite crystals and leukocyte counts less than 500 per cubic millimeter are common, as is disruption of the rotator cuff, subluxation of the humerus, and destruction of cartilage and bone. Joint damage may progress rapidly. Pain may be present only with use of the joint. Treatment includes rest, administration of analgesics or NSAIDs, and joint replacement.

(heterozygous) deficiencies of C2 and C4, which are quite prevalent in the US population, also increase the risk of SLE. Among whites, the human leukocyte antigen (HLA) DR2 as well as the shared haplotype that includes HLA-B8 and HLA-DR3 also impart increased risk of SLE (as well as various other autoimmune diseases).

Determinants of risk for SLE have been localized to a segment of chromosome 1 that includes many genes of importance to the immune system, including genes encoding various cytokines and growth factors. Among them, the gene encoding interleukin (IL)-10 and the *bcl-2* gene may be of particular importance, and it has been suggested that an individual possessing the high-risk form of both genes is at particularly high risk of acquiring SLE. Family studies have confirmed that genetically encoded strong expression of IL-10 is a powerful risk factor for SLE. Inasmuch as SLE develops in a subset of patients during the first two decades of life, these individuals may have a largely genetically determined disease, the expression of which occurs after maturation of the immune system or in response to endocrine changes. From a practical point of view, the occurrence of overt SLE among relatives of patients is seen infrequently, and the role of triggering factors and other environmental influences that may be responsible for disease initiation and/or perpetuation must therefore be considered.

ENVIRONMENTAL FACTORS

Among triggers for lupus disease activity, ultraviolet light stands out as the most undisputed and widely recognized. Many patients with SLE experience photosensitive rashes, frequently accompanied by general malaise, fever, and other signs of systemic inflammation. The mechanism of disease activation by ultraviolet light may include induction of antigenic epitopes in the dermis or epidermis, the release of nuclear material by light-damaged skin cells, or dysregulation of immune cells in the skin. Clinical observations suggest that in some patients ultraviolet light exposure plays a role in first acquiring SLE as well.

Various other environmental factors also have been implicated in lupus. Such medications as procainamide and hydralazine—and, rarely, minocycline (used in patients with rheumatoid arthritis)—can cause drug-induced LE (DILE), a disease with similarities to but also notable differences from SLE (see “Drug-Induced Lupus Erythematosus”). Perhaps more interesting is the observation that some antirheumatic drugs, such as sulfasalazine, can induce an illness that is akin to SLE in clinical and serologic features. Whether a new class of antirheumatic agents that antagonize tumor necrosis factor (TNF) also belong to this group is not yet clear.

Diverse chemicals, particularly aromatic amines, have been implicated as the cause of lupus-like syndromes. These syndromes are usually more similar to drug-induced than to systemic lupus and resolve after the exposure ends. Hair care products, such as hair dyes, and silicone breast implants have been largely cleared from suspicion of causing SLE after extensive epidemiologic research. A few reports regarding geographic clusters of lupus, suggesting an environmental factor, have not been confirmed.

The nonessential amino acid L-canavanine has come under suspicion, owing to the development of a lupus-like disease in monkeys after ingestion of large quantities of alfalfa sprouts, which contain L-canavanine. Exposure to this amino acid has been implicated in a few instances of transient autoimmune manifestations in humans as well. The presence in the environment of increasing quantities of plant-derived estrogens (phytoestrogens) has been proposed as an explanation for the apparent increase in the incidence of SLE over the past 30 years.

Infectious agents may play a role in disease activation. Once a patient has SLE, common infections of the respiratory or urinary tract are frequently followed by flare-ups of disease activity. Animal studies suggest that retroviruses may induce autoimmune phenomena akin to SLE. A recent study in children with SLE suggests that infection with the Epstein–Barr virus is a necessary prerequisite, but certainly not a sufficient cause, for SLE. Cases of SLE arising in the wake of physical or chemical exposures, accidents, or physical and psychological trauma are encountered fairly often in clinical practice. No distinct pattern has emerged, and the causality of these associations remains speculative.

HORMONAL INFLUENCES

Clinical observations suggest the role of sex steroids as a source of SLE. These observations include the higher incidence of SLE in women of childbearing age, increased SLE disease activity during pregnancy, and a slightly higher risk of acquiring SLE among postmenopausal women who take estrogen supplements. Moreover, subtle hormonal abnormalities have been found in patients with SLE, including preferential hydroxylation of estrone at the 16a position, resulting in more immunologically active metabolites; accelerated oxidation (inactivation) of testosterone in female patients; and generally lower serum levels of androgens, including the adrenal androgen dehydroepiandrosterone (DHEA). The net result of these findings implicates a relative excess of estrogens and deficiency of androgens in the pathogenesis of SLE.

Sex steroids have immunoregulatory properties that may put some of these observations into context. Estrogen has several immunomodulating effects, including a general immunostimulating effect on antibody formation and more ambivalent effects with respect to cellular immunity. Prolactin has powerful immunostimulating properties, while progesterone tends to be more immunosuppressive. Androgens may have mild immunosuppressive properties, antagonizing some of estrogen's up-regulatory effects with respect to humoral immunity. In animal models, DHEA has been implicated in a change in the phenotype of T cells away from the T_H2 phenotype characterized by the production of IL-4, IL-5 and IL-10; this T-cell phenotype would result in an environment more likely to produce pathogenetic autoantibodies than the T_H1 phenotype characterized by production of IL-2 and interferon- γ . In summary, many clinical as well as experimental observations suggest that a high-estrogen, low-androgen state may be conducive to SLE in predisposed individuals and that hormone levels can influence disease activity and expression in the patient via their immunomodulatory effects.

PATHOGENESIS

The pathologic characteristics of SLE are those of an inflammatory disorder with evidence of self-reactivity (autoimmunity). The most important immunologic abnormalities seen in SLE reflect the presence of antibodies that target self-antigens. Virtually all patients have antinuclear antibodies (ANAs), which is really a large family of antibodies that target nuclear antigens. While ANAs are helpful in clinical terms, only some of them are believed to be important from a pathophysiologic perspective. About half of all patients have anti-DNA antibodies, which are very specific and may be pathogenetic (see “Laboratory Findings”). Many other autoantibodies are seen in SLE, including anti-Smith (anti-Sm), anti-Ro, anti-La, anti-ribonucleoprotein (anti-RNP) and anti-proliferating cell nuclear antigen antibodies as well as autoantibodies more typically associated with other diseases, such as rheumatoid factor. Whether the formation of these autoantibodies reflects an abnormality of the target autoantigen, a primary defect in B cells, or a defect in regulatory T cells remains the subject of debate. Autoantibodies may lead to disease manifestations through at least three pathophysiologic mechanisms of action: the formation of immune complexes, the direct effects of pathogenetic autoantibodies on their targets, and antibody-mediated thromboembolic phenomena.

IMMUNE COMPLEXES

Many SLE manifestations are reflected at the histopathologic level by immune complex deposition, subsequent complement activation, and chronic lymphocytic inflammation. Thus, the skin lesions in SLE frequently contain immune complexes at the dermal–epidermal junction, and the glomerular lesion of lupus nephritis is defined to a great extent by the granular deposits that contain immunoglobulins and complement factors. The origins of these immune complexes are uncertain. Even in the best-studied situation, namely, the immune complexes containing anti-DNA antibodies in lupus nephritis, considerable uncertainty persists as to whether the antibodies bind antigen (DNA) in the circulation or within the target tissue and even as to whether they bind DNA or a cross-reacting antigen. It is also not clear whether the primary defect is the excessive formation of immune complexes or the ineffective clearance of such complexes. Evidence for the latter theory includes the association of SLE with complement deficiencies and the relatively low expression of complement receptor CR1 in patients with SLE.

AUTOANTIBODIES

Some SLE disease manifestations are the result of pathogenetic autoantibodies acting directly on their targets. They include autoimmune thrombocytopenia, hemolytic anemia, leukopenia, and possibly even some of the neurologic manifestations of lupus. Cell-specific autoantibodies can cause complement-mediated cytolysis or, through opsonization, can induce phagocytosis of the cell in the reticuloendothelial system. Whether antibody-mediated cellular cytotoxicity, antibody-induced apoptosis, or other mechanisms also play a role is unclear. Neonatal lupus, a disease provoked by maternal anti-Ro (SSA) antibodies reaching the infant's circulation through the placenta, is a remarkable “experiment of nature” that proves that this antibody can be the direct cause of various lupus manifestations, including skin lesions, pleuropericarditis, arthritis, alopecia, and heart block.

THROMBOEMBOLIC PHENOMENA

Several of the classic characteristics of lupus, such as Libman–Sacks endocarditis, are now known to be primarily thrombotic manifestations of the hypercoagulability seen in the antiphospholipid antibody syndrome. This syndrome is encountered as a concomitant condition in a sizable subset of patients with SLE as well as in a primary form (without SLE). Hypercoagulability is believed to be the result of antibodies binding to coagulation factors or cofactors, platelets, or endothelium.

Several manifestations of SLE appear to be independent of the presence of immune complexes and cannot be attributed to specific autoantibodies or thromboembolism. The pathologic substrate for such diverse disease manifestations as pulmonary alveolar hemorrhage, organic brain syndrome, or myalgias cannot be identified in many instances. Vasculopathy induced by cytokines (Shwartzman phenomenon) is one of the proposed mechanisms of development.

Finally, the cytokine tumor necrosis factor α (TNF- α) has come under scrutiny as a therapeutic target in a variety of autoimmune diseases, including rheumatoid arthritis and Crohn's disease. It is therefore of importance to recognize the ambiguous findings regarding TNF- α in SLE. Although TNF- α is broadly proinflammatory, it is beneficial in the NZB/NZW animal model of SLE. IL-10 is known to down-regulate TNF- α , yet high levels of IL-10 appear to be a risk factor for SLE. Moreover, patients treated with TNF- α antagonists sometimes form autoantibodies reminiscent of SLE, and at least one patient developed transient SLE-like symptoms following such treatment.

CLINICAL FINDINGS

The clinical picture of SLE is extremely variable, both in terms of actual organ involvement in the disease at any particular point in time and the severity of disease manifestations in that organ. In addition, the chronological course of the disease varies considerably from patient to patient. Thus, lupus can be visualized as myriad possibilities along the dimensions of organicity and severity, evolving along the dimension of time. The severity can range from mild or moderate to severe or even life-threatening. Because of the multisystem diversity of its clinical manifestations, lupus has replaced syphilis as the “great imitator.” A selection of SLE manifestations is given in [Table 178.2](#).

Manifestation	General Therapy	Specific Therapy	Prognosis
Fever	NSAIDs	Glucocorticoids	Good
Weight loss	NSAIDs	Glucocorticoids	Good
Fatigue	NSAIDs	Glucocorticoids	Good
Butterfly rash	NSAIDs	Glucocorticoids	Good
Discoid lupus	NSAIDs	Glucocorticoids	Good
Mucocutaneous lesions	NSAIDs	Glucocorticoids	Good
Alopecia	NSAIDs	Glucocorticoids	Good
Oral ulcers	NSAIDs	Glucocorticoids	Good
Sicca syndrome	Artificial tears	Glucocorticoids	Good
Arthritis	NSAIDs	Glucocorticoids	Good
Myalgia	NSAIDs	Glucocorticoids	Good
Fibromyalgia	NSAIDs	Glucocorticoids	Good
Thrombotic events	NSAIDs	Glucocorticoids	Good
Renal disease	NSAIDs	Glucocorticoids	Good
Pulmonary disease	NSAIDs	Glucocorticoids	Good
CNS disease	NSAIDs	Glucocorticoids	Good
Hematologic abnormalities	NSAIDs	Glucocorticoids	Good

TABLE 178.2. SELECTED MANIFESTATIONS OF SLE AND TREATMENT RECOMMENDATIONS

Most patients with SLE have mild to moderate disease with chronic smoldering symptoms, punctuated by gradual or sudden increases in disease activity (flare-ups). The disease course in a smaller percentage of patients is characterized by alternating flare-ups and complete clinical remissions. Rarely, a patient has a single episode of active SLE followed by a sustained remission. The clinical description of SLE is complicated further by two issues. First, while SLE can cause many symptoms and signs, not all symptoms and signs in a patient with SLE are the result of the disease. Many intercurrent illnesses, particularly viral infections, can mimic SLE. Second, side effects of medication, particularly those of long-term glucocorticoid use, must be distinguished from the symptoms and signs of SLE.

CONSTITUTIONAL MANIFESTATIONS

Fever is present in most patients with active SLE, but infectious causes always must be considered as well, particularly in patients under immunosuppressive therapy. Weight loss may occur early in the course of disease, whereas weight gain, especially in glucocorticoid-treated patients, may be more typical later. Fatigue and general malaise are among the most common and often most debilitating symptoms of the disease. The exact origin of these symptoms is often uncertain—disease activity itself, medication side effects, subtle neuroendocrinologic disturbances, and psychogenic factors all play a role.

MUCOCUTANEOUS MANIFESTATIONS

The classic butterfly rash, an erythematous rash over the malar area of the cheeks and the bridge of the nose that spares the nasolabial folds, is seen in about half of all patients. It may be raised and very inflammatory, persisting for weeks or months. It resolves without scarring. In contrast, the lesion of discoid lupus can result in disfiguring scars. It is found in 20% to 25% of patients with SLE but is usually seen without any other lupus manifestations. These erythematous plaques with adherent scale and telangiectases develop mostly on the face, neck, and scalp. Acute cutaneous lupus in the form of intense inflammatory erythema can be triggered by exposure to ultraviolet light. Subacute and chronic lupus lesions are frequently found on the areas of the skin that have long been exposed to the sun (forearms, V-region around the neck), but without immediately preceding sun exposure. Many other skin lesions are encountered from time to time in SLE, including livedo reticularis, periungual erythema, palmar erythema, palmar nodules, vesicular or even bullous lesions, acute or chronic urticaria, panniculitis, vasculitic purpura, and non-healing vasculitic ulcers.

Alopecia may develop as the result of typical lupus lesions on the scalp, but it is much more common as a nonspecific feature of a lupus flare-up, often following a period of intense disease activity. Alopecia tends to be reversible, except when there are discoid lesions on the scalp. Its specificity for SLE is higher when it appears in patches rather than as diffuse loss. Oral and nasal ulcers are fairly common and may be either painless or painful; the latter ulcers must be distinguished from fungal and viral lesions. Dry eyes and dry mouth (sicca syndrome) can result from autoimmune lacrimal and salivary gland inflammation, which can be considered an overlap with Sjögren's syndrome. More frequently, dry eyes and dry mouth are the result of medication side effects.

MUSCULOSKELETAL MANIFESTATIONS

The arthritis of SLE is typically inflammatory and accompanied by synovitis and pain, but it is nonerosive and nondeforming. Rarely, patients have Jaccoud's deformities, which resemble rheumatoid arthritis but are reducible and not associated with radiographic evidence of cartilage or bone destruction. Whereas muscle weakness is often seen in SLE as the result of glucocorticoid or antimalarial therapy, true myositis with elevated muscle enzyme levels is rare and suggests an overlap syndrome. Tenosynovitis and bursitis are seen frequently. Tendon rupture may be a complication of long-term glucocorticoid treatment. Osteonecrosis (avascular necrosis) is a major concern in patients with SLE, since both the disease itself and treatment with glucocorticoid contribute to the risk. The femoral head, humeral head, tibial plateau, and talus are the sites most often affected. Joint pain without objective evidence of inflammation (arthralgia) and myalgia are among the most common symptoms of SLE. They may be related to the disease itself, medication side effects, the “glucocorticoid withdrawal syndrome,” endocrinopathies, or psychogenic factors. The diagnosis of fibromyalgia is best reserved for patients in whom all these causes have been ruled out.

CARDIOVASCULAR MANIFESTATIONS

Pericarditis is a typical symptom, with positional substernal chest pain and sometimes a rub. Echocardiography may show an effusion or, in chronic cases, a thickened, fibrotic pericardium. Tamponade or constrictive hemodynamics are rare. Myocarditis is unusual, but it must be suspected in any patient with active SLE and atypical chest symptoms, minimal electrocardiographic changes, arrhythmias, or hemodynamic changes. Myocarditis can lead to dilated cardiomyopathy, with signs of left ventricular failure. Echocardiography or thallium perfusion scintigraphy are useful diagnostic tests to rule out subclinical lupus myocarditis.

Noninfectious thrombotic endocarditis (Libman–Sacks) is uncommon and often asymptomatic, but in rare cases it can cause valvular dysfunction of the mitral or aortic valve or embolization. Premature arteriosclerosis with angina pectoris and myocardial infarction has emerged as one of the most serious long-term sources of morbidity and mortality in patients with SLE. The disease itself, hypercoagulability, chronic glucocorticoid therapy, premature menopause, and dietary and lifestyle

factors may all contribute to arteriosclerosis. Raynaud's phenomenon, that is, cold-induced reversible vasospasm of the fingers and toes, is common in SLE and is rare in rheumatoid arthritis. Irreversible arterial narrowing in the hands and feet is sometimes seen in overlap syndromes with features of scleroderma. A similar pathologic picture in the pulmonary circulation may give rise to pulmonary hypertension, an unusual but frequently fatal complication of SLE.

PULMONARY MANIFESTATIONS

Pleurisy is very prevalent in SLE. Pleuritic chest pain, a rub, and effusions are evident on radiography in some patients, while others may have convincing symptoms without objective findings. Inflammation in the lung parenchyma, referred to as pneumonitis or alveolitis and evidenced by cough, hemoptysis, and pulmonary infiltrates, is uncommon but possibly life-threatening. It requires an aggressive and expeditious workup to rule out infectious causes and institution of glucocorticoid and immunosuppressive therapy. Diffuse alveolar hemorrhage may be present with or without acute pneumonitis and carries a very high mortality rate. Chronic lupus pneumonitis with mostly fibrotic lung changes behaves similarly to idiopathic pulmonary fibrosis, with a slowly progressive course and, ultimately, a poor prognosis. Restrictive lung disease also may be caused by long-standing pleuritic changes, myopathy, or fibrosis of the respiratory muscles, including the diaphragm, and even neuropathy of the phrenic nerve. Recurrent pulmonary emboli resulting from antiphospholipid antibodies must be ruled out in all patients with unexplained pulmonary symptoms.

RENAL MANIFESTATIONS

Lupus nephritis is present in about half of all patients with SLE. The spectrum of pathologic involvement can vary from almost completely asymptomatic mesangial proliferation to aggressive, diffuse membranoproliferative glomerulonephritis that progresses to renal failure. The World Health Organization (WHO) classification scheme for lupus nephritis ([Table 178.3](#)) has been very useful in categorizing the histopathologic features. The clinical picture of lupus nephritis can be characterized by minimal findings, including mild proteinuria and microscopic hematuria; the nephrotic syndrome, with high-level proteinuria, hypoalbuminemia, peripheral edema, hypertriglyceridemia, and hypercoagulability; or the nephritic syndrome, with hypertension, erythrocytes and erythrocyte casts in the urine sediment, and a progressively declining glomerular filtration rate with rising serum creatinine and uremia. The nephrotic syndrome is often seen with membranous nephritis (WHO class V), and the nephritic syndrome usually accompanies membranoproliferative disease (WHO class IV); the latter condition is often associated with high-titer anti-DNA antibody and low complement levels. The most important point is that the renal histopathologic characteristics *cannot* be predicted accurately by the clinical manifestations alone. Transition from one form of glomerulonephritis to another in the course of SLE is not uncommon.

Class	Description	Clinical Findings	Prognosis	Treatment
I	Minimal change glomerulonephritis	None	Excellent	None
II	Focal proliferative glomerulonephritis	Low cellularity, mild proteinuria, microscopic hematuria, and mild to moderate proteinuria	Fairly good	Use to moderate doses of corticosteroids
III	Diffuse mesangiocapillary glomerulonephritis	Nephritic syndrome, hematuria with red blood cell casts, progressive azotemia	Poor (without therapy)	High-dose corticosteroids plus cyclophosphamide or azathioprine
V	Membranous glomerulonephritis	Nephrotic syndrome, high-level proteinuria, peripheral edema, hypertriglyceridemia, hypercoagulability	Fair to poor	Corticosteroids (high-dose) plus immunosuppressing agents (cyclophosphamide or azathioprine)
IV	End-stage	Progressive renal failure	Poor	Requires renal dialysis and transplantation

*The classification is summarized in simplified form. Therapeutic decisions need to be directed by complete histopathologic and clinical evaluation.

TABLE 178.3. THE WORLD HEALTH ORGANIZATION (WHO) CLASSIFICATION OF LUPUS NEPHRITIS^a

NEUROLOGIC AND PSYCHIATRIC MANIFESTATIONS

Central nervous system (CNS) involvement occurs in 5% to 15% of patients with lupus and is sometimes referred to as neuropsychiatric SLE or lupus cerebritis. It can have such objective manifestations as aseptic meningitis or meningoencephalitis, seizures, chorea, ataxia, stroke, and transverse myelitis. In such patients, the diagnosis can be supported by abnormal findings on cerebrospinal fluid (CSF) analysis, such as elevated protein levels, pleiocytosis, and/or characteristic autoantibodies; on computerized tomography scanning or magnetic resonance imaging, such as inflammatory white and gray matter lesions; or even on leptomeningeal biopsy, with evidence of inflammation (usually indicated only if an alternative diagnosis is also suspected). Infectious causes must always be ruled out, as must drug-induced disease, for example, aseptic meningitis induced by ibuprofen.

An alternative picture of CNS lupus is a major psychiatric disorder, that is, psychosis. In this case, CSF and imaging studies may show normal results, and the differential diagnosis from primary psychogenic disease and/or drug reactions can be very difficult to determine. Compounding the problem is the relatively large group of patients with milder cognitive and personality disturbances. Some studies of neuropsychologic functioning indicate that more than half of all patients with SLE have impaired memory, attention, concentration, reasoning, executive skills, and so on. These symptoms occur largely in the absence of any demonstrable abnormalities on CSF analysis or conventional imaging, but they can be verified by neuropsychologic testing. Whether they represent subtle organic manifestations of the disease in the form of CNS inflammation below the threshold of detection, CNS changes in response to chronic stress, long-term treatment effects, or psychological adjustments to chronic disease remains unclear; a combination of all of these factors seems most likely.

Headaches are common in patients with SLE and can be as easy or as difficult to manage as they are in the general population. The particularly severe, often migraine-like “lupus headache” that responds only to glucocorticoids is unusual, and most headaches in patients with SLE should be addressed as they would be in other individuals. Cranial and peripheral neuropathies are encountered now and then in patients with SLE; they may represent small-vessel vasculitis or infarction.

GASTROINTESTINAL MANIFESTATIONS

Nonspecific gastrointestinal symptoms, including diffuse abdominal pain and nausea, are typical in patients with SLE. Sterile peritonitis with ascites is an uncommon but serious abdominal complication. Many upper-gastrointestinal symptoms are related to therapy, in the form of nonsteroidal anti-inflammatory drug (NSAID) and/or glucocorticoid-related gastropathy. Duodenitis can become symptomatic. In rare cases, vasculitis of the bowel in SLE can provoke an acute surgical emergency. On occasion, pancreatitis can be a manifestation of lupus itself, but it results more frequently from the use of glucocorticoids or azathioprine. Liver enzyme elevations are sometimes associated with SLE in the form of noninfectious hepatitis, which is indistinguishable in histologic features from chronic autoimmune hepatitis. To confuse the issue further, the latter disease is sometimes called “lupoid hepatitis.” Liver enzyme elevations can also occur with the use of NSAIDs, azathioprine, or methotrexate, and long-term glucocorticoid use can result in “fatty liver” changes with mildly elevated transaminases.

HEMATOLOGIC MANIFESTATIONS

Splenomegaly and diffuse lymphadenopathy are common, nonspecific findings in active SLE. Anemia is a typical feature of SLE, often stemming from several sources. Lupus may cause anemia through hemolysis, with a positive Coombs test result, low haptoglobin levels, and high lactate dehydrogenase levels, or through autoimmune myelosuppression. Indirect mechanisms of action include decreased erythropoietin synthesis and uremic myelosuppression in patients with lupus nephritis. The picture may be complicated further by occult blood loss and dietary insufficiency. Leukopenia and lymphopenia are very common in lupus but rarely reach levels of clinical concern. Leukocytosis can be caused by glucocorticoids, but this symptom should raise concerns about infections. Mild thrombocytopenia (platelet count 100,000 to 150,000/ μ L) is seen frequently, particularly in patients with antiphospholipid antibodies. Severe autoimmune thrombocytopenia (platelet count less than 50,000/ μ L), caused by antiplatelet antibodies, may predate the diagnosis of SLE and may be diagnosed initially as idiopathic thrombocytopenic purpura.

OPHTHALMOLOGIC MANIFESTATIONS

Cotton-wool exudates and retinal infarcts (“cytoid bodies”) are relatively uncommon and nonspecific findings. Conjunctivitis and episcleritis are sometimes seen in active disease. Dry eyes may represent an overlap with Sjögren's syndrome. Transient or permanent blindness can be the result of optic neuritis or occlusion of the

retinal arteries or veins.

LATE LUPUS SYNDROME

Patients with SLE who have had the disease for decades frequently suffer a set of symptoms that are partly the result of end-organ damage caused by SLE and partly due to medication side effects, particularly from chronic glucocorticoid use. This “late lupus syndrome” is characterized by widespread arteriosclerotic disease, skin atrophy, osteoporosis, osteonecrosis, diabetes mellitus, chronic renal failure, adrenal insufficiency, cognitive impairment, depression, and deconditioning. It is likely that the long-term survival and the quality of life of patients with lupus are limited to a great extent by this constellation of symptoms.

SPECIAL PRESENTATIONS OF SYSTEMIC LUPUS ERYTHEMATOSUS

Several clinical syndromes within the spectrum of SLE have been defined more clearly as information regarding specific autoantibody involvement, course, and outcome has evolved (Table 178.4). Other patients manifest symptoms, signs, and laboratory test abnormalities that are suggestive of SLE as well as another autoimmune disease: such patients can properly be considered to have an overlap syndrome. Finally, some patients have incontrovertible evidence of autoimmune disease, but their conditions defy all attempts at classification; they can be identified as having “undifferentiated connective tissue disease.”

Discoid lupus	Inflammatory skin lesion resulting in atrophic scar	ANA may be positive but other lab results negative
Subacute cutaneous lupus erythematosus	Characteristic rash, mild systemic disease	Anti-Ro (SSA) and/or SSB
Mixed connective tissue disease	Overlap features of SLE, polymyositis and scleroderma, nephritis/CNS disease, sicca	High-titer anti-RNP
Drug-induced lupus erythematosus	Neuropriocarditis, arthritis, no nephritis or anti-DNA	Antihistone antibodies
Neonatal lupus	Heart, alopecia, cytopenia, conduction disorder (rare)	Anti-Ro (SSA) acquired passively from the maternal circulation
Antiphospholipid antibody syndrome	Arterial and venous thrombosis, obstetrical complications, thrombocytopenia	May occur with or without SLE, anticardiolipin antibodies, lupus “anticoagulant,” false-positive VDRL

SLE, systemic lupus erythematosus; CNS, central nervous system; ANA, antinuclear antibody; RNP, ribonucleoprotein.

TABLE 178.4. CLINICAL SUBSETS OF SYSTEMIC LUPUS ERYTHEMATOSUS

SUBACUTE CUTANEOUS LUPUS ERYTHEMATOSUS

SCLE represents a subset of patients with primarily cutaneous disease in the form of a papulosquamous, psoriasiform, or annular rash, mostly on the routinely sun-exposed areas of the body (face, neck, V-region, lower arms). Bouts of arthritis and serositis may occur episodically. Anti-Ro (SSA) and anti-La (SSB) antibodies are very common in this group of patients, and they have a favorable prognosis.

NEONATAL LUPUS

Soon after birth, the baby born to a mother with anti-Ro (SSA) antibodies (whether in the context of SLE, Sjögren's syndrome, or another rheumatic disorder) may experience a syndrome of arthritis, photosensitive skin eruption, alopecia, serositis, cytopenias, and, rarely, cardiac conduction disorders, including heart block. This disease, termed neonatal lupus, is almost certainly the result of the maternal autoantibodies that have passed across the placenta and exert their effects in the neonate. Over time, as the antibodies are cleared and replaced by the neonate's own, the disease subsides; however, the conduction disorder may be permanent. Whether anti-La (SSB) or other antibodies can cause the same syndrome is unclear.

DRUG-INDUCED LUPUS ERYTHEMATOSUS

Several medications have been implicated as the cause of DILE, a clinical and immunologic syndrome similar to SLE (Table 178.5). The data are strongest for hydralazine and procainamide, which have been the subject of large prospective studies. These agents do not appear to cause disease flare-ups when taken by patients with SLE. There are several important differences between DILE and SLE:

Definite Association	Possible Association
Procainamide	Quinidine
Hydralazine	Propylthiouracil
Isoniazid	Sulfonamides
Minocycline	β-blockers
Chlorpromazine	Phenytoin
Methyldopa	Carbamazepine
Sulfasalazine ^a	Other anticonvulsants
o-penicillamine	L-dopa
	Lithium
	Tetracyclines
	Thiazide diuretics
	Atisoma ^b
	Etanercept ^b

^a More than 100 medications or even categories of drugs have been implicated in drug-induced lupus; most of these associations are very rare.

^b Can cause anti-DNA positivity in patients with rheumatoid arthritis.

TABLE 178.5. SELECTED MEDICATIONS ASSOCIATED WITH DRUG-INDUCED LUPUS ERYTHEMATOSUS^a

- The sex ratio for DILE is equal, whereas SLE is found predominantly in women.
- The symptoms of DILE tend to be milder and primarily involve the skin, joints, and serous membrane.
- DILE is reversible after discontinuation of the drug.
- Renal and CNS disease is rare in DILE.
- Anti-DNA and low complement are uncommon in DILE, though DILE induced by sulfasalazine is an exception to this rule.
- DILE is almost invariably associated with antihistone antibodies.

ANTIPHOSPHOLIPID ANTIBODY SYNDROME

A subset of patients with SLE, as well as otherwise healthy individuals, may have a history of recurrent venous and/or arterial thromboembolism and obstetrical complications, particularly intrauterine growth retardation and fetal demise. Such patients may also have moderate thrombocytopenia, livedo reticularis, migraine headaches, and Libman–Sacks endocarditis. The presence of antiphospholipid antibodies can be established by enzyme-linked immunosorbent assay for anticardiolipin (ACL) antibodies (which is a special class of antiphospholipid antibodies), a false-positive test result for syphilis, or evidence of the “lupus anticoagulant” (which is a misnomer—see “Laboratory Findings”). These patients are in a hypercoagulable state and should be treated accordingly. Frequently, the treatment of the two conditions—SLE and the antiphospholipid antibody syndrome—must be pursued completely separately in the same patient.

OVERLAP SYNDROMES

Patients with SLE may have features suggestive of other rheumatic diseases as well (Fig. 178.1). Patients who clearly exhibit features of more than one disease can be said to have an overlap syndrome. It is important to emphasize to the patient that this is hardly likely to represent a chance occurrence of two disorders

simultaneously! Instead, it illustrates the failure of our somewhat arbitrary categories to fit each patient's unique disease characteristics. Equally important is the recognition that patients may not remain in one particular diagnostic category; some patients may have classic symptoms of more than one autoimmune disease at different points in time (Fig. 178.1). The most common overlap syndromes are MCTD, SLE combined with Sjögren's syndrome, SLE with scleroderma, SLE with thyroiditis, and SLE with microangiopathic hemolytic anemia.

Mixed Connective Tissue Disease

MCTD is the most well-defined overlap syndrome, a clinical entity with features of SLE, scleroderma, and myositis. Typical manifestations include Raynaud's phenomenon, sclerodactyly, chronic dermatitis of sun-exposed skin, arthritis, serositis, esophageal dysmotility, and myositis. The finding of high-titer anti-RNP (1:100,000 or more) antibodies identifies this subset of patients. CNS and renal involvement is uncommon. These patients generally do well, but lung fibrosis and/or pulmonary hypertension mark a poorer prognosis.

Systemic Lupus Erythematosus and Sjögren's Syndrome Overlap

Sjögren's syndrome is autoimmune inflammation of the lacrimal and salivary glands, which may be associated with systemic features. The characteristic symptoms and signs are recurrent keratoconjunctivitis of the eyes, recurrent problems with dental and periodontal disease, and difficulty in swallowing; symptoms of dry eyes and dry mouth are by far too nonspecific to permit diagnosis. Anti-Ro (SSA) and anti-La (SSB) antibodies are common in patients with Sjögren's syndrome, as is rheumatoid factor. A minor salivary gland biopsy (lip biopsy) can help establish the diagnosis. Patients with Sjögren's syndrome may be at higher risk of interstitial lung disease and peripheral neuropathies.

Systemic Lupus Erythematosus and Scleroderma

The combination of SLE and scleroderma is suggested by a characteristic hardening of the skin, severe Raynaud's phenomenon, and esophageal dysmotility. Inasmuch as the pathologic lesion of scleroderma is a merging of fibrosis and arterial hyperplasia, neither of which is likely to respond to glucocorticoid therapy, the distinction is important to make from a clinical point of view. For example, both SLE and scleroderma can cause severe renal disease, but the treatments are very different. Frequently, renal biopsy is needed to make the distinction.

Systemic Lupus Erythematosus with Autoimmune Thyroiditis

Autoimmune thyroiditis occurs often in the course of SLE; the condition may be hypothyroid, euthyroid, or hyperthyroid. As a general rule, the workup of any new set of symptoms in a patient with SLE should include thyroid function tests. Antithyroglobulin and antimicrosomal antibodies may support the diagnosis of autoimmune thyroiditis.

Systemic Lupus Erythematosus with Microangiopathic Hemolytic Anemia

SLE with microangiopathic hemolytic anemia is present when a patient with severe, active SLE and kidney, CNS, and hematologic symptoms also manifests evidence of significant microangiopathy, such as can be found on peripheral blood smear or by histopathologic examination. The clinical syndrome thus resembles thrombotic thrombocytopenic purpura or hemolytic-uremic syndrome. Evidence suggests that this overlap may be caused by antibodies directed against von Willebrand's factor–cleaving serum protease. Treatment for such patients should include plasma exchange.

Undifferentiated Connective Tissue Disease

Patients who do not fit into any of the disease categories discussed, but who nevertheless have clear evidence of a systemic autoimmune disorder, can be said to have undifferentiated connective tissue disease (Fig. 178.1). If the symptoms have been present for a relatively short period of time (less than 1 year), the disease may eventually declare itself. On the other hand, a number of patients will continue to exhibit the same set of limited symptoms for many years and never progress to a more well-defined rheumatic illness.

LABORATORY FINDINGS

A routine complete blood cell count often shows evidence of systemic inflammation, such as normocytic, normochromic anemia (anemia of chronic disease) and thrombocytosis. Modest leukocytosis is a general feature of most inflammatory diseases, but patients with SLE more often exhibit leukopenia and lymphopenia; the former tends to be obscured once glucocorticoid therapy is begun. Renal function is usually preserved in early-stage disease, even if active nephritis is present, but urinalysis may show evidence of proteinuria and microscopic hematuria. Erythrocyte casts are a sign of severe glomerulonephritis. Liver function test results are usually normal; a small subset of patients may have autoimmune liver inflammation with elevated transaminase levels. Widely used markers for inflammation include the erythrocyte sedimentation rate and C-reactive protein. The erythrocyte sedimentation rate can be markedly elevated in patients with severe disease, but on occasion it may be within the normal range despite convincingly active SLE. C-reactive protein levels are usually elevated more modestly in SLE and more significantly in the case of acute infections, helping to differentiate the two.

Immunologic studies are of cardinal importance in the correct diagnosis of SLE and other related disorders. The ANA test result is virtually always positive in patients who have SLE. The converse is not true: many individuals with a positive ANA test result do not have SLE! The titer of positivity (the highest dilution of serum at which the immunofluorescent stain is seen) does not by itself say much about the diagnosis. It should be borne in mind, however, that a low-positive titer can well be false-positive (by definition, at least 2.5% of the population ought to fall outside the "normal" range). On the other hand, a high-positive titer probably has an explanation, though the explanation does not have to be SLE. The pattern of staining on occasion can provide a diagnostic clue: for example, a nucleolar pattern points to a diagnosis of scleroderma. Most ANAs, however, give a diffuse (homogeneous) or speckled (heterogeneous) staining pattern, and these patterns do not provide further helpful information. A possible way of evaluating a positive ANA result is given in Fig. 178.2.

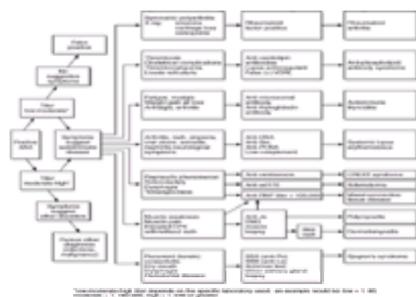

FIGURE 178.2. Evaluating a positive antinuclear antibody (ANA) result.
EVIDENCE LEVEL: C. Expert Opinion.

The presence of antibodies against double-stranded (native) DNA is the most helpful confirmatory test for SLE. In a reasonable clinical context, a positive result all but proves the diagnosis. This is particularly true if an immunofluorescent method (Crithidia test) is used. Tests for anti-single-stranded or denatured DNA are not very helpful from a clinical perspective. A positive anti-double-stranded DNA antibody test also increases the likelihood that the patient has or will have lupus nephritis. These antibodies, in fact, may have pathogenetic significance. In some patients, anti-DNA titers may reflect disease activity accurately, and a sudden increase in titer may even predict impending flare-ups. Anti-Sm and anti-proliferating cell nuclear antigen antibodies are also very specific for SLE, but are found

infrequently. Antiribosomal P antibodies and antineuronal antibodies support a diagnosis of CNS lupus. Antihistone antibodies are seen in virtually all cases of DILE.

Anti-Ro (SSA) and anti-La (SSB) are two autoantibodies originally described in patients with Sjögren's syndrome. They are found in up to half of all patients with lupus and indicate a higher likelihood of cutaneous manifestations, photosensitivity, and neonatal lupus in the offspring of women of childbearing age. Anti-RNP at a low titer is a nonspecific finding in SLE, while anti-RNP at extremely high titers (1:1,000,000) suggests the diagnosis of MCTD. Many other autoantibodies can be found in patients with SLE, but they are more typically associated with other diseases, including rheumatoid factors and antithyroid antibodies. An overview of autoantibodies found in SLE is given in [Table 178.6](#).

Antibody Specificity	Disease Association
Anti-DNAse B	SLE, nephritis
Anti-Smith (SMA)	SLE, nephritis
Anti-Ribonucleoprotein (RNP)	SLE, nephritis; various autoimmune diseases, including SLE
Anti-Ribonucleoprotein (RNP)	SLE, MCTD (very high titer); SLE (low to moderate titer)
Anti-Ro (SSA)	Sjögren's syndrome, SLE, SCLL, neonatal lupus
Anti-La (SSB)	Sjögren's syndrome, SLE, SCLL
Anti-Histone	Drug-induced lupus erythematosus
Anti-Proteinase 3	SLE
Anti-Nuclear antigen	CNS lupus with psychosis
Anti-Ribosomal P	CNS lupus
Anti-Johnston	Autoimmune thyroiditis
Anti-Tyroglobulin	Rheumatoid arthritis, SLE (low titer)
Anti-Rheumatoid factor	Anti-phospholipid antibody syndrome
Anti-Cardiolipin	CREST syndrome
Anti-Centromere	

SMA, Smith's; SLE, systemic lupus erythematosus; MCTD, mixed connective tissue disease; SCLL, subcutaneous lupus erythematosus; CNS, central nervous system; CREST, calcinosis, Raynaud's, esophageal dysmotility, sclerodactyly, telangiectasia; ds, double stranded; ss, single stranded.

TABLE 178.6. AUTOANTIBODIES FOUND IN SYSTEMIC LUPUS ERYTHEMATOSUS

Low complement levels, particularly C3, C4, and CH50 (total hemolytic complement), are important both in the diagnosis of lupus and in monitoring disease activity. Low C4 levels may reflect disease activity but also can be the result of a (partial) deficiency of this complement product, whereas low C3 nearly always implies activation of complement. It has been suggested that measuring complement split products (e.g. C3d) is even more helpful in monitoring SLE—higher levels imply complement activation as a result of the disease process.

Various tests can indicate a thromboembolic tendency, including those for ACL antibodies and the so-called lupus anticoagulant; while these features can be found in otherwise healthy individuals, they are distinctly more common in patients with SLE. The term *lupus anticoagulant* is a misnomer: patients with this abnormality are at risk of venous and arterial embolism. The reason for the misnomer is that the activated partial thromboplastin time in these patients is prolonged. The lupus anticoagulant is therefore an anticoagulant in vitro but a procoagulant in vivo. This abnormality can be confirmed by mixing and platelet absorption studies. ACL antibodies also imply increased risk of thromboembolic events, particularly if they are of the IgG isotype. The risk correlates with the titer of the antibody. ACL antibodies are a special example of the larger group of antiphospholipid antibodies; laboratories can screen for a whole range of antiphospholipid antibodies, but their clinical significance is not always clear. ACL antibodies will result in a false-positive VDRL or rapid plasma reagin test for syphilis; a negative fluorescent treponemal antibody absorption test helps rule out true syphilis.

Cerebrospinal fluid in patients with overt CNS lupus can show pleiocytosis and elevated protein levels, and antiribosomal P and antineuronal antibodies can be found in some patients' CSF even when results are negative in serum. Ancillary diagnostic studies are of great importance in the evaluation of patients with suspected or confirmed SLE. These tests generally can be guided by the symptoms, signs, and findings on laboratory studies. They include radiographs of heart, lungs and affected joints; echocardiography for the evaluation of peri-, myo-, and endocardial involvement; high-resolution computed tomography of the lungs to define parenchymal lung disease; and magnetic resonance imaging of the CNS to evaluate patients with CNS lupus. Specialized diagnostic studies of the CNS are under investigation because of the difficulties in correlating CNS symptoms with objective findings in some patients, but positron emission tomography, single-positron emission computerized tomography, magnetic resonance spectroscopy, and others are still largely experimental.

Biopsies are invaluable in the evaluation of skin and kidney disease. The skin biopsy result of patients with SLE shows the "lupus band test," deposition of immune complexes and complement products in a granular pattern at the dermal-epidermal junction. This pattern can be seen even in clinically unaffected skin. The kidney biopsy in SLE may evince any of a number of histopathologic changes; they have been distinguished as WHO classes I to VI, the higher classes reflecting more serious disease ([Table 178.3](#)). Both immunofluorescence and electron microscopy are necessary for correct interpretation of the renal histopathologic features of SLE.

OPTIMAL MANAGEMENT

DIAGNOSIS

The time when a patient is first diagnosed with SLE marks a watershed in the individual's life and should be treated with due respect. The failure to diagnose SLE when it is present is usually of less dramatic consequence than the mistake of diagnosing SLE incorrectly. A false diagnosis of SLE results in great distress for the patient, and a common practical problem is that it is very difficult to reverse this incorrect diagnosis, particularly in those individuals who experience symptoms for which no other explanation has been found.

[Figure 178.3](#) indicates a suggested path to follow when considering the diagnosis of SLE. The diagnosis of SLE should be considered only when suspicion is aroused by an appropriate set of symptoms. In such individuals, a positive ANA test result can strengthen the suspicion, whereas a negative test result should direct the evaluation toward other, more likely diagnoses. A positive ANA result also opens up the possibility of finding more disease-specific autoantibodies, such as anti-DNA. After completion of this evaluation, one can take stock of the net result in terms of positive and negative findings. The ACR criteria can serve as a useful reference frame, but many other symptoms and signs can be present or absent in patients under evaluation. Important clues that SLE is the correct diagnosis include previous episodes in the patient's history of unexplained inflammatory disease (arthritis, pleurisy, pericarditis, aseptic meningitis) or obstetrical complications, persistent subtle markers of systemic inflammation (non-iron deficiency anemia, elevated erythrocyte sedimentation rate), unexplained leukopenia, photosensitivity, hair loss, nonspecific rashes, lymphadenopathy, and temperature elevations. Conversely, the absence of all these symptoms should prompt due hesitation about the diagnosis.

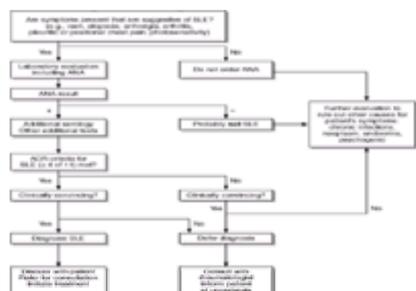

FIGURE 178.3. Diagnosis of systemic lupus erythematosus (SLE). EVIDENCE LEVEL: C Expert Opinion.

If such a rigorous workup uncovers four or more ACR criteria plus a host of other consistent findings, the diagnosis should be made and discussed with the patient. More frequently, uncertainty will persist even when the diagnosis is likely correct. In either instance, confirmatory consultation with a rheumatologist (second opinion)

is appropriate. Unless there is abundant evidence to suggest SLE, the diagnosis probably should be deferred. A relatively common situation arises when patients have objective evidence of chronic mild systemic inflammation and some evidence of autoimmunity, without other explanation. One example would be a female patient in her late twenties who for a year has experienced generalized malaise and myalgias. There are no signs on physical examination, but she has persistent, modest anemia; an elevated sedimentation rate; a positive ANA result, and low complement levels. Chronic infections, malignancies, and drug side effects have been ruled out. This patient does not meet any set of criteria for SLE, but, on the other hand, she does have a demonstrable disorder. Two key points can be made about such patients: long-term follow-up suggests that they do not progress to overt SLE or other specific rheumatic disorders, and their quality of life can be seriously jeopardized by iatrogenic complications from the use of glucocorticoids and immunosuppressive drugs in response to the presumptive diagnosis of SLE. It is appropriate to give these patients a diagnosis such as undifferentiated connective tissue disease [which is an International Classification of Diseases (ICD)-9 category], provided that sufficient explanation is also offered. Terms such as incomplete lupus, latent lupus, or atypical lupus can be used with caution to convey the fact that a mild immune disturbance may be present. It behooves the physician to acknowledge the limitations of our knowledge in caring for such a patient.

TREATMENT

The variability and heterogeneity of SLE frustrate attempts to prescribe any one treatment course for all patients. Several principles can be applied, and they can be divided into those that should guide the treatment of acute SLE flare-ups, including the de novo development of symptoms that result in the diagnosis of SLE, and the management of the chronic, smoldering phases of the disease. A simplified decision-making strategy for the therapy of lupus is given in [Fig. 178.4](#).

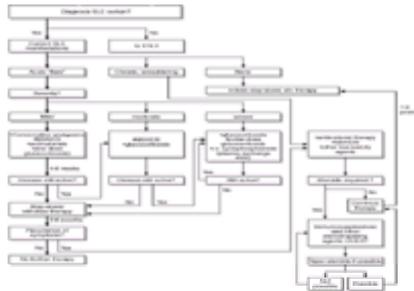

FIGURE 178.4. Treatment of systemic lupus erythematosus (SLE).
EVIDENCE LEVEL: C Expert Opinion.

Acute and/or Severe Systemic Lupus Erythematosus

In the active phase of SLE, the emphasis must be on rapid control of disease symptoms tailored to the individual patient. The medications chosen to accomplish this goal must be adapted to the organs involved and the activity of the disease in those organs ([Table 178.2](#)), taking into account the potential for end-organ damage. For example, the patient with an acute flare-up of arthritis, pleurisy, or pericarditis can sometimes be treated with NSAIDs. This class of agents is not easy to use in lupus patients, because several toxicities can interact unfavorably with lupus manifestations per se. For example, the nephritis and hypertension common to SLE can be aggravated by NSAIDs, and some NSAIDs, including ibuprofen, can cause aseptic meningitis, particularly in patients with SLE. There are no rules that predict which NSAID would be of most benefit for which patient. The development of new COX-2-selective NSAIDs may limit toxicity, but data as to efficacy in patients with SLE are lacking.

The mainstay of therapy in active SLE is glucocorticoids. The efficacy of glucocorticoids and their rapid onset of action make them particularly suitable for treatment of newly developed severe lupus manifestations, whether at the first presentation of the illness or as a flare-up punctuating a more chronic course. Glucocorticoids are usually effective when taken orally, though the intravenous route can be chosen with more predictable pharmacokinetics in acutely ill patients. Initial dosages should be the equivalent of 1 mg per kilogram per day of prednisone, given in two or three divided doses. While halfhearted attempts at controlling disease with lower doses (in order to minimize side effects) are well intended, they frequently backfire by leading to more prolonged glucocorticoid treatment with higher cumulative dosages in the long run. The optimal treatment duration has not been defined. Many clinicians treat for 1 month and then taper off over 2 to 6 months. The tapering regimen can allow for greater decrements at the higher dosage levels, but more long-term, low-dose therapy cannot always be avoided. In patients with very severe flare-ups of SLE, bolus or pulse doses of glucocorticoids are sometimes used, for example, 1,000 mg of methylprednisolone per day given intravenously for 3 consecutive days.

Immunosuppressive drugs are usually not effective for acute episodes, though there is anecdotal evidence that cyclophosphamide has immediate benefit in some patients with CNS lupus. Nevertheless, in the patient who experiences a severe flare-up of lupus affecting the CNS, heart, lung parenchyma, or kidneys, an intravenous bolus dose of cyclophosphamide (0.5 to 1.0 g, administered intravenously) is often added to the initial treatment regimen. In this event, and provided the lupus flare-up is controlled with this regimen, the intravenous bolus dose of cyclophosphamide is usually repeated monthly while glucocorticoids are being tapered, for 6 to 12 months. Other agents used for the treatment of the acutely ill lupus patient include intravenous gammaglobulin and plasmapheresis, though data supporting such use exists for only narrowly defined subsets of patients.

Lupus Nephritis

Kidney involvement represents a special case of therapy, because the potential for end-organ damage (renal failure) is not always apparent from the clinical signs and symptoms and because clinical studies show long-term benefits with immunosuppressive treatment, particularly with cyclophosphamide. Management of lupus nephritis depends critically on the renal histologic features, and consultation with a nephrologist and a rheumatologist is essential. [Table 178.3](#) summarizes current guidelines for treatment of lupus nephritis. Note that patients with SLE who have reached end-stage renal disease and are undergoing dialysis often have very little active SLE and can be good candidates for renal transplant if a donor is available.

Chronic Phase of Systemic Lupus Erythematosus

The management of SLE in the chronic phase is of a different nature from that of acute lupus symptoms. Prevention of long-term consequences, in terms of both the disease and iatrogenic damage, is paramount. Basic lifestyle advice, such as the use of sunscreen, general health maintenance, balanced nutrition, and psychosocial support, must not be neglected. Conservative treatment options include glucocorticoid creams for skin lesions, physical therapy and splints for mild muscle and joint symptoms, and analgesic agents when needed.

Antimalarial agents are very useful in the long-term management of SLE. The therapeutic properties of this class of agents may have to do with their ability to interfere with antigen-processing steps in the immune response; however, other mechanisms of action may be more important, because antimalarials are not generally immunosuppressive. The most clearly proven benefit of hydroxychloroquine is prevention of SLE flare-ups; a lessening of arthritis and lupus skin lesions, diminished photosensitivity, and, possibly, a mild cholesterol-lowering effect and a slight antithrombotic effect may all play a role. Some patients perceive improvements in general symptoms, such as fatigue and lassitude. Hydroxychloroquine is administered as a single daily dose of 200 to 400 mg, and routine eye exams are advocated by some clinicians, to monitor for the very rare eventuality of irreversible retinal damage. Chloroquine given at 60 to 250 mg per day can be substituted, but it may be more retinotoxic.

Glucocorticoids are not well suited for long-term use. The wide range of side effects, many of which are a virtual certainty with prolonged treatment, makes it imperative to try to minimize glucocorticoid exposure. On the other hand, many patients experience flare-ups of disease activity when these agents are tapered below a critical threshold, often in the range of 5 to 15 mg per day of prednisone. To facilitate tapering, alternate-day dosing with glucocorticoids is advocated by some clinicians, but it is not often successful. The symptoms encountered when glucocorticoids are tapered are sometimes difficult to classify: while some patients experience true SLE flare-ups, others have diffuse, nonspecific symptoms that are the result of glucocorticoid-withdrawal syndrome or even adrenal insufficiency.

Joint and muscle pain without objective inflammation, that is, arthralgias and myalgias, should be treated as conservatively as possible. The patient's expectations

may need to be addressed, since some degree of joint or muscle discomfort may be impossible to avoid. Nonpharmacologic interventions, including physical therapy, are preferable. Some patients respond well to mild analgesics or low doses of antidepressants. Vigilance is needed to rule out other causes of noninflammatory pain, especially since thyroid abnormalities and psychogenic causes of pain (depression, somatization disorder) are relatively common in patients with SLE. If patients consistently fail to gain sufficient control of their disease symptoms with glucocorticoids and/or consistently experience flare-ups when they are tapered, the use of immunosuppressive medications as steroid-sparing agents is appropriate. Azathioprine, methotrexate, and cyclosporin A are possible choices. Individual patients with chronic skin lesions can benefit from treatment with dapsone or thalidomide. Chronic hematologic lupus sometimes can be treated with danazol.

Experimental Therapy

In patients with mild to moderate SLE, DHEA at a dosage of 200 mg per day has been reported to produce benefits with respect to overall disease activity, glucocorticoid requirements, and reduction in flare-ups. In a large clinical trial, DHEA treatment allowed more patients to lower their glucocorticoid dosages to a physiologic level. Smaller studies suggest that DHEA may have additional benefits with respect to bone metabolism and cognitive function in patients with SLE. If these results are confirmed in ongoing clinical trials, DHEA may gain an important role in the long-term management of SLE.

Total lymph irradiation has been used in some patients with severe, refractory SLE. More radical approaches to therapy, including high-intensity chemotherapy and even myeloablative chemotherapy with autologous stem-cell transplant, are being tried in investigational studies in several centers; these treatments are clearly appropriate for only a small group of patients with the most severe forms of disease. Novel approaches to induce immunologic tolerance for DNA or to interrupt the T-cell activation that occurs in SLE are under investigation in clinical trials. Innumerable treatment alternatives have been proposed, but few have been tested in a rigorous manner.

The Antiphospholipid Antibody Syndrome

Attempts to control the hypercoagulability state seen in patients with the antiphospholipid antibody syndrome by administering glucocorticoids or immunosuppressive drugs have been largely unsuccessful, and the current recommendations for management of this syndrome rely entirely on anticoagulation. For patients who have experienced thromboembolic events, lifelong anticoagulation with warfarin at an international normalized ratio of 3.0 to 4.0 is recommended. For patients without any such previous events but with positive test results, low-dose aspirin seems to be a reasonable form of prophylaxis. Pregnant women with antiphospholipid antibodies generally require treatment with heparin, low-molecular-weight heparin, and/or aspirin; they should be treated by an obstetrician who is experienced in high-risk pregnancies.

Preventive Therapy

Patients with SLE will want to know how to prevent lupus flare-ups. Although there are no proven ways of doing so, the following list gives common-sense recommendations that are valid for most patients:

- Avoid ultraviolet light exposure not only through the use of sunscreens but by staying out of the sunlight or wearing protective clothing.
- Avoid exercising to exhaustion. Whereas a solid cardiovascular workout is very beneficial, the effects of extreme physical efforts are likely to trigger increased lupus activity, possibly through the release of nuclear material from damaged cells into the circulation or through the release of cytokines.
- Avoid infections. Many common respiratory infections can be prevented by frequent washing of the hands and other simple hygiene measures.
- Pregnancy may entail a slightly increased risk of a lupus flare-up, and the patient facing the highly personal decision of becoming pregnant is entitled to know this. She also should be informed that breast-feeding may increase the risk of a postpartum flare-up (through the proinflammatory effects of prolactin).

Prevention of disease-related as well as treatment-related long-term consequences of SLE is very important. Risk factors for arteriosclerotic disease should be identified and treated aggressively. Most patients on prolonged treatment with glucocorticoids have some degree of dyslipidemia, hypercholesterolemia, or hypertriglyceridemia. Appropriate dietary advice and, if necessary, lipid-lowering therapy should be provided. An elevated serum homocysteine level is an independent risk factor for arteriosclerosis and may be present to an even higher degree in patients with SLE. Diagnosis of this condition and treatment with vitamins B₆ and B₁₂ and folic acid is likely to minimize morbidity and mortality.

Patients on moderate- to high-dose glucocorticoids and immunosuppressive agents, such as cyclophosphamide, have a higher risk of infection. Common-sense avoidance of potential sources of infection (hand washing, use of disinfectants) can be discussed with each patient. Prophylaxis against *Pneumocystis carinii* pneumonia can be considered. Immunizations have been scrutinized with regard to the potential of inducing SLE flare-ups; on balance, vaccines against influenza and pneumococcus are appropriate for patients with lupus, whereas live/attenuated vaccines should be avoided in a person with immunosuppression.

Prevention of osteoporosis should begin before bone is lost, that is, at the inception of glucocorticoid therapy. Calcium (1,000 to 1,500 mg per day) and vitamin D supplementation should be prescribed to all patients, and the benefits of weight-bearing activities must be explained. Patients at higher risk of osteoporosis may be candidates for antiresorptive medications (bisphosphonates, calcitonin). Whether postmenopausal women with SLE should receive hormone replacement therapy is the subject of controversy; it seems that the slight risk of enhanced SLE activity could be outweighed readily by advantages with respect to arteriosclerotic disease and bone metabolism. The adrenal androgen DHEA, which is under investigation for the treatment of SLE, may have benefits for bone metabolism as well.

Treatment of Overlap Syndromes

The treatment of patients with overlap syndromes as well as those with undifferentiated connective tissue disease is targeted to the specific organ systems involved. For example, the manifestations of Sjögren's syndrome seen in the context of SLE can be treated as they would in the primary disease: artificial tears for the eyes, pilocarpine or saliva substitutes (which are less successful than was hoped), and increased dental care. Sclerodermatous features often respond poorly to immunosuppressive therapies and may require more conservative measures. On the other hand, scleroderma renal disease responds well to angiotensin-converting enzyme inhibitors, and, in the case of gastrointestinal scleroderma, the use of pro-motility agents can improve quality of life.

COURSE AND PROGNOSIS

The 5- and 10-year survival rates of SLE have improved considerably over the past several decades. Renal disease can be treated more effectively, but SLE affecting the CNS, lungs, heart, and gastrointestinal tract can still be frustrating at times. The prognosis for the individual patient depends on many factors, including the clinical symptoms, affected organ systems, and comorbid conditions. The long-term consequences of SLE, including the late lupus syndrome, are of concern. Nevertheless, the closing years of the twentieth century have seen an unprecedented increase in our knowledge and understanding of SLE as well as the introduction of large-scale clinical trials of several new therapeutic agents with new and, in some instances, unique modes of action that, if successful, will herald a new era in the treatment of SLE.

CHAPTER 179: SCLERODERMA AND RAYNAUD'S SYNDROME

JAMES R. SEIBOLD

[Incidence and Epidemiology](#)
[Etiology and Pathogenesis](#)
[Clinical Findings](#)
[Laboratory Findings](#)
[Course and Prognosis](#)
[Approach to Assessment](#)
[Other Clinical Syndromes](#)
[Optimal Management](#)

Systemic sclerosis (scleroderma) is characterized by thickening and fibrosis of the skin (scleroderma) and by distinctive forms of internal organ involvement. The cause and pathogenesis are unknown, and effective disease-modifying treatment is lacking. Morbidity and mortality are related directly to the extent and severity of visceral involvement, which in turn are related closely to the pace of disease progression and the extent of skin involvement. The recognition of well-defined subgroups within the diagnosis of scleroderma is important in determining prognosis and planning therapy.

INCIDENCE AND EPIDEMIOLOGY

Modern studies have suggested an annual incidence of scleroderma of 1 to 2 per 100,000 population. The onset of scleroderma is highest in the fourth and fifth decades of life, and the disease is four times more common in women. It is likely that many cases of scleroderma are misdiagnosed as isolated Raynaud's phenomenon (RP), primary pulmonary hypertension, or primary biliary cirrhosis, particularly in individuals with limited and subtle skin changes. The development of scleroderma is not linked to race or geography in any consistent fashion, and familial occurrence is uncommon. Genetic contribution is suspected from studies of a case cluster in Choctaw Indians of Oklahoma. Case reports and series linking silicone gel breast implants and occupational exposures to organic solvents have not been supported by epidemiologic surveys.

ETIOLOGY AND PATHOGENESIS

Any hypothesis concerning the pathogenesis of scleroderma must account for the heterogeneity of patterns of disease progression and extent, the common and somewhat characteristic immunologic abnormalities, the accelerated rate of accumulation of collagen and other extracellular matrix components, and the prominent and characteristic abnormalities of vascular structure and function. The sporadic occurrence of scleroderma and the absence of strong genetic or environmental causative factors have prevented recognition of a "prescleroderma" state. Therefore, reasonable information on early pathogenesis is lacking.

Raynaud's phenomenon is the initial complaint in about 70% of patients and results largely from narrowing of digital arterial lumina secondary to intimal accumulation of ground substance and collagen. Similar fibrotic and arteriosclerotic changes occur in the vasculature of the heart, lungs, kidneys, and gastrointestinal tract and contribute to the dysfunction of these organs. Swelling and disruption of the endothelium of the arteriolar and capillary beds occur at the earliest recognizable stages of disease. Examination of the nail fold tissues by *in vivo* wide-field microscopy reveals enlargement and tortuosity of capillary loops interspersed with areas of capillary obliteration. Similar changes occur in the microvasculature of the internal organs. The factors responsible for this vascular injury are unknown. Chronic, ongoing endothelial injury and repair is suggested by the finding of increased levels of factor VIII/von Willebrand's factor and adhesion molecules as well as by measures of *in vivo* platelet activation. Vascular inflammation is uncommon.

The biology of established disease has been more amenable to study. Early tissue lesions feature the ingress of immigrant inflammatory cell populations, including helper-inducer T lymphocytes, monocytes, and mast cells. These cells in turn release proinflammatory and profibrotic growth factors/cytokines locally. Autocrine effects of growth factors such as transforming growth factor β from nonlesional cell populations such as circulating platelets also are implicated. The net effect of this complex array of cells and signals is the accumulation of extracellular matrix, predominantly collagen but also glycosaminoglycan, fibronectin, adherence molecules, and tissue water (edema). Cytokine-driven selection of hypersecretory and hyperproliferative dermal fibroblast subpopulations in involved skin of patients with scleroderma results in excessive accumulation of the principal skin collagens, types I and III. The collagen is biochemically normal, and the proportion of type I to type III collagen is that of normal skin. Studies with clonal DNAs have demonstrated increased transcription of messenger RNA for types I and III collagen and no evidence of a disease-associated genomic polymorphism for collagen. Dermal collagenase activity appears to be unaffected.

Elevated levels of serum interleukin-2, interleukin-6, and soluble interleukin-2 receptors are present in scleroderma and are linked to the clinical progression of disease. This evidence of T-cell activation suggests a role for lymphokines that stimulate collagen production or that stimulate other cells, such as monocytes or mast cells. Human chronic graft-versus-host disease is associated with similar dermal fibrotic changes. There is evidence of fetal microchimerism both in peripheral blood and involved skin of patients with scleroderma lending credence to the hypothesis that scleroderma may be partially graft-vs.-host in mechanism. Mast cell infiltrates and evidence of local mast cell degranulation are present in skin and internal organs. Marked and persistent reduction of collagen accumulation by scleroderma dermal fibroblasts in response to interferon- γ has focused attention on the potential role of the monocyte. Transforming growth factor β and other platelet-derived growth factors are released during platelet activation and may mediate fibroblast proliferation and further endothelial injury in scleroderma.

Tissue injury in internal organs is centered around the small arteriole and, as in the skin, features varying contributions of fibrosis, inflammation, and obliterative vascular change.

Serum antinuclear antibodies are present in 90% of patients with scleroderma and disease-specific serologic abnormalities have been defined. About 60% to 70% of patients with limited scleroderma have serum antibodies to centromeric and kinetochore proteins. About 30% to 40% of patients with diffuse or generalized disease have serum antibodies to DNA topoisomerase I (previously known as Scl-70). The antigenicity of DNA topoisomerase I resides in an 11-amino-acid sequence closely homologous to that of a group-specific antigen of some mammalian retroviruses. An additional 30% to 40% of patients with diffuse scleroderma have antibodies to RNA polymerases I and III. Cell injury in conditions of hypoxemia/reperfusion leads to selective release of scleroderma-specific antigens.

CLINICAL FINDINGS

EARLY DIAGNOSIS

Scleroderma is variable in extent and progression but can be grouped into two principal syndromes of prognostic and therapeutic importance. Patients with diffuse or generalized scleroderma are at risk for rapidly progressive and widespread skin involvement and the early development of the full complement of internal organ abnormalities. A nearly equal number of patients have slowly progressive skin changes that usually are restricted to the fingers, hands, and face, and may have an extended course of illness before the development of visceral abnormalities. Historically termed the CREST syndrome variant of scleroderma (subcutaneous calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, telangiectasia), these patients have limited scleroderma.

RAYNAUD'S PHENOMENON

Raynaud's phenomenon is the clinical syndrome of episodic color changes of the digits in response to cold and, in some patients, emotional stress. Although not all patients have the complete syndrome, the typical sequence is pallor (arterial constriction), followed by cyanosis (venospasm and desaturation of hemoglobin), followed by reactive hyperemia.

The exact incidence of RP is not known but may be as high as 10% in selected populations, such as premenopausal women. Most patients with RP have structurally normal blood vessels and no evidence of an underlying disease process (primary RP). Within this larger group are individuals whose presentation is indicative of structural vascular disease and hemorheologic abnormalities (secondary RP). Blood flow to the skin is 10 to 20 times that required for oxygenation and nutrition; alterations of perfusion to the skin are a principal homeostatic mechanism of thermoregulation. Irrespective of cause, patients with RP have undue intolerance to environmental cold. No single pathophysiologic mechanism explains cold-induced vasospasm in all forms of the syndrome, and there is no single form of RP in which

the cause is completely understood. [Table 179.1](#) classifies the diverse clinical syndromes associated with RP according to the assumed principal mechanism: vasospastic, structural, or hemorrhheologic.

(The image shows a very faint and illegible version of Table 179.1, which is a mechanistic classification of Raynaud's phenomenon.)

TABLE 179.1. A MECHANISTIC CLASSIFICATION OF RAYNAUD'S PHENOMENON

RAYNAUD'S PHENOMENON AND SCLERODERMA

The typical sequence of clinical events in all forms of scleroderma is RP, followed by finger and hand edema, followed by tightening and thickening of the skin. The order of events and their temporal association are important clues to clinical classification. In diffuse scleroderma, RP may be concomitant in onset or may be preceded by finger edema, skin thickening, polyarthralgia, or signs of specific internal organ involvement. In limited scleroderma, patients may have RP alone for years, even decades, before more specific manifestations of scleroderma develop.

The assessment of RP as an isolated clinical complaint forces the consideration of a wide range of seemingly unrelated conditions ([Table 179.1](#)). Much information can be obtained from a directed history and physical examination. The criteria for primary RP include the presence of at least two of the three characteristic color changes in response to cold, bilateral involvement, normal radial artery pulsations, absence of digital ischemic injury, and absence of clinical evidence of an underlying causal disease.

A special area of concern is the recognition of early connective tissue disease, particularly in patients suspected of having early limited scleroderma. The age of onset is an important clue because primary RP typically begins in the teens to early 20s, whereas secondary forms of RP begin later in life. Raynaud's phenomenon in men usually is a secondary form of the syndrome ([Table 179.2](#)).

Clinical Feature	Primary Raynaud's Phenomenon	Raynaud's Phenomenon Secondary to Connective Tissue Disease
Sex	Overwhelmingly female	Male and female
Age of onset	Months	Mid 20s and later
Onset	Usually all digits	Often begins in a single digit
Symptoms	Mild to moderate	Moderate to severe
Associated with renal disease	No	Unusual
Ischemic injury	No	Yes
Finger ulcers	Rare	Common
Pericardial effusion	Rare	Common
Onset of other vascular syndromes (e.g., angiod)	No	Yes

TABLE 179.2. CLINICAL FEATURES HELPFUL IN DISTINGUISHING PRIMARY RAYNAUD'S PHENOMENON FROM RAYNAUD'S PHENOMENON OF EARLY CONNECTIVE TISSUE DISEASE

SKIN INVOLVEMENT

The initial skin edema of the fingers and other sites typically is painless but may be accompanied by symptoms of morning stiffness, arthralgia, and carpal tunnel syndrome, suggesting the diagnosis of early rheumatoid arthritis or systemic lupus erythematosus. As the edema lessens, tightening and thickness of the skin develops, usually beginning on the fingers. In diffuse scleroderma, this transformation usually ensues within weeks to a few months, whereas in limited scleroderma, the edematous phase may persist for years before actual skin thickening occurs. Rare patients have *systemic sclerosis sine scleroderma*, in which typical vascular and internal organ features of scleroderma are seen but skin changes never develop.

MUSCULOSKELETAL FEATURES

As skin thickening worsens, the underlying joints become tethered and restricted in motion. Patients with diffuse disease may have painful involvement of tendon sheaths, which can mimic inflammatory arthritis. Leathery friction rubs may be palpated during active or passive motion of involved areas. Arthritic complaints are common and erosive arthropathy occasionally occurs. Restricted motion leads to disuse atrophy of the muscles, and weakness may be worsened by accompanying skeletal muscle inflammation. Ischemic ulcerations of the fingertips occur in 10% to 20% of patients per year and the fingers themselves may shorten and atrophy from disuse and ischemic resorption of the phalanges. Skin tightening on the face may restrict the ability to open the mouth and impair adequate dental hygiene.

GASTROINTESTINAL INVOLVEMENT

The gastrointestinal tract is involved in all forms of scleroderma. Atrophy of the muscularis is followed by submucosal fibrosis. Weakness of the lower esophageal sphincter is associated with chronic reflux esophagitis. Hypomotility of the lower esophagus causes symptoms of dysphagia for solid foods, which may be worsened significantly by lower esophageal stricture secondary to chronic reflux. Ease of satiety and dyspepsia may occur as a result of impaired motility of the stomach. Small bowel involvement presents as intermittent abdominal cramping and diarrhea. Malabsorption can occur and weight loss is seen in virtually all patients. Bacterial overgrowth in areas of intraluminal stagnation is an important cause of diarrhea and cramping in some patients. Colon involvement is typified by complaints of constipation. Wide-mouthed diverticula may occur but seldom are a source of bleeding. Pseudo-obstruction is common, although hypomotile areas of large and small bowel also can lead to intussusception and volvulus. Gastrointestinal bleeding most commonly results from erosive esophagitis, but "watermelon stomach" also must be considered. Although hepatic involvement is uncommon, patients with limited scleroderma may have primary biliary cirrhosis.

CARDIAC INVOLVEMENT

Patchy fibrosis of the myocardium occurs in as many as 80% of patients with scleroderma. Contraction band necrosis has been reported, suggesting intermittent myocardial ischemia. A Raynaud's-like reactivity of the coronary microvasculature is suspected from studies demonstrating thallium perfusion abnormalities in most patients. Exertional dyspnea and palpitations are common, whereas chest pain and clinical congestive heart failure are not. Although pericardial fluid is demonstrable by echocardiography in 30% to 40% of patients, pericardial rubs and clinical presentations of pericarditis and tamponade are uncommon. Supraventricular and ventricular arrhythmias are seen in 60% to 70% of patients, and the latter are strongly associated with mortality, including sudden death. Involvement of the conduction system and bradyarrhythmias are encountered less commonly.

PULMONARY INVOLVEMENT

Pulmonary involvement is a major cause of morbidity and mortality in scleroderma. No organ illustrates the diversity of pathologic processes operative in scleroderma as well as the lung, in which any combination of interstitial inflammation, fibrosis, and pulmonary vascular injury may be present. Patients with diffuse scleroderma are more likely to have interstitial lung disease typified by basilar rales, abnormal chest radiographs, and loss of lung volume on pulmonary function testing. Patients with limited scleroderma are at risk for progressive pulmonary hypertension in the absence of interstitial lung disease and are more likely to demonstrate a disproportionate loss of pulmonary diffusing capacity. Gallium scanning is relatively insensitive in recognizing pulmonary inflammation. Nonetheless, bronchoalveolar lavage reveals increased numbers of neutrophils, lymphocytes, and, occasionally, eosinophils in 40% to 60% of patients, suggesting that inflammatory alveolitis precedes the interstitial fibrotic change.

RENAL INVOLVEMENT

The sudden onset of accelerated to malignant hypertension and progressive renal insufficiency, usually accompanied by microangiopathic hemolytic anemia, constitutes the syndrome of scleroderma renal crisis. Patients with diffuse scleroderma are at highest risk for this complication, which most often occurs in the first 2 to 3 years of illness, while skin involvement is the most progressive. Obliterative vasculopathy with cortical infarction is present and marked hyperreninemia is the principal mechanism of hypertension. The onset peaks during the cold-weather months. A Raynaud's-like mechanism overlying renal intimal fibrotic arteriosclerosis is supported by the demonstration of transient renal cortical perfusion abnormalities and increases in plasma renin activity during cold pressor tests. If scleroderma renal crisis is not recognized early, progression to irreversible renal failure and death is the rule.

ENDOCRINE AND EXOCRINE FEATURES

Hypothyroidism occurs in up to 50% of patients with scleroderma and often is occult. Although many patients have antithyroid antibodies, lymphocytic infiltration of the thyroid is uncommon and fibrotic replacement is typical. Dryness of the eyes and mouth is common and attributable to fibrosis of the lacrimal and salivary glands. Vaginal dryness and dyspareunia are common. Impotence is recognized as a presenting feature in men and is believed to be vascular in cause. Fertility is decreased in women, probably because of the severity of the illness. Increased fetal wastage and low birth weights are reported, but there is no specific evidence that pregnancy affects the mother's scleroderma.

LABORATORY FINDINGS

Specific laboratory tests that are useful in the assessment of internal organ involvement are discussed later. Nonspecific serologic abnormalities are common in scleroderma, including antinuclear antibodies in around 90% of patients (usually nucleolar in pattern), rheumatoid factor in 30%, and polyclonal hypergammaglobulinemia in 20% to 40%. Many patients have moderate elevations of the erythrocyte sedimentation rate and anemia of chronic disease, although neither abnormality has proven useful in monitoring disease activity. Anticentromere antibody is found in 50% to 60% of patients with limited scleroderma but rarely in those with diffuse disease. Its presence is useful in the classification of scleroderma and in the differential diagnosis of RP. Antibodies to DNA topoisomerase I and RNA polymerases I and III are of low sensitivity, being present as mutually exclusive findings in 20% to 40% of patients with diffuse scleroderma but are highly specific for this diagnosis.

COURSE AND PROGNOSIS

The natural history of systemic sclerosis has not been described adequately. Most of the clinical information has been derived from point prevalence surveys of specific features of the illness. Retrospective studies have suggested that patients with diffuse scleroderma typically have inexorable progression in the extent and severity of skin involvement during the first 2 to 3 years. The risk of new internal organ involvement is highest during this period. The disease then seems to plateau in many patients and skin involvement lessens slowly in later stages of the disease. The risk of new visceral involvement also is reduced, although spontaneous improvement of previously involved organs is unusual. Patients with limited scleroderma progress continually in skin disease and accrual of visceral involvement. Clinical change sometimes is so slow as to be unrecognizable from year to year. At late stages (more than 10 years), improving diffuse scleroderma and worsening limited scleroderma are nearly indistinguishable. Morbidity and mortality are related to visceral involvement. The early accrual of visceral involvement in diffuse scleroderma is responsible for a 5-year survival rate of 60%.

APPROACH TO ASSESSMENT

Once the diagnosis of scleroderma has been established, the clinician faces two principal issues. The first is classification of the disease as diffuse or limited, and the second is assessment of the presence, extent, and type of visceral involvement. [Table 179.3](#) outlines the clinical and laboratory features that should be considered in the classification. Clinical assessment of the extent of skin involvement in scleroderma is the key determinant. The presence of skin thickening proximal to the elbows or knees, or on the chest or abdomen, indicates diffuse scleroderma. Restriction of skin changes to sites distal to the elbows, knees, and clavicles suggests limited disease. Because skin changes always begin on the extremities, a patient with early diffuse disease may have somewhat limited skin changes at the first assessment. Repeated, closely spaced clinical evaluations are necessary at this early, unclassifiable stage of disease.

	Diffuse Scleroderma	Limited Scleroderma
Onset of Raynaud's phenomenon	<2 y	>2 y
Initial symptoms	Finger edema Ankles/pa	Raynaud's phenomenon (0-90%)
Tendon friction rubs	Raynaud's phenomenon Visceral complaint	<1%
Extent of skin involvement	40%	Extremities only
Rate of skin involvement	Extremities and trunk Rapid in first 2 y	Minimal
Visceral involvement*		
Gastrointestinal	90% early	70% early
Lung	20% early	40% late
Heart	50% early	50% late
Kidney	25% early	Rare
Anticentromere antibody	<5%	60-70%
Anti-topoisomerase I antibody	30-40%	<5%
Anti-RNA polymerase antibodies	20-30%	<5%

* Type of visceral involvement, total percentage risk, peak incidence of onset (early = first 3 years; late = after 3 years).

TABLE 179.3. CLASSIFICATION AND ASSESSMENT OF SYSTEMIC SCLEROSIS

Baseline determinations of internal organ involvement are important to follow-up care and recognition of changing status. Esophageal function can be assessed by a thin barium recumbent cinesophagography, manometry, or radionuclide esophagography. Small bowel involvement is studied best by D-xylose absorption. Barium enemas usually have no clinical value in scleroderma. Pulmonary function studies, including measures of diffusing capacity, and chest radiography are essential. The presence of alveolitis is determined by bronchoalveolar lavage or high-resolution computerized tomography. Ambulatory electrocardiography is believed to be the most sensitive and clinically valuable test of cardiac involvement. Urinalyses and measures of creatinine clearance should be performed. No reliable laboratory tools for the assessment of scleroderma activity are available. Serum-soluble interleukin-2 receptor levels are useful in predicting disease progression and mortality.

OTHER CLINICAL SYNDROMES

Scleroderma means "hard skin," and several clinical disorders are included in this differential diagnosis ([Table 179.4](#)). All of these disorders should be suspected in patients who do not have RP and in whom the skin changes begin at locations proximal to the digits. Eosinophilia–myalgia syndrome linked to contaminated L-tryptophan supplements and the closely related eosinophilic fasciitis syndrome are characterized by rapidly developing inflammation and induration of the arms, legs, and trunk. The involved skin typically has an "orange-peel" appearance, and warmth and erythema are common. Joint contractures, neuromyopathy, and interstitial lung disease develop early. The diagnosis is established by full-thickness biopsy (skin to skeletal muscle) demonstrating inflammation and fibrosis centered in the deep fascia. Peripheral eosinophilia and an elevated erythrocyte sedimentation rate are present at early stages. Corticosteroid therapy is palliative and

improvement to clinical resolution may occur in 2 to 5 years. Scleredema and scleromyxedema present as nonpitting edema and brawny induration of the face, upper back, chest, and shoulder girdles. Both conditions have been linked to underlying plasma cell dyscrasias, and about half of all adults with scleredema have associated diabetes mellitus. Scleroderma localized to the skin as linear scleroderma in children or as morphea in adults and children is not associated with visceral involvement. The subtle clinical features of limited scleroderma may be overlooked in patients believed to have "primary" biliary cirrhosis and pulmonary hypertension.

Disorders Characterized by Scleroderma
 Eosinophilic fasciitis
 Eosinophilia—myalgia syndrome
 Scleredema adultorum
 Scleromyxedema (papular mucinosis)
 Bleomycin therapy
 Chronic reflex sympathetic dystrophy
 Chronic graft-versus-host disease
 Subcutaneous morphea
 Localized scleroderma
 Calcinosis skin change
 Overlap syndromes
 Chronic diabetes mellitus

Disorders Characterized by Similar Internal Organ Involvement
 Primary pulmonary hypertension
 Primary biliary cirrhosis
 Intestinal pseudo-obstruction
 Collagenosis cutis
 Infiltrative cardiomyopathies
 Idiopathic pulmonary fibrosis

Disorders Characterized by Raynaud's Phenomenon (see Table 179-1)

TABLE 179.4. DIFFERENTIAL DIAGNOSIS OF SYSTEMIC SCLEROSIS (SCLERODERMA)

OPTIMAL MANAGEMENT

RAYNAUD'S PHENOMENON

All patients with RP, irrespective of cause, benefit from simple behavioral changes. Cessation of cigarette smoking is an absolute necessity. Careful planning of cold-weather activities can obviate the need for drug therapy. Dress can be important. In addition to warm mittens and footwear, hats and layered clothing on the trunk can minimize reflex responses to central body cold stimuli.

The choice of drug therapy is complicated by the wide range of available agents and the diverse mechanisms of RP. Many reported clinical trials lack careful definitions of the cause of RP or do not stratify by cause in their data analyses. Measures of therapeutic outcome are without standardization and include subjective parameters such as patient diaries, visual analogue ratings of the severity of RP episodes, and intermittent interviews focused on patient ratings of frequency, severity, and precipitating circumstances of attacks. Response rates to placebo typically are 30% to 40%. Physiologic measures of drug effect include tests of digital perfusion during cold challenge and indirect measures such as time of digital temperature recovery, the latter in effect monitoring only the phase of reactive hyperemia. It is common to encounter favorable subjective response in the absence of physiologic improvement.

Calcium channel blockers cause vascular smooth muscle relaxation by interfering with the transmembrane influx of calcium through membrane channels termed *slow channels*. Their antivasoconstrictive actions are well suited to intermittent vasospastic disorders such as RP, and agents active at receptor-operated calcium influx channels, including nifedipine, isradipine, and amlodipine, seem to be the most effective. Adverse effects include headache, dyspepsia, and fluid retention, but these can be minimized by the use of newly available time-release preparations of these agents. Inhibition of smooth muscle contractility may worsen intestinal dysmotility in patients with scleroderma.

Sympatholytic agents include reserpine, guanethidine, and prazosin. The peripheral vasodilative effects of prazosin, an orally active selective antagonist of α_1 -adrenoceptors, are accompanied by little reflex tachycardia or increases in plasma renin and norepinephrine levels. Controlled studies suggest excellent responses in primary RP and in RP secondary to lupus; this agent is less effective in RP secondary to severe structural changes such as scleroderma. Nitroglycerin preparations are of little use, particularly in disorders typified by endothelial injury or by the concomitant use of cyclooxygenase inhibitors.

Antiplatelet agents, including low-dose aspirin and dipyridamole, often are used in scleroderma and other forms of RP resulting from intimal hyperplasia with endothelial injury and platelet activation. Although they are ineffective for RP itself, their use is associated with a reduction in digital ulceration. Similar effects are reported with pentoxifylline, an aminophylline derivative that enhances red blood cell flexibility and microvascular perfusion. Intravenous prostaglandin E_1 and carbaprostacyclin (Iloprost) are useful in the treatment of digital ulcerations complicating scleroderma but are unavailable in the United States.

Compromised ischemic digits require prompt diagnosis and aggressive treatment. Angiographic studies are useful for localizing sites of vascular occlusion and recognizing arterial emboli. The use of intra-arterial tolazoline in the assessment of reversible vasoconstriction guides subsequent therapeutic choices. Patients who are likely to benefit from sympathectomy can be chosen on the basis of their short-term responses to sympathetic ganglion instillation of bupivacaine.

Precision in clinical diagnosis leads to reasoned selection of therapy. Patients with functional vasospasm in the absence of structural narrowing of their digital arteries (primary RP) are at low risk for ischemic injury and typically have insufficiently severe subjective complaints to warrant therapy with vasoactive agents. Such patients often claim that emotional stress provokes attacks, and physiologic studies support the importance of peripheral adrenergic tone in these cases. Biofeedback and relaxation techniques are therapeutic options for these patients. Patients with secondary RP, including those with scleroderma or arteriosclerosis, commonly have functional evidence of diminished peripheral sympathetic tone. These patients are at high risk for digital ischemic injury.

SCLERODERMA

A successful disease-modifying therapy for scleroderma would enhance survival and reduce disability and comorbidity from the disease. These effects are equated with the behavior of internal organ involvement. An effective therapy for lung involvement would improve survival whereas an effect on skin involvement would likely enhance quality of life and function.

AN APPROACH TO THERAPY

The goals of therapy in scleroderma include prevention of disease worsening and/or reversal of accomplished tissue injury. At present, no therapies have emerged that influence the vascular component of disease although prostacyclin preparations are under study for scleroderma pulmonary hypertension. Modern prevention approaches utilize immunosuppressants with the theoretic goal of slowing development of fibrotic tissue injury. Well-controlled trials of methotrexate, chlorambucil, 5-fluorouracil, interferon-alpha and extracorporeal photoactivated methoxypsoralen have proven their lack of benefit. Uncontrolled studies of cyclophosphamide hint at efficacy for alveolitis and slower loss of forced vital capacity. Immunoablation with stem cell transplantation, thalidomide, and oral tolerization to Type I collagen are the subjects of ongoing trials.

Reversal of fibrosis would be expected to benefit patients with scleroderma. D-penicillamine has been used for its known effects in inhibiting intermolecular and intramolecular cross-linking of collagen. However, a multicenter comparison of 1,000 mg per day versus 125 mg every other day failed to demonstrate effect on survival, skin thickening, or internal organ status. Recombinant human relaxin, a pregnancy-related hormone with antifibrotic effects, is the subject of ongoing trials.

There are currently no therapies proven effective for the basic fibrotic features of scleroderma and none that could be described as disease-modifying.

Supportive Therapy

The range of potential clinical problems facing patients with scleroderma is broad and requires attentive and individualized monitoring.

Musculoskeletal Features

Impaired hand function is seen in all patients with scleroderma. Skin thickening and tendon involvement restrict the ability to extend the fingers and to close the fist. Raynaud's phenomenon combined with ischemic injury to the digital pulp results in impaired tactile sensibility. Arthralgia and arthritis can be present, as can median nerve compression. In addition to ischemia of the digital tip, traumatic ulcerations are common over flexion-contracted interphalangeal joints and in areas of spontaneously extruding subcutaneous calcinosis. Vigorous, long-term occupational and vocational therapy are important in maintaining hand function. Nonsteroidal anti-inflammatory drugs are useful in relieving pain. Ulcerations of all types should be treated promptly with wound care and topical or systemic antibiotics. Physical therapy for proximal joint contractures and gentle aerobic conditioning programs should be considered. Skeletal muscle inflammation often responds to corticosteroid therapy.

Gastrointestinal Involvement

Reflux esophagitis is common in scleroderma and often responds to simple measures such as elevating the head of the bed and avoiding postprandial recumbency, large meals, and clothing that is tight around the waist. Postprandial antacids and cimetidine, ranitidine, famotidine, or nizatidine are useful in reducing symptoms and may help to delay or prevent secondary lower esophageal stricture. Omeprazole is dramatically effective for symptoms of pyrosis. Agents to enhance lower esophageal sphincter tone or to improve lower esophageal motility, such as cisapride, urecholine, and metoclopramide, are effective mainly in the early stages of the disease before esophageal smooth muscle is lost. There is a clear correlation between the degree of lower esophageal dysmotility and the prevalence and severity of erosive esophagitis. Stricture can be managed with periodic dilatation. The small bowel symptoms of diarrhea and cramping sometimes respond to broad-spectrum antibiotics for presumed bacterial overgrowth but otherwise are not amenable to therapy.

Cardiac and Pulmonary Involvement

Although heart and lung involvement are independently important causes of mortality in scleroderma, little is known about effective treatment. Ventricular arrhythmias are associated with sudden death and overall mortality, but no studies are available regarding the usefulness of antiarrhythmic therapy. Hypoxemia, if present, should be corrected with nocturnal or continuous ambulatory supplemental oxygen. Pulmonary hypertension has been recognized increasingly in late limited scleroderma and may be responsive to prostacyclin preparations.

Renal Involvement

The availability of angiotensin-converting enzyme inhibitors for controlling the accelerated hypertension of scleroderma renal crisis has revolutionized the management of this complication. Before the development of these agents, rapidly progressive renal insufficiency and early death were the expected outcome. If treatment is begun at an early stage, arrest of renal insufficiency and occasional improvement in renal function results. In those patients with more advanced renal insufficiency, dialysis may be required and eventual renal transplantation considered.

Because these autoantibodies are found only in patients with inflammatory myopathies and identify clinically distinct subsets of patients, it is possible that they play a pathogenic role.

TABLE 180.2. CONDITIONS THAT CAN MIMIC IDIOPATHIC INFLAMMATORY MYOPATHIES

The association of different class II immunohistocompatibility antigens with different disease subsets indicates a role for genetic factors. Individuals with HLA-DR3 are at increased risk for the development of polymyositis and dermatomyositis. All patients with anti-Jo-1 antibodies have HLA-DR52, and whites with anti-Jo-1 also have a higher prevalence of HLA-DR3 and DR6. HLA-DR5 is associated with anti-signal recognition particle (SRP) antibodies and DR7 plus DRw53 with anti-Mi2. In inclusion body myositis, the prevalence of HLA-DR1 is significantly increased.

CLINICAL FINDINGS

Symmetrical proximal muscle weakness is the dominant feature of all idiopathic inflammatory myopathies. Although strength can be essentially normal at the time of presentation, with rare exception, significant weakness develops during the course of the disease. The weakness can be accompanied by myalgia and tenderness. Atrophy can develop over time. The inflammatory myopathies are systemic diseases, and patients may complain of malaise, fatigue, morning stiffness, arthralgia, and anorexia. These symptoms may be accompanied by weight loss and low-grade fever.

POLYMYOSITIS IN THE ADULT

Adult-onset polymyositis begins insidiously with no identifying precipitating event. An abrupt onset associated with clinically evident rhabdomyolysis is unusual. Initially, weakness occurs in the shoulder and pelvic girdles, with the latter slightly more involved. Distal weakness is seen only late in the course of severely afflicted patients. The neck flexors become involved in about half of all cases. Pharyngeal muscle weakness may cause dysphonia, hoarseness, and difficulty swallowing, each a poor prognostic sign. Facial and bulbar muscle weakness are rare and ocular muscle involvement does not occur.

Additional systems become involved in some patients. Periorbital edema may occur. Pulmonary manifestations may include interstitial fibrosis with fine, dry rales heard on chest auscultation, or interstitial pneumonitis with dyspnea, a nonproductive cough, and hypoxia. Cardiac involvement is uncommon and usually restricted to clinically insignificant changes identified only on the electrocardiogram. However, heart block, supraventricular arrhythmia, or cardiomyopathy may develop, causing palpitations, syncope, or congestive heart failure. Esophageal dysmotility may be associated with epigastric pain or swallowing difficulties. This problem and pharyngeal muscle weakness may lead to aspiration pneumonia. Arthralgia is common, but frank synovitis is rare. Raynaud's phenomenon is reported as an early finding. The neurologic portion of the physical examination is normal except for motor function, although deep-tendon reflexes may appear diminished because of severe muscle weakness.

These manifestations can develop at any time during the course of the illness and can occur in any combination. The presence of a circulating myositis-specific autoantibody tends to identify patterns of involvement ([Table 180.2](#)). For example, compared with patients who have no autoantibody, those with antisynthetase antibodies have a significantly higher prevalence of interstitial lung disease, arthritis, Raynaud's phenomenon, and fever.

DERMATOMYOSITIS IN THE ADULT

The clinical picture of dermatomyositis includes all of the manifestations described for polymyositis plus cutaneous features. At times, rash is the presenting complaint and may predate the onset of weakness by as much as 4 years. Rarely, the cutaneous manifestations of dermatomyositis occur without evidence of muscle involvement. The terms *dermatomyositis sine myositis* and *amyopathic dermatomyositis* are applied to this condition.

Skin involvement varies widely from patient to patient. Some patients have a variety of cutaneous manifestations. Some have only one type. In others, the rash can change from one variety to another during the course of the illness. In some, the rash and muscle weakness tend to flare and remit together. In others, the activities of the two processes have no apparent connection.

The classic skin changes of dermatomyositis are Gottron's papules. These are pink to violaceous scaly areas usually seen over the knuckles, elbows, and knees. Other characteristic changes include heliotrope (red–lilac) discoloration of the eyelids or periorbital regions; macular violaceous erythema covering the dorsal aspects of the hand, extensor aspects of the forearms, posterior shoulders, and neck (shawl sign), a “V” area of the anterior chest and neck, or face; and capillary nail fold changes with periungual telangiectasia and dystrophic cuticles. Linear erythematous discoloration may develop around nail beds. Over time, the cutaneous lesions can develop scaling, become hypopigmented or hyperpigmented, or turn brawny and indurated. Darkened or dirty-appearing horizontal lines can be seen across the lateral and palmar aspects of the hands. These changes are termed *mechanic's hands* because they are similar to changes seen in the hands of individuals who perform heavy, manual labor.

JUVENILE (CHILDHOOD) DERMATOMYOSITIS

Although children may have myositis with clinical pictures similar to those seen in adults, more often the usual inflammatory myopathic process has a highly characteristic pattern. As in adults, the general features of juvenile dermatomyositis are rash and weakness. However, the process differs from that of the adult form because of the coexistence of vasculitis, ectopic calcification, flexion contractures, and lipodystrophy.

MYOSITIS WITH OTHER CONNECTIVE TISSUE DISEASES

Muscle weakness is found in many patients with connective tissue diseases, including systemic lupus erythematosus, scleroderma, mixed connective tissue disease, Wegener's granulomatosis, polyarteritis nodosa, giant cell arteritis, hypersensitivity vasculitis, and Sjögren's syndrome. In some cases, the myopathic features, which may be indistinguishable from those of polymyositis, dominate the clinical picture. More commonly, however, the signs and symptoms of the other condition predominate.

MYOSITIS AND MALIGNANCY

Malignancy and inflammatory myopathy can occur together, but the relationship between the two is unclear. If there is a connection, the greater association probably is with dermatomyositis. The two conditions often develop within a year of each other. The clinical features of the myositis in patients with malignancy are not unique and the activities of the myositis and the malignancy usually do not coincide. The incidence of malignancy in patients with myositis increases with age. With the exceptions of ovarian cancer in women with dermatomyositis, and nasopharyngeal cancer in parts of the world where it is prevalent, the sites and types of tumors are the same as those found in other patients of the same age and gender.

INCLUSION BODY MYOSITIS

Inclusion body myositis is similar to polymyositis in many ways but different in others. Inclusion body myositis usually begins more insidiously, often progressing slowly for 2 to 6 years before being diagnosed. Proximal muscles are involved in a symmetrical fashion, but lower extremity weakness tends to predominate, especially early in the course. The most distinctive clinical feature is the involvement of distal muscles. Distal muscle weakness is present in about 50% of patients at the time of diagnosis and develops in a higher percentage over time. Dysphagia is a prominent feature in about one-third of patients and is attributed to weakness of the cricopharyngeus muscle. Myalgia is uncommon and muscle tenderness is rare. Diagnosis can be made on histologic and electron microscopic sections.

FOCAL OR LOCALIZED MYOSITIS

Occasionally, weakness or myalgia is present in only one limb or in a focal nodular area. In some cases, the findings remain localized for several years. In others, this is an atypical presentation of polymyositis and progresses to a more typical distribution after a few days to weeks. These lesions must be differentiated from a skeletal muscle tumor or myositis ossificans.

DIFFERENTIAL DIAGNOSIS

If the response to glucocorticoid therapy is poor, and especially if there is no response at all, the accuracy of the diagnosis should be questioned. The criteria for idiopathic inflammatory myopathy are nonspecific and the diagnosis always should be made by excluding other potential causes. A wide variety of conditions that may not respond to glucocorticoids can satisfy some or all of the criteria for an inflammatory myopathy ([Table 180.3](#)).

Polymyositis
Dermatomyositis
Myositis with an associated connective tissue disease
Myositis with an associated malignancy
Inclusion body myositis
Localized or focal myositis

TABLE 180.3. IDIOPATHIC INFLAMMATORY MYOPATHIES

LABORATORY FINDINGS

Proximal muscle weakness in patients with idiopathic inflammatory myopathy is associated with elevated serum levels of enzymes derived from skeletal muscle and evidence of inflammation by electromyographic and muscle tissue examinations. Changes in these parameters can occur in a variety of patterns or combinations with no single finding being specific or diagnostic. Consequently, the diagnosis of an inflammatory myopathy is made by recognizing characteristic combinations of findings and excluding other causes for the abnormalities ([Table 180.3](#)).

SERUM TESTS

Serum levels of enzymes released as a result of muscle cell damage are elevated in all types of inflammatory myopathy. These enzymes include creatine phosphokinase, aldolase, glutamine-oxaloacetic transaminase, glutamic-pyruvic transaminase, and lactate dehydrogenase. However, high levels of these enzymes are not specific for inflammatory myopathy. The creatine phosphokinase level is the most sensitive and is elevated in almost every patient with an inflammatory myopathy at some time during the course of the illness. In most patients the creatine phosphokinase level is a helpful indicator of the severity of muscle damage and can be used to gauge disease activity and response to therapy. Normal creatine phosphokinase levels are encountered in patients who are seen early in the disease course, in patients with severe disease late in the course after significant atrophy and fibrosis have developed, in patients with active disease who have a circulating inhibitor of creatine phosphokinase activity, and in some patients with myositis and malignancy. However, elevated creatine phosphokinase levels are not specific for inflammatory muscle diseases. They can be encountered as a result of a variety of disorders.

HEMATOLOGIC STUDIES

The erythrocyte sedimentation rate is abnormal in 50% of patients with inflammatory myopathy and exceeds 50 mm per hour in less than 20%. The sedimentation rate usually does not correlate well with disease activity. Anemia is not a common finding in polymyositis, and leukocytosis occurs in about 15% of patients.

IMMUNOLOGIC STUDIES

Most patients with idiopathic inflammatory myopathy have circulating autoantibodies. Antinuclear antibody testing is positive at low titers in a few patients with polymyositis, about 60% of patients with juvenile dermatomyositis, and almost all patients with an associated connective tissue disease. The last of these patients also may have the antibodies indicative of the associated disease. Myositis-specific autoantibodies have been reported in approximately 40% of patients with inflammatory myopathies in research studies ([Table 180.2](#)).

ELECTROMYOGRAPHY

No electromyographic changes are diagnostic of an inflammatory myopathy. However, some are suggestive. Classic findings include the triad of increased insertional activity, fibrillations, and sharp positive waves; spontaneous, bizarre, high-frequency discharges; and polyphasic motor unit potentials of low amplitude and short duration. There is significant variability because the complete triad is found in only about 40% of patients; 10% of patients have normal examinations. In some patients, changes are localized (limited to the paraspinal muscles) despite widespread weakness. Typically, the only electromyographic changes are those consistent with a myopathic process. The exception occurs in patients with inclusion body myositis, one-third of whom also have neuropathic features.

MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging is a noninvasive method of identifying abnormal muscle. Regions of high signal intensity indicative of inflammation can be observed using a standard T2-weighted or fat-suppressive technique. Magnetic resonance imaging can be used to establish the extent of the disease process and to localize sites for biopsy. It also can be valuable in selected cases for evaluating the response to therapy, particularly in dermatomyositis.

MUSCLE HISTOLOGIC STUDIES

Muscle histologic studies are extremely helpful in the evaluation of patients with inflammatory myopathy. However, no change is truly pathognomonic and wide variations can be seen both in the tissue of an individual patient and between different patients.

The characteristic histologic changes of polymyositis include an endomysial inflammatory infiltrate with lymphocytes surrounding and invading non-necrotic fibers, degenerating and regenerating fibers, areas of fibers necrosis, and fibrosis. In some cases, changes are minimal and type II fiber atrophy is the only identifiable abnormality. In dermatomyositis, the infiltrate includes lymphocytes, plasma cells, and macrophages localized to perivascular areas. Fiber necrosis may be minimal,

but perifascicular atrophy may be prominent. The diagnosis of inclusion body myositis is defined by histologic changes similar to those seen in polymyositis (with angulated fibers in patients with a neuropathic component), by the characteristic changes of lined vacuoles on histology, and by tubular or filamentous inclusions on electron microscopy.

OPTIMAL MANAGEMENT

The management of an inflammatory myopathy begins with an objective assessment of the patient's clinical status. Pretreatment testing of muscle strength can be performed by manually grading the strength of various muscle groups. A timed-stands test (measuring the amount of time it takes a patient to rise 10 times from a chair without using his or her arms) can be used to assess lower extremity strength. Without an accurate baseline assessment, it may be difficult to differentiate between the subjective and objective effects of therapy or to detect small changes in strength. Blood pressure measurement, chest examination, chest radiography, and pulmonary function studies should be performed. Fluoroscopic studies with contrast material may be important if the patient has swallowing problems or dysphonia. Serum levels of muscle enzymes and laboratory tests that might be affected by the medications used should be measured.

PHYSICAL THERAPY

Physical therapy can play an important role in the treatment of inflammatory myopathy. When the disease activity is severe, bed rest is used and passive range-of-motion exercises are performed to prevent joint contractures and overuse of regenerating muscle bundles. A soft cervical collar may be helpful for patients with significant neck involvement. Active exercises can be prescribed as improvement is observed, even in the presence of elevated creatine phosphokinase levels.

GLUCOCORTICOIDS

Glucocorticoids are the first drugs used in patients with any type of idiopathic inflammatory myopathy. Initially, prednisone is prescribed in a single oral morning dose of about 1 mg per kg. In severe cases, the daily dose can be divided and up to 2 mg per kg can be given. Once instituted, high-dose daily prednisone therapy is continued until muscle strength improves. Improvement may occur in the first weeks or gradually over 3 to 6 months. The variability in improvement is related to the timing of treatment and the specific inflammatory process. In general, the earlier in the course medication is given, the more satisfying is the result. Inclusion body myositis is more refractory to therapy than other forms of idiopathic inflammatory myositis.

Patients should be followed up with regular objective evaluations of muscle strength and measurements of serum enzyme levels. The prednisone dosage is maintained at high levels for 6 weeks as improvement occurs, then gradual tapering is performed over many months on an individualized basis.

Glucocorticoids have a beneficial effect in 90% of patients and produce complete remission in 50% to 75%. If remission is not evident after 6 to 12 weeks of high-dose prednisone therapy, a second agent should be added. Both azathioprine and methotrexate have been used successfully in this situation. In adults, azathioprine usually is prescribed to be taken by mouth at dosages up to 3 mg per kg per day. Methotrexate is taken on a weekly basis, with dosages ranging between 7.5 mg by mouth and 50 mg by intravenous or intramuscular routes.

With therapy, some patients who have experienced varying degrees of improvement actually lose strength. This is usually a flare-up of the basic disease or the development of steroid myopathy. Laboratory tests, electromyography, and muscle biopsy are not helpful in differentiating the cause. The situation can be resolved only by giving a provocative challenge with higher dose glucocorticoids or tapering the dosage rapidly and assessing the clinical response.

In refractory cases, the combination of prednisone, azathioprine, and methotrexate has proven beneficial in some patients. Cyclophosphamide, cyclosporine, chlorambucil, and tracolimus have been variably beneficial. Although intravenous immune globulin has been used early in treatment, it is perhaps best employed as a "bridging therapy" when initiating one of these agents in refractory cases.

Special consideration should be given to patients within certain groups. The cutaneous manifestations of dermatomyositis (but not the myositis) may respond to hydroxychloroquine. The myositis in patients with associated connective tissue diseases may respond dramatically to glucocorticoid therapy, even at lower dosages. Emphasis should be placed on treating the neoplasms in patients with associated malignancies. Removal, debulking, or cure of the cancer may be accompanied by remission of the myositis. Inclusion body myositis may be refractory to therapy; in many patients, strength declines progressively despite therapy. Patients with interstitial lung disease and myositis also tend to have a poor prognosis. The presence of densities on chest radiography consistent with aspiration pneumonia in these patients portends an unfavorable outcome.

CHAPTER 181: VASCULITIS: ITS MANY FORMS

GARY S. HOFFMAN AND BRIAN F. MANDELL

[Definition and Classification](#)
[Clinical Findings](#)
[Proving the Diagnosis](#)
[Specific Forms of Vasculitis](#)
[Treatment of Systemic Vasculitis](#)

DEFINITION AND CLASSIFICATION

Classification of the vasculitides remains a work in progress. Despite the publication of diagnostic guidelines and proceedings of consensus conferences, areas of controversy remain. The benefits of an accurate classification scheme for the vasculitides include (a) facilitation of communication about disorders that share certain traits or etiologies; (b) recognition that certain systemic vasculitides have distinct prognoses and may respond to particular therapies; (c) assurance that patients enrolled in clinical studies have the same disease; and (d) generation of diagnostic guidelines that aid clinicians in the recognition of patients with alternative illnesses that may mimic specific vasculitides. A definitive classification scheme should be based on an understanding of the pathogenesis of the diseases under study and the presence of pathognomonic clinical, laboratory, imaging, or histopathologic features that make distinctions between categories unambiguous. Because these conditions are uncommonly met in vasculitis, classification systems have utilized various combinations of these features.

When applying pathology criteria to an individual patient, the physician must recognize that biopsy-derived data are subject to sampling error and site selection bias, and that a biopsy represents a picture of an evolving disease process at only a single point in time. Because vasculitic lesions often occur in a seemingly random pattern of "skip lesions" within a particular vessel or organ, false-negative biopsy results may occur. Vasculitis may be present, but the histology of the tissue sample being evaluated may reveal only nonspecific inflammation or ischemic changes, whereas more characteristic features (e.g., granulomata, arteritis) may be present in a contiguous area. In addition, if a biopsy is obtained in an area in which the predominant vessel size is arterioles, capillaries, and venules (e.g., skin, nasal, or enteric mucosa), one may make the diagnosis of a small-vessel vasculitis or ischemic necrosis and not recognize additional involvement of larger vessels because they have not been evaluated. Similar concerns apply to arteriography, which has adequate resolution to evaluate large and medium-size vessels, but not microscopic vessels.

Classification guidelines derived from patient data have generally included patients who have established, well-differentiated vasculitis. Patients with diseases that are in an early stage of evolution or have ambiguous features are often excluded from these analyses, although such presentations may not be uncommon in a clinical practice. Thus, published criteria may achieve the desired goal of having high degrees of specificity but have limited sensitivity in identifying the entire spectrum of disease. Early in the disease course, patients may not express sufficient characteristic features of a vasculitic disorder to warrant a specific diagnostic label.

Published criteria for classification of the vasculitides have not been thoroughly evaluated for their ability to distinguish vasculitis mimics from primary systemic vasculitis, and the diagnosis must always be made with the proviso that multisystem disorders, including infections, coagulopathies, drug reactions, and malignancy, are excluded. The American College of Rheumatology (ACR) 1990 Criteria for Classification of Vasculitis provided the cautionary note that classification systems cannot include the full spectrum of disease features and are therefore not appropriate for diagnosis of individual patients. A more recent effort to refine nomenclature (Table 181.1) was initiated at the Chapel Hill Consensus Conference (CHCC). Emphasis was placed on the clinical pattern of disease and the presence or absence of demonstrable tissue immune complexes, and associations with antineutrophil cytoplasmic autoantibodies (ANCA). Specific recognition of microscopic polyangiitis (MPA), distinct from classical polyarteritis (PAN), was emphasized. An increasing number of studies have demonstrated the important association between certain viral infections and specific vasculitic syndromes, especially disease phenotypes that mimic MPA and PAN.

Vasculitic Syndrome	Defining Features
Large vessel vasculitis	Stenosis or aneurysm of the aorta and its major branches, with a predilection for the aortic arch and its major branches. Involvement of the aorta and its major branches is usually present in patients younger than 50.
Takayasu's arteritis	Stenosis or aneurysm of the aorta and its major branches, usually present in patients younger than 50.
Medium vessel vasculitis	Stenosis or aneurysm of medium size or small arteries without glomerulonephritis or necrotizing vasculitis.
Wegener's granulomatosis	Stenosis or aneurysm of medium size or small arteries, and associated with immunoneutralizing antibodies against cytoplasmic antigens (ANCA) in patients younger than 50.
Small vessel vasculitis	Stenosis or aneurysm of small arteries, capillaries, and venules without glomerulonephritis or necrotizing vasculitis.
Microscopic polyangiitis	Stenosis or aneurysm of small arteries, capillaries, and venules, with immunoneutralizing antibodies against cytoplasmic antigens (ANCA) in patients younger than 50.
Churg-Strauss syndrome	Stenosis or aneurysm of small arteries, capillaries, and venules, with eosinophilia and asthma.
Microscopic polyangiitis (ANCA-negative)	Stenosis or aneurysm of small arteries, capillaries, and venules, without immunoneutralizing antibodies against cytoplasmic antigens (ANCA).
Microscopic polyangiitis (ANCA-positive)	Stenosis or aneurysm of small arteries, capillaries, and venules, with immunoneutralizing antibodies against cytoplasmic antigens (ANCA).
Essential cryoglobulinemia vasculitis	Stenosis or aneurysm of small arteries, capillaries, and venules, with cryoglobulins and associated with immunoglobulin G (IgG) in patients younger than 50.
Essential cryoglobulinemia vasculitis	Stenosis or aneurysm of small arteries, capillaries, and venules, with cryoglobulins and associated with immunoglobulin G (IgG) in patients younger than 50.

TABLE 181.1. NOMENCLATURE OF THE VASCULITIDES ADAPTED FROM THE CHAPEL HILL CONSENSUS CONFERENCE^a

CLINICAL FINDINGS

For most physicians, recognition and treatment of the systemic vasculitides is difficult. There are multiple distinct forms of primary systemic vasculitis. Each is uncommon and likely to be confused with other systemic illnesses. Processes that may be confused with a primary vasculitis include sepsis (particularly bacterial endocarditis), drug toxicities and poisonings (especially with agents that are likely to produce vasospasm), coagulopathies, malignancies, cardiac myxomas, generalized atherosclerosis, and multifocal emboli from large-vessel aneurysms.

The pattern and degree of critical organ involvement and the rate of disease progression determines the intensity and pace of the diagnostic evaluation, the ultimate diagnosis, and treatment decisions. The physician may be confronted by a patient with rapidly deteriorating clinical condition in whom suggestive features of systemic vasculitis cannot be distinguished from occult infection or malignancy. Under such circumstances, one may be forced to treat multiple possible diagnoses prior to achieving a final diagnosis. To minimize the risk implied with such an approach, the evaluation should be insightful and aggressive.

The diagnostic process is best facilitated by recognizing clinical patterns of competing diagnoses, rather than by depending on nonspecific serologic and immunologic studies. The greatest certainty in the diagnosis of a specific vasculitic disorder results from combining compatible clinical features with pathologic proof of vasculitis. Certain types of systemic vasculitis may present with a characteristic clinical phenotype. For example, the presence of upper and lower airway inflammation, inflammatory eye disease, and red blood cell casts in the urine sediment, suggests Wegener's granulomatosis (WG). Hypertension, constitutional features, subclavian bruits, and extremity claudication in a girl or young woman should suggest Takayasu's arteritis. Unfortunately, many patients with vasculitis do not present with such characteristic features. Instead, one often has to depend on combinations of less specific clues. A patient with fever, an active urine sediment, and peripheral neuropathy is likely to have vasculitis, especially if competing diagnoses (Table 181.2) have been excluded; however, the specific type of vasculitis may not be immediately evident. Such features occurring in the setting of an established autoimmune disease, such as rheumatoid arthritis, systemic lupus erythematosus (SLE), Sjögren's syndrome, or relapsing polychondritis, further enhance the likelihood of vasculitis being present, although in this setting the vasculitis is likely related to the underlying systemic autoimmune disorder and not to a primary vasculitic syndrome. A patient with active hepatitis B or C infection and a similar clinical syndrome very likely has vasculitis, with or without cryoglobulinemia.

^a Vasculitis may or may not occur as a secondary event.

TABLE 181.2. MIMICS OF PRIMARY SYSTEMIC VASCULITIS

Concern for the presence of a systemic vasculitic disorder should be increased in a patient with multisystem symptoms or findings, constitutional features, or otherwise unexplained tissue ischemia or infarction. The presence of purpura is extremely suggestive of cutaneous vasculitis. However, there is a broad differential diagnosis for purpura (Table 181.3), and even when leukocytoclastic angiitis is documented by histopathology, the complete diagnosis may not yet be identified. Documenting the presence of cutaneous vasculitis is not equivalent to diagnosing a systemic vasculitis, and its presence does not mandate immediate systemic immunosuppressive therapy. As in all patients with possible multisystem disease, a very detailed history and physical examination must be obtained. Particular attention should be paid to the ocular, upper respiratory tract, neurologic, vascular, and lymph node examinations. We view the examination of a fresh sample of urine sediment by the physician as an *absolutely necessary* component of the evaluation. Glomerulonephritis is generally asymptomatic until the onset of uremia; early diagnosis will only be made by a carefully performed urinalysis. The history and physical examination may strengthen or weaken the clinician's suspicion of a specific primary vasculitis and thus direct the appropriate laboratory testing to support the most reasonable diagnoses. Laboratory tests alone should not generate initial suspicion of systemic vasculitis. Elevated acute phase reactants, elevated rheumatoid factor levels, or hypocomplementemia do not necessarily indicate the presence of a primary vasculitis. Anemia, leukocytosis, and thrombocytosis are commonly present in patients with systemic vasculitis but are not specific findings. Eosinophilia may occur in Churg–Strauss syndrome (CSS) or WG, but it may also be found in patients with atherosclerotic embolization and some malignancies. Leukopenia and thrombocytopenia are not characteristic of any of the primary vasculitic syndromes, although they may occur in patients with polyarteritis associated with hairy cell leukemia, sarcoidosis, SLE, Felty's syndrome, and in the setting of hypersplenism associated with chronic hepatitis.

TABLE 181.3. PURPURIC SKIN LESIONS

PROVING THE DIAGNOSIS

Definitive diagnosis requires the visualization of vasculitic lesions in affected tissue. In patients with proven vasculitis, the yield from biopsies of clinically normal sites is considerably less than 20%. Therefore, a biopsy of apparently normal tissue is not recommended. Biopsies of abnormal organs provide diagnostically useful information in over 65% of cases. Biopsy results must be coupled with the clinical pattern of disease to define the disorder. A 100% yield is not observed because involvement of vessels in systemic vasculitis is not uniform. Heterogeneity of pathology occurs within vessels as well as throughout solid organs. This has been convincingly demonstrated in the serial sectioning of temporal arteries in patients with giant cell arteritis, in angiographic imaging of large vessels in Takayasu's arteritis, and in chest radiographs of patients with WG. These observations are compatible with the clinical experience that larger excisional biopsies of abnormal tissue provide a greater yield than needle biopsies.

A biopsy may not be practical in certain circumstances. Consider the patient with symptoms of visceral ischemia, carotidynia, and findings of unequal extremity blood pressures. Biopsy of large vessels or diagnostic laparotomy in the absence of an acute abdomen is impractical. In this setting, angiography may be helpful. Evidence of vascular injury may be apparent from areas of vascular stenosis and/or aneurysm formation, but these findings must be distinguished from atherosclerotic injury. Angiography is not generally adequate to detect vascular injury of the smaller arterioles, capillaries, and venules, as might occur in Henoch–Schönlein purpura.

Angiography is particularly useful for patients with diseases that involve large (Takayasu's arteritis, giant cell arteritis of the elderly) and medium-size vessels (e.g., polyarteritis nodosa). Angiographic abnormalities may not indicate *active* arteritis. Certain caveats need to be considered before one can assume that suspicious angiographic images are confirmatory of vasculitis or that a negative study indicates the absence of vasculitis:

- Angiographic changes are not as specific as histopathologic abnormalities.
- Inflammation of blood vessels may produce symptoms before observable changes occur in the vascular lumen.
- Angiographic lesions that may be confused with primary vasculitis have been described in patients who (a) have used drugs that produce vasospasm (e.g., cocaine, amphetamines), (b) have embolic injury from cardiac myxomas, (c) have been afflicted with peritoneal carcinomatosis, (d) have fibromuscular dysplasia, and (e) have vascular infections. Infection due to slow-growing organisms (e.g., tuberculosis, syphilis, fungi) may not produce the usual systemic features that one might expect from acute bacterial infections.

Once the diagnosis of vasculitis is clearly established, based on the strongest of circumstantial evidence or biopsy documentation of vascular inflammatory injury, one must still determine whether the disorder is due to *secondary vasculitis* from bacterial, fungal, or viral infection (e.g., parvovirus, hepatitis B or C, HIV, or cytomegalovirus) or malignancies. Paraneoplastic vasculitis should be considered on the basis of a suspicious history; in the setting of significant adenopathy, leukopenia, or thrombocytopenia; and in patients who fail to respond to usually effective aggressive immunosuppressive therapy. Aggressive diagnostic efforts are warranted, since potentially life-threatening immunosuppressive therapy is frequently used in the treatment of the systemic vasculitides.

SPECIFIC FORMS OF VASCULITIS

TAKAYASU'S ARTERITIS

Takayasu's arteritis is a large-vessel vasculitis of unknown cause that involves the aorta and its major branches. It affects young women about ten times more often than men. Morbidity results from arterial stenosis and organ ischemia (extremity claudication, cerebral ischemia, renal artery hypertension, congestive heart failure, coronary syndromes, mesenteric vascular insufficiency). Stenotic lesions are characteristic, but aneurysms may also form, particularly in the aortic root, which may produce aortic regurgitation. Mortality is primarily due to hypertensive or primary cardiac, renal, and central nervous system (CNS) vascular disease. Estimates of mortality range from 3% at 8 years to 35% at 5 years after diagnosis. The presence of symptoms or findings of large-vessel obstruction or hypertension in young patients, necessitates careful examination of pulses and blood pressures in all four extremities, and a search for vascular bruits. Rarely will Takayasu's arteritis

present as unexplained fever alone.

Symptoms of increasing extremity or visceral ischemia may indicate active disease. When these occur in the setting of an elevated erythrocyte sedimentation rate (ESR), along with malaise, myalgias, arthralgias, night sweats, and fever, active disease is likely and should be evaluated by angiography to establish the initial diagnosis and to provide a baseline vascular image. In known cases of Takayasu's arteritis, repeat angiography is useful to assess the degree of disease progression. A significant number of patients may have a normal ESR, not have constitutional or new vascular symptoms, and still experience progressive disease. Until we are better able to accurately judge the degree of disease activity in Takayasu's arteritis, outcomes will continue to be compromised. Studies are currently under way to evaluate refinements in ultrasound and magnetic resonance techniques that may enable the clinician to detect qualitative abnormalities in the vessel wall that imply inflammatory change. Active disease, as indicated by vascular pain (e.g., carotidynia), constitutional symptoms, fever, and high ESR, may also occur in the absence of angiographic progression. This would suggest that vascular inflammation may need to be present for an extended period to produce structural changes. Although rarely reported, skin lesions, pulmonary infiltrates, and glomerulonephritis are not characteristically present. There are no specific diagnostic serologic tests. Isolated involvement of the abdominal aorta and lower extremities is uncommon. Sarcoidosis with vasculitis and giant cell arteritis of the elderly may mimic Takayasu's arteritis.

Approximately 60% of patients with Takayasu's arteritis will achieve remission with glucocorticoid therapy (e.g., prednisone 1 mg per kilogram per day). However, tapering of glucocorticoid therapy has been associated with disease relapse in over 40% of patients. Glucocorticoid-resistant or relapsing patients may respond to the addition of daily therapy with low doses (approximately 2 mg per kilogram) of cyclophosphamide (CP) or weekly therapy with methotrexate (15 to 25 mg per week). About 40% of patients who are treated with a cytotoxic agent and glucocorticoids will achieve remission, but about half of these patients will also relapse, leading to the requirement for chronic immunosuppressive therapy in about one-fourth of all patients.

A discussion of only anti-inflammatory strategies ignores the significant hemodynamic effects of vascular lesions and other potentially useful interventions. Patients may suffer clinical deterioration due to fixed critical stenoses or aneurysms. This is most evident with regard to hypertension that may affect 21% to 90% of patients. In Asia and Mexico, Takayasu's disease is one of the more common causes of hypertension in the young adult population. Inadequately treated hypertension may lead to cerebral, cardiac, and renal injury. One of the most common errors in clinical management of Takayasu's arteritis relates to the physician not knowing which extremity is representative of aortic root pressure. Because over 90% of patients have stenotic lesions, and the most common site of stenosis is the subclavian artery(ies), blood pressure recordings in one or both arms may not reflect even critically elevated pressures in the aorta. If aortic root pressure is elevated, unrecognized, and untreated, the risk of hypertensive complications is enhanced. Thus, angiographic procedures must include intravascular pressure recordings ([Fig. 181.1](#)). In the setting of renal insufficiency, the potential of contrast agents to cause further renal impairment may limit exploring the extent of all possible vascular lesions. However, if contraindications are not present, patients with Takayasu's arteritis should have the entire aorta and its primary branches included in vascular imaging studies. Magnetic resonance angiography lacks the ability to measure intravascular pressures in patients with stenoses that may have created clinically significant pressure gradients. However, if the clinical examination does not suggest that extremity lesions are present and extremity pressures are equal, a magnetic resonance study may be sufficient for routine follow-up evaluations. Whenever feasible, anatomical correction of clinically significant lesions should be considered, especially in the setting of renal artery stenosis and hypertension. In about 20% of patients, aortic root involvement may lead to valvular insufficiency, angina, and congestive heart failure. Severe or progressive changes may require aortic surgery, with or without valve replacement. Since disease activity may be difficult to determine, all such surgeries should include sending vascular specimens for histopathologic evaluation. Occasionally, the diagnosis of Takayasu's arteritis is first made at time of aortic surgery. If arterial bypass procedures are planned, it is advisable to avoid placing grafts that originate from the subclavian or innominate arteries, which are at high risk of becoming stenosed in the future. The most suitable origin for carotid or subclavian bypass procedures is the aortic root.

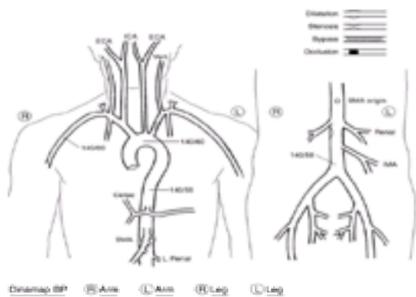

FIGURE 181.1. Standard vascular diagram used by the authors to summarize angiographic and blood pressure data in patients with Takayasu's arteritis. An ascending thoracic aortic aneurysm is present in this 21-year-old woman. Blood pressure in the right arm is a reliable measure of aortic root pressure, but left arm blood pressure by either catheter or cuff recordings is not. Hemodynamically insignificant abdominal aortic stenosis is present. Right-arm blood pressure (BP), 135/60; left-arm BP, 80/-; right-leg BP, 145/65; left-leg BP, 145/65.

GIANT CELL ARTERITIS OF THE ELDERLY

Giant cell arteritis (GCA) and Takayasu's arteritis are the principal diseases that are associated with sterile granulomatous inflammation of large and medium-size vessels. Whereas Takayasu's arteritis has a predilection for young women of childbearing age, GCA occurs in people older than 50 years. The mean age for patients in most series is 70 years. Women are affected more often than men, but the degree of female predominance (2–3:1) is not as striking as in Takayasu's arteritis. The demographic characteristics of patients with GCA is the same as for patients with polymyalgia rheumatica (PMR), and 30% to 50% of patients with GCA may concurrently have features of PMR. The most common characteristics of GCA are represented in [Table 181.4](#). Some patients may exhibit only systemic features, but this is uncommon. Occasionally, patients have inflammatory arthritis of peripheral joints. The new onset of severe headaches, scalp or temporal artery tenderness, acute visual loss, and claudication of the muscles of mastication are among the most compelling features to suggest the diagnosis. When such abnormalities are present in conjunction with marked elevations in the ESR, a clinical diagnosis of GCA can be presumed and treatment initiated, even without the benefit of a temporal artery biopsy. However, because biopsy generally does not cause significant morbidity, it is often performed when clinical features are not entirely classical ([Fig. 181.2](#)). The yield of positive temporal artery biopsies in patients strongly suspected to have GCA has been estimated to be about 50% to 80%, depending on the size of the biopsy, the clinical features of the illness, and whether bilateral samples have been obtained. These data are obviously affected by whether the practice of the clinical investigator is to biopsy patients with classic features (as opposed to only individuals with vague or nonspecific systemic symptoms). A diagnostic biopsy may be obtained even after more than a week of glucocorticoid therapy. The clinical diagnosis should be questioned if dramatic improvement does not occur within 24 to 72 hours of initiating high-dose glucocorticoid therapy.

Abnormality	Frequency (%)
Atypical headache	60–90
Tender temporal artery	40–70
Systemic symptoms not attributable to other diseases	20–50
Fever	20–50
Polymyalgia rheumatica	30–50
Acute visual abnormalities	12–40
Blindness	5–17
Transient ischemic attack	5–10
Claudication	
"Jaw"	30–70
Extremities	5–15
Aortic aneurysm	15–20

Dramatic response to glucocorticoids – 100. Positive temporal artery biopsy – 50 +.

TABLE 181.4. GIANT CELL ARTERITIS: CLINICAL PROFILE

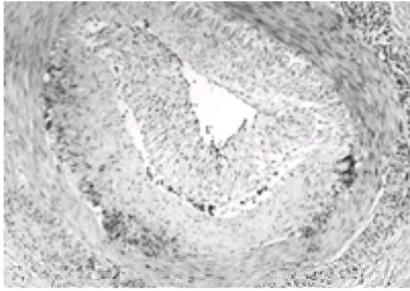

FIGURE 181.2. Temporal artery biopsy in a 64-year-old woman with new onset severe headaches, scalp tenderness, and polymyalgia rheumatica. Note the intense inflammatory changes in the adventitia and media, where giant cells are present. Intimal proliferation has caused luminal narrowing. See [color figure 181.2](#).

Aortitis may be part of GCA in at least 15% of cases. The primary branches of the aorta are affected in a similar number of individuals. Consequently, some patients present with features resembling those of Takayasu's disease. Among the elderly with large-vessel inflammatory disease, the same considerations and precautions must be applied in GCA as in Takayasu's arteritis. Recent studies have demonstrated that patients with GCA were more than 17 times more likely than age-matched controls to have thoracic aortic aneurysms, and about 2.5 times more likely than aged matched controls to have abdominal aortic aneurysms. Because such aneurysms were found either in the course of routine care or at post mortem, these may be conservative estimates. The finding of large-vessel disease, including aortic aneurysms, in elderly persons with GCA should not be assumed to be secondary to atheromatous disease.

Glucocorticoids are the most effective therapy for GCA. Prednisone (0.7 to 1 mg per kilogram per day) will reduce symptoms within 1 to 2 days and often eliminate symptoms within a week. About a month after clinical and laboratory parameters, particularly tests (e.g., ESR or C-reactive protein) for acute phase reactants, have normalized, tapering of glucocorticoid therapy can begin. Unfortunately, the ESR does not always normalize even with disease control, so it should not be relied on as the only measure of disease activity. Steroids may also lower the ESR even if elevation is due to alternative etiologic factors (infection, monoclonal gammopathy). Patients either may not achieve complete remission or may experience a flare-up in their disease as the glucocorticoids are tapered. Cytotoxic or immunosuppressive agents are often recommended for such patients, but the utility of these agents in controlled trials has not been adequately investigated. Some authors have advocated initiation of therapy with less than 0.5 mg per kilogram of daily prednisone in patients without severe visual symptoms with the hope of limiting side effects of steroid therapy. Large, prospective, dose comparison studies have not been performed.

As many as 40% of patients with PMR may have histologic proof of GCA, even in the absence of symptoms of GCA. This has continued to fuel controversy about whether all patients with PMR should be initially treated with high doses of glucocorticoids. This issue is not likely to be resolved any time soon. The clinical overlap of these disorders obligates careful vascular evaluations of patients with PMR.

WEGENER'S GRANULOMATOSIS

Disease manifestations of WG result from aseptic inflammation with necrosis, granuloma formation, and vasculitis affecting the upper and lower respiratory tracts, ears, eyes, kidneys, skin, or nervous system. Musculoskeletal features are common, but joint deformity or destruction is rare. About 25% of cases have peripheral or CNS disease ([Table 181.5](#)). The most common sources of morbidity are related to airway, renal, auditory, and ocular disease. Combination immunosuppressive therapy is generally very effective but is often associated with serious complications.

Abnormality	Frequency at Presentation (%)	Frequency During Disease Course (%)
Upper airways	73	92
Lower airways	48	85
Kidneys	18	75
Joint	32	67
Eye	15	52
Skin	13	46
Nerve	1	20

(Data from Hoffman GS, et al. *Ann Intern Med* 1992;116:488-498.)

TABLE 181.5. WEGENER'S GRANULOMATOSIS: CLINICAL PROFILE

At initial presentation, about 80% of patients do not have renal involvement and about 50% do not have overt lung disease. However, over the course of illness, more than 80% will develop pulmonary and/or renal disease. Most patients first seek medical care because of upper and/or lower airway symptoms. Nasal, sinus, tracheal, and/or ear abnormalities are responsible for initial symptoms in 73% of patients. Over 90% of patients eventually develop upper airway and/or ear abnormalities. These problems may be acute, subacute, or most often indolent, and may initially be assumed to be secondary to allergy or infection. Persistent symptoms and complications, especially recurrent epistaxis, mucosal ulcerations, nasal septal perforation, nasal deformity, or hearing loss, should lead to suspicion of WG and more extensive evaluation. The findings of asymptomatic hematuria (especially with red blood cell casts) on urinalysis, pulmonary infiltrates or nodules, elevated ESR, unexplained anemia, and ANCA may prompt pursuit of definitive diagnosis by biopsy of one or more involved organs.

Pulmonary infiltrates and/or nodules are initially present in about 50% of patients ([Fig. 181.3](#)). Symptoms may include cough, dyspnea, hemoptysis, and/or pleuritis. Bronchospasm is not common. Wheezing and stridor should prompt evaluation of subglottic stenosis or main stem bronchial stenoses. About 85% of patients will eventually develop lung disease. About 33% of patients may have asymptomatic pulmonary involvement. We periodically evaluate patients with chest computed tomography (CT) scans to aid in therapeutic decisions regarding the tapering of medication; CT scans are more sensitive than chest radiographs in demonstrating nodules and infiltrates. Auditory and ocular problems are common. The latter may include scleritis, tear duct obstruction, or orbital pseudotumor.

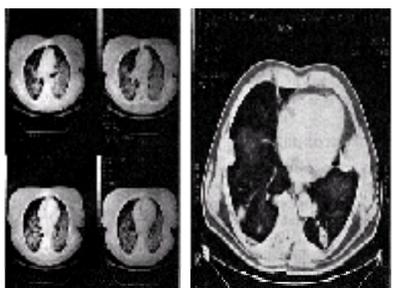

FIGURE 181.3. Wegener's granulomatosis pulmonary disease may present as diffuse pulmonary hemorrhage (**A**) or pulmonary nodules, which may cavitate (**B**).

Less than 20% of patients have glomerulonephritis at presentation. Until the point of uremia, renal disease is generally asymptomatic. This is a critically important observation that necessitates frequent evaluation of the urine to detect glomerulonephritis as early as possible because such discovery warrants intensification of therapy. About 75% of WG patients eventually develop glomerulonephritis. Thus, the concept of “limited” WG (not involving the kidney) in a given patient must be recognized as a description of disease status at one point in time that carries no guarantees about organ involvement in the future.

Ideally, the diagnosis of WG should be suspected on clinical grounds and confirmed by histopathologic examination. Lung tissue is the most likely to yield an unequivocal diagnosis. Open-lung biopsy usually demonstrates areas of geographic necrosis with giant cells, vasculitis, and often some eosinophils. Transbronchial biopsy specimens are often inadequate to diagnose WG but are useful in excluding infection. Nasal biopsies may be “consistent with” the diagnosis in one-third of cases but may not have all classical features. Renal biopsy may provide evidence of glomerulonephritis, with little or no evidence of immune complex deposition.

A positive immunofluorescence test for ANCA is present in approximately 90% of patients with active generalized disease. In patients with milder forms of WG, without renal involvement, positive tests may only occur in 50% to 70% of cases. In a majority of WG patients antibody specificity is to proteinase 3 (PR3), but in others the antibodies may be directed to myeloperoxidase (MPO). Anti-PR3 specificity usually produces a cytoplasmic pattern (C-ANCA) and MPO antibodies usually produce a perinuclear pattern (P-ANCA), by indirect immunofluorescence techniques. Tissue diagnosis should be aggressively pursued if there are atypical clinical features, including a slow response to therapy, reasons to suspect possible malignancy or infection, or comorbid processes that may require alternative or additional therapy. ANCA titers should not be used as the only guide to adjusting therapy.

Prior to the 1970s, only 50% of patients with WG survived for 5 months from the time of diagnosis and 82% of patients died within a year. In 1973, Fauci and Wolff noted that 13 of 15 WG patients who were treated with glucocorticoids plus an adequate trial of daily low-dose cyclophosphamide (CP) (14 patients) or azathioprine (1 patient) experienced remissions. As of 1991, the National Institutes of Health (NIH) WG cohort included 158 patients followed for 6 months to 24 years (mean = 8 years). Among all patients treated with daily CP and glucocorticoids, 143 (91%) patients had marked improvement, and 118 patients (75%) achieved remission. Unfortunately, 50% of remissions were later associated with at least one relapse. Ninety-nine patients were followed for more than 5 years, of whom 44% had remissions of more than 5 years' duration. Over a mean follow-up period of 8 years, mortality from disease and/or treatment was 13%—a dramatic improvement over historical series in which 50% mortality occurred over 5 months. Initial treatment of severe generalized WG should include glucocorticoid therapy in conjunction with CP. After substantial improvement has occurred, usually within 1 month, high-dose glucocorticoids can be tapered over several months. Cytotoxic therapy should be continued for at least a year following the induction of remission. For patients who do not have severe, immediately life-threatening or critical organ-threatening disease, weekly methotrexate therapy has been successfully used in place of CP during the initial phase of treatment. Methotrexate has also been effectively utilized as maintenance therapy after induction of remission with CP. Daily treatment with trimethoprim–sulfamethoxazole has been shown to decrease the frequency of upper airway flare-ups in WG, without influencing the course of renal or pulmonary disease. The mechanism for this effect may relate to alteration of staphylococcal or other bacterial flora in the upper airway, and it may be a useful adjunct in patients with smoldering upper airway disease. It should not be relied on as a primary treatment for visceral WG.

MICROSCOPIC POLYANGIITIS

Microscopic polyangiitis, as defined by the Chapel Hill Consensus Conference, is a systemic necrotizing vasculitis, with sparse or no immune complex deposition. It affects small vessels (capillaries, venules, or arterioles) but, like PAN, can also affect medium-size arteries ([Table 181.1](#)). Like WG and CSS, MPA has a predilection to involve the lungs (e.g., pulmonary infiltrates and hemorrhage), the kidneys (glomerulonephritis), and the peripheral nervous system. The pathologic process of MPA does not include granulomas, which are more characteristic of WG and CSS. MPA may pose an immediate threat to life in the setting of pulmonary hemorrhage and rapidly progressive renal failure. Once diagnosed, MPA necessitates aggressive treatment.

Because MPA and PAN have only recently been differentiated from one another, there exists a sparse historical literature on the incidence of clinical characteristics of MPA beyond glomerulonephritis and pulmonary capillaritis. Most patients with MPA experience myalgias, arthralgias, or arthritis, and a significant minority may have purpuric skin lesions, symptoms of intestinal ischemia, and axonal peripheral neuropathy. Diffuse alveolar hemorrhage and rapidly progressive renal failure may be reversible with aggressive therapy but nevertheless are poor prognostic markers. It is critical to note that the clinical expression of idiopathic PAN, MPA, and cryoglobulinemic vasculitis can be the same as that seen with viral infections complicated by vasculitis (e.g., hepatitis B and C, or HIV). Proof of viral infection in these disease phenotypes would support the use of antiviral therapies, which may minimize immunosuppressive treatment and their inherent toxicities.

Diagnosis of MPA should be confirmed pathologically whenever possible. Transbronchial biopsy may not provide sufficient tissue to confirm the diagnosis, even in the setting of alveolar hemorrhage. Renal biopsy in the clinical setting of an active urine sediment may confirm suspicion of necrotizing crescentic glomerulonephritis. P-ANCA, usually specific for MPO in this setting, occurs in 40% to 80% of patients with MPA. The specificity of this test is *not* 100%. Cases of infection-related or drug-induced ANCA have also been described.

Treatment is often similar to that described for WG. The usefulness of apheresis in the treatment of MPA has not been demonstrated convincingly. However, in the setting of acute, life-threatening alveolar hemorrhage, with or without renal failure, apheresis therapy should be considered especially if anti-basement membrane disease has not yet been excluded.

POLYARTERITIS NODOSA

Descriptions of PAN are quite variable because a consistent disease definition has not been utilized by all authors. What some authors have in the past called PAN, with pulmonary vasculitis or glomerulonephritis, would today be considered MPA. If one is guided by the CHCC nomenclature, PAN is a disease of medium-size or small arteries that can affect patients of any age. Glomerulonephritis and pulmonary capillaritis are not present based on this definition. Significant gender preferences are not appreciated. Affected patients may have fever, musculoskeletal symptoms, skin findings of livedo, nodules, ulcers or gangrene (but not palpable purpura), neurological abnormalities (peripheral more than central), cardiac disease and GI vasculitis ([Table 181.6](#)). Glomerulonephritis is not a feature of CHCC-defined PAN, but patients may experience renal failure or hypertension due to involvement of renal arteries. Peripheral neuropathy may have a pattern of mononeuritis multiplex or symmetrical polyneuropathy.

Abnormality	Frequency (%)
Fever	36–76
Weight loss	30–71
Hypertension	25–70
Kidney	8–77
Gastrointestinal	14–78
Cardiac	10–56
Nervous system	
Peripheral	23–60
Central	3–41
Musculoskeletal	
Arthralgia/arthritis	33–58
Myalgia	8–77
Skin	28–65
Eye	1–67
Testicular pain	1–4

^a Incidence represents a compilation of data from several series prior to recent acceptance of the concept of microscopic polyangiitis being distinct from polyarteritis nodosa.

TABLE 181.6. POLYARTERITIS NODOSA: CLINICAL PROFILE^a

Diagnosis is ideally achieved by biopsy of symptomatic or abnormal structures. If this approach is impossible or unrewarding, and visceral or systemic symptoms are present, angiography should be considered. To maximize the diagnostic yield, a complete study should include the celiac artery and its principal branches, the superior and inferior mesenteric and renal arteries ([Fig. 181.4](#)). Angiographic abnormalities may be present even without apparent clinical compromise of the perfused organ. Symptomatic GI, cardiac or renal vasculitis with hypertension, are poor prognostic markers. ANCA are generally absent in PAN.

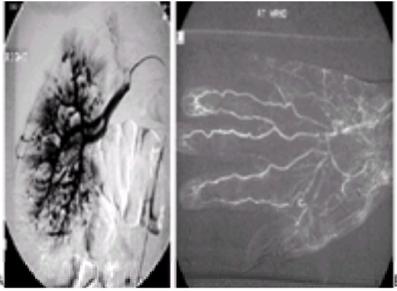

FIGURE 181.4. A: Polyarteritis nodosa. Renal angiogram. Multiple vascular stenoses and aneurysms are noted in this patient with new onset severe hypertension, abdominal pain and mononeuritis multiplex. **B:** Angiography reveals occlusion of multiple digital arteries that lead to gangrene of the distal thumb and fifth digit.

Untreated PAN has a >85% mortality rate at 5-year-follow-up. Treatment with high-dose glucocorticoids may improve this figure to 48%, and the combination of glucocorticoids plus cytotoxic agents may lead to about 80% 5-year survival. Indications for the use of initial concurrent therapy with glucocorticoids and CP, as opposed to glucocorticoids alone have not been fully defined. However, most authorities agree that critical organ involvement should be treated with glucocorticoids plus a cytotoxic agent, usually CP during the initial phase of therapy. Any concerns regarding the effects of glucocorticoids on wound healing or risk of infection should be secondary to the need for suppression of the inflammatory process that is the cause of gut ischemia, ulceration, and/or hemorrhage. This concept would appear to be valid for ischemia due to any form of vasculitis involving critical organs.

CHURG–STRAUSS SYNDROME (ALLERGIC ANGIITIS AND GRANULOMATOSIS)

Churg–Strauss syndrome is a rare, hypereosinophilic, granulomatous disorder that affects small and medium-size vessels, with a predilection for smaller arteries, arterioles, capillaries, and venules. There is no clear sexual preference, and persons of any age may be affected. This syndrome differs clinically from PAN, MPA, and WG in that the systemic vasculitis occurs in the setting of asthma and/or allergic rhinitis. Apart from asthma and eosinophilia, it is similar to WG in that it can affect the upper and lower airways and kidneys. Pathologic studies reveal intra- and/or extravascular granulomas and inflammatory lesions rich in eosinophils. Asthma usually precedes the clinical features of vasculitis by months to many years; but in up to 20% of cases both processes begin simultaneously. Unlike WG, allergic nasal and sinus disease of CSS is generally not a destructive process, pulmonary nodules are less common than fleeting infiltrates, and nodules, when they do occur, usually do not cavitate, as often occurs in WG. The degree of blood and tissue eosinophilia in CSS is usually more marked than in WG and renal involvement is usually milder. Coronary arteritis, myocarditis, and gut involvement is more common in CSS.

Churg–Strauss syndrome is generally more responsive to glucocorticoid therapy alone than are MPA, PAN, or WG. Response to high doses of prednisone (1 mg per kilogram per day) is often prompt. Cytotoxic agents should be reserved for severe, progressive, or acute critical organ-threatening (e.g., CNS, heart, renal, gut) or life-threatening disease.

SMALL-VESSEL VASCULITIS

Vasculitis that exclusively involves arterioles and predominantly postcapillary venules can occur as a limited cutaneous disease or be part of a more severe systemic vasculitic process. Limited cutaneous vasculitis, often purpuric, has been termed “hypersensitivity vasculitis” even though a triggering antigen is not usually identifiable. Biopsy of the skin usually demonstrates leukocytoclastic angiitis, with or without immune complex deposition. The presence of cutaneous vasculitis does not necessarily imply a systemic, visceral vasculitic process, but warrants evaluation for visceral disease. Cutaneous vasculitis may also occur in association with infections (bacterial endocarditis, *Neisseria*, *Rickettsia*, hepatitis B and C, cytomegalovirus, HIV), malignancies (predominantly myeloproliferative and lymphoproliferative, but also “solid” tissue carcinomas), drug allergic reactions, cryoglobulinemia (which may be secondary to malignancy or infection, particularly hepatitis C) and other systemic autoimmune disorders such as rheumatoid arthritis, SLE, or Sjögren's syndrome. Rarely, small-vessel vasculitis may present as urticarial vasculitis. Nonvasculitic causes of purpura and chronic urticaria should be excluded ([Table 181.3](#)).

If cutaneous vasculitis is mild and of recent onset, skin integrity is not compromised, and careful evaluation does not reveal a precipitant (e.g., new drug, recent infection) that can be eliminated or treated, only cautious observation may be warranted. However, progression or visceral involvement would require treatment. Extremity edema associated with the skin lesions can be treated with the use of compressive stockings. Pharmacologic therapy with nonsteroidal anti-inflammatory drugs, colchicine, dapsone, or pentoxifylline can be tried. Unfortunately, the benefits of such therapy are inconsistent at best. Glucocorticoids should be used sparingly and cytotoxic therapy generally avoided for isolated cutaneous disease. If extremely high levels of cryoglobulins are present, apheresis may be of benefit. Controlled studies of apheresis in this setting have not been performed.

HENOCH–SCHÖNLEIN PURPURA

Henoch–Schönlein purpura (HSP) is a systemic small-vessel vasculitis that predominantly affects postcapillary venules. Children of any age may be affected (peak age 4 to 6 years). Less often, adults may suffer from HSP as well. Neither sex is particularly favored. Non-thrombocytopenic palpable purpura is characteristic. Skin lesions may also be nonpurpuric. Mild glomerulonephritis, heme-positive stools (often with abdominal pain), and arthralgias are common components of the syndrome. In typical cases, the skin lesions all appear to be at the same stage of development, and they may recur in “crops” ([Fig. 181.5](#)). When measured early in the course of illness, circulating immune complexes can be found in serum and immunoglobulin and complement identified in vessel walls. Although IgA is the predominant immunoglobulin noted in circulating and tissue deposited immune complexes, IgG and IgM may be found as well.

FIGURE 181.5. Henoch–Schönlein purpura. Skin lesions in this 14-year-old girl are particularly striking. Fever, polyarthralgias, and purpura cleared without glucocorticoid therapy. However, several recurrences followed a period of wellness. See [color figure 181.5](#).

In more than two-thirds of patients, an upper respiratory infection will have preceded HSP by 1 to 3 weeks. The syndrome is characterized by an urticarial or purpuric rash (100%) that is most striking in gravity-dependent areas, fever (75%), musculoskeletal symptoms (68%), GI pain and/or bleeding (70%), and glomerulonephritis (45%). Diagnosis is more difficult if rash is not an initial feature, which is the case in 10% to 30% of patients. Most children with HSP experience one episode of illness that usually lasts less than 4 weeks. However, up to 40% may have recurrences following a period of well-being. Recurrences usually occur during a 3-month period after the initial episode but may rarely persist for years. The majority of patients do well without glucocorticoids or other immunosuppressive treatment. A minority will have serious GI complications including massive hemorrhage, intussusception, infarction, perforation, or obstruction. Treatment with glucocorticoids usually achieves prompt relief of nonsurgical GI symptoms. At what point glucocorticoids should be used is a matter of judgment, but we usually institute such therapy for GI bleeding,

peritoneal inflammation, severe abdominal or testicular pain, and renal failure. Such patients should also be followed closely by surgical staff.

About 40% of patients have mild renal involvement, half of whom will have elevations of blood urea nitrogen or creatinine. Renal biopsy is seldom necessary but if done will reveal IgA and complement deposition. Progressive renal failure occurs uncommonly. Whether glucocorticoid and cytotoxic therapy effectively alter the course of progressive renal disease is uncertain. Until definitive data are available, it would seem prudent to treat progressive glomerulonephritis with aggressive immunosuppressive therapy.

In adults, acute leukocytoclastic vasculitis resembling HSP of children can occur and may be associated with recent respiratory infection, medication hypersensitivity, or parasitic infection. However, in most cases no significant association is apparent. The GI manifestations are less common in adults, being noted in about 25% as compared with 66% of children. If a coincidental infectious process is present it should be treated, and if an exogenous antigen is suspected, such as a medication, it should be eliminated.

BEHÇET'S DISEASE

Behçet's disease (BD) can occur in people of any age, with the mean age being about 35 years. Sex ratios favor men (2:1) in Asia and eastern Mediterranean countries, where the disease is most prevalent, but a more even distribution between the sexes occurs in the United States. Behçet's disease is a very unusual vasculitic process; it affects vessels of all sizes, from capillaries and venules to the aorta and vena cava. It may resemble the small-vessel leukocytoclastic vasculitides, PAN, or Takayasu's arteritis. Diagnosis of BD is confounded by the observation that typical features of this illness may be separated from each other in time, over months to years. It is best recognized by a combination of features including recurrent aphthous stomatitis (without which the diagnosis cannot be made), genital aphthous ulcers, uveitis, cutaneous vasculitis, arthritis, GI disease, and meningoencephalitis. The pathergic response, an exaggerated local inflammatory reaction to trauma such as a needle stick, is perhaps more common in patients in the Middle and Far East than in North America ([Table 181.7](#)). Gastrointestinal Behçet's may affect any site in the GI tract, from the mouth to the anus. Distinction from Crohn's disease may at times be difficult. Mucosal ulcers are the most common finding. In most cases, ulcers are well marginated, like those in the mouth or on the genitalia, and intervening GI mucosa usually appears normal. Ulcer depth varies from superficial to complete penetration and perforation, which may occur in up to half of patients with GI involvement, or 25% of all BD cases. Gastrointestinal ulcers are usually multiple and most often located in the ileocecal region and right colon. Multiple perforations and potential perforations and fistulas may be present, increasing the risk of recurrent acute abdominal events and reoperation. Surgery for "apparently" limited ileal, cecal, or right colonic ulceration should consider at least a 1-m resection from the terminal ileum to healthy mucosa, beyond visible ileocecal abnormalities. Transmural inflammation, including noncaseating granuloma, oral ulcers, ocular problems, arthritis, and skin lesions, are seen in both BD and Crohn's disease. The presence of genital ulcers and CNS abnormalities favors the diagnosis of BD.

Abnormality	Frequency (%)
Aphthous oral ulcers	100
Aphthous genital ulcers	67-74
Uveitis	50-80
Cutaneous vasculitis	56-84
Arthritis	30-50
Meningoencephalitis	10-30
Gastrointestinal inflammation/ulcers	~50

(Data from Shimizu T, et al. *Semin Arthritis Rheum* 1979;8:223-260; O'Duffy JD, Chapter 69, *Textbook of Rheumatology*; Third ed., 1989; Baba SM, et al., *Dis Colon Rectum* 1976;19:428-440.)

TABLE 181.7. BEHÇET'S DISEASE: CLINICAL PROFILE

The treatment of BD is far from satisfactory. Spontaneously relapsing and remitting features make evaluation and treatment complex and confusing. Controlled studies using colchicine have yielded conflicting results. Thalidomide may be effective in reducing oral and genital ulcers. Mucocutaneous lesions have been shown to respond to thalidomide, although relapses usually follow drug discontinuation. Thalidomide use is limited to men and women who do not have reproductive potential. Treatment may be complicated by sedation or neuropathy. Because of neurotoxicity and teratogenicity its use is restricted and consent forms are required. Pentoxifylline has been reported to be effective in the treatment of mucosal ulcers, as has therapy with interferon-alpha 3 to 7 times weekly. Glucocorticoids have provided dramatic improvement in some cases, but temporary or no improvement in others. Some of the best treatment studies have been conducted in ocular BD. Visual complications may affect up to 85% of patients and lead to blindness in 25%.

Controlled studies of azathioprine and cyclosporine have convincingly demonstrated that each of these agents provides palliation for ocular BD, beyond that achieved with only glucocorticoids or colchicine. Although not specifically analyzed, extraocular features of BD also improved in most patients. CP and weekly methotrexate have been less well studied in BD, but appear to be efficacious and may be considered for severe systemic disease. Death directly attributed to BD occurs in about 4% of cases. Major contributing causes include GI perforation, vascular rupture of aneurysms, and CNS disease.

COGAN'S SYNDROME

Cogan's syndrome is a rare disorder of young adults (peak ages 15 to 30 years). There is no sexual predilection. Characteristic features include acute episodic interstitial keratitis that may eventually impair vision in 25% of cases and vestibulo-auditory dysfunction that may cause permanent severe hearing loss in 60% of cases. Vestibulo-auditory dysfunction may be indistinguishable from that of Ménière's disease. Eye and ear disease may occur and recur independently of each other. The dominant ocular lesion in some cases may not be interstitial keratitis. Other ocular features include scleritis, episcleritis, retinal artery occlusion, chorioretinitis, and retinal hemorrhages. A small number of postmortem examinations have revealed vasculitis of small vessels of the optic and acoustic nerves, and of large vessels including the aorta and its branches. However, most specimens from sensory organs do not reveal features of vasculitis. Aortitis, which occurs in approximately 10% of cases, may mimic Takayasu's disease both angiographically and histologically. Aortitis, coronary arteritis, and myxomatous inflammatory changes of the aortic valve may lead to life-threatening events. About 33% of patients develop abdominal pain, some of whom have associated GI bleeding. Although such features have been demonstrated to be the result of vasculitis, limited histologic and angiographic data preclude making conclusions regarding the frequency with which GI bleeding is due to vasculitis as opposed to other forms of inflammatory injury.

Systemic glucocorticoid therapy is indicated for severe ocular disease, vestibulo-auditory dysfunction, and vasculitis. As would be expected for any inflammatory disorder, the sooner glucocorticoids are provided, the greater the likelihood of preserving function. Whether cytotoxic therapies have a role in glucocorticoid-resistant disease is uncertain, but we offer this therapy to patients with life- or organ-threatening glucocorticoid-resistant disease. Cochlear implants have restored hearing for patients who have had severe bilateral sensory neural deafness.

KAWASAKI'S DISEASE

Kawasaki's disease (KD) is an acute febrile illness that primarily affects children less than 4 years old. It is extremely rare in children older than 8 years (mean age in Japan is 12 months and in the United States 2.8 years). The most prominent features are included in the case definition guidelines of the U.S. Centers for Disease Control and are provided in [Table 181.8](#). The illness is usually self-limiting within 4 to 8 weeks, and mortality is 2%. Deaths are usually due to acute thrombosis of coronary artery aneurysms, the result of prior vasculitis. Using noninvasive techniques, coronary artery aneurysms are noted in 20%, compared with 60% of cases studied by angiography. Data from postmortem studies have also demonstrated vasculitis of the aorta, celiac, carotid, subclavian, and pulmonary arteries. Rare case reports of gut vasculitis in KD exist; GI morbidity may result from small- rather than large-vessel disease. The conjunctivitis is nonpurulent. Adenopathy is most prominent in the cervical nodes. Oral mucous membrane changes should be sought on physical examination. Desquamation of hands or feet may begin several days into the illness or be delayed. This is not specific to Kawasaki's disease and may follow staphylococcal or streptococcal infections with toxic shock syndrome.

Fever \geq 5 days without other explanation, plus at least four of the following:

1. Bilateral conjunctival injection
2. Mucous membrane changes: injected or fissured lips; injected pharynx or "strawberry" tongue
3. Extremity abnormality: erythema of palms/soles, edema of hands/feet, or generalized or peripheral desquamation
4. Rash
5. Cervical lymphadenopathy

Note: 80% cases < 4 years old; rare > 8 years old.
CDC, U.S. Centers for Disease Control and Prevention.

TABLE 181.8. CDC CASE DEFINITION OF KAWASAKI'S SYNDROME

Treatment with high doses of aspirin (30 mg per kilogram per day) or intravenous g-globulin may prevent aneurysms or hasten their regression. Glucocorticoids have been felt to be of little value, perhaps even exacerbating the coronary artery disease. Nonetheless, in cases that do not respond rapidly to the initial therapy with intravenous g-globulin and aspirin, glucocorticoids are often added and have appeared to be beneficial.

POLYANGIITIS OVERLAP SYNDROMES

The term polyangiitis overlap syndrome has been applied to patients who have had typical features of vasculitis common to more than one diagnostic entity. An example would be a patient with arteriographic features of PAN and biopsy or angiographic evidence of Takayasu's arteritis. Some patients who cannot be easily classified may be best served with the tentative diagnosis of undifferentiated systemic vasculitis. These individuals may evolve to have a more clearly defined syndrome. Assessment of disease severity, anatomical distribution of disease, rate of progression, and comorbid conditions should determine the aggressiveness of therapy.

ANTINEUTROPHIL CYTOPLASMIC AUTOANTIBODIES

Antineutrophil cytoplasmic autoantibodies have become a prominent part of the literature of vasculitic disease over the past 15 years and thus warrant specific discussion as to their utility and limitations. Certain types of ANCAs have been recognized to be useful adjuncts to clinical diagnosis. Currently, two types of assays are commonly used for the detection of ANCAs: the indirect immunofluorescence technique and antigen-specific enzyme-linked immunosorbent assay (ELISA).

C-ANCA and P-ANCA are patterns of immunofluorescence that result from antibodies binding to antigens that are widely distributed in the cytoplasm (C-ANCA) or antigens that have been artifactually displaced, by ethanol fixation, to the perinuclear region (P-ANCA). Fluorescence is produced by using an antihuman immunoglobulin with a fluorescein tag. The characteristic C-ANCA pattern is usually caused by antibodies against PR3, a neutral serine protease present in the azurophil granules of neutrophils. Differentiating the characteristic centrally accentuated granular C-ANCA fluorescence from other diffuse types of cytoplasmic fluorescence may at times be difficult. In addition, autoantibodies against PMN cytoplasmic antigens other than PR3 can occasionally also cause cytoplasmic fluorescence. It is the anti-PR3/C-ANCA pattern that has the greatest specificity for patients with WG.

ELISA techniques have identified many antigens that are associated with autoantibodies causing P-ANCA fluorescence. MPO is the P-ANCA target antigen with the greatest clinical utility because of the frequent association of MPO-ANCA with MPA and necrotizing crescentic glomerulonephritis with few or no immune complexes. However, autoantibodies against elastase, cathepsin G, lactoferrin, lysozyme, and azurocidin have all been identified as causing the P-ANCA phenomenon. In a significant proportion of P-ANCA-positive sera the target antigens have not been characterized. The significance of finding P-ANCAs with specificities other than MPO is not defined.

The clinician should know how the laboratory determines ANCA or at least be able to contact someone in the laboratory who is knowledgeable about the limitations of the assays and can advise how to proceed in situations where the clinical findings are inconsistent with the reported ANCA test result. The indirect immunofluorescence technique results should be corroborated with antigen-specific testing for PR3 and MPO.

Since the first descriptions of ANCA, the number of diseases in which ANCA may occur has continued to increase. In addition to the systemic vasculitides, the list now includes rheumatic autoimmune diseases, inflammatory bowel disease (40% to 80% of ulcerative colitis patients), autoimmune liver diseases, infections, malignancies, myelodysplastic processes, and many others. Increasing numbers of case reports and small series have associated diseases and certain drug reactions with the presence of ANCAs. The following drugs have been linked to ANCA production and autoimmune syndromes, including vasculitis: allopurinol, hydralazine, propylthiouracil, and minocycline. Therefore, a positive ANCA test does *not* equate to a diagnosis of a primary vasculitis.

TREATMENT OF SYSTEMIC VASCULITIS

GENERAL COMMENTS

The NIH protocol for WG has become a standard treatment approach for other forms of vasculitis, such as PAN, when critical organ involvement is present. For this reason, the principles of this protocol will be reviewed in depth. Initial treatment consists of CP 2 mg per kilogram per day orally, simultaneously with prednisone (1 mg per kilogram per day orally). Daily prednisone is continued for approximately 4 weeks. If marked improvement has occurred, prednisone is gradually (over 3 months) converted to an alternate-day regimen (60 mg on alternate days). After conversion to an alternate-day regimen, the dose is gradually tapered for several months until the patient is no longer receiving prednisone and is maintained solely on CP. The CP is continued for at least a full year after the patient is in complete clinical remission. After this period, which varies among patients, a tapering schedule is begun in which the dose of CP is lowered by 25-mg decrements every 2 to 3 months. The drug is then either discontinued or a dosage is reached below which the patient may have a flare-up of disease activity. When patients are critically ill with presenting symptoms that include severe alveolar hemorrhage or rapidly progressing renal failure due to glomerulonephritis, "pulse" dosing of glucocorticoids (1 g daily of intravenous methylprednisolone for 3 days in single or divided doses) is frequently utilized. CP is concurrently provided in a dose of 3 to 5 mg per kilogram per day for 2 to 3 days and then reduced to 2 mg per kilogram per day. This latter practice has evolved through experience, without controlled trials. During periods of intense immunosuppression, antibiotic prophylaxis against *Pneumocystis carini* should be provided.

The peripheral leukocyte count should be used as a guide in adjusting the CP dosage to avoid undue risks of toxicity. It is desirable to not allow the leukocyte count to drop below 3,000 to 3,500 per cubic millimeter or the neutrophil count to drop below 1,000 to 1,500 per cubic millimeter. Observation of the slope of decrease of the leukocyte count is essential to the proper adjustment of dosage. The effect of a given dose of CP on the leukocyte count is generally seen within 1 to 2 weeks after it is administered. If the leukocyte count approaches neutropenic levels, dose reductions should be made. In the early induction phase of therapy, it is advisable to follow the leukocyte count about every 2 to 3 days and, after the leukocyte count stabilizes, to follow the counts at intervals no greater than every week until a stable dose has been achieved. It cannot be over-emphasized that therapeutic benefits do not require leukopenia or neutropenia. Patients undergoing long-term CP therapy must be reminded to sustain excellent hydration to maintain dilute urine so that acrolein, the principal bladder-irritating metabolite of CP, will exert minimal toxicity. The appropriate degree of dose adjustment of CP in the setting of renal failure is unclear, but it seems prudent to decrease the dose when the glomerular filtration rate is decreased by 50% in all but the most life-threatening circumstances. Following the peripheral white blood cell count is crucial. Occasionally in the setting of profound leukopenia, neutrophil growth factors may be briefly required as supportive therapy.

Treatment Toxicity and Changing Strategies

In recent years, several prospective studies have evaluated the utility of alternative therapies to daily CP. These studies have included use of glucocorticoids plus intermittent high-dose intravenous ("pulse") CP, or weekly low-dose (15 to 25 mg) methotrexate (MTX) therapy. Preliminary results indicate that pulse CP and glucocorticoids may provide substantial initial improvement but are not as effective as daily low-dose CP therapy in maintaining improvement. There is also concern regarding the inflexibility of dose modification following the initial "pulse" in the severely ill patient; neutropenia may occur while the patient is still in an intensive care

unit and at high risk for nosocomial infection. The role for pulse CP therapy remains a subject of controversy and continued study.

The use of MTX (with glucocorticoids) in systemic vasculitis has been under study at the NIH for over 10 years. One protocol enrolled 42 patients with WG without life-threatening pulmonary or rapidly progressive renal disease (or serum creatinine more than 2.5 mg per deciliter). Initiation of treatment was with 0.3 mg per kilogram once weekly, followed by a gradual increase in dose to the maximum tolerated, not to exceed 25 mg per week; folic acid supplementation was also prescribed. Seventy-one percent of these patients achieved remission within a mean period of 4.2 months. Thirty-six percent of patients subsequently relapsed over a mean period of 29 months and required retreatment. These results compare quite favorably to those with daily CP, but concurrent comparisons of these agents in comparable patients were not made. MTX and azathioprine have also been successfully employed as maintenance agents for patients in whom marked improvement or remission has been achieved with CP during the first 3 to 6 months of treatment. The hope in using MTX instead of CP is that there will be decreased late toxicity from the CP. MTX is cleared rapidly following each dose by the kidney, and administration of MTX to a patient with significant renal insufficiency (or on dialysis) may result in severe bone marrow suppression. MTX use is contraindicated in advanced renal failure.

Daily CP therapy produces transient hair loss in about 20% of patients. MTX-induced hair loss is much less common. Examples of persistent morbidity include CP cystitis (50%), bladder cancer (16% at 15-year follow-up), myelodysplasia (2%), and commonly recognized toxicities of glucocorticoids such as cataracts (21%), osteoporosis-related fractures (11%), and aseptic necrosis (3%). Less often, CP may cause thrombocytopenia, profound anemia, or prolonged leukopenia, even after the drug is discontinued. A marrow examination is appropriate in this setting. The malignancy rate in WG patients in the NIH cohort was compared to that in the National Cancer Institute Registry for adults in the general population. The results indicate a 2.4-fold overall increase in malignancies, a 33-fold increase in bladder cancer, and an 11-fold increase in lymphomas. The latency period from the start of CP therapy to detection of transitional cell carcinoma of the bladder varied from 7 months in one man who was receiving daily CP for active WG to 12 years in another who was in remission and had not received CP for 10 years. Almost all patients who had CP-associated bladder cancer were previously noted to have had either microscopic or gross hematuria. If hematuria is not due to glomerulonephritis, cystoscopy should be performed. Urine cytology is a relatively insensitive screening test in this setting. Once CP cystitis is demonstrated by the cystoscopic appearance of either mild to severe mucosal erythema, erosion(s), hemorrhage, pallor, and/or telangiectases, follow-up surveillance cystoscopy should be routinely instituted at intervals of about a year, depending on the degree of abnormality and the quality of subsequent urinalyses and cytologic evaluations. CP therapy should be avoided when CP cystitis has been recognized.

Infection remains a serious and common complication of intense immunosuppressive therapy. Of the patients with WG treated at the NIH, 50% developed serious infections. Eleven of 180 patients (6%) developed *Pneumocystis carini* pneumonia. All of the *Pneumocystis*-infected patients had been receiving glucocorticoids plus a cytotoxic agent, were in the earliest phase of treatment for disease exacerbation, and were lymphopenic (mean lymphocyte count 303 per cubic millimeter). We and others now recommend chemoprophylaxis for *Pneumocystis* during periods of intense immunosuppressive therapy.

Although chronic therapy with CP has dramatically altered outcomes for many types of severe vasculitis, long-term toxic effects have led to numerous ongoing studies of alternative protocols.

CHAPTER 182: INFECTIOUS ARTHRITIS

MARY M. STIMMLER

[Bacterial Arthritis](#)
[Viral Arthritis](#)
[Fungal Arthritis](#)

BACTERIAL ARTHRITIS

Infection of the joint with a bacterial organism is a medical emergency. Prompt diagnosis and initiation of treatment is necessary to avoid excessive morbidity and mortality.

NONGONOCOCCAL INFECTIONS

Incidence and Epidemiology

No decrease in the frequency of septic arthritis has been noted in spite of advances in antibiotic therapy and sophisticated methods of detecting infection. Most patients have one of the risk factors listed in [Table 182.1](#).

Risk Factor	Specific Disease
Extremes of age	Infants, elderly
Joint injury or manipulation	Arthrocentesis, intra-articular injection
Chronic debilitating disease	Cirrhosis, alcoholism, diabetes, cancer, uremia
Altered joint integrity	Rheumatoid arthritis, osteoarthritis, hemophilia
Immunosuppression	Human immunodeficiency virus, hypogammaglobulinemia, systemic lupus erythematosus, systemic steroids, cytotoxics
Intravenous drug use	—
Prosthetic joint	—

TABLE 182.1. RISK FACTORS FOR INFECTIOUS ARTHRITIS

Etiologic Factors

Most organisms reach the joint by the hematogenous route from transient bacteremia or prolonged sepsis. Direct inoculation occurs following trauma and arthrocentesis. Infection can extend from adjacent tissue such as bone, bursa, tenosynovium, or abscess. Cartilage is rapidly destroyed and joint integrity altered by direct effects of the bacteria, proteolytic effects of the polymorphonuclear leukocytes, an intrasynovial immune response, and cytokine release.

The age of the patient and presence of comorbid conditions aid in identifying the infecting organism. Most infections in neonates are caused by *Staphylococcus aureus* and gram-negative bacilli. *Haemophilus influenzae* infection is now almost nonexistent in children who have received *Haemophilus influenzae* type b vaccine. The organisms seen in children are *S. aureus* and *Streptococcus* species, and affect knees and hips. Gram-positive cocci predominate in healthy adults, the elderly, and the immunosuppressed.

Polyarticular infection is usually caused by *S. aureus* and occurs more often in rheumatoid arthritis, hemophilia, and immunocompromised states. *Staphylococcus aureus* is the most common infecting organism after joint aspiration and injection. Anaerobes may accompany *S. aureus* and other organisms in a traumatized joint. Gram-negative bacilli (*Pseudomonas* species) and *S. aureus* reflect the skin and oral flora of intravenous drug users who lick and share needles. *Staphylococcus epidermidis* is found in early postoperative prosthetic joint infection, and gram-positive cocci and anaerobes are found in late infections. *Salmonella* species are associated with sickle cell disease and systemic lupus erythematosus. Joint infection in hemophilia is becoming more common as patients self-inject coagulation factor. *Staphylococcus aureus* accounts for 50% of these cases, followed by streptococci and gram-negative bacilli. *Ureaplasma urealyticum* should be considered in hypogammaglobulinemia, and *Brucella* species are found in patients who drink unpasteurized milk.

Clinical Findings

Patients present acutely with decreased range of motion in a painful, warm, swollen joint. Signs of inflammation are often less impressive in patients with chronic disease. Most infections are monoarticular and involve the knees (42%), hips (13%), ankles and shoulders (10% to 12%). Polyarticular disease in the immunocompromised host involves the knees, elbows, shoulders, and small joints more frequently than the hips. Fibrocartilaginous joints of the axial skeleton (sternoclavicular, sacroiliac, symphysis pubis, and intervertebral disc spaces) are involved in intravenous drug abusers. The patient keeps the infected joints immobilized in a flexed position to relieve elevated intra-articular pressure. Signs of systemic infection may be lacking in diabetics, the elderly, and patients taking immunosuppressive drugs. Fever may be high (more than 39°C), but 20% are afebrile and only 63% of rheumatoid patients with polyarticular infection have fever. Diagnosis of infection is frequently delayed in patients with rheumatoid arthritis when inflamed joints are mistaken for flaring joints with active disease and should be suspected when one or two joints are more inflamed than the remaining joints.

Laboratory Findings

Diagnostic evaluation includes a complete blood count, cultures of blood and other possible sites of infection, arthrocentesis, and baseline joint radiographs. The peripheral white blood cell (WBC) count is normal in as many as 40% to 50% of cases. The C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR) are usually strikingly elevated. Blood cultures are obtained before antibiotics are started and often are the only means of identifying the offending organism. They are positive 30% to 50% of the time, and may be positive in as many as 75% of cases of polyarticular sepsis. When all possible sites of infection are cultured, the source is identified in up to two-thirds of cases.

The most valuable information comes from analysis of the synovial fluid, and all suspect joints should be aspirated before antibiotic therapy is begun. Typical findings are outlined in [Table 182.2](#). A cell count higher than 50,000 WBC per cubic millimeter is usually indicative of infection, although lower cell counts are seen in 30% to 60% of cases. Glucose in septic joint fluids is moderately low. A positive (50%) Gram stain can be helpful in selecting antibiotics. Both aerobic and anaerobic cultures are requested, along with Thayer–Martin media if gonococcal infection is suspected. Use of blood culture bottles may increase the chance of identifying the infecting organism. Bacterial cultures are frequently positive (up to 95%) and should be requested on all joints aspirated. The polymerase chain reaction assay has been used on synovial fluid and tissue in selected cases to detect specific bacterial nucleic acid base sequences.

Organism	Appearance	WBC/mm ³	% Positive	
			Serum	Culture
Bacterial	Opportunistic	>50,000	>90	50-90
Gonococcal	Opportunistic	30,000-100,000	>90	<5
Tuberculous	Opportunistic	10,000-20,000	>90	20

WBC, white blood cell count; PMN, polymorphonuclear neutrophil leukocyte.

TABLE 182.2. SYNOVIAL FLUID CHARACTERISTICS IN INFECTIOUS ARTHRITIS

Radiographs of the involved joints may show only soft tissue swelling and effusion early in the disease but should be obtained to rule out an underlying osteomyelitis. Technetium and gallium bone scanning may be helpful in diagnosing osteomyelitis and evaluating structures that are difficult to visualize, such as the sacroiliac, sternoclavicular, and facet joints. Computed tomography is useful in delineating areas with bony overlap and to look for abscesses. Magnetic resonance imaging is the method of choice for evaluating the hip and can be used to look for soft tissue infection and to confirm the presence of osteomyelitis.

Optimal Management

Treatment consists of parenteral antibiotics and drainage of the affected joint. Initial antibiotic therapy is directed to the most likely organism given the clinical setting, age of the patient, underlying disease, and results of Gram stain and cultures. Therapy is modified when the organism is identified and antibiotic sensitivities are available. Specific recommendations are given in [Table 182.3](#). Nonsteroidal anti-inflammatory drugs (NSAIDs) can confuse the picture and should not be used until response to antibiotics has been documented.

Bacteria	Patient Characteristics	Antibiotics
<i>Staphylococcus aureus</i>	Children, adult, polyarticular, rheumatoid arthritis, immunocompromised	Nafcillin 2 g q6h IV + 2-4 wk, then oral + 2 wk
<i>Streptococcus pneumoniae</i>	Elderly, children, immunocompromised	Penicillin G 2 million U q6h IV
Group A Non-group A (meningococci)	Prosthetic joints	Ampicillin 1-2 g q6h IV plus gentamicin 1 mg/kg q8h + 2-4 wk, then oral + 2 wk
Gram-negative bacilli	Nonacute, elderly, intensive drug abuse	Ceftazidime 1 mg/kg q8h IV or third-generation cephalosporin plus nafcillin 2 g q6h IV
<i>Escherichia coli</i>		(pending culture) + 2-4 wk, then oral + 2 wk
<i>Pseudomonas</i>		
<i>Salmonella</i>	Still ill, systemic lupus erythematosus	
<i>Haemophilus influenzae</i>	Immunocompromised children	

IV, intravenous.

TABLE 182.3. ANTIBIOTIC THERAPY FOR NONGONOCOCCAL INFECTIOUS ARTHRITIS

Drainage is accomplished by daily aspiration of the joint with a large-bore needle until the effusion is minimal and WBC counts are less than 50,000 per cubic millimeter. Reaccumulation of the effusion and failure to respond to therapy may be due to lack of sensitivity to the antibiotics, the presence of multiple organisms, or loculation of fluid. Treatment failure has occurred when blood or synovial fluid cultures remain positive after 72 hours or symptoms persist after 5 days of therapy.

Immediate surgical intervention is required for infections of the hip and shoulder, and for unresponsive organisms in a damaged joint. Arthroscopy with lavage of the joint and removal of bacterial and cellular debris can be used in easily accessible joints and in patients who are poor surgical candidates. Infection of a joint prosthesis requires removal of the prosthesis, extensive debridement, and prolonged antibiotic treatment. Timely initiation of physical therapy is important in maintaining range of motion.

Parenteral antibiotics are given for 2 to 4 weeks depending on the underlying disease and response to therapy, followed by oral antibiotics for an additional 2 to 4 weeks. Indolent organisms, polyarticular infection, and treatment of prosthetic joint infections may require a longer course of treatment.

Prognosis

Outcome is related to the time elapsed from onset to diagnosis, host defenses, virulence of the organism, and integrity of the joint. Complete function is recovered in 50% to 70% of cases. Poor outcome is associated with a delayed diagnosis in infants or the elderly, polyarticular infection, an unknown organism, and previously damaged joints. Mortality has changed little since the 1960s (5% to 10%) and is as high as 29% in polyarticular infection. In patients with rheumatoid arthritis, complete recovery occurs in only 35%, and the mortality is as high as 56% in those with polyarticular infection.

GONOCOCCAL ARTHRITIS

Incidence and Epidemiology

Neisseria gonorrhoeae is the most common organism causing bacterial arthritis, accounting for almost 75% of infections in healthy, sexually active young adults. Disseminated gonococcal infection (DGI) follows spread of infection from mucosal surfaces. Characteristics of the cell wall proteins and antigenic structure of the pili have been associated with virulence and dissemination. DGI is more common in women than men. Pregnant women, women in the immediate postpartum period, or those within 1 week of their menses are at increased risk for dissemination. Also at risk are those with complement component deficiencies, especially the terminal C5 to C8 components, owing to their inability to form the membrane attack complex that is necessary for bacterial killing.

Etiologic Factors

Gonococcal bacteremia results in spread of the organism to the joint. Viable organisms have been cultured from the blood and synovial fluid. There is also evidence that arthritis may occur in the absence of viable organisms.

Clinical Findings

Two forms of DGI have been described that may represent either separate entities or two different ends of a spectrum. The *bacteremic form*, resembling serum sickness, occurs in about two-thirds of patients and consists of a triad of polyarthralgia, tenosynovitis, and dermatitis. It begins with migratory polyarthralgias, fevers, chills, and constitutional symptoms. A tendinitis or tenosynovitis may affect the wrists, fingers, ankles, or toes. Skin lesions are papular or pustular on an erythematous base ([Fig. 182.1](#)). They are usually found on the extremities and trunk and may continue to appear for up to 48 hours on antibiotics. Aspiration reveals sterile fluid.

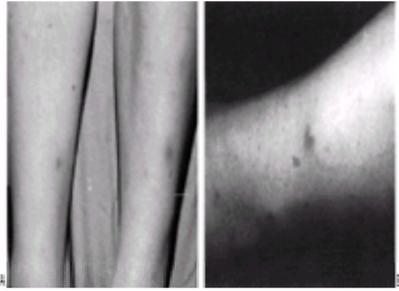

FIGURE 182.1. Dissemminated gonococcal infection. **A:** Multiple skin lesions on lower extremities. **B:** Papule on hemorrhagic base. (Courtesy of Thomas H. Rae, MD.) See [color figure 182.1](#).

The second form consists of a nonerosive, *suppurative arthritis* that is usually monarticular (75%) and affects the knees, feet, and ankles. The patient may be febrile, but rash and tenosynovitis are usually absent at this stage. Synovial fluid is inflammatory ([Table 182.2](#)).

Other features of DGI may include sore throat (gonococcal pharyngitis), urethral or vaginal discharge, dysuria, pericarditis, and hepatitis.

Laboratory Findings

A mild leukocytosis may be present, as well as a mild to moderate increase in the ESR. During the bacteremic phase there may be a transient elevation of the transaminases. Circulating immune complexes, if present, are found in the early bacteremic phase. There may be a small, bland joint effusion that becomes inflammatory once the arthritis is well established.

The diagnosis of gonococcal arthritis is made by demonstrating the organism on culture of body fluids. Handling of specimens is of utmost importance. Swabs for Gram stain and culture are obtained from all mucosal surfaces that could yield bacteria and immediately plated on antibiotic-impregnated culture medium that will inhibit the growth of the other organisms colonizing these areas. Thayer–Martin medium is used for swabs of the urethra, endocervix, rectum, and pharynx. Blood and synovial fluid are plated on chocolate agar. Plates should be kept for 7 days. Blood cultures are positive in up to 30% of cases in the bacteremic phase and are negative in the purulent phase localized in joints. Synovial fluid cultures are positive in about 50% of cases of purulent arthritis. The yield on urogenital cultures is much higher, with best results obtained on cervical culture (80% to 90%). DNA probes are sensitive and specific for bacterial rRNA but do not allow for testing of antibiotic sensitivity. Cultures are also sent for *Chlamydia trachomatis*, which is a coinfection in as many as 40% of cases of gonorrhea. A Venereal Disease Research Laboratory test is obtained and repeated in 6 weeks to rule out incubating syphilis.

Optimal Management

Patients improve dramatically within 48 hours of beginning treatment with appropriate antibiotics. Therapy is initiated in the hospital with intravenous antibiotics until the fever has resolved and symptoms are controlled, followed by a week of oral antibiotics. Typically, 3 to 4 days of intravenous therapy is adequate in the dermatitis–tenosynovitis form and 7 to 10 days in purulent arthritis. Although the arthritis usually is not destructive, daily aspirations may be required for the first few days to ensure adequate response to therapy. The hip also does well with closed-needle aspiration.

Therapy is initiated with a penicillinase-resistant cephalosporin as outlined in [Table 182.4](#). All patients, except pregnant women, should also receive 1 week of doxycycline 100 mg twice daily for *C. trachomatis* coinfection.

Patient Characteristics	Antibiotics
Healthy, young, sexually active	Ceftriaxone 1 g IM/IVid × 2–3 d, then cefuroxime or ciprofloxacin 500 mg po b.i.d. × 7 d plus doxycycline 100 mg b.i.d.
Penicillin sensitive	Penicillin G 10 million units/d IV, then ampicillin 500 mg/clavulanic acid 125 mg po t.i.d. × 7 d plus doxycycline 100 mg b.i.d.
Penicillin allergic	Spectinomycin 2 g IM q 12 h, then ciprofloxacin 500 mg po b.i.d. plus doxycycline 100 mg b.i.d.
Pregnancy*	Spectinomycin 2 g IM q 12 h, then erythromycin base 500 mg po q.i.d.

* Erythromycin stearate and ciprofloxacin are contraindicated in pregnancy.
IV, intravenous; IM, intramuscular.

TABLE 182.4. ANTIBIOTIC THERAPY IN GONOCOCCAL INFECTIOUS ARTHRITIS

MYCOBACTERIAL INFECTIONS

Mycobacterium tuberculosis

Although the prevalence of tuberculosis in the United States and western Europe had been steadily decreasing since the 1960s, there has been a significant resurgence of tuberculosis since the mid-1980s, related to the worldwide epidemic of HIV infection. The prevalence of extrapulmonary tuberculosis (15%) remains the same, with bone and joint infections accounting for 15% to 20% of the extrapulmonary cases or about 1% to 3% of cases overall. Infection reaches the joint by either the hematogenous route or direct extension from adjacent osteomyelitis. Three forms of joint involvement are seen. Tuberculosis of the spine (Pott's disease), which formerly occurred commonly in children and young adults, is now seen most frequently in patients older than 40 years. Collapse of the anterior vertebral bodies gives the characteristic “gibbous deformity” on x-ray. Extension to the disc space and adjacent vertebral bodies occurs along the anterior longitudinal ligament. Paraspinal abscess formation is common (50% to 95%). Involvement of the sacroiliac joint is unusual. Diagnosis is made by identifying organisms obtained in biopsy of the involved bone.

Peripheral joint infection with tuberculosis is manifested by a chronic monarticular arthritis of a weight-bearing joint and usually is seen in males. The knee is most commonly involved. The infection is indolent and delay in diagnosis is common. Palpation of the joint reveals a doughy synovial thickening. The purified protein derivative test is usually positive, but pulmonary involvement is seen in only 50% of cases of tuberculous arthritis. Synovial fluid is mildly inflammatory ([Table 182.2](#)) and culture of synovial fluid is positive (80%). Radiographs may be normal or show bony involvement.

An unusual presentation is an acute, recurrent, sterile polyarthritis of hands, knees, and ankles associated with visceral tuberculosis (Poncet's disease).

Treatment of tuberculous arthritis begins with isoniazid, rifampin, and pyrazinamide. Ethambutol is added in areas of endemic drug resistance. Pyrazinamide can be stopped after 2 months and the other medications continued for 10 to 24 months, depending on the clinical response. Surgical debridement may aid in healing when extensive bony involvement is present.

Atypical Mycobacteria

Indolent and chronic infection with atypical mycobacteria occurs more frequently in patients who have had previous manipulation of a joint or who are immunocompromised (Table 182.1). Tenosynovitis, arthritis, and osteomyelitis are often accompanied by cutaneous lesions. The joints and tendon sheaths of the hand are frequently involved (50%), followed by the knee. *Mycobacterium marinum*, *M. kansasii*, and *M. avium* complex are the most common organisms in the HIV-negative host. *Mycobacterium marinum* is associated with aquatic hobbies and is frequently resistant to therapy; a five-drug regimen, including either azithromycin or clarithromycin, is usually required.

VIRAL ARTHRITIS

RUBELLA

An acute, painful, symmetrical polyarthritis occurring during rubella infection affects 30% to 50% of women but is rare in men or children. The fingers, knees, and wrists are painful and stiff, without heat or swelling. The arthritis occurs within 5 to 6 days of the morbilliform rash and follows the usual prodrome of malaise, fever, coryza, and posterior cervical adenopathy. Joint effusions are small and synovial fluid is inflammatory (15,000 to 60,000 WBCs per hpf). It is self-limited and resolves within a month. The arthritis becomes chronic in 15% to 30% of women. Viral particles have been identified in the synovial fluid and in mononuclear cells of blood and synovial fluid, suggesting that the virus directly infects the synovial membrane. Aspirin and NSAIDs provide symptomatic relief.

A causal role of rubella vaccine in both acute and chronic polyarticular arthritis has been established in 5% to 10% in women receiving the RA 27/3 strain. Acute arthralgias and arthritis occur 1 to 6 weeks after vaccination with live attenuated virus.

HEPATITIS

One-third of patients with acute hepatitis B infection have arthritis, often accompanied by an urticarial rash. The arthritis is usually symmetrical and polyarticular. It affects the small joints of the hands, knees, shoulders, ankles, and elbows in the preicteric phase and resolves when jaundice becomes apparent. Demonstration of circulating immune complexes containing hepatitis B surface antigen, immunoglobulins, and complement components suggests that the rash and arthritis is an immune complex-mediated phenomenon. The synovial fluid is noninflammatory with lymphocytic predominance. The arthritis is self-limited and responds to NSAIDs. A reactive arthritis can follow hepatitis B vaccination and last for up to 6 months. Other rheumatologic conditions associated with hepatitis B infection include *polyarteritis nodosa* and *mixed cryoglobulinemia*.

Hepatitis C infection is associated with polyarthralgias and polyarthritis in both the acute and chronic stages and may be difficult to differentiate from rheumatoid arthritis. Autoimmune phenomena include the presence of autoantibodies [antinuclear antibodies (10% to 30%), anti-smooth muscle antibodies (60% to 70%) and rheumatoid factor (60% to 80%)], mixed cryoglobulinemia, glomerulonephritis, sialoadenitis, and induction of thyroid disease. Many of the autoimmune features respond to treatment with interferon- α , but relapse when treatment is stopped.

ARBOVIRUS

A number of arboviruses cause sporadic outbreaks of polyarthritis. Epidemics commonly follow heavy rainfall in endemic areas where mosquitoes multiply. They are characterized clinically by severe but self-limited polyarthralgias, rash, and varying degrees of fever and constitutional symptoms. Diagnosis is confirmed by seropositive tests. Treatment consists of aspirin and narcotic analgesics. Arthritis rarely lasts longer than 2 weeks.

Ross River virus affects adults and is endemic in Australia, Fiji, and other South Pacific islands.

Chikungunya virus is a cause of hemorrhagic fever and is endemic in Africa, Southeast Asia, and the Philippines.

O'nyong-nyong is endemic in Africa and affects older children and adults.

PARVOVIRUS (ERYTHEMA INFECTIOSUM)

An acute symmetrical polyarthritis resembling rheumatoid arthritis occurs in about 50% of adult women with parvovirus infection. The "slapped cheek" rash seen in children is often lacking. Arthritis begins after a flulike prodrome coincident with the antibody response, suggesting an immune-mediated mechanism. The serum B19-IgM response lasts for 1 to 3 months and is diagnostic of recent infection. Anti-IgG is found in 40% to 60% of adults. B19-DNA has been detected in serum, bone marrow, and synovial fluid using polymerase chain reaction but is not diagnostic of infection. The arthritis is nonerosive and usually is self-limited. A mild but definite exfoliation of skin on the hands is occasionally seen. Symptomatic treatment with NSAIDs is helpful. There is some evidence that B19 DNA can be found in synovium of patients with rheumatoid arthritis. A definite causal role of the virus has not been established.

Other viruses occasionally associated with arthritis include mumps, smallpox, adenovirus, and the herpesviruses (varicella-zoster, herpes simplex virus 1, Epstein-Barr, and cytomegalovirus).

HUMAN IMMUNODEFICIENCY VIRUS

Musculoskeletal manifestations are found in 5.5% to 72% of patients with HIV infection (Table 182.5).

Autoimmune manifestations

TABLE 182.5. MUSCULOSKELETAL MANIFESTATIONS OF HIV INFECTION

Articular Syndromes

Arthralgias are seen in patients with acute HIV infection along with sore throat, fever, and malaise. Up to one-third of patients may have nonspecific generalized arthralgias of mild to moderate degree that recur intermittently and respond to NSAIDs.

A *painful articular syndrome* is characterized by severe, debilitating oligoarticular pain without synovitis. It occurs suddenly, is unresponsive to NSAIDs, and requires narcotic analgesics. The joint pain resolves within 48 hours without sequelae.

Reiter's syndrome is the most frequently observed inflammatory arthritis associated with HIV infection. It can precede the diagnosis of HIV. An incomplete form is seen more frequently than the classic triad. The arthritis is usually severe, persistent, and oligoarticular, involving primarily the large joints of the lower extremities. Extra-articular manifestations include urethritis, conjunctivitis, circinate balanitis, keratoderma blennorrhagicum, enthesopathies, and oral ulcers. Some cases appear

reactive in nature, precipitated by culture-negative urethritis or diarrhea. Reiter's syndrome is frequently described in homosexuals, in whom the disease is usually human leukocyte antigen (HLA)-B27 related. It is not seen commonly in intravenous drug abusers, and it is not related to HLA-B27 in Africans who acquire HIV through heterosexual contact. The arthritis responds poorly to NSAIDs and variably to sulfasalazine.

Psoriasis was the first rheumatic syndrome described in HIV infection. The skin disease can be severe and arthritis seen in less than half of patients. The arthritis is asymmetrical, oligoarticular, and frequently accompanied by enthesopathy. It can be erosive, rapidly progressive, and refractory to treatment.

HIV-associated arthritis is a nonerosive, oligoarticular arthritis affecting knees and ankles. It is characterized by moderate to severe pain, mildly inflammatory synovial fluid, and a mild chronic synovitis. Some relief is seen with NSAIDs, and the arthritis resolves in 6 weeks to 6 months.

Septic arthritis in AIDS is uncommon. Involvement is usually monoarticular with *S. aureus* or *Candida albicans*. Multiple joints may be involved with fungal or mycobacterial organisms later in the disease when CD4 counts are low. *Mycobacterium haemophilum*, *M. kansasii*, and *M. avium* complex are the most common organisms. Septic arthritis appears to be related to the intravenous drug abuse and its complications, just as Reiter's syndrome appears to be related to homosexual behavior. Hemophiliacs seem to be at particular risk for septic joints.

Myopathies

Myalgias can be generalized or confined to the thighs. They are a common finding, tend to recur, and respond well to analgesics. Inflammatory polymyositis is indistinguishable from idiopathic polymyositis and patients respond to treatment with systemic corticosteroids.

Zidovudine (azidothymidine, AZT) therapy has been associated with an inflammatory myositis with muscle tenderness, weakness, and elevated creatine phosphokinase. Some cases resolve when the AZT is stopped. *Staphylococcus aureus* is the organism most commonly identified in *pyomyositis*. Other myopathies reported are nemalin rod myopathy, myositis ossificans, and a necrotizing myositis.

Sjögren's Syndrome

A seronegative Sjögren's syndrome (keratoconjunctivitis sicca and xerostomia) described in AIDS tends to predominate in men and consists of significant parotid swelling and lymphadenopathy in the absence of arthritis.

Vasculitis

Several types of vasculitis can be seen in HIV disease, including a systemic necrotizing vasculitis of the polyarteritis nodosa type, peripheral neuropathy, mononeuritis multiplex, and hypersensitivity vasculitis.

Autoimmune Manifestations

There is a striking similarity between HIV-related disease and many of the autoimmune diseases. Clinical findings are often identical and autoantibody production is common.

FUNGAL ARTHRITIS

Fungal arthritis is increasing in incidence and affects the compromised host. A self-limited hypersensitivity reaction with polyarthritis may accompany initial pulmonary infection (erythema nodosum in histoplasmosis, acute valley fever in coccidioidomycosis) or the fungus may directly infect the joint. Fungal infections typically present as a chronic monoarticular arthritis, with an indolent course that results in a delay in diagnosis.

Coccidioides immitis is found in the soil of the desert areas of the southwestern United States, northern Mexico, and Central and South America. Fever is common and arthritis affects the weight-bearing joints, especially the knees. The organism can be seen in synovial fluid. Serologic testing of serum and synovial fluid by complement fixation may be helpful in establishing the diagnosis.

Blastomyces dermatitidis is endemic in the midwestern and southeastern United States and affects outdoor workers who have contact with the soil. It is one of the few fungal infections that presents with an acute monoarthritis, affecting the knee, ankle, elbow, or wrist. Organisms are easily seen in joint fluid.

Arthritis is rare in *sporotrichosis*, occurring after cutaneous inoculation. It is an occupational disease seen in people working in agricultural jobs with exposure to soil or plants. Arthritis affects the knees, wrists, and hands and may mimic rheumatoid arthritis. Systemic symptoms are present in the polyarticular form but absent with monoarthritis. Synovial fluid is inflammatory and cultures are frequently negative.

Monoarticular arthritis occurs after introduction of atypical species of *Candida* (*C. parapsilosis*, *C. guilliermondii*) into the knee during aspiration and articular injection, or by contamination of the knee or hip at surgery with *C. albicans*, *C. tropicalis*, or *C. parapsilosis*. A monoarticular or polyarticular arthritis results from hematogenous spread in immunocompromised patients. Intravenous drug abusers have involvement of the knee or fibrocartilaginous joints with *C. albicans*. Brown heroin use is associated with a triad of ocular and cutaneous lesions and arthritis of the costochondral joints.

OPTIMAL MANAGEMENT

Intravenous amphotericin B is the drug of choice in critically ill patients. Flucytosine is a useful adjunct in recalcitrant *Candida* and *Cryptococcus* infections. Fluconazole can be used as first-line therapy in *Candida* or *Cryptococcus* arthritis and itraconazole in *Blastomyces* and *Aspergillus* arthritis. Either drug can be used for maintenance therapy following amphotericin. Treatment should continue for at least 6 weeks, combined with surgical synovectomy and debridement.

CHAPTER 183: LYME DISEASE

LEONARD H. SIGAL

- Definition
- Incidence and Epidemiology
- Etiology
- Pathogenesis
- Clinical Findings
- Laboratory Findings
- Optimal Management: Treatment and Prevention

DEFINITION

Lyme disease (LD) is a multisystem inflammatory condition caused by spirochetes, known collectively as *Borrelia burgdorferi*, that are spread by *Ixodes* ticks. It was first described in studies of an outbreak of presumed juvenile rheumatoid arthritis in Connecticut, which led to the identification of Lyme arthritis. As nonarticular features were identified, the full spectrum of LD became clear.

Early localized LD occurs days to weeks after the tick bite and is characterized by a distinctive rash known as *erythema migrans* at the site of the bite and associated symptoms. Early disseminated LD develops within a similar period as a result of spirochetemia and can include multiple lesions of erythema migrans, cardiac disease, and neurologic problems. Late LD occurs weeks to months after infection and features the often insidious development of arthritis or neurologic problems. Patients do not always progress smoothly through each phase of LD. Some have erythema migrans and no further disease, whereas others never have the rash and the first manifestations of LD may be late features. In addition, rarely in the United States but more commonly in Europe, two other cutaneous features of LD are observed: *lymphadenosis benigna cutis* (*lymphocytoma*) in early disseminated LD and *acrodermatitis chronica atrophicans* in late LD.

The U.S. Centers for Disease Control and Prevention (CDC) has developed an epidemiologic definition of LD ([Table 183.1](#)). Because the definition is epidemiologic, it should not be used in clinical practice as a set of diagnostic criteria; however, it is useful insofar as LD must be reported to the CDC. Much has been made about how difficult it is to diagnose LD. However, a complete history and physical examination, proper use of testing, an unbiased synthesis of the information obtained, and familiarity with LD allow easy diagnosis and treatment.

Presence of erythema migrans
EM

Cases with at least one late manifestation and laboratory confirmation of infection. The late manifestations include any of the following unless an alternate explanation is first found:

1. Acute-onset erythema migrans (EM) consisting of a single, expanding, erythematous annular lesion with a central clearing, surrounded by a double red border, and associated with symptoms such as fever, malaise, headache, or myalgia.
2. Acute-onset EM consisting of a single, expanding, erythematous annular lesion with a central clearing, surrounded by a double red border, and associated with symptoms such as fever, malaise, headache, or myalgia.
3. Acute-onset EM consisting of a single, expanding, erythematous annular lesion with a central clearing, surrounded by a double red border, and associated with symptoms such as fever, malaise, headache, or myalgia.

CDC, U.S. Centers for Disease Control and Prevention; CDC, nonproprietary fund.

TABLE 183.1. CDC CRITERIA FOR LYME DISEASE

INCIDENCE AND EPIDEMIOLOGY

Lyme disease is spread by the bite of infected *Ixodes* ticks (*I. scapularis* in the eastern and north central United States, *I. pacificus* in the western United States, *I. ricinus* in Europe, and *I. persulcatus* in Asia). The areas where LD is found are those where ixodid ticks abound. About 90% of U.S. cases occur in the following nine states: Massachusetts, Connecticut, Rhode Island, New York, New Jersey, Pennsylvania, Minnesota, Wisconsin, and California. Within each state, there are hot spots of disease (i.e., the incidence is not uniform across the state). In New Jersey in 1991, the incidence of LD in urban Hudson County was 0.36 per 100,000 population; in suburban/rural Ocean, Atlantic, Somerset, and Hunterdon counties, the incidence was 30 to 50 per 100,000. Obtaining a travel history from the patient is crucial; even if a patient does not reside in an endemic area, he or she may have vacationed in one.

Ixodid tick larvae hatch from the egg mass in the summer and then search for a blood meal, usually from mice (or small mammals or birds). About 99% of ticks are born uninfected, even in hyperendemic areas; the ticks acquire the organisms during their first blood meal from spirochetemic (but healthy) mice. Having fed, the ticks molt and reemerge in the spring as nymphs, which then seek a blood meal, usually from the same type of host that fed the larvae. The vast majority of LD is spread by infected nymphs, which explains the seasonal variation in incidence: nymphs are looking for a blood meal in the late spring, summer, and early fall: “LD season.” Once fed, the ticks drop off the hosts and molt to adults in the fall. Adults seek a blood meal in the late fall, winter, and even spring, and their preferred hosts are white-tailed deer, although other mammals are used. LD can be acquired from adult ticks, but they are more easily seen and felt, and more protective clothing is worn in the fall and winter than in the summer. Females lay their eggs in the leaf clutter on the forest floor and the 2-year life cycle repeats itself. Ticks seeking a meal reside on the undersides of low-lying shrubs or grass; ticks do not jump, hop, fly, or descend from trees. Ticks sense a warm body exhaling carbon dioxide and latch on if it brushes against them. Therefore, when walking along a deer path, the main area of risk is the foliage at the edges; an individual should walk in the center of the path.

In unfed ticks, *B. burgdorferi* resides on the midgut wall. Shortly after the blood meal, which occurs 24 hours or more after attachment, the organism multiplies and disseminates, eventually reaching the salivary glands. The tick excretes excess water from the blood meal back into the host throughout its meal, and this is how the organism invades the host. It takes 48 hours or more after tick attachment for *B. burgdorferi* to spread to the unwitting host of the tick. This helps explain why so few individuals contract LD after known tick bites. A study suggests that in an area where 40% of adult ixodid ticks carry *B. burgdorferi*, LD develops in only about 1% of individuals who were bitten.

Lyme disease may be obtained on vacation, on the job, or near home. Homes with properties sculpted from surrounding forest provide a perfect “eco-niche” of low-lying shrubs and grasses for white-footed field mice. Old stone fences can serve as “apartment complexes” for mice. Mice are often attracted to the seeds spilled from bird feeders kept near suburban homes. Deer wandering across the property also suggest an increased risk in that environment. Ticks do not survive on open lawns and fields for long because they desiccate rapidly; ticks prefer the higher humidity of the leaf clutter at the forest floor.

ETIOLOGY

Lyme disease is caused by three closely related genospecies, all of which are included in the term *B. burgdorferi sensu lato* (“in the general sense”). *Borrelia burgdorferi sensu stricto* (“in the strict sense”) is the cause of LD in the United States and also is found in Europe and Asia. *Borrelia afzeli* and *B. garinii* cause LD in Europe and Asia. Lyme disease is found across Europe and Asia, including Japan, Korea, and China. It has been suggested that the differences between European and American LD (a greater incidence of arthritis and multiple erythema migrans lesions and a lower incidence of neurologic disease in the United States) may be the result of differences in the organisms, as well as differences in the immunogenetics of the human victims.

Borrelia burgdorferi is a microaerophilic, fastidious organism that grows in Barbour–Stoener–Kelly medium. A paucity of organisms in tissue makes histologic or immunologic staining a low-yield diagnostic test. Likewise, low yields in culturing the organism make this a poor diagnostic tool.

PATHOGENESIS

The way in which *B. burgdorferi* causes LD and may cause disease of long duration is a matter of debate. The organism does not make exotoxins or directly cause local tissue damage. There is evidence to suggest that the organism can bind and activate the host's proteolytic enzymes, which may facilitate tissue invasion and dissemination. *Borrelia burgdorferi* has been identified in erythema migrans lesions, myocardium, spinal fluid, and synovial fluid by culture, polymerase chain reaction, and histologic examination. Local inflammation at these sites presumably results from the immune response to the organism. It is likely that persistence of dead or effete organisms can cause ongoing inflammation. A mechanism much like that seen in the antigen-induced model of rheumatoid arthritis may be at work. In this model, persistence and resistance to proteolytic degradation of an antigen causes the antigen to be a focus of inflammation; as long as the antigen persists, the inflammation persists, and every time there is a "boost" in the systemic immune response to that antigen, there is a flare-up of arthritis. Persistence of antigen also may result in ongoing production of cytokines, which may cause local and nonspecific systemic symptoms. Vasculitis has been implicated in some cases of peripheral neuropathy. Finally, there is in vitro evidence implicating molecular mimicry as a mechanism in neurologic and articular LD. The organism's flagellin contains an epitope that cross-reacts with a human axonal protein, and a monoclonal antibody to this epitope can modify neural cell tumor lines in vitro. Chronic, antibiotic-resistant arthritis is linked to the presence of HLA-DR-B*0401 and the emergence of measurable anti-outer surface protein A (OspA) antibody, which suggested that autoimmunity might play a role in the immunopathogenesis of Lyme arthritis. Recent studies have shown that an epitope in OspA of *B. burgdorferi* cross-reacts with one on human lymphocyte function-associated protein (LFA-1); how this cross-reactivity can be implicated in the pathogenesis of chronic arthritis is not yet clear.

CLINICAL FINDINGS

EARLY LOCALIZED DISEASE

Early localized disease includes erythema migrans and associated findings. Erythema migrans occurs in 50% to 90% of patients, usually less than 1 month after the tick bite. About 30% of patients recall having been bitten by a tick. In adults erythema migrans is typically found in or near the axilla or inguina; in children, the neck and hairline are common sites of erythema migrans. The lesion is usually asymptomatic, but it may burn or itch.

Erythema migrans expands over the course of a few days, often with central clearing, although it can be uniformly red or have a more complex "bull's eye" appearance (Figure 183.1); the bull's-eye lesion is classic for LD but constitutes less than 30% of all erythema migrans lesions. About 10% of all patients with erythema migrans have multiple lesions, as a result of spirochetemia; satellite lesions are less likely to have central clearing. Early localized disease may be associated with nonspecific complaints resembling a viral syndrome. In the absence of erythema migrans, there is nothing about this syndrome that is diagnostic of LD. Further details of the syndrome are listed in Table 183.2.

Manifestation	Frequency	Notes
Erythema migrans	50%–90%	Usually less than 1 month after tick bite
Joint pain	Common	Often migratory
Headache	Common	
Malaise	Common	
Neurologic symptoms	10%	Includes meningitis, radiculoneuropathy, etc.
Carditis	8%	Includes any degree of conduction system disease

TABLE 183.2. CLINICAL MANIFESTATIONS OF LYME DISEASE

EARLY DISSEMINATED DISEASE

Early disseminated disease (Table 183.2) develops days to months after the tick bite and can occur in the absence of any features of localized LD. Early disseminated LD can be the initial presentation of *B. burgdorferi* infection, with no antecedent erythema migrans or documented tick bite. Neurologic findings are seen in about 10% of untreated patients and include lymphocytic meningitis; cranial nerve palsy, especially of cranial nerve VII (which may be bilateral); and radiculoneuropathy. The neurologic features of early disseminated LD usually resolve spontaneously, although there are rare cases of irreversible neurologic damage, e.g., persisting seventh nerve palsy, focal encephalopathy with seizure disorder, persisting weakness due to radiculoneuropathy. Therapy is directed at preventing progression to later features of LD or hastening their resolution. About 8% of patients with untreated LD (Table 183.2) have carditis that can include any degree (or combination of

degrees) of heart block and mild myopericarditis (including subclinical congestive heart failure detected by reversible echocardiographic and/or radio-graphic changes). *Borrelia burgdorferi* has been implicated in chronic congestive cardiomyopathy in Europe, but this association has not been substantiated in the American experience. Cardiac features of LD usually begin to resolve during or even before the initiation of antibiotic therapy, although there have been a few cases of permanent heart block requiring insertion of a pacemaker.

LATE DISEASE

Late disease occurs months to years after the onset of infection and may not be preceded by other features of LD. About 80% of patients with untreated LD will develop musculoskeletal symptoms, including arthralgia (20%), intermittent episodes of arthritis (50%), and chronic monarthritis (10%), usually of the knee. Patients with chronic monarthritis usually complain more about knee stiffness than pain; they often develop very large effusions that reaccumulate quickly after aspiration. Many patients with arthritis had previous arthralgia. Oral antibiotic therapy is usually effective for the arthritis, with intravenous antibiotics reserved for refractory cases; synovectomy and disease-modifying treatment (e.g., hydroxychloroquine) occasionally are necessary. The other feature of late LD is tertiary neuroborreliosis, a term that refers to tertiary neurosyphilis, to which it bears some resemblance. Encephalopathy, neurocognitive dysfunction, and peripheral neuropathy are characteristic. The two neurologic stages of LD are compared in [Table 183.3](#).

	Early Disseminated Neuroborreliosis	Tertiary Neuroborreliosis
Time since EM manifestations	Weeks to months	Months to years
Associated manifestations	Facial palsy Peripheral nerve palsies Meningitis Meningoencephalitis	Encephalopathy Myelitis Peripheral neuropathy
Associated manifestations	EM Cardiac disease Lymphocytic pleocytosis	Lyme arthritis Intrathecal antibody production
Cerebrospinal fluid	Intrathecal antibody production May be positive, occasionally IgM	Routinely seropositive
Serologic testing		

EM, erythema migrans.

TABLE 183.3. CONTRASTS BETWEEN EARLY DISSEMINATED AND TERTIARY NEUROBORRELIOSIS

Other medical problems have been ascribed to LD, often on the basis of only a positive blood test result; such “proof” is not enough to ensure causality. Some less well established features of LD include ophthalmologic findings (inflammation of all eye structures has been described), liver dysfunction (mild hepatitis in early LD), splenitis, and myositis. Established cutaneous features of *B. burgdorferi* infection, more common in Europe than in the United States, are lymphocytoma and acrodermatitis chronica atrophicans.

Nonspecific complaints (e.g., headache, fatigue, arthralgia) may persist after the treatment of LD, often lingering for months with slow, spontaneous resolution. In the absence of objective evidence of LD, there is no justification for antibiotic therapy in such patients. Fibromyalgia syndrome is common after LD. The aches of fibromyalgia should not be mistaken for Lyme arthritis, and fatigue and forgetfulness should not be misdiagnosed as central nervous system LD. There is an ongoing controversy in regard to “chronic LD.” Lack of response to therapy can occur, although there are no isolates of *B. burgdorferi* shown to be resistant to the standard antibiotics used for LD. Cases of refractory LD are uncommon and should prompt a search for objective evidence of inflammation and/or tissue dysfunction in order to document damage of true ongoing infection. The most common cause for lack of response to therapy is initial misdiagnosis, i.e., the patient never had LD in the first place! Competent clinicians should search assiduously for alternate explanations for such patients' complaints.

LABORATORY FINDINGS

The widely available immunologic tests used in LD are the enzyme-linked immunosorbent assay (ELISA) and the Western blot, but neither should be referred to as a Lyme disease test; they are actually measurements of anti-*B. burgdorferi* antibodies. The diagnosis of LD should be made on clinical grounds (objective signs of inflammation and/or tissue dysfunction), with testing used only for confirmation. Thus, they are more properly used as seroconfirmatory tests rather than serodiagnostic tests. False-positive ELISA results can occur in other spirochetal diseases (e.g., syphilis, other borrelioses, gingivitis); in rheumatologic diseases (e.g., rheumatoid arthritis); and in other infections (e.g., endocarditis, Epstein-Barr virus). Specific antibodies made to other organisms (e.g., the flagellin of *Escherichia coli*) also may bind the *B. burgdorferi* flagellin, so that antibodies binding to *B. burgdorferi* in ELISA do not necessarily indicate prior infection. All positive and equivocal ELISA results must be corroborated by Western blot. ELISA results may not become positive for 6 to 8 weeks, although seroconversion may become apparent within 2 weeks; in general the more sensitive Western blot can detect seroconversion earlier than ELISA. ELISA and Western blot may never become positive if the patient receives antibiotic therapy early in the course of LD, even if the total dose received is inadequate to cure the infection. There is no role for follow-up testing of asymptomatic patients because antibody levels (even IgM) may stay elevated for years. There may be a transient rise in antibody levels following the treatment of early LD, presumably representing the momentum of the immune response; with resolution of the infection the antibody levels will either fall or stabilize.

In patients with LD, a further rise in ELISA level or an increase in the number of bands in the Western blot test in the presence of lingering complaints may indicate persistent LD. The finding of higher antibody levels in inflammatory (e.g., spinal, synovial) fluids relative to serum is definitive evidence that the neurologic or joint disease is caused by *B. burgdorferi* ([Fig. 183.2](#)). Modifications of the criteria developed by Dressler and Steere for the interpretation of Western blot tests ([Table 183.4](#)) are now generally accepted. Studies suggest that the polymerase chain reaction, which identifies the nucleic acids of the organism, may be useful in the diagnosis of LD, but this has not been proven in clinical practice. There is no established role for measurement of borrelial antigens in the urine. Neuropsychological testing, electrophysiologic testing (cardiac and neurologic), brain magnetic resonance imaging, and single photon emission computed tomography (SPECT) can be helpful in documenting objective abnormalities but are not specific markers of damage caused by *B. burgdorferi*; there is no pattern in any of these tests unique for or diagnostic of LD.

Disease	IsoType Tested	Bands To Be Considered
First few weeks of infection	IgM	Two of the eight following: 18, 21, 28, 31, 41, 45, 58, 93
		OR
After first weeks of infection	IgG	Two of the three following: ospC (23), 39, 41* Five of the ten following: 18, 21, 28, 31, 35, 41, 45, 58, 66, 93

Alternate criteria for IgM reactivity proposed by a Centers for Disease Control and Prevention conference. Other points noted at that conference were the need for standardization of antigen preparation and techniques used.
Adapted from Dressler E, Whalen JA, Reinhardt BK, et al. Western blotting in the serodiagnosis of Lyme disease. *J Infect Dis* 1992;165:292.

TABLE 183.4. CRITERIA FOR POSITIVE WESTERN BLOT (IMMUNOBLOT) ANALYSIS IN THE SEROLOGIC CONFIRMATION OF INFECTION WITH *BORRELIA BURGENDORFERI* (LYME DISEASE)

OPTIMAL MANAGEMENT: TREATMENT AND PREVENTION

Antibiotics are the appropriate therapy for LD. Timely treatment prevents progression to later disease stages, although it may not decrease the duration or severity of many of the symptoms of early LD. Suggested drug regimens for each feature of LD are given in [Table 183.5](#). There is no evidence that oral therapy in follow-up of intravenous therapy, more prolonged or higher dose treatment, use of combinations of different antibiotics, or any other changes in these regimens are helpful. Five

percent to 10% of patients with early LD have a Jarisch–Herxheimer reaction within the first days of therapy (a worsening of many of the signs and symptoms of LD). This usually lasts for less than a day and has never been reported as fatal in LD; there is no documentation of recurrent “Herxheimer-like reactions” and such reports must be investigated on a case-by-case basis. Pregnant patients with LD should be treated as appropriate for the features of the disease, although some clinicians recommend the use of parenteral therapy for all pregnant patients; there is no proof that this practice provides a better outcome for mother or fetus. There have been adverse outcomes reported in cases of pregnancy complicated by LD, but there is no firm proof that in utero infection with *B. burgdorferi* occurs or that it causes congenital anomalies or prematurity. Lack of response to antibiotic therapy should suggest the possibility that the current problems are not due to LD: either the initial diagnosis was in error or the LD has been successfully treated and the patient either has a “post-LD syndrome” (e.g., fibromyalgia) or another medical problem totally unrelated to *B. burgdorferi*. Because studies suggest that the risk of contracting LD from a known tick bite is small, prophylactic therapy is not recommended. A human outer surface A protein vaccine has been approved for use in adults. It may be a useful adjunct in the prevention of LD, but persons at risk for LD must take personal precautions (e.g., tick checks after time spent in an endemic area). In many LD-endemic areas, coinfection with *Babesia microti* or the human granulocytic *Ehrlichia* has been documented. Of course, neither of these *I. scapularis*-borne infections is prevented by the LD vaccine.

Oral Therapy for Early Localized Lyme Disease		
Amoxicillin	500 mg qid	2-4 wk ¹
Doxycycline	100 mg bid	2-4 wk ¹
Cefuroxime	500 mg bid	2-4 wk ¹
Penicillin V	250 mg qid	2-4 wk ¹
Clarithromycin	500 mg bid	2-4 wk ¹
Trimethoprim-sulfamethoxazole	160/800 mg bid	2-4 wk ¹
Intravenous Therapy for Early Disseminated and Late (or Chronic) Lyme Disease		
Ceftriaxone	2 g qd	2-4 wk
Cefotaxime	2 g qd	2-4 wk
Penicillin G	18-24 million units qd	2-4 wk
Clarithromycin	500 mg bid	2-4 wk
Trimethoprim-sulfamethoxazole	160/800 mg bid	2-4 wk
Clarithromycin	500 mg bid	2-4 wk
Penicillin G	18-24 million units qd	2-4 wk
Penicillin G	18-24 million units qd	2-4 wk

1. This chart is intended as a guideline only. Therapeutic decisions should be based on the clinical situation and the patient's response to therapy. The use of oral therapy for early Lyme disease should be based on the patient's clinical response to therapy. The use of oral therapy for late Lyme disease should be based on the patient's clinical response to therapy. The use of oral therapy for chronic Lyme disease should be based on the patient's clinical response to therapy. The use of oral therapy for late Lyme disease should be based on the patient's clinical response to therapy. The use of oral therapy for chronic Lyme disease should be based on the patient's clinical response to therapy.

CHAPTER 184: INFILTRATIVE, NEOPLASTIC, AND ENDOCRINOLOGIC CAUSES OF MUSCULOSKELETAL COMPLAINTS

JUAN J. CANOSO

[Infiltrative Conditions](#)
[Neoplastic and Related Conditions](#)
[Primary Tumors in Joints](#)
[Endocrinologic Causes of Musculoskeletal Complaints](#)

Many illnesses that originate in tissues outside the joint affect articular structures or simulate arthritis at some time in the course of the disease. Occasionally, these musculoskeletal manifestations provide the physician with diagnostic clues.

INFILTRATIVE CONDITIONS

SARCOIDOSIS

Rheumatic manifestations of sarcoidosis include arthropathy, myopathy, and bone lesions ([Table 184.1](#)). Sarcoid arthropathy can be acute or chronic. Acute cases, which are the most common, are characterized by abrupt, bilateral, inflammatory lower leg edema with painful limitation of ankle and subtalar motion. Often there is a periartthritis involving tissues around the joint without true synovial involvement. Erythema nodosum is common in these patients. Joint fluid analysis and synovial biopsy are nonspecific. Bilateral hilar adenopathy shown by chest radiography or, when this is negative, computed tomography (CT) confirms the diagnosis of sarcoidosis. When doubt exists, transbronchial, lymph node, or liver biopsy can be used to exclude other disease processes. (Systemic sarcoid is discussed in [Chapter 373](#).) Nonsteroidal anti-inflammatory drugs usually are effective in treatment. Colchicine occasionally has nonspecific beneficial effects.

Acute
Ankle arthritis and periartthritis
Erythema nodosum (bilateral hilar adenopathies on chest radiographs)
Chronic
Indolent arthritis and tenosynovitis
Skin lesions
Bone lesions
Myositis, focal subclinical or nodular (fibrosis and/or adenopathy on chest radiographs)

TABLE 184.1. RHEUMATIC MANIFESTATIONS OF SARCOIDOSIS

Episodic, or indolent, sarcoid arthritis is less common, occurring in patients with chronic pulmonary interstitial disease. It often is associated with skin and bone lesions, and assays of synovial biopsy specimens often are positive. Clinical sarcoid myopathy is rare in patients with chronic pulmonary interstitial disease. However, noncaseating granulomas are found on random muscle biopsy in more than half of these patients. Proximal muscle weakness resembling polymyositis and palpable intramuscular nodules with little change in strength are unusual manifestations of chronic sarcoidosis. In bone sarcoidosis, expansion of intraosseous granulomas leads to pain and fusiform enlargement of the digits. Typical radiographic findings consist of focal cystic rarefaction and coarse trabeculation in the bones of the hands. Other bones rarely are affected. The treatment of chronic sarcoidosis is described in [Chapter 373](#).

CROHN'S DISEASE

Synovium, muscle, bone, and skin granulomas all can occur in patients with Crohn's disease. Pathologically, the lesions resemble sarcoidosis; extraintestinal granulomatous involvement is limited in Crohn's disease, however, and transmural bowel inflammation is not a feature of sarcoidosis.

HEMOCHROMATOSIS

An arthropathy that looks like rheumatoid arthritis but feels like osteoarthritis is seen in about half of all patients with hemochromatosis. Pain on motion is severe but morning stiffness is minimal. Synovial proliferation is missing, although knobby bone enlargement at joint margins can be palpated directly under the skin. Pathologic changes include massive hemosiderin deposits in the synovial lining, cartilage loss, and osteophytosis. Calcium pyrophosphate dihydrate (CPPD) and basic calcium phosphate crystals often are present in cartilage. Radiographic findings are consistent with a diagnosis of osteoarthritis; lesions at the metacarpophalangeal joint of the index and middle fingers, wrists, and knees are particularly prominent. Chondrocalcinosis is present in about 20% of patients. The arthropathy of hemochromatosis can occur with few other symptoms of the disease. Treatment of the excess iron stores has little effect on the arthropathy.

AMYLOIDOSIS

Amyloid arthropathy resulting from synovial and capsular deposits of light-chain amyloid is an uncommon complication of multiple myeloma and nonmyelomatous plasma cell dyscrasias (see [Chapter 235](#)). Amyloid arthropathy resembles rheumatoid arthritis, but the soft-tissue swellings observed are rubbery and more firm than is the rheumatoid synovium. Amyloidosis is suggested further by manifestations such as macroglossia, bilateral carpal tunnel syndrome, cardiomyopathy, prominence of the shoulders ("shoulder pads" sign), osteolytic masses (amyloidomas) at single or multiple bone sites, and a negative rheumatoid factor in serum. A monoclonal spike usually is present on serum or urine electrophoresis. The diagnosis is confirmed by the presence of amyloid in abdominal fat pad, rectal, synovial, or other tissue biopsy specimens.

In patients undergoing hemodialysis and peritoneal dialysis, synovial and bone amyloid deposits often lead to carpal tunnel syndrome, tenosynovitis, painful limitation of the shoulders, and bone cyst formation. The constituent of this amyloid (AH) is β_2 -microglobulin, a serum protein that normally is excreted by the kidney. Because this protein is poorly filtered out by cellulosic membranes, high plasma levels occur in patients receiving hemodialysis. Visceral deposition in AH amyloidosis is minimal, and abdominal fat biopsies usually are negative.

NEOPLASTIC AND RELATED CONDITIONS

Musculoskeletal complaints are common in patients with malignancies. Although these complaints may result from tumor extension, metastasis, or nonmetastatic manifestations of malignant disease, other possible causes of arthritis are more probable and should not be overlooked.

The diagnosis of malignancy usually precedes rheumatic complaints, but musculoskeletal manifestations can appear first. For example, in one patient with recent-onset polyarthritides, digital clubbing prompted a chest radiograph that revealed lung cancer. The following atypical manifestations suggest the possibility of underlying malignant disease: excessive nonhemorrhagic anemia (hematocrit less than 20%) or thrombocytopenia in a patient with juvenile rheumatoid arthritis (acute leukemia); bone lysis in a patient with monarthritides (metastatic disease); a Baker's cyst that remains hard when the knee is flexed (sarcoma); tender bones in a patient with polymyalgia rheumatica (metastases, multiple myeloma); thrombocytosis in a patient with dermatomyositis (cancer); thrombocytosis in a patient with lupus (ovarian tumor); acute Dupuytren's contractures, hand swelling, and joint restrictions (ovarian, tubal, lung carcinoma); and digital vasculitis with gangrene in a patient

without ergot ingestion, evidence of cryoglobulins, or connective tissue disease.

METASTATIC ARTHRITIS

Carcinomatous joint involvement is relatively rare, given the frequency of solid tumors in the general population. There is evidence that articular cartilage inhibits angiogenesis and interferes with the articular penetration of bone metastases. Metastatic arthritis usually is monoarticular and subacute, and tends to involve the knee in patients with known malignant disease.

LYMPHOMA

Bone involvement in lymphoma can be primary (5% of all non-Hodgkin's lymphomas), or it can develop in the course of disseminated disease. In some patients, bone deposits lead to pain and nonspecific joint effusion. Lymphomatous infiltration of the synovium is rare.

LEUKEMIC SYNOVITIS

Leukemic synovitis occurs predominantly in acute myelogenous leukemia and in the blastemic phase of chronic myelogenous leukemia. Synovial involvement also has been reported in T-cell leukemia. Clinically, leukemic synovitis can be distal and symmetrical, or it can be asymmetrical, involving large joints. Bone tenderness often is present. In synovial fluid, in contrast to the peripheral blood, mature polymorphonuclear cells predominate. Leukemic cell infiltration is found inconsistently on synovial biopsy specimens. The process is rapidly reversible with successful chemotherapy.

MALIGNANT SPINAL DISEASE

Nocturnal predominance and spinal point tenderness characterize the back pain of metastatic disease, multiple myeloma, lymphoma, primary (benign and malignant) tumors of the spine, spinal osteomyelitis, and osteoporotic fractures. Clinical differentiation of these lesions can prove difficult. The erythrocyte sedimentation rate is high in patients with malignant lesions and osteomyelitis, and normal (barring associated diseases) in those with benign tumors and osteoporotic fractures. Seen on radiographs, areas of bone lysis (or sclerosis) indicate malignancy, whereas disc narrowing and end-plate erosions are features of spinal osteomyelitis. Unfortunately, all of these changes appear late. Bone scans are useful in the initial assessment, except in patients with multiple myeloma. Magnetic resonance imaging (MRI) detects early disease, and the findings usually are diagnostic. More important, because it provides direct evidence of peridural or intradural involvement, MRI has become essential in the evaluation of back pain in patients with cancer. Bone needle biopsy may be required for culture or to establish cell type in malignant lesions of unknown origin.

HYPERTROPHIC OSTEOARTHROPATHY

Hypertrophic osteoarthropathy is a poorly understood arthropathy that complicates lung cancer, pulmonary metastases, intrathoracic lymphomas, pleural tumors, and mediastinal malignancies. Nonmalignant causes of hypertrophic osteoarthropathy include pulmonary granulomas, chronic lung abscesses, congenital heart diseases with right-to-left shunts, and subacute bacterial endocarditis. Hypertrophic osteoarthropathy occasionally results from a miscellany of extrathoracic conditions, and there also is a hereditary familial form. Characteristic manifestations of hypertrophic osteoarthropathy include digital clubbing, long-bone tenderness (particularly near joints), and arthritis affecting predominantly the knees and ankles. Leg edema and finger and toe paresthesia also occur. Synovial fluid findings include high viscosity, low leukocyte count (less than 800 cells per liter), and predominance of mononuclear cells. Periosteal new bone formation, a salient feature of the disease, usually is seen on radiography. Earlier lesions can be detected by bone scintigraphy. Pain in hypertrophic osteoarthropathy is well controlled by indomethacin. Complete, predictable resolution follows resection of the intrathoracic mass if present, or even from a thoracotomy alone.

PRIMARY TUMORS IN JOINTS

Persistent monoarticular swelling should suggest the possibility of a tumorous condition. The diagnostic challenge is to differentiate an articular swelling caused by synovial effusion or proliferation from an extra-articular mass that is cystic (bursa, ganglion, meniscal cyst), adipoid, vascular, or neoplastic. As an example, in the knee, joint effusions bulge medial, proximal, and lateral to the patella, and fluid can be freely displaced. In contrast, effusions in the prepatellar bursa occur superficial to the patella while the previously described areas remain flat. Localized swelling distal to the patella is investigated while the quadriceps is isometrically contracted; a tense patellar ligament allows the differentiation of subcutaneous bursitis from deep swelling caused by hypertrophy of the fat pad or deep infrapatellar bursitis. Swelling in the lateral aspect of the knee usually indicates a meniscal cyst; typically, the bulging is prominent when the joint is in partial flexion and decreases with further flexion or extension. Popliteal (Baker's) cysts occur in the medial third of the popliteal fossa in the cleft between the semimembranosus tendon and the medial head of the gastrocnemius.

Unlike other popliteal swellings, Baker's cysts soften with knee flexion (Foucher's sign). Masses that remain firm in flexion include sarcomas, ganglions, and popliteal artery lesions such as aneurysms and cystic degeneration of the vessel wall.

Relatively localized areas of thickening within a joint may represent pigmented villonodular synovitis (PVNS), synovial chondromatosis, or, less commonly, angiomas, lipomas, or fibromas; arthroscopy is the preferred method of diagnosis. Extra-articular masses can be evaluated by ultrasonography, CT, or MRI. Ultrasonography is confirmatory in Baker's cysts and assists in the diagnosis of popliteal artery lesions, in which flow can be detected by a Doppler effect. Solid masses are investigated best by MRI and, subsequently, biopsy.

PIGMENTED VILLONODULAR SYNOVITIS

Pigmented villonodular synovitis is a locally invasive process that can affect a joint, a deep bursa, or a tendon sheath. Polyarticular cases are rare and often associated with congenital malformations. The lesions can be nodular or diffuse; diffuse lesions have a tendency to invade bone. Histologically, both forms feature giant cells, macrophage aggregates, foam cells, and hemosiderin deposits.

Collagenase and stromelysin genes are expressed abundantly in lining cells and deep cellular infiltrates in diffuse PVNS. It is not known as to whether PVNS represents a benign neoplasm or a chronic infection. Clinically, nodular cases are characterized by intermittent joint swelling and locking, whereas diffuse cases behave as a chronic, often destructive monoarthritis. The erythrocyte sedimentation rate is normal. Synovial fluid is hemorrhagic or chocolate-colored, with a variable leukocyte content. Although the diagnosis of PVNS has been facilitated by MRI, which shows thickened synovium with a peculiar intermediate signal, biopsy is required to rule out chronic infection. Treatment is by arthroscopic or open resection. Unfortunately, PVNS has a tendency to recur. Total joint arthroplasty is useful in recurrent disease and as a definitive form of treatment.

SYNOVIAL CHONDROMATOSIS

Multifocal, self-limited synovial cartilaginous metaplasia characterizes the monoarticular condition known as synovial chondromatosis. In rare cases, the site of the lesion is a bursa or a tendon sheath. The cartilaginous nodules may remain in the synovium or be released into the joint cavity. Ossification is common. Clinically, synovial chondromatosis features intermittent joint locking and noninflammatory synovial effusions. Multiple intra-articular bodies with stippled calcification on radiography are pathognomonic of the condition. The differential diagnosis includes osteoarthritis and chondrocalcinosis, both of which can lead to secondary osteochondromas. Most cases must be treated by synovectomy.

SYNOVIAL SARCOMA

Synovial sarcoma is a highly malignant tumor that rarely originates in joints; most cases appear in the soft tissues of the limbs, sometimes in the proximity of a joint. The adjective *synovial* denotes histologic similarities with the inner lining of joints. However, certain electron microscopic, immunohistologic, and chromosomal findings in synovial sarcoma are not present in normal or diseased synovium. The synovial histogenesis of this tumor is uncertain.

ENDOCRINOLOGIC CAUSES OF MUSCULOSKELETAL COMPLAINTS

Endocrine diseases often have prominent rheumatic manifestations ([Table 184.2](#)). Although musculoskeletal findings usually occur in the context of florid disease, they are the presenting features in some patients. When faced with patients with peripheral arthritis, fibromyalgia, aseptic necrosis of bone, crystal synovitis, disseminated idiopathic skeletal hyperostosis, back symptoms, myopathy, carpal tunnel syndrome, frozen shoulder, certain fibrotic syndromes, and neuropathic arthropathy, the clinician should include endocrine disease in the differential diagnosis.

TABLE 184.2. RHEUMATIC FEATURES OF ENDOCRINE DISORDERS

SERONEGATIVE “POLYARTHRITIS”

Articular symptoms resembling those of rheumatoid arthritis can occur in hypothyroidism and acromegaly. Certain clinical characteristics should suggest the diagnosis of endocrine disease. Myxedematous arthropathy occurs in the context of weight gain, cylindrical leg edema, and profound carpal tunnel syndrome. There may be little morning stiffness, and the erythrocyte sedimentation rate is normal or minimally elevated. Joint effusions in myxedema are extremely viscous and noninflammatory. Resolution of symptoms with thyroid replacement is slow and often incomplete.

Acromegalic arthropathy is characterized by joint pain and stiffness in the shoulders, elbows, knees, and back. Unexpectedly severe degenerative changes are found on radiographs, particularly in the shoulders. The height of the intervertebral discs and the width of the joint spaces (hyaline cartilage) in the hand may be increased, leading to a larger glove size. These changes in association with bilateral carpal tunnel syndrome strongly indicate acromegaly.

FIBROMYALGIC PAIN

A diffuse myalgic syndrome resembling fibromyalgia can occur in patients with hypothyroidism, hyperthyroidism, or chronic adrenal insufficiency, and in those undergoing rapid reduction of long-term glucocorticoid therapy. Glucocorticoid reduction fibromyalgia can be confused with enteropathic arthritis in patients with inflammatory bowel disease and interpreted as polymyalgia rheumatica in patients with temporal arteritis. The diagnosis is based on the presence of multiple tender points on physical examination, a normal erythrocyte sedimentation rate, and resolution of symptoms with resumption of a higher glucocorticoid dosage. Slower dosage reduction often circumvents this problem.

OSTEONECROSIS

The protracted use of glucocorticoids often results in osteonecrosis, a condition that is comparatively uncommon in patients with endogenous Cushing's syndrome. Important pathogenic factors include expansion of intramedullary fat, leading to tissue hypertension with hypoperfusion and subsequent tissue death. Disease susceptibility varies among patients; in systemic lupus erythematosus risk factors for osteonecrosis include high steroid doses, Cushing's syndrome, the presence of IgG anticardiolipin antibodies, and findings of thrombophlebitis or vasculitis. In retrospective studies, most patients with osteonecrosis received high, protracted daily dosages of oral glucocorticoids. The first symptomatic joint usually is the hip, and osteonecrosis should be suspected immediately when patients receiving long-term glucocorticoid therapy complain of hip pain. A high index of suspicion is required when the underlying condition features synovitis; hip pain that develops while the remaining joints are stable, improving, or in remission should prompt investigation. In early cases, radiographs are normal; the classic radiographic findings of osteonecrosis appear late. Bone scintigrams initially show hypoperfusion followed by increased uptake around the wedge of dead bone. Magnetic resonance imaging is extremely useful in the detection of early lesions. There is controversy regarding the treatment of early cases with core decompression biopsy. This procedure consists of drilling a tunnel through the trochanter into the femoral head to relieve osseous hypertension and promote epiphyseal revascularization. In advanced cases, collapse of the necrotic portion of the femoral head leads to secondary osteoarthritis, and arthroplasty eventually is required in most patients. In contrast, osteonecrosis of the shoulder is well tolerated.

CRYSTAL ARTHRITIS

Occasionally, patients with CPPD deposition disease are found to have hyperparathyroidism. Removal of the parathyroid adenoma does not affect the chondrocalcinosis and may be followed transiently by an increased frequency of pseudogout. Colchicine prophylaxis should be used in this setting.

DIFFUSE IDIOPATHIC SKELETAL HYPEROSTOSIS

About half of all patients with diffuse idiopathic skeletal hyperostosis (DISH) have non-insulin-dependent diabetes mellitus. The basic pathologic finding is ossification of paraspinal ligaments and tendons at the attachment sites. Little is known about the pathogenesis of this disorder. There is an absence of inflammation. In diabetes, DISH tends to occur more frequently in patients with dyslipidemia and hyperuricemia. Vitamin D-resistant rickets, fluorosis, and prolonged retinoid therapy for severe acne are associated with tendon and ligament ossification resembling DISH.

The usual form of DISH, occurring in about 10% of the elderly, is manifested by subclinical ossification of the anterior longitudinal ligament in the thoracic spine. More extensive cases feature prominent neck and lower back pain, spinal rigidity, and decreased joint motion closely resembling the findings in younger men with ankylosing spondylitis. Anterior cervical osteophytes may cause dysphagia. Cord compression may result from involvement of the posterior longitudinal ligament or from nonunion of a traumatic fracture across an ankylosed segment of the spine. The treatment of DISH includes analgesics and physical therapy; neck lesions may require surgery.

BACK PAIN AND OSTEOPENIA

Back pain based on compression fractures with osteopenia on radiographs is a prominent manifestation of endogenous and exogenous Cushing's syndrome and some cases of hyperthyroidism, hyperparathyroidism, and hypogonadism. The importance of measures to prevent steroid-induced osteoporosis cannot be overemphasized.

MYOPATHY

Hyperthyroidism and hypothyroidism can be attended by myopathic (proximal) weakness. In patients with hypothyroidism, myopathic weakness, elevation of creatine kinase levels, carpal tunnel syndrome, and arthralgia may suggest the erroneous diagnosis of polymyositis. Myopathy, sometimes profound, complicates endogenous Cushing's syndrome and long-term glucocorticoid therapy. In this setting, iliopsoas muscle weakness precedes diffuse myopathic weakness, and serum creatine kinase levels are normal. Resistive exercises, begun early on, are believed to be important in the prevention of steroid-induced myopathy. Finally, proximal weakness is common in acromegaly. Diabetes mellitus may result in muscle infarction, which usually affects the thigh and is manifested by focal swelling and tenderness. Patients are afebrile and regression occurs in weeks.

CARPAL TUNNEL SYNDROME

Carpal tunnel syndrome sometimes complicates diabetes, is commonly associated with late pregnancy, and is a classic finding in myxedema and active acromegaly (see [Chapter 185](#)).

FROZEN SHOULDER

Frozen shoulder is seen in diabetes, hyperthyroidism, and hypothyroidism (see [Chapter 185](#)).

FIBROTIC SYNDROMES

Diabetes results in a variety of fibrotic syndromes that include Dupuytren's contracture (fibrosis involving the palmar fascia), so-called trigger finger (fibrosis at the proximal flexor tendon sheath), frozen shoulder (capsular fibrosis), and a unique syndrome known as *cheirarthropathy*. Diabetic cheirarthropathy (palmar and digital fibrosis) correlates with microangiopathy and is characterized clinically by thickened, waxy skin and incomplete contact of the palms in the praying position.

NEUROPATHIC ARTHROPATHY

Neuropathic arthropathy, also known as a Charcot joint, is the mechanical failure of a joint in a patient whose sensory input is impaired. Charcot's joints develop in patients with peripheral neuropathy, such as in diabetes, leprosy, amyloidosis, and chronic renal failure; syringomyelia; tabes dorsalis; and congenital indifference to pain. The process initially may be painful, but the degree of pain falls short of the degree of anatomical distortion, which can be extreme. Neuropathic arthropathy is characterized by a lack of involuntary fixation that is the rule in severely damaged joints, a range of motion that is normal or increased, coarse bone-on-bone crepitation, and joint swelling that represents synovial effusion at first, and synovial, cartilage, and bone overgrowth late in the disease. Synovial fluid usually is hemorrhagic and noninflammatory; CPPD crystals have been found in some joints. As in other peripheral neuropathies, Charcot joints in patients with diabetic neuropathy involve the midfoot or the forefoot. Occasional cases involve the knee or the spine. Diabetic osteolysis, an aseptic destructive lesion of metatarsal heads, is another complication of the diabetic denervated foot. In syringomyelia, neuropathic arthropathy classically occurs in the shoulder. In tabes dorsalis, the knee and the spine are more likely to be involved. Because the treatment of Charcot joints is unsatisfactory, emphasis should be placed on prevention. Full attention should be paid to seemingly minor injuries in a hypoesthetic limb. In the foot, the principles developed for the treatment of patients with leprosy are applied: aggressive treatment of early ulcers and shoes designed to spread the strain of weight bearing equally over the foot. Braces are useful in the neuropathic knee and spine. Total joint replacement, initially considered ineffective, has produced favorable results in neuropathic knees.

CHAPTER 185: FIBROMYALGIA (FIBROSITIS), CHRONIC FATIGUE SYNDROME, BURSITIS, AND OTHER NONARTICULAR RHEUMATIC COMPLAINTS

JUAN J. CANOSO

[Fibromyalgia](#)
[Chronic Fatigue Syndrome](#)
[Bursitis](#)
[Other Nonarticular Rheumatic Complaints](#)

FIBROMYALGIA

A typical patient with fibromyalgia complains of chronic widespread pain, fatigue, and stiffness. She may have received diagnoses such as hypochondria, chronic fatigue syndrome, psychogenic rheumatism, or undetermined connective tissue disease. The condition may have been attributed to a local pain syndrome, such as Tietze's syndrome, costochondritis, tennis elbow, or trochanteric bursitis. Many surgical procedures may have been performed. The results of laboratory tests have been entirely normal. On direct questioning, she reports a sleep disturbance that involves repeated awakening and greater fatigue on rising in the morning than on retiring at night. She also may complain of depression, migraine, irritable bowel, temporomandibular joint pain, and orthostatic intolerance. The diagnosis of fibromyalgia is confirmed by a physical examination that reveals multiple symmetrical tender points ([Table 185.1](#)).

Lateral epicondyle (R & L): The tennis elbow site, actually 1–2 cm distal to the epicondyle
Trapezius (R & L): The midpoint of the upper trapezius in a somewhat firm portion of the muscle
Supraspinatus origin (R & L): Above the scapular line, near the medial border of the scapula
Occiput (R & L)
Low cervical (R & L): At the anterior aspect of the intertransverse ligaments, C4–5 or C5–6
Second costochondral junction (R & L): Close to the origin of the pectoralis major
Buttock (R & L): In the midportion of the outer quadrant of the buttock, in the anterior portion of the gluteus medius
Greater trochanter (R & L)
Knee (R & L): In the fat pad medial to the knee

^a Fibromyalgia criteria: widespread pain (axial plus upper and lower extremities plus left- and right-sided pain) in combination with tenderness at 11 or more of the 18 specified sites yielded a sensitivity of 86.4% and a specificity of 81.1% in a study of 293 patients with fibromyalgia and 265 control subjects.
R, right; L, left.
(From Wolfe F, Smythe HA, Yunus MM, et al. The American College of Rheumatology 1990 criteria for the classification of fibromyalgia. *Arthritis Rheum* 1990;33:1771, with permission.)

TABLE 185.1. SITES OF TENDERNESS IN FIBROMYALGIA^a

In contrast to normal tenderness, the tenderness of fibromyalgia is characterized by an exaggerated emotional response, withdrawal of the tender part, and worsening of pain after examination. Examination often reveals the presence of previously unknown tender areas. Fibromyalgia is believed to be a multifactorial neurophysiologic disturbance in which environmental or endogenous stress deteriorates the non-rapid eye movement sleep. This disturbed sleep results in perceptual (mainly pain) amplification, depression, and fatigue. These, in turn, lead to additional stress plus physical and cardiovascular deconditioning. Fibromyalgia may present alone or in association with conditions such as systemic lupus erythematosus, rheumatoid arthritis, osteoarthritis, hypothyroidism, metastatic cancer, AIDS, and Lyme disease. In addition, a transient fibromyalgic state is not uncommon during acute viral and bacterial illnesses, corticosteroid withdrawal, or alcohol and narcotic withdrawal. Fibromyalgia should be distinguished from myofascial pain, a regional pain condition in which pressure to a trigger point causes the pain to radiate to the entire painful area.

The treatment of fibromyalgia includes tricyclic medications, an exercise program, and measures to reduce stress. Low doses of amitriptyline (25 mg at night) or cyclobenzaprine (20 to 30 mg per day) tend to improve the sleep pattern; patients wake up with less fatigue and less pain. Tramadol may be used as an interval or adjunct medication. To further decrease pain and restore endurance, a structured aerobic exercise program including stretching and flexibility exercises is recommended. Relaxation techniques such as yoga are a helpful adjunct to the overall treatment program. Patients must understand that fibromyalgia is not a crippling disease and should be encouraged to move away from beliefs and behaviors that may be perpetuating symptoms and disability.

CHRONIC FATIGUE SYNDROME

Chronic fatigue syndrome (CFS) affects predominantly young women. The onset is abrupt, often in the aftermath of a viral-like illness. Profound fatigue, sore throat, tender adenopathy (by history rather than documented on examination), headache, general achiness, and an array of neurologic complaints ranging from mild memory impairment to sensory disturbances characterize the condition. Unrefreshing sleep and depression often are present. The 1994 Consensus Criteria for the Diagnosis of CFS are shown in [Table 185.2](#). The reported prevalence of chronic fatigue in the general population is 1% to 3%, whereas in general medical practices it may reach 10%. Medical conditions to be ruled out in patients complaining of chronic fatigue include anemia, chronic infection including HIV infection, liver disease, chronic adrenal insufficiency, hypothyroidism, and systemic lupus erythematosus. Physical examination often reveals fibromyalgic tenderness, which, if absent, may appear in subsequent visits at times of greater psychological distress. Laboratory investigation should include a complete blood count; an erythrocyte sedimentation rate; measurements of liver enzymes, thyroid-stimulating hormone, and antinuclear antibody; cortisol levels before and after adrenal stimulation in some cases; and, possibly, screening for HIV. A chest radiograph also should be obtained. In CFS, all test results should be normal. Chronic fatigue syndrome bears similarities to the neurasthenia of the nineteenth century, the obscure epidemic neuromyasthenia seen early this century, the postwar syndromes seen in Vietnam and Persian Gulf veterans, and today's fibromyalgia.

A. Clinically evaluated, unexplained, persisting, or relapsing fatigue that is of new or definite onset; is not the result of ongoing exertion; is not substantially alleviated by rest; and results in substantial reduction in previous levels of occupational, educational, social, or personal activities.
AND

B. Four or more of the following concurrent and persistent symptoms:

1. Impaired short-term memory or concentration
2. Sore throat
3. Tender cervical or axillary lymph nodes
4. Muscle pain
5. Multijoint pain without arthritis
6. Headaches of a new type, pattern, or severity
7. Unrefreshing sleep
8. Postexertional malaise lasting more than 24 h

Note: Chronic fatigue denotes self-reported, persistent, or relapsing fatigue lasting for 6 or more consecutive months; prolonged fatigue denotes self-reported persistent fatigue lasting for a month or longer.
(From Fukuda K, Straus SE, Hickie I, et al. Chronic fatigue syndrome: a comprehensive approach to its definition and study. *J Am Intern Med* 1994;121:953, with permission.)

TABLE 185.2. CHRONIC FATIGUE SYNDROME: DIAGNOSTIC CRITERIA

A critical review of published data would suggest that CFS and fibromyalgia basically describe the same entity: a cluster of fatigue, pain, depression, and dysautonomia that is probably caused by chronic stress and is clearly modulated by psychological distress. Internists, based on the analysis of patients who predominantly complain of fatigue, call it CFS. Rheumatologists, because they see patients who are in pain, call it fibromyalgia. Chronic fatigue syndrome and fibromyalgia are treated similarly, the mainstays being reassurance, tricyclic antidepressants, physical exercise, and stress management. Cognitive behavior therapy has been used in CFS with variable success. Low-dose hydrocortisone has been somewhat effective in short-term controlled trials, but subsequent hypoadrenalism,

plus unavoidable long-term side effects, outweigh any reported benefits of glucocorticoids in CFS. Acyclovir treatment has failed to improve patients' symptoms.

BURSITIS

Bursae are synovium-lined sacs located in the subcutaneous tissue (subcutaneous bursae) or between tendons, muscles, and bones (deep bursae) to promote tissue gliding.

SUBCUTANEOUS BURSITIS

The olecranon bursa and prepatellar bursa are the most common sites of bursitis in adults and children, respectively. Adventitious bursae, which are acquired sacs in areas of abnormal stress, such as prominent bunions or amputation stumps, also can be involved. Usual causes of subcutaneous bursitis include trauma, bacterial infection, gout, and rheumatoid arthritis. Most septic cases are caused by *Staphylococcus aureus* followed by *Streptococcus hemolyticus*; other agents, such as anaerobic bacteria, mycobacteria, fungi, and algae (*Prototheca*), rarely are involved. Most infections occur through the skin; hematogenous bursitis is rare. Bacteremia is uncommon, but toxic shock can occur.

Subcutaneous bursitis usually is manifested as a cystic lump. However, confusion arises when the inflammation is severe or bursal rupture occurs. Acute arthritis and bursitis can be differentiated on the basis of passive motion. In acute arthritis of the elbow or knee, the limb is held in partial flexion, and full passive extension or flexion is prevented by pain; in acute bursitis, however, passive extension is painless. Bursal rupture is characterized by massive forearm and hand edema, suggesting extensive cellulitis or axillary vein thrombosis. The correct diagnosis is indicated by fluctuation at the elbow tip and is confirmed by bursal aspiration.

The macroscopic appearance of bursal fluid can be deceiving; clear fluids with low leukocyte counts are common in septic bursitis and gout, and turbidity may result from cholesterol crystals. Routine analysis must include a cell count and differential, crystal search by polarizing microscopy, Gram stain, and cultures. Findings in the various types of bursitis are summarized in [Table 185.3](#).

	Leukocytes (per μ L)	Polymorphonuclear		Crystals	Culture
		Cells (%)			
Traumatic (n = 175)	200 (0-2000)	1 (0-90)		None	Negative
Septic (n = 57)	1250 (100-45,000)	94 (30-100)		None	Positive ^a
Gout (n = 25)	2375 (600-12,000)	40 (2-90)		MSI in all	Negative
Rheumatoid arthritis (n = 13)	2200 (200-25,000)	30 (2-90)		Cholesterol in 6	Negative

^a*Staphylococcus aureus* = 42, *Staphylococcus epidermidis* = 1, *Streptococcus* = 5
^bn, number of observations; MSI, monosodium urate crystals.
 (Modified from Cannon J. Bursal infections and fluid. In Cohen AS, ed. Laboratory diagnosis procedures in the rheumatic diseases. Third ed. Orlando: Grune & Stratton, 1983.)

TABLE 185.3. BURSAL FLUID FINDINGS IN SUBCUTANEOUS BURSITIS

Most cases of traumatic bursitis resolve spontaneously within 3 months if repetitive trauma is avoided. Refractory cases can be treated by glucocorticoid injection. Septic bursitis is treated with repeated bursal aspirations and systemic antibiotics, which are administered orally in routine cases involving the olecranon bursa. Intravenous antibiotics are used in patients with prepatellar bursitis, in weakened hosts (diabetes, alcoholism, AIDS, immunosuppressant therapy), and in patients with suspected bacteremia. A 10-day course usually is sufficient.

DEEP BURSITIS

The only clinically significant bursae are the subacromial, trochanteric, anserine, gastrocnemius-semimembranosus, and retrocalcaneal bursae. Subacromial bursitis (a misnomer for rotator cuff tendinitis) is diagnosed in patients with acute lateral shoulder pain featuring pain on resisted motion and a relatively normal passive motion. The injection of glucocorticoids produces prompt relief of symptoms; these agents should be administered skillfully and never abused. Alternatively, high doses of a nonsteroidal anti-inflammatory drug can be used. Ancillary measures include the use of a sling for 24 hours, pendular exercises, and abduction and rotation exercises, which are initiated promptly once pain is brought under control.

Trochanteric and anserine bursitis often represent tendinous strain rather than bursal inflammation. Trochanteric bursitis is characterized by lateral hip pain and greater trochanter tenderness, and pain prevents the patient from lying in bed on the affected side. This syndrome results from abnormal stresses generated by hip or knee disease, leg-length discrepancy, and scoliosis, among other conditions. Anserine bursitis is characterized by medial knee pain on walking up or down stairs. There is tenderness in the medial upper tibia corresponding to the pes anserinus insertion. This syndrome commonly results from knee osteoarthritis. Both trochanteric and anserine bursitis respond well to glucocorticoid infiltration; an attempt should be made to correct the primary abnormality of gait.

Baker's cysts occur when excessive fluid formation in knee processes leads to the distention of communicating gastrocnemius-semimembranosus bursae. Baker's cysts may present clinically in several ways: local pain; compression of the popliteal artery, the deep veins, and or the tibial nerve or its branches; or acute inflammation in the calf (pseudothrombophlebitis) from rupture of the cyst. Pseudothrombophlebitis is suggested by the presence of knee effusion, a history of knee pathology, knee swelling or pain just preceding the calf symptoms, or point tenderness between the gastrocnemius and the semimembranosus. Unruptured Baker's cysts can be palpated and the diagnosis confirmed by echography if necessary. In patients with a tender, swollen calf echo imaging is extremely useful to distinguish a ruptured Baker's cyst from thrombophlebitis. In the occasional patient both conditions are present. Heparin treatment instituted on the basis of an erroneous diagnosis of thrombophlebitis can result in massive calf hematoma in patients with ruptured Baker's cysts. Baker's cysts regress with the successful treatment of synovitis in the knee. Rupture of tense, tender cysts can be prevented with intra-articular glucocorticoids and splinting of the knee in partial flexion.

Retrocalcaneal bursitis, or inflammation of the bursa located between the calcaneus and the Achilles tendon, occurs commonly in the spondyloarthropathies, often in association with Achilles tendinitis and plantar fasciitis. The diagnosis can be made clinically on the basis of posterior heel pain plus medial and lateral swelling in the angle between the Achilles tendon and the calcaneus. Retrocalcaneal bursitis is treated with the general treatment of the underlying condition, a higher heel, and, in some cases, a walking cast.

OTHER NONARTICULAR RHEUMATIC COMPLAINTS

CARPAL TUNNEL SYNDROME

The tight boundaries of the carpal tunnel make the traversing median nerve vulnerable to compression. Compressive neuropathy of the median nerve at the carpal tunnel is characterized by nocturnal (then permanent) pain and paresthesia in the palmar aspect of the radial half of the hand. Shaking the hand relieves the symptoms and allows the patient to fall asleep again. Increased interstitial fluid explains the syndrome in pregnancy, myxedema, and vascular shunts, whereas tissue growth is the culprit in rheumatoid arthritis and other synovitides, repetitive trauma, amyloidosis, diabetes, acromegaly, leprosy, anomalous muscle, ganglions, and lipomas. Helpful in diagnosis are Tinel's sign (paresthesia produced or accentuated by light percussion of the median nerve at the wrist) and Phalen's sign (symptoms elicited or accentuated by maximal passive wrist flexion maintained for 1 minute). Electromyographic and nerve conduction studies are used in atypical cases and in the preoperative evaluation of patients with refractory disease.

The treatment of carpal tunnel syndrome consists of wrist splinting with additional measures that depend on the cause. Resting splints help because carpal tunnel pressures are lowest when the wrist is held in the neutral position. Glucocorticoid infiltration may be required. Resistant cases must be relieved by open or endoscopic surgery to prevent permanent nerve damage.

FROZEN SHOULDER

Frozen shoulder, also known as shoulder capsulitis or periarthritis, is characterized by deep pain in the lateral aspect of the upper arm, limitation of passive shoulder motion in all planes, absence of laboratory evidence of inflammation, and radiographic films showing normal findings or (late) osteopenia. Pathologically, there is capsular fibrosis and retraction; early cases may exhibit synovial inflammation. Frozen shoulder may be primary (idiopathic); may occur in the aftermath of stroke, myocardial infarction, or upper extremity cardiac catheterization; and may complicate diabetes and untreated thyroid disease. Primary cases, and those that follow stroke, myocardial infarction, and cardiac catheterization, usually are unilateral and have a regressive course.

Predominantly nocturnal pain and rapid loss of glenohumeral joint motion characterize the initial 4 to 8 weeks of disease. As nocturnal symptoms subside, pain on motion becomes the salient complaint; joint motion remains restricted, with painful end points. After several months, all pain ceases and motion improves gradually over 1 to 2 years. Frozen shoulder is treated with low-dose oral corticosteroids (e.g., prednisone, 10 mg per day) for 4 to 6 weeks or a single dose of intra-articular corticosteroids (e.g., triamcinolone hexacetonide, 40 mg) preferably administered under fluoroscopic control, and pendular exercises every 2 hours while awake until maximal improvement has been achieved. The diabetic frozen shoulder is less likely to undergo spontaneous resolution. Arthroscopic release surgery is usually effective in these and other unyielding cases.

STENOSING TENOSYNOVITIS

Stenosing tenosynovitis is a fibrotic constriction of the tendon sheath that interferes with the free gliding of the tendon within the sheath. In the digits, the lesion results in the familiar "trigger finger," which is characterized by snapping on finger action. When the abductor pollicis brevis sheath is involved in the lateral aspect of the wrist, the condition is known as de Quervain's syndrome. Overuse of the hand and diabetes mellitus are important risk factors in the development of stenosing tenosynovitis. Multicentric cases, which should be differentiated from rheumatoid tenosynovitis, may be primary or may complicate diabetes, acromegaly, ochronosis, and amyloidosis. Glucocorticoid infiltrations are highly effective in stenosing tenosynovitis.

DUPUYTREN'S CONTRACTURE

Dupuytren's contracture is characterized by fibrosis and retraction of the palmar fascia, leading in severe cases to finger contractures. Dupuytren's contracture is common among the elderly; the prevalence is close to 30% in individuals older than 65 years of age. There is a strong genetic influence. Risk factors include tobacco smoking, diabetes mellitus, alcoholism, and possibly microtrauma. Disabling Dupuytren's contracture can be treated surgically.

CHAPTER 186: HERITABLE DISORDERS OF CONNECTIVE TISSUE

UTA FRANCKE

Connective tissue is present in all organ systems. Therefore, inherited disorders that affect its composition and stability are characterized by multisystem involvement. Depending on whether the molecular defect resides in a gene for collagen, fibrillin, elastin, or other matrix protein, the bones, ligaments, joints, blood vessels, eyes, or skin are affected to various degrees. This chapter focuses on the more common clinical entities that often are not diagnosed until adulthood.

Inheritance patterns usually are autosomal dominant, but there is considerable heterogeneity with respect to organ involvement and disease severity both between and within families. The family history may be negative because many cases occur as new mutations.

Autosomal recessive inheritance patterns usually are associated with defects in an enzyme, such as homocystinuria resulting from cystathionine b-synthase deficiency, the kyphoscoliosis type of Ehlers–Danlos syndrome resulting from lysyl hydroxylase deficiency, and the dermatosparaxis type of Ehlers–Danlos syndrome resulting from procollagen N-proteinase deficiency.

Although the literature contains reports of occasional autosomal recessive inheritance disorders that usually are autosomal dominant (e.g., osteogenesis imperfecta), disease recurrence in siblings born to unaffected parents frequently results from gonadal mosaicism in one parent. In such cases, the mutation occurred in an early embryonal or gonadal precursor cell and gave rise to a carrier individual who may display no or only minimal somatic features of the disorder but is identified as a mosaic by having more than one affected offspring.

Systemic connective tissue abnormalities also occur as secondary manifestations of primary defects in copper metabolism, as in X-linked cutis laxa, Menkes' syndrome, and occipital horn disease. Furthermore, systemic connective tissue disorders are not always genetic but can have an autoimmune basis.

Considerable phenotypic overlap exists between the nosologically defined disease entities ([Table 186.1](#)). For example, fragmented elastic fibers are the hallmark of the disorders in the cutis laxa group but also are seen in the aortas of patients with Marfan-like disorders and those with dominant and recessive forms of pseudoxanthoma elasticum. Redundant and lax skin, as seen in cutis laxa, also is one of the distinctive features of severe Marfan syndrome of prenatal onset that leads to early infantile death. Whereas ascending aortic aneurysms typically are associated with Marfan syndrome, they may also be present in the vascular type of Ehlers–Danlos syndrome (formerly type IV) and forms of osteogenesis imperfecta.

TABLE 186.1. CHARACTERISTICS OF HERITABLE DISORDERS WITH PRIMARY DEFECTS IN CONNECTIVE TISSUE COMPONENTS

The molecular pathology of disorders caused by mutations in structural molecules of the extracellular matrix, such as collagen or fibrillin, involves dominant-negative interference of the abnormal products of the mutant alleles in the formation of the matrix, despite the presence of a normal allele. Fundamental differences in the phenotypic consequences of different types of mutations have to be considered. For intracellular proteins, such as enzymes, a null mutation that does not generate a mutant product (because of gene deletion, disruption, promoter mutation, premature termination codon that leads to messenger RNA instability, or missense mutation that leads to instability of the mutant polypeptide), if present in the homozygous state, causes a more severe phenotype than does a point mutation that yields a partially functioning molecule. The opposite is true for connective tissue disorders that are dominantly inherited and in which the primary defect involves the gene for a structural protein. When the mutant product is synthesized in the cell, secreted, and incorporated into the extracellular matrix by interacting with other molecules (fibrillar collagens or fibrillin), the consequences of null mutations are less severe, whereas heterozygous expression of a structurally abnormal protein is more severe (dominant-negative or poison protein). Homozygosity (or compound heterozygosity) for missense mutations has the most severe clinical consequences.

This point is illustrated by the fact that in osteogenesis imperfecta and Marfan syndrome, a distinct correlation exists between mutations that cause absent or low levels of expression of the mutant allele and a mild phenotype. In contrast, certain point mutations that are associated with normal levels of expression of the mutant allele are correlated with severe neonatal lethal forms that result from new mutations.

The practical consequences of these considerations are manifold. One is the realization that identification of the gene in which the disease-causing mutation resides is not likely to provide a definitive clinical diagnosis. In the study of connective tissue disorders, more than in any other field, different disorders have been shown to arise from different types of mutations in the same gene. Molecular defects in specific extracellular matrix components may cause phenotypes that are clearly separated on nosologic grounds (e.g., *COL1A1* and *COL1A2* mutations lead to various types of osteogenesis imperfecta, Ehlers–Danlos syndrome, and osteoporosis). *COL2A1* defects are responsible for numerous bone dysplasias with a wide range of clinical severity, including achondrogenesis type II, hypochondrogenesis, spondyloepiphyseal dysplasia congenita, Kniest dysplasia, Stickler syndrome, and osteoarthritis with mild skeletal dysplasia. Fibrillin-1 mutations are common in Marfan syndrome but also have been identified in familial isolated aortic aneurysm and familial ectopia lentis. Heterozygous deletion or disruption of the gene for tropoelastin is responsible for autosomal dominant supravalvar aortic stenosis, while frameshifts resulting in synthesis of a truncated tropoelastin molecule cause autosomal dominant cutis laxa. The elastin gene also is deleted in most patients with Williams–Beuren syndrome that includes supravalvar aortic stenosis and results from a 1.6 mega base pair deletion of chromosome band 7q11.23.

The presentation of disease nosology provided in [Table 186.1](#) must be considered preliminary. The group of Ehlers–Danlos syndromes that are characterized by loose-jointedness, stretchable skin, and easy bruising has recently been reclassified. Molecular defects have been identified in both chains of collagen type V (*COL5A1* and *COL5A2*) in the classic type of Ehlers–Danlos syndrome, in collagen type III (*COL3A1*) in the vascular type, and in genes encoding collagen-processing enzymes in the kyphoscoliosis, arthrochalasia, and dermatosparaxis types.

The clinical classification of osteogenesis imperfecta subtypes (the Silience classification in [Table 186.1](#)) is not entirely satisfactory; considerable overlap exists, particularly in types I and IV. One-fourth to one-third of all patients cannot be classified into one of the subtypes listed, suggesting a phenotypic continuum. Because most osteogenesis imperfecta subtypes involve mutations in one of the two α chains of collagen type I (gene symbols *COL1A1* and *COL1A2*), the type of molecular defect is likely to determine the phenotype associated with a particular mutation. The clinical findings range from minimal (e.g., benign joint hypermobility, occasional fractures) to significant (e.g., intrauterine fractures with neonatal lethal presentation, adult-onset forms with life-threatening consequences). Therefore, accurate clinical classification is important for counseling patients in regard to prognosis and for instituting prophylactic therapy.

Mutations in nonfibrillar collagen genes have been found in other disorders, such as collagen type VII mutations in dystrophic epidermolysis bullosa and involvement of genes for collagen types IV and V in Alport syndrome.

The clinical treatment of patients with heritable connective tissue disorders requires ongoing contributions from multiple specialists and is coordinated best through a

multidisciplinary clinical center. The rapid progress being made in gene identification and mutational analysis may lead to major revisions in the classification of these disorders. However, the specific diagnoses will continue to be made in the clinic rather than the molecular genetics laboratory.

Therapy is directed at preventing complications through the use of protective orthopedic measures, b-adrenergic blockade for aortic disease, and cardiovascular, orthopedic, or plastic surgical procedures. If the connective tissue manifestations are caused by an inborn error of metabolism, such as in homocystinuria resulting from cystathionine synthetase deficiency, early diagnosis and systemic treatment can prevent some of the clinical complications. Treatment with intravenous bisphosphonates (such as pamidronate) appears to reduce the number of fractures in children with severe osteogenesis imperfecta type I.

CHAPTER 187: INHERITED DEFICIENCIES OF COMPLEMENT AND IMMUNOGLOBULINS

GEORGE F. MOXLEY

[Inherited Complement Deficiencies](#)
[Inherited Immunoglobulin Deficiencies](#)

While younger normal children have episodic otitis, gastroenteritis, and upper respiratory infections, repeated serious bacterial infections are distinctively uncommon in older children and adults. Older children or young adults with repeated serious pyogenic infections (e.g., with *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Escherichia coli*, *Neisseria gonorrhoeae*, or *N. meningitidis*) may have an underlying predisposition from an inherited complement or immunoglobulin deficiency. Except for selective IgA deficiency, all are rare.

INHERITED COMPLEMENT DEFICIENCIES

Complement deficiencies typically predispose to bacterial infections. An outline is presented in [Table 187.1](#). The complement system aids host defense by linking immunoglobulin recognition of pathogens with specific protective effects. C3 cleavage fragments that are covalently bound to immune complexes prevent immune complex precipitation in tissues, dissolve precipitated complexes, and attach immune complexes to cell surface receptors, resulting in clearance of immune complexes and microbial invaders. Such immune adherence also helps to localize such complexes to immune cells such as follicular dendritic cells and B lymphocytes, with subsequent activation of T cells. Other consequences are vascular effects through release of anaphylatoxins, contraction of smooth muscle, and attraction of inflammatory cells through generation of chemotactic factors. Complement kills some pathogenic microorganisms, such as *Neisseria* species, by lytic mechanisms.

TABLE 187.1. INHERITED COMPLEMENT DEFICIENCIES

Except for properdin deficiency (X-linked recessive inheritance) and the control protein C1 inhibitor (C1-INH) (autosomal dominant), total complement protein deficiencies are inherited as autosomal recessives. The alleles are expressed codominantly, and carriers of null alleles typically have about half-normal levels. For complement deficiencies other than C1-INH, the spectrum of clinical manifestations includes recurrent serious bacterial infections and immune complex-mediated diseases (systemic lupus erythematosus, glomerulonephritis, and others). For deficiencies in complement proteins of the classic pathway (C1q, C1r, C1s, C4, and C2), inflammatory rheumatic and renal diseases predominate. With deficiencies of the alternative pathway (factor B, factor D, and properdin), infections with encapsulated organisms are most common. For C3 and its control proteins, factor H and factor I, deficiencies result in severe bacterial infections and nephritis. In a deficiency of the membrane attack complex (C5, C6, C7, C8, and, to some extent, C9), recurrent infections with *Neisseria* species (*N. gonorrhoeae* and *N. meningitidis*) are most prominent. In C1-INH deficiency, subcutaneous and mucosal edema is the major feature; C1-INH deficiency also has been associated with a higher than usual frequency of immune complex diseases.

Homozygous C2 deficiency is associated with recurrent pyogenic infections and systemic lupus erythematosus with prominent skin manifestations, including photosensitivity and a lower frequency of serious renal disease.

The most common homozygous complement deficiency in humans is C2 deficiency, which occurs in about 0.01% of all whites. The C2 gene is between the HLA-B and HLA-D region genes of the human major histocompatibility complex. Defects in C2 deficiency include nonfunctional C2 genes and absent secretion of C2. About half of all C2-deficient individuals have no symptoms, but others have manifestations of inflammatory rheumatic and renal diseases. These include systemic lupus erythematosus, discoid lupus, juvenile rheumatoid arthritis, polymyositis, Henoch–Schönlein purpura, and vasculitis. The clinical picture of systemic lupus erythematosus associated with homozygous C2 deficiency differs from that of idiopathic systemic lupus erythematosus by milder renal disease, more skin manifestations, and lower titers of antinuclear antibody (ANA). The ANA specificities include anti–Sjögren syndrome A (SSA) (Ro) and anti-SS-B (La). Recurrent serious infections with pyogenic organisms also can occur.

C1-INH deficiency results in hereditary angioneurotic edema with episodic swelling of subcutaneous tissues, intestinal pain and obstruction from gut swelling, and sometimes respiratory obstruction from swelling of the upper respiratory tissues.

C1-INH is a serine protease inhibitor that controls not only the C1r and C1s proteases of the complement system but also kallikrein of the contact system and factors XIa, XIIa, and plasmin of the clotting system. Genetic C1-INH defects lead to the syndrome of angioneurotic edema. The illness is characterized by 2- to 3-day-long episodes of nonpitting subcutaneous edema (angioedema) and intestinal and respiratory obstruction caused by edematous mucosal tissue. Although most such individuals with C1-INH have an affected relative, about 1 in 10 persons with C1-INH deficiency has an apparently new mutation. The more common pattern in C1-INH deficiency is relative inhibitor absence, but about 15% of cases result from mutations with normal levels of a dysfunctional C1-INH protein. Because of complement consumption from uncontrolled activation, C4 and C2 levels are low, even between episodes. Episodes of hereditary angioneurotic edema may occur spontaneously or after trauma. During an attack, C1-INH, C4, and C2 levels are depressed even more than between attacks.

One may suspect an inherited complement deficiency in the context of recurrent, serious bacterial infections with pyogenic bacteria or *Neisseria*. To screen for inherited complement deficiencies other than C1-INH deficiency, the total hemolytic complement (50%) should be measured on a specimen properly collected and stored at -70°C . For angioedema with respiratory or intestinal tract obstruction, the appropriate screening test for C1-INH deficiency is the C4 level antigen followed by a C1-INH test if the C4 level is low. For most complement deficiencies, no replacement is necessary. For hereditary angioedema, supportive care such as maintenance of a patent airway and fluid administration may be necessary until the episode subsides. C1-INH plasma concentrate (or if not available, fresh frozen plasma) is available for serious acute attacks. Attenuated androgens increase levels of normal C1-INH and may lengthen the period between acute attacks. However, long-term use of these androgens can cause liver damage, masculinization, and diminished growth.

INHERITED IMMUNOGLOBULIN DEFICIENCIES

Immunoglobulin deficiency also predisposes to recurrent bacterial infections. Antibodies normally contribute to immunity by neutralizing bacteria, viruses, and toxins and serving as surface receptors for certain cells of the immune system.

The clinical spectrum of inherited immunoglobulin deficiencies ranges from incidental asymptomatic findings (such as some persons with selective IgA deficiency or certain IgG subclass deficiencies) to life-threatening infections. An outline is presented in [Table 187.2](#). Some antibody deficiencies are accompanied by defects in cellular immunity. Many antibody deficiency syndromes are associated with autoimmune diseases (e.g., Bruton's agammaglobulinemia, Wiskott–Aldrich syndrome, selective IgA deficiency, common variable immunodeficiency), and some also are associated with malignancies (e.g., Bruton's agammaglobulinemia, Wiskott–Aldrich

syndrome, ataxia-telangiectasia, Duncan's disease).

TABLE 187.2. INHERITED IMMUNOGLOBULIN DEFICIENCIES

As a rule, persons with inherited immunoglobulin deficiencies tend to have recurrent infections with encapsulated bacteria. The exceptions are hyperimmunoglobulinemia M syndrome and common variable immunodeficiency, which may also have opportunistic infections associated with them. Most are inherited as autosomal recessives or X-linked recessives.

The most common inherited immunoglobulin deficiency is selective IgA deficiency. Persons with selective IgA deficiency tend to have recurrent episodes of sinus and lung infections as well as urinary tract and gastrointestinal infections.

IgA is the major immunoglobulin normally found in the secretions on mucosal surfaces, and it contributes to protection against external toxins and pathogens. Some individuals with selective IgA deficiency are entirely asymptomatic. Others, particularly those with accompanying IgG2 subclass deficiency, have recurrent infections of the paranasal sinuses and lungs. Gastrointestinal manifestations include giardiasis, idiopathic inflammatory bowel disease, and a sprue-like syndrome. Atopy and various organ-specific autoimmune diseases also can occur. Individuals with selective IgA deficiency typically have circulating and cell-bound anti-IgA antibodies that may predispose to anaphylaxis on exposure to whole blood or blood constituents contaminated with IgA. Because most preparations of immune serum globulin contain trace amounts of IgA and may cause anaphylaxis, and because immune serum globulin does not restore the deficient mucosal IgA, most authorities consider immune serum therapy to be unwarranted.

Screening tests for inherited immunoglobulin deficiencies may include blood counts and differential counts of leukocytes. Although IgG subclass determinations are usually not helpful, quantitation of IgG, IgA, and IgM may aid in diagnosis. One may also measure antibodies directed to defined antigens such as blood group antigens. One may also test for antibodies prior to and after immunization with specific immunogens such as diphtheria and tetanus toxoids and polysaccharide antigens from *Haemophilus influenzae* or *S. pneumoniae*.

Infections in inherited immunoglobulin deficiencies are treated with appropriate antimicrobial therapy. In addition, for persons lacking the ability to generate protective IgG antibody responses directed to organisms causing systemic infections, intravenous administration of g-globulin may be indicated. Because globulin replacement therapy does not prevent serious respiratory infections, chronic antimicrobial therapy is typically required. The use of vaccines with live organisms (e.g., bacille Calmette–Guérin, attenuated polio) should be avoided in individuals with suspected antibody deficiency syndromes.

CHAPTER 188: USE OF LABORATORY TESTS IN RHEUMATOLOGY AND CLINICAL IMMUNOLOGY

JOHN A. HARDIN

[Erythrocyte Sedimentation Rate and Acute Phase Proteins](#)
[Synovial Fluid Examination](#)
[Rheumatoid Factors](#)
[Antineutrophil Cytoplasmic Autoantibodies](#)
[Antinuclear Antibodies](#)
[Antibodies to Cardiolipin](#)
[Approach to the Evaluation of Patients with Specific Rheumatic Syndromes](#)

Numerous tests are relevant in the evaluation of connective tissue diseases. Some of them are helpful diagnostically, particularly when applied to a patient population enriched in the disease in question, and others are useful for estimating disease activity.

ERYTHROCYTE SEDIMENTATION RATE AND ACUTE PHASE PROTEINS

Many different processes, including surgical wounds, bacterial infection, necrosis of tumors, tissue ischemia, myocardial injury, and inflammation secondary to connective tissue diseases, are associated with characteristic alterations in the protein components of plasma. All of these conditions share features of tissue injury or inflammation. They lead to the generation of a variety of cytokines capable of altering the metabolic activity of hepatocytes. The result is that plasma proteins, such as C-reactive protein and serum amyloid A, increase 1,000-fold or more in a matter of a day, whereas others, such as fibrinogen, complement components, and haptoglobin, increase one- to fourfold over several days. In contrast, other proteins such as transferrin and, especially, albumin exhibit a decrease in the circulation because of a reduction in their synthesis by hepatocytes. These alterations are referred to as the *acute phase plasma protein response*.

The erythrocyte sedimentation rate (ESR) is a simple method for evaluating the extent of this response, and it is helpful to understand the responsible mechanisms. Red blood cells (RBCs) suspended in plasma normally repel each other because of their surrounding net negative charge. Large asymmetrical molecules in the supporting plasma act as dipoles and bridge charges between individual cells. Fibrinogen is especially effective in this regard. As the concentrations of such molecules increase, RBCs aggregate more readily to form rouleaux structures that fall through plasma at an accelerated rate.

Measurement of the ESR usually is carried out by the Westergren or Wintrobe method. Because the former is not affected by the packed volume of RBCs, it is considered superior. Normal ESRs usually range slightly higher in women than in men, and aging is associated with a moderate increase. Normal values at 50 years of age are considered to be 20 mm per hour for men and 30 mm per hour for women. Many individuals older than 70 years of age have ESRs in the range of 40 to 50 mm per hour without any apparent tissue injury or inflammation. This should be remembered when treating elderly patients with diseases such as temporal arteritis or polymyalgia rheumatica. In some cases, even with adequate therapy, ESRs do not fall below this range. Occasionally, an unusually low ESR (less than 1 mm per hour) is observed and may be associated with abnormal immunoglobulins that form cryogels. Chronic liver disease or other illnesses that can generate low serum albumin and a high globulin fraction produce high ESR measurements.

Measurement of the ESR is useful diagnostically and as a guide to treatment in selected clinical circumstances. The ESR can supplement clinical efforts to differentiate inflammatory from noninflammatory joint disease (e.g., rheumatoid arthritis from osteoarthritis). In addition, marked elevations in the ESR (greater than 100 mm per hour) are associated particularly with severe deep-tissue infections, systemic lupus erythematosus (SLE), polymyalgia rheumatica, giant cell arteritis, and malignancy. Most patients with polymyalgia rheumatica or giant cell arteritis have ESRs greater than 50 mm per hour. However, 8% to 20% of patients with either condition have been noted to have ESRs less than 30 to 40 mm per hour. In several rheumatic diseases, longitudinal ESRs reflect relative disease activity and may be helpful for adjusting therapy. Fibrinogen and many other acute phase proteins that contribute to the ESR have half-lives of 3 to 5 days, limiting the rate at which effective therapy can alter the ESR. In addition, patients with rheumatoid arthritis and SLE occasionally have obvious active disease but normal ESRs.

The ESR is not useful as a screening test for occult disease. It can be within normal limits even when a serious disease is obvious. Conversely, with the exception of transient elevations in otherwise normal individuals, a high ESR almost always is accompanied by a clinically apparent disorder.

Information about the acute phase response can be supplemented by measurement of the C-reactive protein level. Acute inflammation, such as intercurrent infection, causes the concentration of this protein in the circulation to increase rapidly. In contrast, chronic inflammation, such as that which accompanies rheumatoid arthritis or SLE, may be associated with lesser elevations in C-reactive protein. As a marker, the C-reactive protein level rises sooner after the onset of bacterial infection and declines more rapidly after successful therapy than does the ESR. Unlike the ESR, C-reactive protein is not influenced by circulating levels of albumin, immunoglobulins, or rheumatoid factor. For this reason, C-reactive protein may provide a more accurate assessment of inflammation per se in diseases such as rheumatoid arthritis.

SYNOVIAL FLUID EXAMINATION

The examination of synovial fluid often is the most informative part of the evaluation in patients with arthritis. The aim is to distinguish between inflammatory and noninflammatory joint diseases and to detect the presence of such causative agents as bacteria and crystals. The small joints of the hands and feet, the wrists, the elbows, the shoulders, the knees, and the sternomanubrial joints are readily accessible for aspiration in the physician's office. Usually, as much fluid as possible should be removed. Its color and viscosity should be observed, and separate samples should be reserved for a leukocyte count (citrate tube), a crystal examination (no anticoagulant), culture, and Gram stain. Sometimes only a few hundred microliters of fluid can be obtained from small joints. In such cases, it often is best to express a small amount onto a swab for culture and the remainder onto a glass slide, where it can be examined for crystals and used for Gram and Wright stains.

Normal synovial fluid is an ultrafiltrate of plasma to which synovial cells add elements, most notably hyaluronic acid (a macromolecule that accounts for the high viscosity of synovial fluid). Fibrinogen and other large molecules do not enter the joint space readily, and normal synovial fluid does not clot. With mild inflammation, however, some clot formation may be noted. With severe inflammation, proteolysis may degrade clotting factors, so that no clot forms.

In addition to a routine leukocyte count, culture, Gram stain, and crystal examination, several special analytic studies may be indicated. Synovial fluid glucose levels normally are slightly lower than those of peripheral blood, but in infectious arthritis and in rheumatoid arthritis, they may be less than half as high. For these measurements to be meaningful, the samples must be obtained after at least 6 hours of fasting. Occasionally, neoplastic processes involving joints can be diagnosed through cytologic examinations of synovial fluid. In most clinical settings, measurements of complement and other plasma proteins rarely provide much additional information. The mucin clot test is not a useful diagnostic test.

The diagnostic implications of various synovial fluid findings are presented in [Fig. 188.1](#). One of the most important findings is whether the synovial fluid is inflammatory or noninflammatory. In most patients with osteoarthritis or traumatic joint disease, the total number of leukocytes is less than 2,000 cells per microliter. Occasionally, osteoarthritis accompanied by mild inflammation is associated with leukocyte counts as high as 5,000 cells per microliter. Systemic lupus erythematosus, scleroderma, and related overlap syndromes usually are associated with relatively non-inflammatory synovial fluids, even when joint inflammation is clinically striking. Synovial fluid leukocyte counts vary widely in rheumatoid arthritis, juvenile rheumatoid arthritis, psoriatic arthritis, Lyme disease, and Reiter's syndrome but typically are in the range of 20,000 to 40,000 cells per microliter. Sometimes, leukocyte counts in rheumatoid joint fluid are in excess of 100,000 cells per microliter. All of these disorders are associated with about 75% to 90% polymorphonuclear neutrophil leukocytes.

enabling element. The patterns in which the ANAs occur also provide important clues. Most patients with SLE exhibit high titers of a limited number of antibodies directed against various components of one or several nucleoprotein particles. For example, in many patients antibodies directed against the five different histones and DNA represent the predominant specificity. Others produce multiple antibodies to the polypeptide components of the U series of small nuclear ribonucleoprotein (snRNP) particles known as “snurps,” which mediate the splicing of pre-mRNA in the cell nucleus. These observations suggest that individual nucleoprotein particles are selected as targets for attack by the immune system much as occurs with a foreign infecting agent. One explanation is that an infecting agent might bear a cross-reactive epitope that generates an initial response to a self-epitope. A process referred to as epitope spreading might then account for the entire array of antibodies found to the “self” particle.

The pattern in which ANAs occur is helpful diagnostically ([Table 188.1](#)). For example, in SLE the major specificities are directed against DNA and histones (the antichromatin response), the U series of snurps [anti-U1 RNP and anti-Smith (anti-Sm) antibodies], and the Ro particle (which is a specific RNA-protein particle of unknown function). In scleroderma, the predominant targets are nucleolar components such as topoisomerase I (scl-70 antigen), the RNA polymerases (which synthesize pre-messenger and ribosomal RNAs and a variety of small RNAs), and the U3 ribonucleolar particle (which processes rRNA). Scleroderma contrasts with the CREST (calcinosis, Raynaud's phenomenon, esophageal motility disorder, sclerodactyly, and telangiectasia) variant because the latter is much more likely to be accompanied by antibodies that bind components of the chromosomal centromere. In polymyositis, the major antibodies are directed against tRNA synthetase complexes such as tRNA-histidyl synthetase (the Jo-1 antigen) and, less commonly, against the signal recognition particle (SRP) and the U2 RNP particle. Sjögren's syndrome is characterized by the presence of anti-La antibodies, which bind a protein associated with RNA polymerase III transcripts. These antibodies are usually accompanied by the anti-Ro specificity. High titers of ANAs that are restricted in specificity to polypeptide components of the U1 snRNP (particularly the 70-kd polypeptide) are typical of mixed connective tissue disease. An uncommon ANA known as anti-Ku is of special interest because its target, the Ku protein, has turned out to be the regulatory component of the nuclear enzyme known as DNA-dependent protein kinase. This enzyme plays a central role in double-stranded DNA break repair and in V(D)J recombination of immunoglobulin and T-cell receptor genes.

Initial screening for the presence of ANAs should be carried out with the fluorescent antinuclear antibody assay (FANA). Several considerations apply to interpretation of the FANA assay results. Determination of positive end-point titers is subjective and there is considerable test-to-test variability, particularly when individual sera are examined in different laboratories. A recent multilaboratory study demonstrates that nearly one-third of normal individuals have FANA titers of 1:40 but less than 5% have titers of 1:160 or greater. In SLE, scleroderma, and Sjögren's syndrome, FANA titers of 1:160 were found in 94.7%, 86.5%, and 73.7% of individuals, respectively. Other studies have noted that asymptomatic individuals with positive FANAs do not generally progress to overt connective tissue disease. In other words, a positive FANA in the absence of signs and symptoms of inflammation should not be regarded as evidence for a lurking connective tissue disease. A negative FANA argues strongly against the diagnosis of SLE. A notable exception occurs with sera that contain only antibodies to the Ro antigen, which can be difficult to detect because of its limited quantity in cells. Therefore, if the clinical situation suggests connective tissue disease but the FANA result is negative, antibodies directed at the Ro particle or cytoplasmic antigens such as ribosomes and Jo-1 should be sought by specialized assays such as those based on ELISA or immunoprecipitation.

When the FANA result is positive, the pattern of staining yields important information. *Homogeneous* staining is associated with antibodies to chromatin (histones and DNA) and occurs with sera from patients with SLE and many other diseases. This is the only pattern that is consistent with the diagnosis of drug-induced lupus because patients with this disorder usually produce antibodies to histones exclusively. The *rim* pattern, which is associated with antibodies directed at DNA, correlates most strongly with SLE. Although DNA is distributed throughout the nucleus, sera containing anti-DNA antibodies produce preferential staining at the nuclear margin because the chromatin is packaged more densely in this region, and because these sera tend to contain associated antibodies directed at components of the nuclear membrane and the nuclear lamin proteins that reside just underneath the nuclear membrane and to which the chromatin fibers are anchored. The *speckled* pattern results largely from antibodies directed at RNPs, such as the U series of snRNP particles. This pattern is consistent with anti-U1 RNP antibodies that bind exclusively the U1 snRNP particles, and with anti-Sm (anti-Smith) antibodies, which bind the U1, U2, and U4–6 snRNP particles. Anti-Sm antibodies are found almost exclusively in patients with SLE, whereas anti-U1 RNP antibodies occur in both SLE and its variants, such as mixed connective tissue disease. The *nucleolar* pattern is associated with a variety of autoantibodies that bind components of nucleoli, including the Pm/Scl antigen (which is a complex of multiple proteins found in nucleoli) and other nucleolar components. This pattern is most common among patients with scleroderma. Individual sera often produce homogeneous or rim patterns at low dilutions and speckled or nucleolar patterns at high dilutions; such variable patterns reflect the presence of multiple ANA specificities.

ANTIBODIES TO CARDIOLIPIN

Antibodies to cardiolipin and other phospholipids are found in about 25% of patients with documented SLE and in certain patients characterized as having a *primary* antiphospholipid antibody syndrome, manifested by recurrent fetal loss and thrombosis of venous and arterial vessels in the absence of criteria for lupus. These antibodies also occur occasionally in a wide range of other diseases including rheumatoid arthritis, scleroderma, temporal arteritis, Sjögren's syndrome, Behçet's syndrome, various infections, and in association with drug therapy (especially phenothiazines, hydralazine, procainamide, and phenytoin).

Historically, antiphospholipid antibodies were detected as the lupus anticoagulant that produced a prolonged activated partial thromboplastin time that did not correct when test plasma was combined with normal plasma (so-called mixing study). Subsequently, this factor was shown to be an autoantibody to phospholipid (platelet factor III) that interfered with the generation of the prothrombin activator complex (comprising clotting factors III, V, X, and calcium). Typically, in an *in vitro* assay, this interference results in a relatively normal prothrombin time but a prolonged partial thromboplastin time. Most of the antibodies that give positive results in this test and some additional specificities can be readily detected in ELISAs using phospholipids (e.g., cardiolipin) as substrate. The addition of β_2 -glycoprotein 1 enhances the binding of many sera in these assays. IgM class anticardiolipin antibodies are responsible for the biologically false-positive test result for syphilis (Venereal Disease Research Laboratory). Comprehensive testing for the lupus anticoagulant syndrome should be carried out with a functional clotting assay, such as the activated partial thromboplastin time, kaolin clotting time, or dilute Russell viper venom time, in combination with a specific antibody test, such as an ELISA based on cardiolipin and, possibly, additional negatively charged phospholipids.

It seems reasonable to test all patients who have had recurrent miscarriages or unexplained thrombotic events for antiphospholipid antibodies because positive individuals are candidates for therapeutic interventions. However, the isolated finding of anticardiolipin antibodies in asymptomatic individuals is not an indication of high risk for future thrombosis. In the cardiolipin ELISA, it may be worthwhile to determine whether the autoantibodies are of the IgM or IgG class because individuals with high titers of antibodies of the latter class are thought to be at the greatest risk for thrombotic complications ([Table 188.2](#)).

TABLE 188.2. LABORATORY TESTS IN RHEUMATOLOGY: SUMMARY OF KEY POINTS

APPROACH TO THE EVALUATION OF PATIENTS WITH SPECIFIC RHEUMATIC SYNDROMES

For diagnostic purposes, it usually is most cost-effective to formulate an initial impression on the basis of the history and physical examination and to attempt to support that diagnostic hypothesis with a limited array of applicable laboratory tests. A *rheumatology screen* is not necessary, and often results in needless costs and reliance on imprecise assay methods.

MONARTHROSIS OR POLYARTHROSIS

As a first approximation, a patient with monarthritis may be considered to have infection, crystal-associated arthritis, or traumatic joint disease, whereas one with polyarthritis may be considered to have rheumatoid arthritis, osteoarthritis, some form of reactive arthritis, or a systemic connective tissue disease that is not fully expressed. In this setting, the ESR or C-reactive protein is useful as supplemental information about the presence of inflammation. Synovial fluid examination and culture are indicated to confirm or exclude from further consideration infection and crystal-associated arthritis, and as another means of identifying inflammatory joint disease. A test for rheumatoid factor helps to confirm a clinical impression of rheumatoid arthritis and yields information about the potential for this disease to cause tissue injury. If the patient has had a tick bite and lives in an endemic area, an assay for antibodies to *Borrelia burgdorferi*, the causative agent of Lyme disease, should be considered.

Radiologic studies usually are helpful for identifying the characteristic changes of osteoarthritis and chondrocalcinosis, for excluding fractures, and for determining whether the disease produces purely periarticular osteopenia and bone erosions (e.g., rheumatoid arthritis) or both erosive and proliferative changes of bone (e.g., Reiter's syndrome, inflammatory bowel disease, ankylosing spondylitis), usually without associated osteopenia. Changes in bone evolve slowly. The earliest sign in inflammatory synovitis often is periarticular osteopenia, which may appear within weeks after onset of disease. Bone erosions and proliferative changes usually are not seen until the disease process has been present for several months. Patients with erosive disease should be followed up with serial radiographs because progression of bone injury warrants more aggressive therapy. Technetium bone scans are useful for identifying metastatic disease, bone infections, and aseptic necrosis, and often yield clues to these diagnoses earlier than do conventional bone radiographs.

BACK PAIN

When a patient's main complaint is back pain, the first goal is to establish on clinical grounds the likelihood of a mechanical injury such as a herniated nucleus pulposus, an inflammatory spine disease such as ankylosing spondylitis, a neoplasm, or an infectious process. It is helpful to determine the mode of onset of the pain, whether there is a history of trauma or evidence of neurologic impingement, whether the pain is exacerbated by activity (suggesting a mechanical lesion) or by rest (suggesting inflammatory disease), and whether motion is limited in all planes (inflammatory) or predominantly in one plane (mechanical). After this initial assessment, laboratory studies should be used judiciously with the aim of confirming or denying the initial clinical hypothesis.

In most cases, the clinical evaluation suggests a mechanical or inflammatory disorder. In such cases, ESR can provide data that further distinguish these two categories. Human leukocyte antigen phenotyping provides an approach to identifying patients who fall into higher risk categories for the development of reactive arthritis. The HLA-B27 phenotype occurs in about 8% of healthy whites and is present in at least 90% of patients with ankylosing spondylitis, 80% of patients with reactive arthritis caused by *Yersinia*, *Shigella*, or *Salmonella* infections, 70% of patients with Reiter's syndrome, and 50% of patients with psoriatic spondylitis. This phenotype is not increased in patients with inflammatory bowel disease or psoriasis, and is increased only marginally in patients with peripheral arthritis uncomplicated by spondylitis.

Plain radiographs are of limited use for detecting intervertebral disc disease. Many patients exhibit disc space narrowing without having symptoms, and most surgically proven herniated discs are not associated with disc space narrowing. Similarly, hypertrophic changes such as osteophyte formation around the vertebral bodies do not correlate with pain. Degenerative changes of the apophyseal joints, however, do correlate with symptoms. Technetium Tc 99 diphosphonate bone scans can demonstrate early evidence for inflammatory spine disease and are helpful for excluding tumors and infection. These studies are limited by the fact that any process associated with bone proliferation, including hypertrophic osteoarthritis, produces increased uptake. After affected spinal levels have been identified, computed tomography and magnetic resonance imaging can provide highly accurate means of documenting a herniated nucleus pulposus and spinal stenosis.

DIFFUSE CONNECTIVE TISSUE DISEASE

Patients with connective tissue diseases (e.g., SLE, scleroderma, dermatomyositis, polymyositis, Sjögren's syndrome) often have evidence of multiple organ involvement. Signs and symptoms involving the skin and joints are particularly common. These diseases share certain important pathogenetic features, including prominent autoimmune responses to nucleoproteins. The analysis of ANAs often is an important step in their diagnosis ([Table 188.1](#)).

The FANA assay result is positive in about 95% of patients with SLE. When the result of this test is negative, it rarely is profitable to order specialized tests for individual nuclear autoantigens such as DNA. However, some patients mainly produce autoantibodies to cytoplasmic nucleoproteins. If a certain connective tissue disease is suggested strongly, it may be worthwhile to test specifically for individual ANA specificities.

Low levels of C3 and C4 can indicate active complement fixation at sites of immune complex deposition in SLE. A normal C3 but a low total hemolytic complement (CH_{50}) can indicate a deficiency of one or more other components of complement. C3 levels are usually normal in rheumatoid arthritis, scleroderma, and polymyositis.

In patients with suggested inflammatory muscle diseases or muscle weakness, it is important to determine whether serum levels of enzymes derived from muscle tissue are elevated. The serum creatine kinase level is elevated in about 90% of patients with polymyositis or dermatomyositis. This enzyme, a dimer made up of polypeptide subunits known as M and B, is found within brain and muscle tissue and exists in three isoenzymatic forms, referred to as MM (skeletal and cardiac muscle), MB (cardiac muscle), and BB (brain and smooth muscle). In cardiac muscle, the MB form constitutes 20% to 30% of the total amount of this enzyme. Although only a minute portion of the creatine kinase in normal skeletal muscle is of the MB form, regenerating skeletal muscle may contain considerable amounts of this isoenzyme fraction, and levels may reach 20% or more in some patients with inflammatory muscle diseases or muscular dystrophy. Moderate exercise in untrained individuals also can lead to elevated serum levels of creatine kinase. In addition, other enzymes, such as aldolase and lactate dehydrogenase, are released from muscle tissue, but these enzymes also are found in other tissues.

VASCULITIS

When vasculitis is suspected, measurements of the ESR or C-reactive protein and of complement components can provide information about the presence of humoral alterations. One straightforward method that is available to nearly all clinicians is examination of serum for cryoglobulins. Cryoglobulins form when serum is chilled. In practice, blood for cryoglobulin assays can be drawn at room temperature, but it should be clotted at 37°C to prevent cryoprecipitable proteins from becoming incorporated into the fibrin clot. After storage at 4°C for 48 hours, the serum should be observed for a precipitate. Tiny amounts of cryoprecipitable proteins are present even in normal serum but usually are barely visible; precipitate that is grossly visible can be measured. Large amounts of cryoglobulins accompanied by high titers of rheumatoid factor are present in virtually all patients with essential mixed cryoglobulinemia, a condition that often is accompanied by palpable purpura. Smaller amounts are found in patients with many other inflammatory conditions and are often associated with hepatitis C infections. The correlation of these cryoprecipitates with circulating immune complexes can be improved by demonstrating that they contain immunoglobulins.

Antibodies against leukocyte serine proteases or myeloperoxidase are measured as ANCAs and are useful in patients suspected of having Wegener's granulomatosis or other vasculitides. However, tissue biopsy often is essential for correct diagnosis of these conditions (see [Chapter 181](#)).

CHAPTER 189: ARTHROSCOPY

WILLIAM J. ARNOLD

[Diagnostic Arthroscopy](#)
[Therapeutic Arthroscopy](#)
[The Future](#)

In the last 20 years the widespread availability of arthroscopy has revolutionized the diagnosis and therapy of articular disorders. Sophisticated fiberoptic arthroscopes of various sizes and angulations allow for a thorough and precise inspection of all intra-articular structures. Minimally invasive arthroscopic inspection of the joint has provided direct evidence for the relation of symptoms and abnormal joint anatomy, particularly in the shoulder. Simultaneous videotaping of the procedure provides a permanent visual record for subsequent analysis and also for comparison at the time of a follow-up arthroscopy. In response to this remarkable ability to visualize intra-articular structures, a growing array of specifically designed motorized shavers, forceps, burs, staples, sutures, and other tools have been developed to permit a variety of therapeutic interventions to be performed. Precise removal of only the damaged (symptom-producing) portion of a structure (e.g., partial meniscectomy) with arthroscopic techniques preserves joint integrity. Reconstruction techniques for ligaments and menisci can preserve joint function, allow return to athletic activity, and potentially prevent the subsequent development of degenerative arthritis.

Although today the indications for arthroscopy can be divided into diagnostic and therapeutic categories, the future promises a role for arthroscopy in following new therapies directed at regrowth or preservation of articular cartilage, restoration of joint surfaces with flowable polymers cured in situ, and genetic or immunomodifying therapy of inflammatory arthritis.

DIAGNOSTIC ARTHROSCOPY

Specific indications for use of arthroscopy to diagnose articular disorders includes tuberculous or fungal monoarthritis, pigmented villonodular synovitis, and synovial chondromatosis. In patients with bacterial arthritis, arthroscopic debridement and lavage of the infected joint can assist in both the diagnosis and management. Also, chronic knee pain due to arthrofibrosis and adhesions after total knee replacement (TKR) is best evaluated and treated with arthroscopy.

Although it initially requires general anesthesia and an operating room, knee arthroscopy can often be performed under regional or local anesthesia in an ambulatory surgery center or in the physician's office. In the knee, local skin infiltration at portal sites and intra-articular anesthesia provides excellent patient comfort for routine diagnostic arthroscopy. Almost every joint in the body is amenable to arthroscopic inspection with the appropriate-size arthroscope. Even microarthroscopy of the metacarpophalangeal joint and the proximal interphalangeal joint is now possible. However, arthroscopy is most frequently performed for the knee and shoulder. This is both because the ease of access and frequency of involvement by either trauma or arthritis are greater for these two joints.

Standard 3- to 4-mm diameter, 30-degree fore-oblique, glass rod arthroscopes provide the best visualization in most circumstances, even in smaller joints such as the elbow and wrist. The lavage of 1 to 3 L of saline usually performed during diagnostic arthroscopy has been reported to improve symptoms in patients with osteoarthritis of the knee. Arthroscopy is not indicated for the diagnosis of inflammatory or degenerative arthritis. A thorough history and physical with appropriate laboratory studies and x-rays establish the diagnosis of arthritis in most of these patients.

Arthroscopy is extremely useful in the diagnosis of a joint that is painful after trauma. Arthroscopy permits direct visualization and probing of intra-articular structures while moving the joint. With the advent of magnetic resonance imaging (MRI), diagnostic arthroscopy can be more precisely directed to a possibly damaged structure or sometimes avoided altogether. Damage to the rotator cuff or glenoid labrum in the shoulder and the cruciate ligaments and menisci of the knee can be suspected clinically and usually confirmed by MRI. However, the presence and extent of damage to the articular cartilage, inflammation of the synovium and some meniscal tears in the knee can best be determined by direct arthroscopic inspection and probing.

THERAPEUTIC ARTHROSCOPY

With the excellent visualization provided by the arthroscope, therapeutic techniques have evolved to match the needs of the patients, the understanding of the relation among pain, joint anatomy, and function, the skill of the arthroscopist, and the available technology.

RECONSTRUCTIVE PROCEDURES

In patients with sports injuries, reconstructive procedures have preserved important articular structures and allowed return to full athletic function. Thus, although rupture of the anterior cruciate ligament (ACL) was previously a career-ending injury, modern ACL reconstructive techniques with a B-T-B (bone-tendon-bone) or gracilis/semitendinosis graft often can return a player to competition. Suturing of knee menisci torn during sporting activity can also return function and preserve a vital joint structure. Since degenerative arthritis occurs over time in patients with a torn ACL or surgically absent meniscus, these reconstructive procedures are likely to also prevent the subsequent development of osteoarthritis. In the shoulder, repair of tears of the glenoid labrum and rotator cuff due to trauma are possible.

In swimmers, recurrent dislocation of the shoulder due to capsular laxity can be disabling. Recent evidence suggests that the use of low levels of thermal energy to "shrink" the collagen in the articular capsule can tighten the capsule and decrease the tendency for recurrent dislocation.

For patients with arthritis, reconstructive techniques are not effective for damaged menisci or cruciate ligaments. However, reconstructive techniques for articular cartilage have been attempted in these patients. In patients with osteoarthritis of the knee, abrasion of the subchondral bone on the tibial plateau with a bur or microfracture with a specially designed awl has been attempted to stimulate the formation of articular cartilage from primordial (stem cells) bone marrow cells just under the bony surface. These techniques can be successful in relieving knee pain in some patients. However, the results are unpredictable, particularly in patients over age 60 years with large areas of bare bone and angular deformity of the knee. In addition, subsequent arthroscopic inspection reveals coverage of the tibial plateau by fibrocartilage characterized by the presence of type I collagen, not hyaline cartilage with type II collagen.

In younger patients (under age 30) with isolated chondral defects due to trauma in the medial femoral condyle, transplantation of cultured autologous chondrocytes under a periosteal covering of the defect has been reported to restore the surface of the articular cartilage and relieve symptoms for up to 5 years of follow-up. Another approach is to fill chondral defects with plugs of cartilage obtained from donor sites in the knee.

DEBRIDEMENT PROCEDURES

Debridement procedures are usually performed for patients with chronic pain or mechanical symptoms, such as locking or giving away owing to arthritis, or in patients over 40 years with traumatic injuries in whom reconstructive techniques are not considered appropriate. Local or regional pain in a specific joint due to osteoarthritis should first be managed with a comprehensive medical program consisting of a balance of rest and exercise with the use of thermal modalities, splints and assistive devices (e.g., a cane), analgesics and nonsteroidal anti-inflammatory drugs (NSAIDs), and judicious use of intra-articular glucocorticoid injections. A series of intra-articular injections of a hyaluronic acid preparation may also be useful in relieving pain due to osteoarthritis of the knee. If these measures fail, then arthroscopic debridement may be indicated. Use of motorized shavers and hand instruments, removal of damaged menisci and inflamed synovium, smoothing of articular cartilage flaps, and removal of loose bodies may produce prolonged therapeutic benefit while delaying or avoiding knee replacement surgery. In general, patients with minimal or moderate x-ray changes of osteoarthritis, meniscal tears, and preserved joint alignment experience the greatest benefit from arthroscopic debridement of the knee. In the shoulder, arthroscopic debridement with decompression by release of the coracoacromial ligament can often provide significant relief to elderly patients with osteoarthritis and elevation of the humeral head due to chronic rotator cuff tears. In addition, the saline lavage that accompanies these procedures also augments the pain relief.

Synovectomy

The role of arthroscopic synovectomy in the management of patients with inflammatory arthritis remains controversial. In such patients (e.g., those with rheumatoid or

psoriatic arthritis), the medical management regimen plays a critical role in determining the success of the synovectomy, whether measured by pain relief, preservation of function, or halt in the progression of destructive disease. The optimum outcome of arthroscopic synovectomy is likely to occur in patients who are well controlled on a medical regimen (e.g., with NSAIDs or disease-modifying antirheumatic drugs [DMARDs]), have pain caused by inflammation in a single joint (usually the knee or shoulder) and have minimal evidence of joint destruction on radiograph. These patients should also have at least one joint aspiration and glucocorticoid injection before considering arthroscopic synovectomy.

THE FUTURE

Arthroscopy can provide a method for monitoring the efficacy of new therapies designed to prevent cartilage destruction and reduce synovial inflammation. Serial arthroscopic inspection and grading of articular cartilage damage under local anesthesia in patients with osteoarthritis of the knee (chondroscopy) have been proposed as the optimal method to gauge the efficacy of chondroprotective agents now under development. Quantitation of inflammation in arthroscopically directed synovial biopsies taken during immunomodulator or gene therapy will be useful in monitoring the synovium-specific effect of these interventions. In both of these situations, rheumatologists with appropriate education and skills may provide these procedures as part of a continuum of services to their patients with arthritis.

Driven by the economic impact of the growing number of patients with osteoarthritis and capitalizing on the minimally invasive and cost-effective nature of arthroscopic techniques, new technology to restore articular cartilage or its function will be developed. Restoration of the impact absorption and low coefficient of friction by flowable polymers that can be administered under arthroscopic guidance and cure in situ to form a new surface on denuded bone is now being studied.

Cartilage cell regrowth on joint surfaces from stem cell precursors in the presence of growth factors may provide another option. Since direct visualization and manipulation are always important in developing and evaluating new therapies, arthroscopy is likely to occupy a central and growing position in the management of articular disorders.

CHAPTER 190: IMAGING TECHNIQUES FOR RHEUMATOLOGIC DIAGNOSIS

CURTIS W. HAYES AND AVINASH A. BALKISSOON

[Imaging Techniques](#)
[Imaging Of Specific Anatomical Sites](#)
[Summary](#)

Radiologic imaging plays a pivotal role in the effective diagnosis and management of patients with suspected or known rheumatologic disease. The plain radiographic examination remains the primary imaging test under almost all circumstances. However, choices for secondary imaging studies have increased dramatically in the past several decades. Tomography, arthrography, and radionuclide imaging were previously used to supplement radiographs when necessary. Computed tomography (CT), ultrasonography, and especially magnetic resonance imaging (MRI) are increasingly used to achieve more sensitive and more specific diagnoses for many musculoskeletal disorders. To make the appropriate choice of techniques, the physician must understand the strengths and weaknesses of available imaging examinations, as well as the way in which test results may influence management.

IMAGING TECHNIQUES

Imaging tests may be classified as survey or specific studies. A survey study usually includes a large anatomical area and should be sensitive, although not necessarily specific. A specific study is usually tailored to the symptomatic area and ideally should be specific for diagnosis of a suspected disease.

RADIOGRAPHY

The radiographic examination should be the primary imaging study performed in almost all cases of known or suspected rheumatologic disease. Radiographs provide superb spatial resolution of bony structures and are particularly useful for assessing the hands and feet, erosions, periosteal changes, and soft-tissue calcifications ([Fig. 190.1](#)).

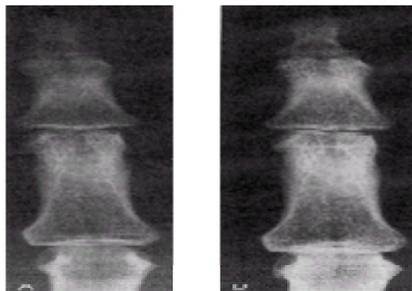

FIGURE 190.1. A: Conventional radiograph of the finger compared with (B) high-resolution radiograph. Magnification has been adjusted for comparison.

Standard radiographic views include anteroposterior (AP) and lateral projections. Specialized projections are added for some areas or when a particular pathologic process is suspected. For the lower extremities, weight-bearing views provide more accurate assessment of the joint space and alignment than non-weight-bearing views ([Fig. 190.2](#)). Radiographs performed with stress applied across the joint allow assessment of ligamentous stability, particularly for the wrist, thumb, and ankle.

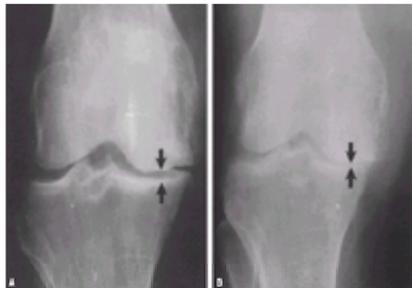

FIGURE 190.2. A: Non-weight-bearing anteroposterior radiographic projection of the knee fails to show the true severity of medial compartment narrowing of the knee (arrows) compared with (B) the weight-bearing view (arrows). (From Hayes CW, Conway WF. Evaluation of articular cartilage: radiographic and cross-sectional imaging techniques. *RadioGraphics* 1992;12:409, with permission.)

Fluoroscopy of a joint allows the operator to assess joint motion dynamically. Subtle abnormalities not seen on static radiographs can sometimes be detected with this technique.

ARTHROGRAPHY

Arthrography is a radiographic technique for the evaluation of joints through the intra-articular injection of contrast agent. The major strength of arthrography is that it outlines the synovial lining, articular cartilage, and other intra-articular structures. There is an opportunity to aspirate joint fluid and to inject intra-articular drugs under accurate fluoroscopic guidance. Studies have shown the safety of arthrography to be high, with serious contrast reactions or infection quite rare.

Arthrography continues to be valuable for assessment of some joints, remaining competitive with more sophisticated techniques such as MRI. Diagnostic arthrography is particularly useful for the shoulder, elbow, and wrist joints, and is an excellent method for evaluating joint prostheses (which cause serious artifacts with MRI). Arthrography is useful for evaluating abnormal communications to a joint, such as synovial cysts. Fluoroscopically guided injection of local anesthetic can provide useful information when one is attempting to localize the source of unexplained periarticular pain, particularly around the hip, ankle, and foot.

COMPUTED TOMOGRAPHY

The development of CT in the 1970s and its subsequent refinement have produced significant advances in all areas of radiology. Fundamentally, CT is based on the principle that the internal structure of a body part can be reconstructed from radiologic data acquired from multiple angles. An x-ray tube rotates in a circular fashion around a body part, as a highly collimated x-ray beam passes through the part from all directions. Image data are reconstructed into a cross-sectional image with greatly improved ability to discriminate between tissue densities. CT has gone through many technical refinements. Spiral CT now provides improved multiplanar

images, with comparatively lower radiation dose.

In patients with rheumatologic disease, CT is useful for showing detailed anatomy of irregular or complex joints, such as the sacroiliac joint, subtalar joints, wrist, and spine. The combination of CT after arthrography (arthroCT) has proved useful in the assessment of several joints, including the shoulder and ankle.

ULTRASONOGRAPHY

Ultrasonography is a relatively inexpensive and noninvasive imaging technique. Significant operator experience is required to achieve technical proficiency. A joint may be examined during motion, which is particularly useful in the shoulder and foot.

Ultrasonography is highly sensitive for the detection of fluid in the soft tissues, including joints, bursae, and around tendons. Aspiration can be performed under ultrasound guidance. In large joints affected by an inflammatory arthritis, ultrasonography provides discrimination of effusion from adjacent proliferative synovium, similar to that of an expert physical examination. It may demonstrate complications of rheumatic disease such as tendinitis or tendon ruptures and can help evaluate periarticular soft-tissue masses by differentiating solid masses from cystic lesions.

Ultrasonography has been used effectively by some authors for the evaluation of rotator cuff and biceps tendon abnormalities in the shoulder. Reports also have demonstrated the usefulness of ultrasonography in the evaluation of carpal tunnel syndrome, pigmented villonodular synovitis, and synovial osteochondromatosis.

MAGNETIC RESONANCE IMAGING

MRI has evolved as an invaluable diagnostic tool in the assessment of musculoskeletal disease. The main advantage of MRI stems from its superb soft-tissue contrast discrimination and the ability to produce images in any plane. MRI is particularly useful in the evaluation of bone marrow, periarticular, and soft-tissue abnormalities ([Table 190.1](#)).

Tissue Type	T1-Weighted Image	T2-Weighted Image
Cortical bone	VL	VL
Red (hematopoietic) marrow	I	I
Yellow (fatty) marrow	H	I
Fat	H	I
Muscle	I	I
Ligaments, tendons	L	L
Fluid	L	H

H, high signal white; I, intermediate signal, light gray; L, low signal, dark gray; VL, very low signal, black.

TABLE 190.1. MAGNETIC RESONANCE APPEARANCES OF SELECTED TISSUE

Disadvantages of MRI include low sensitivity in detecting small calcifications and relatively low spatial resolution for cortical bone. Because of the high magnetic field used with MRI, patients with cardiac pacemakers, cerebral aneurysm clips, and shrapnel near critical organs should not be imaged. Claustrophobic and obese patients are also problematic because of the small aperture of high-field strength in MRI units. Open configurations and low-field strength dedicated extremity units are an alternative for these patients, but image quality is inferior.

MRI has proved to be effective in evaluating many joints, including the knee, shoulder, and hips and is the preferred modality for assessing the spine. It is recommended for assessing possible osteonecrosis and other marrow or trabecular bone abnormalities. MRI is useful in the evaluation of osteochondral lesions and focal cartilage abnormalities. Contrast-enhanced MRI can aid in the differentiation of hypertrophied synovium from an effusion and in the assessment of articular cartilage and joint disease ([Fig. 190.3](#)). Intra-articular MR contrast injection (MR arthrography) provides excellent contrast between the fluid and articular structures and has been shown to be valuable in the assessment of the shoulder and knee.

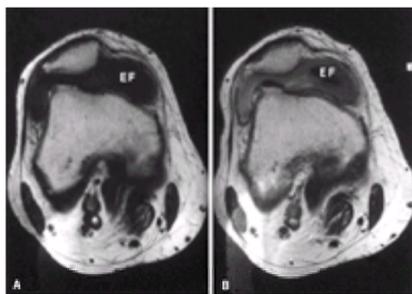

FIGURE 190.3. T1-weighted axial images of the knee (**A**) before and (**B**) 20 minutes after intravenous injection of gadopentetate dimeglumine show enhancement of the large joint effusion (*EF*) in a patient with rheumatoid arthritis.

RADIONUCLIDE IMAGING

Standard bone scintigraphy uses a phosphate compound labeled with technetium Tc 99m, which, when injected intravenously, is bound to the crystal lattice of bone with distribution dependent on blood flow and osteoblastic activity. Images are routinely obtained approximately 4 hours after injection, but can be modified if information on the vascularity of a lesion is important.

Bone scintigraphy is a sensitive but nonspecific indicator of disease activity in joints and in the spine. It therefore can be used to assess the distribution of arthritis and identify joints that subsequently can be radiographed. Three-phase Tc 99m phosphate imaging alone or with gallium citrate Ga 67 or indium In 111-labeled leukocyte imaging are useful and sensitive techniques for the diagnosis of septic arthritis but are no substitute for examination and culture of synovial fluid. Studies have demonstrated mixed results in the use of bone scintigraphy for the differentiation of prosthetic joint loosening from infection.

IMAGING OF SPECIFIC ANATOMICAL SITES

HAND AND WRIST

Rheumatologic diseases that commonly affect the hand and wrist are osteoarthritis, rheumatoid arthritis, spondyloarthropathies, scleroderma, systemic lupus erythematosus, crystal deposition diseases, and infection. The radiographic examination should be the initial and often only examination performed. The routine study usually consists of two to four projections. Radiographs obtained during radial and ulnar deviation or with a clenched fist are useful in the evaluation of wrist instability. Specialized views are available for better demonstration of the first carpometacarpal joint and carpal tunnel.

Radiographs of any joint should be evaluated carefully for several cardinal radiographic features of arthritis: soft-tissue swelling, joint deformity, joint space narrowing, periarticular osteopenia, erosions, sclerosis, and new bone formation (periostitis, osteophytes; [Table 190.2](#)).

Joint space narrowing
Bone erosions
Bone formation (sclerosis, osteophytosis, periostitis)
Bone mineralization
Alignment
Soft-tissue swelling
Soft-tissue calcifications
Distribution

TABLE 190.2. CARDINAL RADIOGRAPHIC FEATURES OF RHEUMATOLOGIC DISEASE

Based on the observation that different arthritides tend to involve predictably different joints, the “target approach” to radiographic interpretation is particularly useful in the hand and wrist ([Fig. 190.4](#)). Most often, osteoarthritis affects the distal interphalangeal joints, the proximal interphalangeal joints, the first carpometacarpal joint, and the radiocarpal joint. Characteristic sites of involvement of rheumatoid arthritis include symmetric involvement of the metacarpophalangeal joints, the proximal interphalangeal joints, the carpus, and the ulnar styloid. Psoriasis and Reiter's syndrome tend to have asymmetric distribution, classically involving the distal interphalangeal joints. With calcium pyrophosphate dihydrate deposition disease, the radiocarpal joint and second and third metacarpal joints are commonly affected.

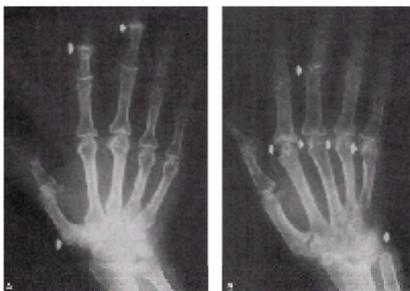

FIGURE 190.4. Posteroanterior radiographs of the hand and wrist showing typical pattern of involvement for (**A**) osteoarthritis (*arrows*) and (**B**) rheumatoid arthritis (*arrows*).

Wrist arthrography is most frequently used for assessing the integrity of the intercarpal ligaments, but it may also be helpful for indicating the presence and extent of synovial inflammation. Ultrasonography can be used to evaluate carpal tunnel syndrome, ganglion cysts, and tenosynovitis. MRI is useful in the evaluation of patients with carpal tunnel syndrome, soft-tissue masses, and suspected avascular necrosis of the wrist.

ELBOW

Common rheumatologic diseases of the elbow include juvenile chronic arthritis, rheumatoid arthritis, secondary osteoarthritis, and gout.

The standard radiographic series consists of AP and lateral projections. The lateral radiograph allows identification of the important fat pads, which are useful indicators of elbow joint effusion. Additional radiographic projections are available to improve visualization of the radial head, capitellum, and coronoid and olecranon processes. CT is useful in the evaluation of complex fractures, bony erosions, and loose bodies.

Arthrography of the elbow is useful for detection of intra-articular loose bodies, assessment of articular cartilage surfaces, and evaluation of synovial abnormalities.

MRI can display tendon and ligament avulsions and strains, osteochondral lesions, and synovial lesions such as pannus, pigmented villonodular synovitis, or osteochondromatosis.

SHOULDER

Common rheumatologic diseases affecting the glenohumeral joint include rheumatoid arthritis, crystal-induced arthropathies, neuroarthropathy, and infection. Primary osteoarthritis of the shoulder is unusual but degenerative changes may be secondary to any of the arthritides or trauma. Osteonecrosis of the humeral head may mimic articular disease.

The radiographic shoulder series usually includes frontal views with the humerus in internal and external rotation and an axillary or lateral scapular view. Radiographs remain most valuable for showing bony erosions, degenerative change, and periarticular calcium deposition. Chronic, complete tears of the rotator cuff can be inferred by a narrow acromiohumeral distance and superior subluxation of the humeral head.

Shoulder arthrography is a safe procedure that can reliably reveal complete and deep surface partial tears of the rotator cuff. Other uses are the identification of loose intra-articular bodies and adhesive capsulitis.

With ultrasonography, experienced operators can reliably show full-thickness rotator cuff tears and biceps tendon abnormalities.

MRI is quickly becoming the technique of choice for the evaluation of the rotator cuff and for the demonstration of synovial disease around the shoulder. It provides information on the site and extent of a rotator cuff tear, although differentiating partial tears from tendinitis may be difficult. MRI can identify erosion of bone, loss of cartilage, synovitis, pigmented villonodular synovitis, synovial osteochondromatosis, amyloid deposition, and osteonecrosis. MR arthrography is accurate in the diagnosis of full and partial rotator cuff tears and in the evaluation of glenohumeral instability.

SPINE

Major rheumatologic diseases affecting the spine include degenerative disc disease, facet joint osteoarthritis, the spondyloarthropathies, infection, and rheumatoid arthritis.

Frontal and lateral radiographs, often supplemented by obliques, may be the only imaging required for the evaluation of rheumatologic disease. Careful assessment of the alignment, disc spaces, and facet joints frequently leads to a specific diagnosis. However, since radiographically visible osseous changes are relatively late

sequelae of degenerative disc disease and discitis, sophisticated imaging is necessary when radiographs have negative findings but clinical suspicion is high.

Discography is a controversial technique of contrast injection directly into the nucleus pulposus of an intervertebral disc under fluoroscopic guidance. Discography remains popular among some advocates as an adjunct to newer imaging modalities for the evaluation of equivocal disc disease. The added diagnostic value of discography, based on the reproduction of pain on injection, remains a controversy and rarely is indicated.

Spinal facet joint injection is advocated by some authors as both a diagnostic and therapeutic study in the management of patients with suspected painful facet joint arthritis.

Increased uptake of radionuclide isotope in spinal articulations and at entheses are early observations in patients with active inflammatory arthritis. For the detection of vertebral infection, three-phase Tc 99m phosphate scans and Ga 67 citrate imaging approximate MRI in accuracy; however, MRI provides greater spatial resolution and is therefore the procedure of choice for suspected spinal infection.

Myelography, the previous standard for intradural and extradural spinal disease, has been largely replaced by MRI in many institutions.

CT is the imaging technique of choice for the assessment of spinal fractures and facet joint arthritis ([Fig. 190.5](#))

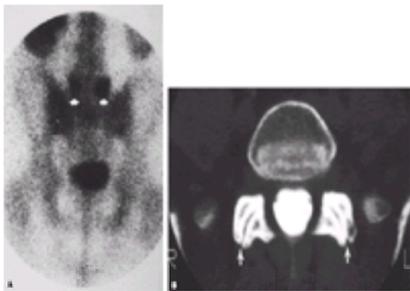

FIGURE 190.5. **A:** Pelvic image from a radionuclide bone scan shows two areas of focal increased uptake at approximately the L4–L5 level (*arrows*). This appearance is nonspecific. **B:** Axial computed tomography image clearly shows severe osteoarthritis of the facet joints at L4–L5 (*arrows*).

MRI has become the preferred method for the evaluation of spinal cord, bone marrow, and intervertebral disc lesions ([Fig. 190.6](#)).

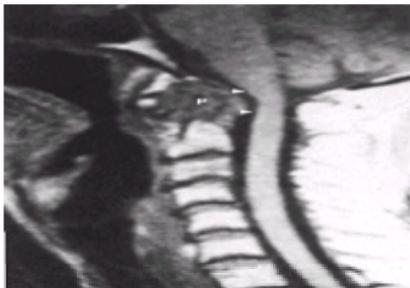

FIGURE 190.6. Midline sagittal T1-weighted magnetic resonance image of the cervical spine shows replacement of the odontoid process of C2 with pannus (*P*), producing deformity of the adjacent spinal cord (*arrowheads*). (From Hayes CW, Jensen ME, Conway WF. Non-neoplastic lesions of the vertebral bodies: findings in magnetic resonance imaging. *RadioGraphics* 1989;9:883, with permission.)

SACROILIAC JOINTS

Rheumatologic diseases commonly affecting the sacroiliac joints are the spondyloarthropathies, osteoarthritis, and infection.

The sacroiliac joints are obliquely oriented and slightly sigmoid shaped, making tangential visualization on the standard AP projection impossible. Overlying stool and bowel gas further complicate the evaluation. Oblique projections or the Ferguson projection (AP with 30-degree cephalic angulation) are often necessary for effective delineation ([Fig. 190.7](#)). Cardinal features to assess include joint space width, erosions, sclerosis, and symmetry.

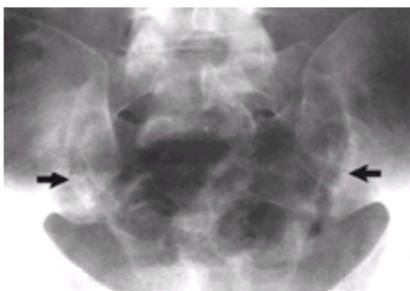

FIGURE 190.7. Ferguson view of the pelvis showing bilateral sacroiliitis (*arrows*).

CT, MRI, and bone scintigraphy have been evaluated for usefulness in establishing a diagnosis of sacroiliitis when radiographs are equivocal. The cross-sectional display of CT is ideally suited for evaluating early bony changes ([Fig. 190.8](#)). Although MRI does not image cortical bone as effectively as CT, the superior soft-tissue and marrow contrast of MRI make it promising for sacroiliac joint evaluation. Conventional bone scintigraphic techniques are sensitive but not specific for sacroiliitis because of a wide range of normal variability.

FIGURE 190.8. Axial computed tomography image through the sacroiliac joints provides optimal visualization of the joints (*arrows*). Note the pneumocyst in the right ilium (*arrowhead*), resulting from osteoarthritis.

HIP

Rheumatologic diseases that commonly affect hip joints include osteoarthritis, rheumatoid arthritis, spondyloarthropathies, crystal arthropathies, and infection. Osteonecrosis, stress fractures, bursitis, tendinitis, and muscular injuries are also common at the hip.

The hip joints can be evaluated well by radiography. The AP projection should include both hips for comparison. The “frog leg” lateral projection should also be performed. In addition to the usual cardinal features of rheumatologic disease, it is useful to assess the direction of migration of the femoral head that results from joint space narrowing ([Fig. 190.9](#)). Osteoarthritis is characterized by superolateral or medial migration, whereas inflammatory arthritides produce uniform cartilage loss that results in axial movement of the femoral head.

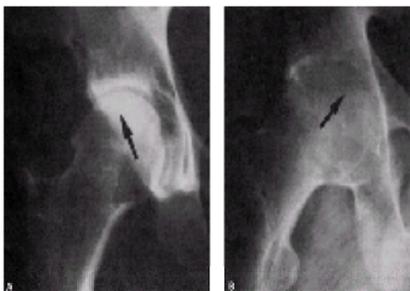

FIGURE 190.9. Anteroposterior radiographs of the hip in patients with (**A**) osteoarthritis and (**B**) rheumatoid arthritis showing typical superolateral (**A**, *arrow*) and axial (**B**, *arrow*) migration of the femoral heads.

Arthrography of the hip joint is valuable in the assessment of complications related to joint prostheses. Arthrography with fluoroscopically directed joint aspiration is the single most useful test to evaluate possible loosening or infection of a hip prosthesis. Bone scintigraphy is useful when one of the following conditions is suspected: osteonecrosis, occult fracture, or transient regional osteoporosis.

When radiographs are nondiagnostic, MRI is our preferred second-line imaging examination. MRI is arguably the most sensitive imaging modality for the detection of osteonecrosis. The volume of osteonecrotic bone in the femoral head can be estimated, which correlates well with the likelihood of subchondral collapse. MRI is a sensitive test for the detection of occult fractures, which can be clinically confused with true articular abnormalities. MRI can help to identify other processes around the hip such as effusions, synovitis, bursitis, tendinitis, pigmented villonodular synovitis, osteochondromatosis, and myopathy.

KNEE

The knee joint is commonly affected by osteoarthritis, rheumatoid arthritis, crystal deposition arthropathies, neuroarthropathy, and infection. Occult fractures, soft-tissue injury, and osteonecrosis may mimic articular disease.

Plain radiographs are frequently all that is necessary to evaluate the knee for rheumatologic disease. In addition to standard AP and lateral projections, a weight-bearing AP view is useful in assessing joint space narrowing and alignment. The tangential or “sunrise” view of the patella is used for assessing patellofemoral arthritis and alignment. The intercondylar posteroanterior (tunnel) view reveals the posterior aspect of the femorotibial joint, commonly the earliest area of localized cartilage loss in primary osteoarthritis of the knee.

In addition to the cardinal radiologic features of rheumatologic disease, it is useful to note the distribution of joint space narrowing in the knee. Osteoarthritis typically results in narrowing of one or two compartments (medial, lateral, or patellofemoral). Inflammatory arthritis affects the joint diffusely, eventually producing narrowing of all three compartments. Isolated patellofemoral involvement is typical of calcium pyrophosphate dihydrate deposition disease. The periarticular soft tissues should be assessed for chondrocalcinosis, loose bodies, and dystrophic calcifications.

Knee arthrography has been replaced by MRI, except in the following situations: contraindication to MRI, evaluation of knee joint prostheses, and evaluation of suspected dissecting Baker's cyst ([Fig. 190.10](#)). Ultrasonography is useful in detecting synovial cysts and other fluid collections around the knee.

FIGURE 190.10. Lateral radiograph from a single-contrast knee arthrogram showing a ruptured popliteal cyst (*solid arrow*) with contrast dissecting distally into the gastrocnemius muscle (*open arrow*).

MRI is the modality of choice for the evaluation of suspected internal derangements of the knee and has been shown to be accurate for the evaluation of menisci and

ligaments, joint effusions, abnormalities of the periarticular soft tissues, and radiographically occult fractures. The value of MRI in the evaluation of nontraumatic rheumatologic disease has been studied less extensively ([Fig. 190.11](#)). Preliminary reports suggest that MRI is capable of showing small bone erosions with greater accuracy than radiographs. The signal intensity of synovial fluid is enhanced after intravenous injection of gadolinium.

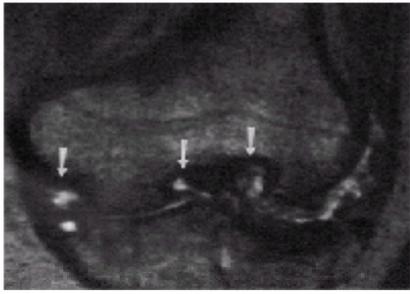

FIGURE 190.11. Coronal T2-weighted magnetic resonance image of the knee showing multiple erosions (*arrows*) in a patient with chronic juvenile arthritis.

Numerous studies have shown that MRI is accurate at showing moderate and advanced cartilage abnormalities such as chondromalacia or osteochondritis dissecans. MR arthrography is advocated by some as the most sensitive imaging examination to evaluate the thickness of articular cartilage ([Fig. 190.12](#)).

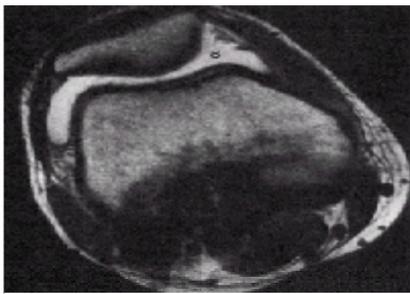

FIGURE 190.12. Axial T1-weighted magnetic resonance arthrogram image of the patellofemoral compartment of the knee shows the joint space (*S*) distended with high-signal contrast agent. This technique is useful for precise evaluation of the articular cartilage.

ANKLE AND FOOT

Rheumatologic diseases affecting the ankle and foot include osteoarthritis, rheumatoid arthritis, spondyloarthropathies, infection, and gout. Neuroarthropathy commonly involves the intertarsal and tarsometatarsal joints. Stress fractures involving the metatarsals and tarsals are also common.

As with the hand and wrist, high-quality radiographs are most valuable in assessing the ankle and foot. Weight-bearing views of the foot are useful in assessing alignment and for the evaluation of the arch of the foot. The target approach for arthritis, similar to that used for the hand and wrist, is useful for the foot. Osteoarthritis most commonly affects the first metatarsophalangeal joint, the tarsometatarsal joints, and the intertarsal joints. The most characteristic site of involvement for early rheumatoid arthritis is the fifth metatarsophalangeal joint. With gout, the first metatarsophalangeal joint is characteristically affected. Reiter's and psoriatic arthritis tend to involve the distal interphalangeal joints; Reiter's arthritis also commonly affects the posterior and plantar aspects of the calcaneus. Neuropathic joint disease affects the ankle and tarsometatarsal joints.

CT may be useful in showing tarsal coalitions or stress fractures in the feet. Ultrasonography can be used to evaluate the tendons and ligaments supporting the ankle and foot. MRI can be useful in the evaluation of tarsal tunnel syndrome, refractory plantar fasciitis, occult fractures, and tendon abnormalities. MRI has been reported to be useful in the evaluation of infection, especially in the setting of the diabetic patient in whom the distinction between foot infection and neuroarthropathy may be difficult. Three-phase bone scintigraphy, Ga 67 imaging, and In 111-labeled leukocyte scans are also useful in this setting.

SUMMARY

Radiologic imaging can be indispensable in the identification and follow-up of patients with musculoskeletal manifestations of rheumatologic disease. The radiographic examination is the initial study of choice in all circumstances. Making the most effective choice for more sophisticated imaging is less straightforward and requires background knowledge of available modalities. [Table 190.3](#) is a comparative summary of the strengths and weaknesses of commonly available imaging modalities.

Modality	Cost	Invasiveness	Bone	Soft Tissue	Joint Space	Comments
Radiography	-	0	++	-	-	Recommended primary examination for all joints
Tomography	++	0	+++	0	0	Unsettled usefulness for complex fractures; subject to arthrographically
Arthrography	++	+	++	+	+++	Direct evaluation of joint space; allows aspiration for analysis, culture (useful for rheumatoid arthritis, osteoarthritis); useful for defining complex bones and joints
Computed tomography (CT)	+++	0	++++	++	-	Excellent useful for rheumatoid arthritis and psoriatic arthritis; useful for evaluating osteitis with ligamentous deposits for rheumatoid arthritis
Ultrasound	++	0	0	-	-	Useful for evaluating osteitis with ligamentous deposits for rheumatoid arthritis
Magnetic resonance imaging	++++	0	++	++++	+++	High sensitive modality for bone marrow and soft tissue; (see evaluation of cartilage bone lesions) for small joints
Radionuclide imaging	+++	0	+	+	0	Sensitive but nonspecific; sensitive useful for infection, osteoarthritis

CHAPTER 191: APPROACH TO THE PATIENT WITH SKIN LESIONS

CHRISTOPHER M. BARNARD

[Skin: Cells, Matrix, and Function](#)
[Cutaneous Manifestations of Internal Disease](#)
[Management of Acute and Chronic Diseases of the Skin](#)

This chapter is an overview of the essential elements an internist needs for the accurate diagnosis and treatment of the patient with skin lesions. Knowledge of the structure and function of normal skin is crucial to the understanding of cutaneous disease and is presented first in this chapter. To describe cutaneous findings accurately, the vocabulary and language of the dermatologist are also presented. The final section provides many useful therapeutic strategies in treating selected dermatologic diseases.

SKIN: CELLS, MATRIX, AND FUNCTION

The skin is the primary site of interface between the human organism and the environment. This fact dictates the need for enormous diversity and adaptability within the organ system. The barrier function of the skin alone serves a multiplicity of functions, including protection from physical injury, infectious organisms, and natural or man-made environmental pollutants. This same barrier function helps to ensure the integrity of the organism by its preservation of internal fluids, electrolytes, and proteins and by serving as the major thermoregulatory effector organ through sweating and vasoregulation. Although these functions have been known for decades, only recently have the profoundly important immunologic, endocrine, and paracrine functions of the skin been understood. The importance of each of the components of the skin is further emphasized by the fact that, after physical damage, the skin manifests its remarkable capacity for regeneration into a nearly perfect, anatomically and functionally diverse organ system.

STRUCTURE AND FUNCTION

The skin is composed of two major layers: the epidermis, of ectodermal origin, and the dermis, of mesodermal origin ([Fig. 191.1](#)). The subcutaneous layer beneath the dermis, although morphologically and functionally different, is of the same origin. The subcutaneous fat serves as a reservoir for fluid and energy and as a means of protecting underlying tissues.

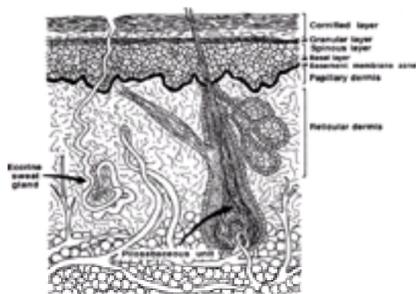

FIGURE 191.1. Diagrammatic representation of the major structures of the skin.

Epidermis

The epidermis consists of a stratified keratinizing epithelium that makes an interface at mucous membrane junctions. Typically, the epidermis is divided into the basal cell layer, which is the germinative layer; the spinous layer, which comprises several layers of cells above the basal layer; and the granular layer, which is a layer of nucleated cells containing cytoplasmic inclusions called *keratohyalin granules*. This layer is important because it is the zone in which cells become devoid of nuclei. Cells become nonviable in the cornified layer (stratum corneum), which is of such importance in the barrier effect. The epidermal cells are attached to each other through desmosomes and to the dermis at least partly through hemidesmosomes. These two structures are important in some hereditary and autoimmune diseases of epidermal dyshesion.

Constant regeneration of the epidermis requires that the terminally differentiated keratinized outer cells be shed continuously. Although variable, transit times from the basal layer to the stratum corneum are 4 or 5 weeks, and about 2 more weeks are required for shedding the cornified cells. Each of these kinetic parameters can be disrupted in certain proliferative and keratinizing diseases of the skin, such as psoriasis and ichthyosis.

The keratins are the principal protein products of the epidermis. The expression of this family of fibrous proteins, ranging in size from 47 to 65 kd, differs in various cornified structures, such as the epidermis, hair, and nails. There are biochemical differences among the keratins of these structures. The differences are, like the kinetic variations, of importance in such diseases as psoriasis and the ichthyoses.

The keratins are organized into structures called *intermediate filaments* (formerly, tonofilaments) whose quantity increases as the cell moves outward. In the granular layer, the filaments associate with the keratolinin granules. These granules also contain the histidine-rich protein filaggrin. The keratins and filaggrin, together with the envelope proteins involucrin and keratolinin, are major cellular proteins in the epidermal barrier. In the stratum corneum, the intercellular space is filled with a variety of lipids. During the transition from the granular layer to the stratum corneum, cells discharge their lipids through lamellar bodies. Among the lipids are long-chain saturated fatty acids that subserve the barrier function. This barrier can be disrupted mechanically or in diseases of the epidermis. Lipophilic substances cross the stratum corneum more readily than water and ions. Indeed, topical application of various materials may exert effects on the entire body. For example, under certain circumstances, percutaneous absorption of glucocorticoids can have significant systemic effects, and certain cardiovascular drugs are now often delivered through the skin.

The epidermis is the major source of photoprotection. In addition to the stratum corneum itself, the melanin synthesized by the melanocyte population of the epidermis absorbs radiant energy and protects the skin from the harmful effects of ultraviolet light. All skin contains pigment-forming cells, regardless of the racial derivation of the individual. Melanocytes synthesize melanin and transfer it to regional keratinocytes through dendritic processes. The racial differences in pigmentation are caused by differences in the packaging of melanin by the melanocytes, rather than by differences in numbers of melanocytes. Decreased or absent pigmentation can be acquired (e.g., after chemical insult or other inflammatory process) or hereditary (e.g., albinism).

The epidermis also harbors important components of the immune system. Cells within the epidermis are important for antigen processing. The Langerhans' cells, once thought to be effete melanocytes, possess both crystalloid fraction and complement receptors and immune-associated surface antigens. These cells operate in the afferent limb of the cutaneous immune system. In addition, epidermal keratinocytes synthesize certain cytokines, including interleukin-1, thus suggesting a role in cutaneous inflammation and repair. The dermis also contains dendritic cells and migrating populations of lymphocytes that participate in both afferent and efferent mechanisms.

Epidermal–Dermal Junction

The interface between the epidermis and the dermis, termed the *epidermal–dermal junction* or the *basement membrane zone*, is under normal conditions an undulating border. This zone, which consists of three morphologically easily identifiable zones—the plasma membrane of the basal cells on the outside, the lamina lucida in the middle, and the lamina densa on the dermal side—in fact comprises additional structures such as hemidesmosomes, anchoring filaments, and anchoring fibrils. Several proteins that anchor the epidermis to the dermis have been defined biochemically. Among these are laminin I, basement membrane proteoglycan, and type IV collagen. In addition, other proteins of importance in hereditary and autoimmune blistering diseases have been identified, including the 230- and 180-kd bullous pemphigoid antigens, laminin V, and type VII collagen. The anchoring fibril complex consists of type VII collagen, which forms loops into the papillary dermis and presumably can interact with other types of interstitial collagens and cells, possibly through domains of fibronectin.

Dermis

The dermis is divided into two major portions, the papillary and the reticular dermis. The biologic function of the dermis is to provide the major structural framework underlying the epidermis and supporting the cutaneous vascular network. The papillary dermis consists of rather fine collagen fibrils and is located outermost. It closely hugs the undulating epidermis and contains the small vasculature. The reticular dermis lies beneath the papillary dermis and makes up the bulk of the dermis with coarse bundles of collagen and elastin. These structures provide strong functional support and resilience to the skin.

Fibroblasts are the major cell type characteristic of the dermis. Interstitial collagen (types I and III) constitutes more than 70% of the dry weight of the skin. The requirement for tensile strength is served by collagen, whereas elasticity, resilience, and hydration are conferred in part by the other connective tissue components, elastin and the proteoglycans. The remaining collagenous components and basement membrane components are found in minor amounts.

The elastic elements of the dermis are made up of two components: *microfibrils*, which are tubular, and an amorphous component, called *elastin*. These, too, are synthesized by the dermal fibroblasts. If the integrity of dermal elastin is compromised, as in *cutis laxa*, the skin hangs loosely in folds. A much more common phenomenon is the wrinkling of the skin resulting from loss of elasticity due to actinic irradiation.

The dermal proteoglycans are synthesized also by the fibroblasts. Their functional importance is poorly defined, but probably involves water trapping within the skin. Their presence in the basement membrane zone further implies a role in the complex interactions of adhesive macromolecules.

Skin Appendages

The skin appendages are the pilosebaceous units and the sweat glands, both eccrine and apocrine. The pilosebaceous unit is the hair follicle with its associated sebaceous gland. These glands secrete complex oils that may function in addition to the lipids released by the keratinocytes in cutaneous lubrication and protection. The distribution of sebaceous glands varies significantly in density over the body. For example, the excessive oiliness of acne or rosacea is often concentrated in areas of the highest number of sebaceous glands.

Similarly, terminal hairs (those that are medullated) do not grow in equal density over the entire body. Indeed, hair growth itself is not continuous; instead, hair grows in cycles. The growth phase is termed *anagen*; the resting phase is *telogen*. At any given time, most of the scalp hair is in the anagen or growth phase. Profound illness, or changes in metabolic states (e.g., at the end of pregnancy) can alter the relative proportion of growing and resting hairs and lead to hair loss (effluvium).

Eccrine sweat glands are found over the entire body and function in thermoregulation. Indeed, their diminished numbers in hypohidrotic ectodermal dysplasia lead to failure of the evaporative cooling effect and to fevers from poor cutaneous heat exchange. In contrast, the apocrine glands are of more restricted distribution and are found principally in the axillae, the inguinal folds, and the breasts. Likewise, they are functionally more restricted, with intermittent rather than continuous secretion.

Aging Skin

Perhaps no situation so dramatically emphasizes the interactive nature of all the components of the skin as the aging process. Although it may be impossible to separate effects of aging from effects of actinic damage, the end results appear in many cases to be similar; decreased keratinocyte proliferation and epidermal atrophy result from years of sun damage. With increasing age, there is an overall decrease in the number of melanocytes. Despite the frequent occurrence of somewhat increased pigmentation in chronically sun-exposed regions, which might be expected to exert a protective effect, there is typically also loss of dermal cellularity and elasticity. This in turn results in loss of vascular support and in large cutaneous ecchymoses.

Loss of hair occurs with aging, and other epidermal appendage structures become attenuated. Sebaceous glands may increase in size, but their secretion of oils decreases. The decreased epidermal proliferation may contribute to one of the most vexing problems of aging, *xerosis*, or dry skin. This problem affects most elderly people. The characteristic loss of skin turgor and resilience may lead to chronic pruritus, scratching, and self-induced skin damage, all of which further compromise the barrier function of the skin.

CUTANEOUS MANIFESTATIONS OF INTERNAL DISEASE

Many systemic diseases have cutaneous findings that may appear before, or concurrently with, the onset of the underlying disorder. These findings are particularly helpful in obtaining a diagnosis when the systemic manifestations of a disease may be difficult to elucidate. The following brief descriptions serve to provide a reference for identifying these cutaneous clues.

ENDOCRINE DISORDERS

Adrenal Disorders

Addison's Disease

Hyperpigmentation of the palmar creases and a generalized darkening of the skin and of the skin covering the joints may occur in persons with Addison's disease. Pigmented macules may develop on the tongue, gingiva, and oral mucous membranes. Longitudinal pigmented bands may be seen within the nails, and the hair may darken in color. Areas that are normally the darkest (areola, axilla, genitalia, perineum, and the skin folds) become even more hyperpigmented.

Cushing's Disease

Striae, atrophy, telangiectasia, purpura, petechia, ecchymoses, poor wound healing, and acne all may develop in persons with Cushing's disease. Subcutaneous body fat increases over the upper back and abdomen and decreases on the extremities in this disorder.

Diabetes

Many cutaneous changes have been associated with diabetes, some of which are seen with a number of other diseases as well. Diabetic dermopathy, a poorly understood phenomenon at best, typically appears as depressed, brown plaques or flat patches over the pretibial surfaces. In long-standing diabetes, bullae (bullous diabeticorum) may develop over the extremities and feet. Necrobiosis lipoidica diabeticorum, which consists of yellowish-brown, telangiectatic, waxy, scaly plaques on the pretibial surfaces, often begins as red papules or nodules and is seen in 0.3% of all diabetics. The face, trunk, and upper extremities may also be involved. Acanthosis nigricans, brown, velvety plaques located around the neck and within the axillary, inframammary, and inguinal folds, can be seen with endocrinopathies such as diabetes, obesity, or with an underlying malignancy. Increased cutaneous fungal infections, especially *Candida*, and bacterial infections may be seen with diabetes. Vitiligo also occurs more frequently in diabetics. Diabetic neuropathy can result in neuropathic ulcers in areas with decreased sensation.

Parathyroid Disease

Hyperparathyroidism is associated with pruritus. Hypoparathyroid disease is associated with xerosis, brittle nails, coarse hair, and chronic mucocutaneous candidiasis.

Pituitary Disease

Hyperpituitary disease may manifest as hyperhidrosis, increased skin folds on the face, thickening of the lips and eyelids, increased pore size, and generalized thickening of the skin. Hyperpigmentation, coarsening of the hair, and increased oiliness of the skin are also noted. Hypopituitary disease manifests as dryness and thinning of the skin, thinning and loss of hair, and pallor.

Thyroid Disease

Hyperthyroidism

Soft, warm, moist skin is typical in persons with hyperthyroidism, with easy flushing and erythema of the face and palms. Increased nail growth with an upward curvature may occur, a condition known as "Plummer's nails." Thinning of the hair is also seen. Pretibial myxedema can occur with Graves' disease. Both hyperpigmentation and hypopigmentation may occur, as well as vitiligo.

Hypothyroidism

Dry, cool, rough, pale skin that bruises easily, along with slowly growing, dry, brittle hair and nails, is seen in persons with hypothyroidism.

RHEUMATOLOGIC AND IMMUNOLOGICALLY MEDIATED DISORDERS

Behçet's Syndrome

Persons affected with Behçet's syndrome have oral aphthae, genital aphthae, and pustular vasculitis are the cutaneous findings in this disease.

CREST/Scleroderma

CREST syndrome includes cutaneous calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and numerous telangiectasias. Systemic sclerosis shows the same changes as CREST syndrome, as well as a cutaneous fibrosis that may be localized or generalized in distribution. Ulcerations of the distal fingertips may result in "pitting scars." Breakdown or trauma to contractures or areas of calcinosis may also produce ulcers. Hyperpigmentation can be widespread or alternating with hypopigmented patches. The proximal nail folds reveal enlarged capillary loops, and telangiectatic mats are commonly seen on the hands.

Dermatomyositis

The most characteristic features are a heliotrope rash (periorbital violaceous rash), malar erythema, and Gottron's papules (e.g., violaceous papules located over the metacarpophalangeal and interphalangeal joints). Similar red to violaceous scaly plaques may be seen over the elbows and knees. The proximal nail folds may show telangiectasia and periungual erythema. Erythema may be widespread and appear with a blotchy pattern over the trunk and extremities. Atrophy, hypopigmentation, and ulcerations may appear at involved sites. Cutaneous calcinosis may be seen in adults but is more often a finding in children with dermatomyositis.

Graft-Versus-Host Disease

In acute graft-versus-host disease, pruritus, palmar erythema, and red macules or papules, which may become confluent and progress to an exfoliative erythroderma, are seen. Chronic graft-versus-host disease may begin with a lichen planus–like eruption of violaceous papules. Localized, and later generalized, sclerosis may develop over the trunk and extremities.

Lupus Erythematosus

The cutaneous lesions of lupus erythematosus may be divided into acute, subacute, and chronic forms. In acute lupus erythematosus, malar erythema and photosensitivity are commonly seen. Erythematous rashes are often maculopapular and pruritic and may involve any area of the body. Other findings may include vasculitis, oral ulcerations, periungual erythema, telangiectasia, and alopecia. With subacute cutaneous lupus, annular, erythematous, scaly patches or psoriasiform papules and plaques may be present. Photosensitivity is common. In chronic discoid lupus, atrophic scarring is usually present after the appearance of erythematous scaly plaques. The typical lesions are hypopigmented atrophic scars surrounded by hyperpigmentation.

Polyarteritis Nodosum

Cutaneous polyarteritis nodosum typically reveals tender nodules or a livedo (reticulated)-pattern vasculitis of the skin only. Systemic polyarteritis nodosum reveals tender nodules of the lower extremities, livedo reticularis, cutaneous ulcerations, urticaria, and digital infarcts.

Vasculitis

Patients with small-vessel vasculitis present with palpable purpura. Large-vessel vasculitis may appear as necrosis, ulcerations, purpura, cutaneous or nail-fold infarcts, subcutaneous nodules, and hemorrhagic bullae.

GASTROINTESTINAL DISORDERS

Biliary Obstruction

In biliary obstruction, cholestasis from all causes can result in significant pruritus, and jaundice may be seen with hyperbilirubinemia.

Celiac Sprue

Gluten-sensitive enteropathy and malabsorption can be seen in association with dermatitis herpetiformis, a vesicular eruption characterized by grouped vesicles located on extensor surfaces. Common locations are the elbows, forearms, shoulders, knees, and buttocks. Crusts and erosions are commonly seen after rupture of the vesicles. Symmetric distribution and pruritus are characteristic features.

Cirrhosis

Spider angiomas and telangiectasias frequently appear on the trunk and face in patients with cirrhosis. Distended abdominal vessels are visible in patients with portal hypertension. Palmar erythema is present in several chronic diseases and may be related to elevated estrogen levels. Dysfunctional synthesis of clotting factors results in purpura and ecchymoses. White nails, or Terry's nails, are typically bright white from the proximal nail fold forward and pink at the distal edge. Pruritus may be severe, particularly when caused by primary biliary cirrhosis. Thinning and loss of body hair are common.

Crohn's Disease

Perineal fissures and fistulas, cutaneous and oral granulomas, pyoderma gangrenosum, oral ulcerations, pustular vasculitis, and erythema nodosum all are seen with

Crohn's disease, an inflammatory bowel disease.

Hemochromatosis

Hemochromatosis is associated with generalized brown or bronze hyperpigmentation with accentuation of the sun-exposed areas and genitalia.

Hereditary Hemorrhagic Telangiectasia

Telangiectatic mats can be found on the mucous membranes, particularly of the lips, tongue, and nose. Progression of the disease results in telangiectasias of the face, palm, and soles.

Hyperlipidemia

Xanthomas associated with hyperlipidemia may be classified into tuberous, tendinous, planar, and eruptive. Tuberous xanthomas appear as pink to yellow nodules over the elbows and knees. Tendinous xanthomas may be seen as skin-colored nodules along the extensor tendons of the elbows, hands, and knees, and the Achilles tendon. Planar xanthomas typically appear within the palmar creases as yellow patches. Eruptive xanthomas are usually yellow to red pruritic papules and may be distributed over any area of the body. Xanthelasma, a soft yellow plaque, may appear over the eyelids.

POLYPOSES

Cowden's Disease

Pseudofissures of the tongue (the so-called scrotal tongue), trichilemmomas (smooth, flesh-colored papules around the nose and face), keratotic papules on the face and hands, and a cobblestone grouping of papules on the oral mucosa are found in persons with Cowden's disease.

Gardner's Syndrome

Multiple epidermal cysts and subcutaneous fibromas in addition to desmoid tumors and osteomas are findings in those with Gardner's syndrome.

Peutz–Jeghers Syndrome

Hyperpigmented macules may appear on the lips, oral mucous membranes, and over the hands and feet of persons with Peutz–Jeghers syndrome.

Ulcerative Colitis

Oral ulcers, pustular vasculitis, pyoderma gangrenosum, and erythema nodosum are seen with ulcerative colitis, an inflammatory bowel disease.

ENDOCARDITIS, RENAL FAILURE, AND SARCOIDOSIS

In persons with *endocarditis*, splinter hemorrhages may appear in the nail plate; Osler's nodes are painful or tender red nodules, which may be present on the fingerpads or toepads; Janeway's lesions are painless red macules on the palms and soles; and petechiae, the most common finding, may be found anywhere on the skin or mucous membranes.

Pruritus, hyperpigmentation, pallor secondary to anemia, xerosis, and cutaneous calcification may be seen in those with *renal failure*. "Half-and-half" nails may be present and consist of a white proximal nail plate and a distal reddish-brown portion.

The cutaneous manifestations of *sarcoidosis* are divided into specific (containing granulomas) and nonspecific (lacking granulomas). Specific lesions include red, brown, or purple papules, plaques, and nodules. Infiltration of scars, ichthyosiform patches, hypopigmented areas, atrophy, and ulcerations are also types of specific lesions. Nonspecific lesions include erythema nodosum, erythema multiforme, pruritus, and erythroderma.

MANAGEMENT OF ACUTE AND CHRONIC DISEASES OF THE SKIN

The proper approach to therapy of skin disorders should be founded on a thorough understanding of the pathophysiology of skin disease and confidence in making one's diagnostic skills. The most common error made by nondermatologists is the choice of improper therapy based on an incorrect diagnosis. After the proper diagnosis is established, excellent references are available that can provide insight into proper therapy. The following section highlights the important aspects of dermatologic therapy and gives examples of the treatment of selected acute and chronic dermatoses.

TOPICAL THERAPY

Compresses and Soaks

Compresses are usually used to clean or debride a wound. They are also commonly used to dry acutely exudative dermatoses, such as those seen in acute contact dermatitis. Wet-to-dry dressings debride more thoroughly than wet dressings. Solutions for wet dressing are numerous; the most common are aluminum acetate (Burow's solution) diluted 1:10 to 1:40, normal saline, and 0.25% acetic acid. Care must be taken not to overuse the compresses, which can cause excessive drying.

Antipruritic Agents

Topical antipruritics are rarely useful enough to replace systemic agents in the treatment of pruritic dermatoses. When combined with emollients, however, they may have a role in the treatment of asteatotic eczema, the dry, erythematous, finely fissured skin that is sometimes seen in elderly patients. Care must be taken to avoid topical antihistamine agents that can sensitize the skin. Useful agents include doxepin cream, pramoxine lotion, and combinations of agents containing menthol, phenol, and camphor.

Antimicrobials

Topical antimicrobial drugs are useful in the prophylaxis and treatment of selected cutaneous bacterial and fungal infections. Numerous purely antibacterial and combination preparations are available. Neosporin contains polymyxin B sulfate, zinc bacitracin, and neomycin sulfate. The potential problem of neomycin sensitivity is avoided by the use of Polysporin, which contains only polymyxin B and bacitracin or mupirocin (Bactroban). The most common use of these agents is in prophylaxis against wound infections after cutaneous surgical procedures or around vascular access sites. They have little role in the treatment of true cutaneous bacterial infections; systemic antibacterial agents are usually required in this setting.

Topical antifungal drugs are widely used for the treatment of cutaneous dermatophyte infections (nail infections respond poorly) and superficial candidiasis. The most effective topical antifungal agents are the synthetic imidazoles (12% miconazole nitrate, 1% clotrimazole, 1% econazole nitrate), all of which are effective against tinea versicolor, dermatophyte infections, and superficial candidiasis. Clotrimazole in troche form is effective for oral candidiasis. Nystatin, a polyene antimicrobial agent that is also effective against *Candida albicans*, can be used as an oral suspension for thrush or as a powder for the candidal infections that develop in bed-ridden patients in skin occluded by the bedsheets. The newer synthetic allylamines (1% naftifine and 1% terbinafine) are effective against most cutaneous dermatophyte infections as well as superficial candidiasis, but are not useful in the treatment of tinea versicolor.

Corticosteroids

Corticosteroids are potent antiproliferative and anti-inflammatory agents; their use has revolutionized dermatologic therapeutics. The dermatoses listed in [Table 191.1](#) are those that are the most responsive to topical corticosteroid therapy.

Eczematous dermatitis
 Allergic contact dermatitis
 Irritant contact dermatitis
 Dyshidrotic eczema
 Atopic dermatitis
 Stasis dermatitis
 Psoriasis
 Seborrheic dermatitis
 Exfoliative erythroderma (secondary to psoriasis or other steroid-responsive disorders)

TABLE 191.1. DERMATOSES RELATIVELY RESPONSIVE TO TOPICAL CORTICOSTEROIDS

The potencies of different topical corticosteroids vary widely, depending on the concentration of the active drug and on structural changes, including fluorination of certain key positions in the basic corticosteroid molecule ([Table 191.2](#)). In general, treatment should be started with low- to intermediate-potency drugs and progress to high-potency agents only if necessary. This is particularly true in infants or small children, in whom the potential for significant systemic absorption is greater. Furthermore, high-potency fluorinated topical corticosteroids should be used with extreme caution on the face, genitals, and intertriginous areas. In these locations, long-term use often results in adverse effects (e.g., corticosteroid acne and atrophy on the face and striae in intertriginous locations).

Highest Potency
 Betamethasone-dipropionate (C, O), 0.05% (Diprolone)
 Clobetasol propionate (C, O), 0.05% (Temovate)
High Potency
 Amcinonide (C, O), 0.1% (Cyclocort)
 Desoximetasone (C, O, G), 0.25% (Topicort)
 Fluocinonide (C, O, G, L) 0.05% (Lidex)
 Halcinonide (C, O, L) 0.1% (Halog)
Intermediate Potency
 Betamethasone valerate (C, O, L), 0.1% (Valisone)
 Fluocortolone (C, O), 0.05% (Cordran)
 Halcinonide (C), 0.05% (Halog)
 Triamcinolone acetonide (C, O, L) 0.1% (Aristocort, Kenalog)
Low Potency
 Desonide (C, O), 0.05% (Desoven, Tridesilon)
 Hydrocortisone valerate (C, O), 0.2% (Westcort)
 Triamcinolone hexacetonide (C, O, L), 0.025% (Aristocort, Kenalog)
Lowest Potency
 Hydrocortisone (C, O, L), 1% (Cort-Dome, Hytone)
 Hydrocortisone (C, O, L), 2.5% (Cyanocort, Hytone)

C, cream; O, ointment; G, gel; L, liquid solution.

TABLE 191.2. CLASSIFICATION OF SELECTED TOPICAL CORTICOSTEROIDS BY POTENCY

Corticosteroid potency is also influenced by the vehicle in which the drug is compounded or the manner in which it is applied. The use of occlusive wraps (e.g., plastic wraps, nylon sauna suits) or ointments, rather than less occlusive creams, gels, lotions, or sprays, results in increased warmth and humidity of the skin, with consequent increased penetration into the skin. Care must be exercised when using long-term occlusion of potent topical corticosteroids, because this may lead to systemic absorption with consequent hypothalamic–pituitary–adrenal axis suppression. Solutions and gels are often best tolerated in hair-bearing areas, whereas creams and ointments are most commonly used in glabrous skin. Occlusive ointment-based drugs should be avoided in intertriginous areas.

Topical corticosteroids are usually applied two or more times daily. Given the risk of tachyphylaxis, however, less frequent use may be indicated. A common practical problem in the use of these drugs has been the underestimation by nondermatologists of the quantity of drug required to treat a particular dermatosis. [Table 191.3](#) provides some realistic guidelines.

Area to Be Treated	Each Application (g)	Weekly Dose With Two Daily Applications (g)
Hands, head, face, or anogenital area	2	28
One arm or anterior or posterior trunk	3	42
Entire body	30–60	420–840

TABLE 191.3. DISPENSING OF TOPICAL CORTICOSTEROIDS

Adverse reactions to topical corticosteroids are listed in [Table 191.4](#). The more prolonged the course of treatment and the more potent the drug, the greater is the risk of these complications. Unfortunately, certain of these adverse effects (e.g., posterior subcapsular cataracts, striae) are sometimes irreversible even after discontinuation of the drug.

Systemic
 Hypothalamic-pituitary-adrenal axis suppression
 Iatrogenic Cushing's syndrome
 Growth retardation
 Avascular bone necrosis
Local
 Cutaneous atrophy
 Striae
 Telangiectasia
 Impaired wound healing
 Steroid rosacea
 Perioral dermatitis
 Hypertrichosis
 Hypopigmentation
 Glaucoma
 Cataracts
 Aggravation of local bacterial or fungal infections
 Exacerbation of psoriasis

TABLE 191.4. ADVERSE REACTIONS TO TOPICAL CORTICOSTEROIDS

An additional problem is that of corticosteroid addiction, which is observed most commonly with the potent, fluorinated, topical corticosteroids. In this situation, the patient may initially experience improvement in the dermatosis, but then experience a rebound effect requiring the more frequent use of the corticosteroid for prolonged periods. Often a vicious cycle ensues, resulting in more profound side effects (e.g., atrophy, steroid rosacea, or striae).

SYSTEMIC THERAPY

The most common systemic agents used in the treatment of skin diseases are the antihistamines, the systemic glucocorticoids, certain antimetabolites, the synthetic retinoids, and selected systemic antibiotics.

Antihistamines

Antihistamines are widely used in dermatologic conditions for the control of pruritic dermatoses such as eczema or urticaria. These agents function as competitive antagonists of histamine tissue receptor sites and may be of the H₁ or H₂ type. The different types of antihistamines are listed in [Table 191.5](#). If a patient fails to respond to one class or type, an agent from a different class should be selected. It is occasionally necessary to use H₁ and H₂ blockers simultaneously to obtain optimal clinical results. Tricyclic antidepressants, which also have antihistaminic activity, can be used instead of, or in addition to, the classic antihistamines.

Class	Examples	Oral Dosage	Comments
H₁ Antagonists			
Ethacrynate	Diphenhydramine (Benadryl)	25–50 mg q 4–6 hr	Noted sedation; significant anticholinergic activity
Chlorbutolite	Triproleptamine hydrochloride	50 mg q 4 hr	Avoid ethacrynate-uric acid patients; moderate gastroenteric effect
Pyramine	Hydroxyzine hydrochloride Pyrrolizine	10–25 mg q 4–6 hr	Most effective drug in histamine-induced pruritus; also used with ethacrynate; sedation
Alimemazine	Brompheniramine maleate (Dimenol)	8 mg q 6 hr	Lower incidence of sedation but higher incidence of stimulation than other H ₁ antagonists
	Chlorpheniramine maleate (Chlor-Trimeton)	4–8 mg q 4 hr	
Phenothiazine	Promethazine hydrochloride	15 mg q 4–6 hr	Sedation; anticholinergic effects; may produce akathisia
Pyridine	Cyproheptadine hydrochloride (Periactin)	8 mg q 6 hr	Antiserotonin activity
	Tetrahydrozoline	50 mg q 12 hr	Non-sedating; treats all pruritus
Other	Azaxone (Mevacor)	10 mg q 4 hr	Caution: monitor of erythema, leukocytosis, and hepatotoxicity is contraindicated
H₂ Antagonist			
Trifluoperazine	Cimetidine (Tagamet)	300 mg q 6 hr	Primarily useful in gastric ulcer disease

TABLE 191.5. SUMMARY OF ANTIHISTAMINES

Adverse effects of antihistamines include sedation and other central nervous system manifestations, such as paradoxical hyperexcitability, gastrointestinal intolerance, dry mouth, urinary retention, diplopia, and other anticholinergic effects. Terfenadine, an H₁ antihistamine, is uniquely able to block peripheral H₁ receptors while sparing central ones. This drug may thus be better tolerated than many other H₁-blocking agents. Topical antihistamines should be avoided because of their potential for eliciting contact sensitization.

Corticosteroids

Systemic corticosteroids (usually prednisone) are frequently given orally in the management of acute inflammatory dermatoses, such as acute contact dermatitis. In this setting, prednisone is typically started at a dosage of 0.5 to 1.0 mg per kilogram per day, which is tapered over a 2-week period. Certain other dermatologic disorders may require the administration of varying doses of systemic corticosteroids. [Table 191.6](#) lists selected skin disorders in which systemic corticosteroids are a major therapeutic option. Other disorders (e.g., urticaria, alopecia areata, psoriasis, atopic dermatitis) may respond temporarily to these drugs but are often significantly exacerbated by tapering or discontinuation of the corticosteroids. It is difficult to rationalize the long-term use of corticosteroids for these disorders.

Disorders Requiring Short-Term Therapy Only*	
Acute contact dermatitis (e.g., Rhus dermatitis)	
Erythema multiforme	
Toxic epidermal necrolysis	
Drug eruption	
Herpes zoster (prophylaxis of postherpetic neuralgia)	
Dyshidrotic eczema	
Disorder Usually Requiring Long-Term Therapy	
Lichen planus	
Pemphigus vulgaris	
Bullous pemphigoid	
Systemic lupus erythematosus	
Dermatomyositis	
Widespread eczematous dermatitis	
Pyoderma gangrenosum	
*Therapy of less than 3 weeks' duration.	

TABLE 191.6. DERMATOLOGIC DISORDERS RESPONSIVE TO SYSTEMATIC CORTICOSTEROIDS

Retinoids

The synthetic retinoids represent an option for selected cutaneous disorders. Isotretinoin is most frequently used for severe, recalcitrant cystic acne. Administration of this drug in a daily dose of 0.5 to 1 mg per kilogram per day for 4 months can produce dramatic long-term remission. Acitretin, the main metabolite of etretinate, has been approved for the management of recalcitrant pustular or exfoliative psoriasis, but must be used with extreme caution because of its long half-life in vivo.

Adverse reactions to the retinoids are numerous and include dry skin and mucous membranes, hair loss, paronychia, exuberant granulation tissue, pseudotumor cerebri, teratogenesis, liver disorders, blood lipid abnormalities, and musculoskeletal abnormalities, including skeletal hyperostoses, premature epiphyseal closure, and extraspinal tendon and ligament calcification. The teratogenicity of these agents must be underscored; retinoids should not be given to women of childbearing age who are not practicing effective contraception.

Cytotoxic and Immunosuppressive Agents

Methotrexate is the antimetabolite most widely used in dermatology for the treatment of severe psoriasis. The drug is usually administered orally or intramuscularly in small (15 to 25 mg) weekly doses. A liver biopsy may be indicated before treatment as well as periodically thereafter (every 1- to 2-g cumulative dose). The adverse effects of methotrexate include hepatic fibrosis, bone marrow suppression, teratogenesis, skin ulceration, mucositis, azotemia, and pulmonary disorders. Cyclosporin A and hydroxyurea have also been used in the management of psoriasis. Success is variable.

Antibiotics

Antibiotics such as tetracycline and erythromycin are often given on a long-term basis to patients with acne vulgaris or acne rosacea. Griseofulvin, ketoconazole, itraconazole, terbinafine, and fluconazole are the most frequently given systemic antifungal agents. Whereas griseofulvin is effective only against dermatophytes, ketoconazole and itraconazole are useful for dermatophyte, candidal, and selected deep fungal infections with cutaneous manifestations. Terbinafine is effective against cutaneous dermatophyte and candidal infections. Fluconazole is reserved for systemic and cutaneous candidiasis.

TREATMENT OF SELECTED ACUTE DERMATOSES

A selected number of dermatoses may present in a dramatic fashion and require expeditious initiation of therapy. Some of these disorders serve as examples of how the therapeutic principles outlined previously can be applied.

Acute contact dermatitis, such as that seen after poison ivy exposure, is manifested by vesicles and surrounding erythema and edema. For reactions limited to small areas of the body, treatment with an intermediate- or high-potency topical corticosteroid can be helpful. Systemic antihistamines (e.g., hydroxyzine, 10 to 25 mg every 4 to 6 hours) are often advisable, depending on the degree of pruritus. In widespread reactions, best results are obtained by the addition of systemic corticosteroids. The initial dosage of 0.5 to 1.0 mg per kilogram per day of prednisone can be tapered over a 2-week period. A rebound of clinical symptoms is often observed if corticosteroids are tapered too rapidly. For weeping lesions, compresses of Burow's solution or 0.25% acetic acid solution for 20 to 30 minutes three or four times a day are helpful.

Exfoliative erythroderma has a number of possible causes. Clinically, patients present with generalized erythema and exfoliation of the skin without frank denudation. Patients with exfoliative erythroderma often demonstrate systemic toxicity, including difficulties with temperature regulation, high-output cardiac failure, anemia, hypoalbuminemia, and fluid and electrolyte abnormalities.

Treatment of patients with exfoliative erythroderma is largely supportive, with efforts made to maintain temperature control and replace fluid and nutritional deficits. While efforts are underway to establish the cause, skin care can be initiated with intermediate-potency topical corticosteroids (e.g., triamcinolone, 0.1% cream or ointment) occluded with a nylon sauna suit. Systemic corticosteroids can be used in selected circumstances, depending on the presumed cause of the exfoliation (e.g., drug allergy, contact dermatitis). Every effort (e.g., skin biopsies, patch tests) should be made to establish a causal diagnosis and to direct care accordingly.

TREATMENT OF SELECTED CHRONIC DERMATOSES

Chronic *eczematous dermatitis*, which can be either widespread or localized, may be caused by a number of factors, including atopic eczema and chronic contact dermatitis. Although an effort should always be made to identify the cause, many cases of chronic eczema remain idiopathic. Effective control can often be achieved with topical corticosteroids, beginning with a nonocclusive intermediate-potency topical corticosteroid. Especially on the hands and feet, higher-potency topical corticosteroids ([Table 191.2](#)) with plastic glove or plastic wrap (e.g., Saran Wrap) occlusion may be needed. Systemic corticosteroids can be used for severe exacerbations, but chronic long-term use should be avoided. The management of chronic *psoriasis* can be specialized, and most patients with this disorder should be evaluated by a dermatologist. For chronic plaque-type psoriasis, the most efficacious therapy is ultraviolet light. Potent topical corticosteroids can be beneficial but occasionally lead to pustular flare-ups of the disease. In some locations (e.g., scalp and other hair-bearing areas), topical corticosteroids in a solution vehicle are helpful. Topical anthralin (Dritho-Creme) in various concentrations can be applied but can lead to skin irritation and reversible, purplish staining. Topical tar preparations can also be used (e.g., crude coal tar 0.5% to 3% [Estargel]).

CHAPTER 192: APPROACH TO THE PATIENT WITH ALOPECIA OR BALDING

SUSAN M. SWETTER

[Normal Hair Cycle](#)
[Androgenetic Alopecia](#)
[Alopecia Areata](#)
[Traction Alopecia](#)
[Telogen Effluvium](#)
[Anagen Arrest](#)
[Lupus Erythematosus](#)

Hair loss may be acquired or congenital, scarring or non-scarring, patchy or diffuse, temporary or permanent, and influenced by heredity, nutrition, illness, and aging. The two most common forms of alopecia are alopecia areata and androgenetic alopecia, the latter of which is commonly referred to as “male pattern” or “female pattern” baldness.

NORMAL HAIR CYCLE

The three phases of the normal hair cycle are anagen, catagen, and telogen. Approximately 90% of scalp hair is in a growing phase, termed *anagen*. This phase usually lasts between 2 and 6 years, with an average length of 1,000 days. Scalp hair normally grows at a rate of 0.35 mm per day, which slows with age. Less than 1% of hair is in the involuting stage, or *catagen*, at any time. The average length of this phase is 10 to 15 days. Ten percent of scalp hairs are in *telogen*, or resting phase, which lasts about 3 months (average, 100 days). Telogen hairs show a distinctive white bulb or “club” proximally. Forty to 100 telogen hairs are normally shed every day as growing hair involutes and rests over a period of several years. Hair washing results in the loss of 200 to 300 hairs in the normal range.

ANDROGENETIC ALOPECIA

Androgenetic alopecia occurs in both men and women. It is the most common type of non-scarring hair loss and typically affects the crown, or vertex, as well as the frontal scalp and bitemporal areas in men. The parietal and occipital portions of the scalp are often spared. Hair thinning occurs without symptoms, inflammation, or scaling of the scalp. It may begin at any time after puberty in men, and the incidence increases with age; that is, 25% of men 25 years of age show hair loss compared with 50% of men age 50 years. Hair loss may be gradual and continuous or episodic. The cause of androgenetic alopecia involves a shortening of the anagen phase of the hair cycle, which is the active growing phase, in response to androgen exposure and genetic factors.

The onset of androgenic alopecia in women is later, typically occurring between 25 and 35 years of age. Hair loss is usually less extensive than in men, with involvement usually limited to the frontal scalp and vertex. The frontal hairline is almost always preserved in women. Diffuse, central thinning may be subtle and preceded by a telogen effluvium in which increased numbers of hairs in the resting phase show synchronized shedding. Both male and female androgenetic alopecia result from a genetically determined end-organ sensitivity to androgens. Thus, family history of common baldness should be obtained in the patient presenting with either localized or diffuse hair loss.

OPTIMAL MANAGEMENT

The options for therapy for androgenetic alopecia have increased in recent years. Surgical scalp reduction may be performed after significant hair loss has occurred on the frontal scalp or vertex. Hair transplantation using grafts from the occiput results in long-term hair regrowth because transplanted hair plugs show site-specific androgen sensitivity from their location of origin; thus, occipital plugs do not develop vertex or frontal scalp androgen sensitivity. Improved techniques in hair grafting have resulted in increased cosmesis with a more natural-appearing hairline.

Only two medical treatments are approved for the treatment of androgenetic alopecia in the United States: the topical application of minoxidil (2% or 5%) or systemic treatment with finasteride 1 mg. Minoxidil (or, rather, its vasoactive metabolite, minoxidil sulfate) works by stimulating the hair follicle to remain in anagen phase for a longer period of time. It has no antiandrogen activity and is not absorbed in significant enough amounts to result in hypotension or other systemic side effects.

A 6-month trial of minoxidil on a twice-daily basis is required to assess response, which may present clinically as cessation of hair shedding or visible hair regrowth, usually of the vellus type. Approximately 30% of patients experience some hair regrowth, although up to 80% notice a reduction or complete cessation of hair loss. Topical minoxidil must be continued indefinitely to remain effective.

Finasteride is a 5- α -reductase type II inhibitor that causes reduction in the androgen, dihydrotestosterone, and has recently been approved as a 1-mg daily dose for men with androgenetic alopecia. It is contraindicated in pregnant women because it may cause feminization of a male fetus. Antiandrogen drugs such as spironolactone and flutamide have been tried for androgenetic alopecia in women, although they tend to be more useful in patients with underlying endocrine dysfunction. Finally, complete or partial hairpieces are available and may be custom-fitted and dyed to achieve a more natural appearance.

ALOPECIA AREATA

Alopecia areata is common, occurring in 1% of the population by 55 years of age. All ages are affected, although the incidence is increased in younger age groups. A family history of alopecia areata is present in more than 30% of patients with onset before age 30 years, compared with only 7% in patients with later onset. Clinical findings include well-demarcated patches devoid of hair and with visible follicles, indicative of a non-scarring process. Alopecia areata involving the entire scalp is termed *alopecia totalis*, whereas progression to involve the eyebrows, body, and pubic hair is called *alopecia universalis*. These two types are associated with a worse prognosis in terms of eventual hair regrowth.

Alopecia areata is believed to be an autoimmune disease and has been associated with other autoimmune diseases such as Hashimoto's thyroiditis, vitiligo, pernicious anemia, and early-onset diabetes mellitus. Abrupt onset of inflammation at the base of the hair follicle is believed to cause a dysfunction of the hair growth cycle with subsequent acute hair loss. Although this process is reversible (i.e., no scarring or loss of follicles occurs), hair regrowth does not always occur.

Most patients with new-onset alopecia areata are healthy. Routine laboratory testing usually is not useful unless there is a family history of thyroid disease. Thyroid function tests may also be helpful in the workup of young children presenting with alopecia areata. Recurrent episodes of alopecia areata are not uncommon and cannot be prevented by prior treatment.

OPTIMAL MANAGEMENT

Treatment options for alopecia areata include intralesional or systemic corticosteroids, production of allergic contact dermatitis with dinitrochlorobenzene, diphenylcyclopropenone, squaric acid dibutylester, or anthralin short-contact therapy, photochemotherapy with psoralin and ultraviolet A light (PUVA), and topical minoxidil. Appropriate treatment depends on the extent of disease, and alopecia may improve or worsen with or without therapy. There is no therapy proven efficacious for diffuse disease, and the likelihood of hair regrowth decreases with increased degree and duration of hair loss.

TRACTION ALOPECIA

Traction alopecia may manifest similarly to alopecia areata with discrete areas of scalp hair loss. When associated with habitual hair pulling or psychological stress, traction alopecia is termed *trichotillomania* and often reverses when a person has psychological counseling. Traction alopecia may also be acquired in the setting of tight braids, hairclips, or ponytails worn for many years and is usually seen in young children or adult women. A chronic folliculitis along the temporal and frontal hairline may result in permanent scarring with loss of visible hair follicles. Reversible traction alopecia occurs if the problem is recognized and corrected early.

TELOGEN EFFLUVIUM

Telogen effluvium is an important cause of hair loss in adults. It is caused by a disruption of the normal hair cycle that synchronizes an increased number of hairs to enter the telogen phase. Those hairs are usually shed 2 to 3 months after the inciting event (the average length of the normal telogen phase) and are thus perceived as a period of increased hair loss. Marked hair shedding may occur with or without evidence of clinical hair thinning.

The most recognizable cause of telogen effluvium occurs in the postpartum period, typically 2 to 3 months after delivery. It is usually self-limited and resolves over 6 months, although normal hair growth equal to that before pregnancy does not always occur. Other causes of telogen effluvium include reduction in protein intake due to "crash dieting," hyperthyroidism or hypothyroidism, severe chronic illness, or drugs such as b-blockers, coumarin, sodium valproate, lithium carbonate, sulfasalazine, or oral contraceptives with increased progestational activity. It is important to obtain a medical history related to these possible causes for the 2 to 3 months preceding the onset of telogen effluvium. Correction of thyroid disease, increased protein intake, or discontinuation of the offending drug usually results in complete reversibility and cessation of increased hair shedding.

ANAGEN ARREST

Anagen arrest occurs in the setting of cancer chemotherapy because hair bulb cells show the greatest mitotic activity of any cells in the human body. Chemotherapeutic agents cause narrowing of the hair shaft and subsequent hair breakage within 1 to 3 weeks. The process is entirely reversible after cessation of chemotherapy. Patients should be warned about the expected time course and abrupt onset of alopecia, and cosmetic hairpieces may be advisable before the onset of hair loss.

LUPUS ERYTHEMATOSUS

The most important disease causing a scarring scalp alopecia is lupus erythematosus. Discoid lupus erythematosus manifests as erythematous, scaly telangiectatic plaques on the malar areas of the face, and up to 50% of patients have similar discoid lesions in the scalp. Pigmentary alteration, including hyperpigmentation and hypopigmentation, telangiectasia, and atrophy of the plaques, occurs with time. Potent topical corticosteroids, intralesional corticosteroids, or systemic immunosuppressive agents such as prednisone or hydroxychloroquine may be used for treatment. Approximately 15% of patients with systemic lupus erythematosus show classic discoid lesions and have possible scalp involvement over the course of their disease. Treatment is similarly directed to prevent permanent scarring and hair loss.

[Table 192.1](#) and [Table 192.2](#) represent a specific approach to the workup and diagnosis of patients presenting with hair loss.

History
 Onset and duration of hair loss
 Does hair come out "by the roots" or is it breaking?
 Family history of hair loss, baldness
 Medical history—menstrual cycle, diet, stress, depression, thyroid disease, pregnancy, current and past medications, history of chemotherapy, history of abrupt weight loss or "crash dieting"
 Hair length and texture—change from hair cosmetics?
 Pattern and duration of hair loss
 Presence or absence of patches with or without hair loss
 Other changes to suggest scarring process—scalp atrophy, pigmentation changes
 Hair "pull test"—does hair in hand with firm tugging character?
 Hair texture—does hair break at shaft, assess for telogen versus anagen hair
Laboratory Work
 Scalp biopsy—helpful in diagnosis of most alopecias (scarring alopecia, or patchy or "moth-eaten" alopecia seen with secondary syphilis)
 Complete blood count, thyroid function tests, serum iron—studies that assist in workup of alopecia areata, patchy alopecia areata, or alopecia of thyroid dysfunction are discussed elsewhere
 Additional studies—thyroid function tests, serum iron, serum iron, or sedimentation rate, and serum albumin

TABLE 192.1. APPROACH TO THE PATIENT PRESENTING WITH HAIR LOSS

	Scarring		Nonscarring		
	Inflammatory	Noninflammatory	Inflammatory	Noninflammatory	Other
Atly	Diffuse	Atly-Diffuse	Atly	Diffuse	Atly-Diffuse
Local alopecia	Diffuse	Localized	Alopecia areata	Alopecia	Androgenic
Diffuse alopecia	Inflammatory	Telogen alopecia	Follicular necrosis	Alopecia	
Local alopecia	Scarring	Telogen alopecia	Secondary syphilis	Scarring alopecia	
Reversible alopecia	Protein	No alopecia		Telogen alopecia	
Itchy	No alopecia	Scarring alopecia		Telogen alopecia

CHAPTER 193: PSORIASIS, LICHEN PLANUS, AND PITYRIASIS ROSEA

CHRISTOPHER M. BARNARD

[Psoriasis](#)
[Lichen Planus](#)
[Pityriasis Rosea](#)

PSORIASIS

Psoriasis is a primary disease of the skin characterized by well-demarcated inflammatory papules and plaques, which are typically covered by thickened, silvery scales.

ETIOLOGY

Psoriasis is a disease of increased proliferation of epidermal cells, the precise cause of which is unknown. Evidence that a genetic (familial) predisposition is a major factor in the clinical expression of psoriasis is supported by the greater than normal incidence in patients with psoriasis of certain human leukocyte antigen (HLA) markers, especially HLA-A1, B13, B17, Cw6, DRw6, and DR7. It has been further suggested that the presence of HLA-DR⁺ keratinocytes in psoriatic plaques correlates with disease activity. Linkage to a gene for familial psoriasis susceptibility has recently been localized to the distal end of chromosome 17q in a study of several kindreds. An incomplete autosomal dominant pattern of inheritance seems most likely; however, a polygenic, multifactorial pattern is also possible.

PATHOGENESIS

Traditional investigations into the pathogenesis of psoriasis have focused on the increased proliferation and hyperplasia of the epidermis. In normal skin, the time for a cell to move from the basal layer through the granular layer is 4 to 5 weeks. In psoriatic lesions, the time is decreased seven to ten times because of a shortened cell cycle time, an increase in the absolute number of cells capable of proliferating, and the fact that, among those cells, an increased proportion of cells are actually dividing. The hyperproliferative phenomenon is also expressed, although to a substantially smaller degree, in the clinically uninvolved skin of psoriatic patients.

Several biologic aberrations have been proposed to account for the enhanced proliferation of keratinocytes. T-cell-mediated immune responses appear to be responsible for the inflammation and hyperproliferation seen in psoriasis. Cytokine production elicited by the dermal immune reaction stimulates abnormal epidermal cell (keratinocyte) proliferation and differentiation. The possibility that a superantigen (e.g., microbial antigen) might activate cutaneous T cells has been studied but not conclusively shown to trigger psoriasis.

Psoriasis is an inflammatory disease in which neutrophils are found within psoriatic lesions. Arachidonic acid, the levels of which are much higher than normal in psoriatic plaques, and its metabolites are probably important in this aspect of the disease because they can act as vasodilators and chemoattractants for neutrophils. The cause, or possibly the effect, of this may be increased levels of plasminogen activator in psoriatic lesions. Enhanced plasminogen activator may lead to neutrophil accumulation through direct complement activation and to enhanced activation of proteases.

Normal skin contains capillary loops within the dermis, which have intact basement membranes. In contrast, psoriatic skin has multiple gaps in endothelial cells that appear to lead to increased vascular permeability. These gaps can be seen in both involved and uninvolved psoriatic skin. It is not clear how the gaps occur, but they may represent cellular injury from the inflammatory responses or abnormalities in other cells in the dermis.

Other cells of the psoriatic dermis also display abnormalities. Psoriatic fibroblasts have increased levels of enzymes involved in collagen synthesis. This phenomenon is probably secondary to expansion of the papillary dermis required to support the hyperproliferative epidermis, rather than a primary abnormality. When fibroblasts are cultured from the skin of unaffected people, 1,25-dihydroxyvitamin D₃ inhibits proliferation; in contrast, fibroblasts from either involved or uninvolved skin of psoriatic patients display a relative resistance to this effect. Vitamin D₃ analogues have been shown to successfully clear psoriatic plaques, although the exact mechanism of action is unknown. Furthermore, when psoriatic fibroblasts from either involved or uninvolved skin are incorporated in vitro into a collagen lattice that functions as a dermal equivalent, they induce hyperproliferation in normal keratinocytes.

Primary immunologic mechanisms have been implicated in initiating the proliferative process of psoriasis. HLA-DR⁺ keratinocytes and Langerhans' cells and activated T lymphocytes with increased numbers of interleukin-2 receptors have been found in active psoriatic plaques. In addition to these laboratory observations, in several well-controlled clinical studies, dramatic clearing of recalcitrant, severe psoriasis has been achieved by using cyclosporin A. The major mechanism of action of cyclosporin A is to inhibit the release of lymphokines produced by activated T lymphocytes. Thus, a hypothesis is that the activated T cells, in response to autologous or exogenous antigens, may release factors that directly result in inflammation and epidermal proliferation or indirectly produce these effects by activating macrophages or keratinocytes, which then release cytokines, mediators of inflammation, or growth factors that can elicit the pathologic condition of psoriatic plaques.

INCIDENCE AND EPIDEMIOLOGY

The incidence of psoriasis in the United States is about 2% of the population. About 3% of whites and 1% of blacks are affected. Occurrence is extremely low in Native Americans. Psoriasis affects both sexes equally. It occurs in about 2.5% of HIV-infected patients and is severe in 25% to 30% of the HIV-infected population.

CLINICAL FEATURES

The typical lesion of psoriasis is a well-demarcated erythematous plaque covered by thick, silvery scales ([Fig. 193.1](#)). A characteristic finding is the isomorphic response (Koebner's phenomenon), in which new psoriatic lesions arise at sites of cutaneous trauma. Lesions are often localized to the extensor surfaces of the extremities, and the nails and scalp are also commonly involved. The entire body, including mucosal, genital, and perineal skin, can be involved. Nail involvement in psoriasis is usually manifested by pitting of the surface or by onycholysis (distal separation of the nail plate from the nail bed).

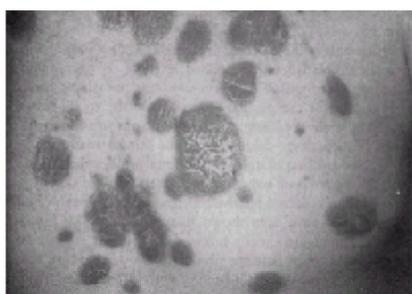

FIGURE 193.1. Chronic plaque-type psoriasis. See [color figure 193.1](#).

Psoriasis can become so extensive as to cause exfoliative erythroderma, in which the entire epidermal surface is in a state of hyperproliferation. In this condition, many of the critical barrier functions of the skin are lost: The cutaneous microvasculature is dilated, leading to heat loss and hypoproteinemia; there is increased transepidermal water loss; and patients often experience profound chilling. Prolonged exfoliation can also lead to anemia, presumably due to iron and folate loss through the skin.

In *guttate psoriasis*, a form of the disease that often erupts after streptococcal pharyngitis, lesions are characteristically 1 to 3 cm in diameter and widely distributed over the body. The course is unpredictable; the disease may go into remission or be a prologue to a more chronic form of psoriasis.

A third form is *pustular psoriasis*, which is characterized by numerous sterile pustules, often 2 to 5 mm in diameter, on the palms and soles or distributed over the body. When they involve the palms and soles, the pustules are associated with hyperkeratosis. In other parts of the body, the pustules may form clusters on oval plaques with an erythematous inflammatory base, which can spread and leave a fine superficial scale. In pustular psoriasis, there may be acute, often explosive, life-threatening episodes in which the patient experiences fever, chills, leukocytosis, hypoalbuminemia, and hypocalcemia. Hypovolemia can also occur. This form of psoriasis demands immediate, vigorous therapy.

Acute exacerbations of previously stable, typical plaque-type psoriasis may occur in patients who acquire HIV infection. These exacerbations may become more refractory to conventional therapy. New-onset psoriasiform dermatitis may signal the possibility of underlying HIV infection. This form of psoriasis, which develops after the onset of HIV infection, tends to appear in association with palmoplantar psoriasis.

Psoriatic arthritis is divided into five types and is described in further detail with the seronegative spondyloarthropathies ([Chapter 176](#)).

LABORATORY FINDINGS

The major procedure required for the diagnosis of psoriasis is skin biopsy. The specimen reveals hyperkeratosis with parakeratosis, which indicates the retention of nuclear fragments, increased proliferation, and defective keratinization. Elongation of the rete ridges (acanthosis) and thinning of the epidermis above the dermal papillae are found. The dermal capillaries are often dilated, and there is a chronic inflammatory infiltrate. Frequently, neutrophils migrate into the stratum corneum to form microabscesses. In pustular psoriasis, the microabscesses are a predominant feature.

COURSE, THERAPY, AND PROGNOSIS

Untreated psoriasis typically follows a chronic course, with some fluctuation in severity. Patients frequently report improvement during the summer, probably from the beneficial effects of natural ultraviolet light. Conversely, exacerbation of psoriasis is common in the winter, possibly owing to low humidity and xerosis, leading to epidermal damage and an isomorphic response. Other modalities that traumatize the skin—abrasion, infection, and various types of dermatitis—also can worsen the disease. As noted, guttate psoriasis can be precipitated by streptococcal pharyngitis.

Several commonly used drugs exacerbate preexisting psoriasis by inducing new types of lesions in patients with psoriasis (e.g., pustular psoriasis in a patient with plaque-type disease), by eliciting new psoriasis in patients without a history of the disease, or by inducing treatment resistance ([Table 193.1](#)). With most of these drugs, the incidence of exacerbation appears to be low, but no prospective studies have been carried out. The most worrisome features of drug-related exacerbation of psoriasis are the unpredictability of its occurrence, the long latent periods (up to several months), and the possibility of severe manifestations, such as exfoliative erythroderma and acute pustular psoriasis.

Drug	Possible Mechanisms of Exacerbation	Types of Exacerbation
Lithium	Inhibition of adenosine triphosphatase Enhanced release of inflammatory mediators Toxic neurotoxicity	Exacerbation of preexisting psoriasis New-onset psoriasis Therapeutic resistance New-onset psoriasis
β-Adrenergic blockers Propylthiouracil Oxytocin Fenfluramine Alprazolam Alprazolam Risperidone Amitriptyline Chloroquine Hydroxychloroquine Quinine Corticosteroids	Decreased β-adrenergic receptor activity with decreased adenosine triphosphatase activity Unknown	Generalized pustular psoriasis Acute pustular psoriasis Exacerbation of preexisting psoriasis
Neuroleptic and sedative agents Isoniazid Phenothiazines Methimazole	Inhibition of cytochrome P-450 acid accumulation, causing inhibition to the long-chain fatty acid and increased leukotrienes (LTA ₄)	Exacerbation of preexisting psoriasis Acute pustular psoriasis Pustular psoriasis

Modified from Gier RA, Neisewander JL, Dentberg BC, et al: Drug-induced exacerbation of psoriasis. *J Am Acad Dermatol* 1986;15:907.

TABLE 193.1. DRUG-RELATED EXACERBATION OF PSORIASIS

Therapeutic efforts in psoriasis are aimed at decreasing the proliferative rate of the epidermis, either by direct action on cell division or through agents that reduce the inflammatory response or vascular permeability. For patients with localized, limited psoriasis, administration of topical corticosteroids is the most convenient outpatient therapy. Rapid improvement may be seen with this approach, but the beneficial short-term efficacy is limited and long-term topical corticosteroid treatment is not advisable. Side effects from long-term topical corticosteroid therapy can include atrophy of the skin, development of a tolerance to the agent used (tachyphylaxis), and serious exacerbation of the disease after discontinuation. Pituitary–adrenal suppression is a potential and serious complication of potent topical corticosteroid therapy, particularly when the agent covers a large portion of the body surface and is used under occlusive dressings. Despite these potential drawbacks, topical corticosteroid therapy, in combination with emollients or used alone, remains the most commonly prescribed treatment for psoriasis.

Calcipotriene 0.005% ointment is a vitamin D₃ derivative, which may be applied topically twice daily to improve plaque-type psoriasis. At recommended dosages, calcium metabolism appears to be minimally affected, although hypercalcemia has been seen in patients using excessive amounts of the topical ointment. The safety and efficacy of this treatment have been established for up to 52 weeks of therapy if dosages are maintained below 100 g per week.

Tazarotene gel (0.05% and 0.1%) is a topical retinoid recently introduced for once-a-day treatment of plaque-type psoriasis. Mild to moderate psoriasis can be controlled after 1 to 12 weeks of treatment, and improvement has been noted to remain for up to 12 weeks after discontinuation of therapy. Local skin irritation has been reported to occur with tazarotene therapy and can be minimized with concomitant topical corticosteroid therapy. As with all retinoids, tazarotene is contraindicated in women who are or who may become pregnant.

Topical coal tar preparations have been effective when used alone to clear psoriatic plaques; however, the unpleasant odor and propensity to stain fabrics reduce their acceptance by patients. Hospitalization may be required for patients with more extensive disease, who are treated with topical coal tar preparations followed by irradiation with B-spectrum ultraviolet light (290 to 320 nm). This regimen, known as *Goeckerman's regimen*, can be modified to include the use of topical corticosteroids.

For patients with extensive disease, systemic antimitotic agents such as methotrexate can be used. Methotrexate is usually administered on an intermittent basis and should not be given more frequently than once weekly. Patients receiving it should be monitored for hematologic and liver toxicity; because methotrexate-induced cirrhosis is a risk, especially after a cumulative dose of 1.5 g has been reached, liver biopsy may be indicated. Treatment with methotrexate in HIV-positive patients has been studied, although its safety has not been clearly established.

Extensive psoriasis can also be treated with photochemotherapy. In this regimen, oral 8-methoxypsoralen produces photosensitization, which is followed by exposure to ultraviolet A (psoralen ultraviolet light A [PUVA], 320 nm). Like Goeckerman's regimen, this therapy inhibits mitotic activity in the epidermis, and it produces remissions in up to 80% of patients with plaque-type psoriasis. It seems to be less useful in patients with pustular psoriasis. Major complications of PUVA therapy are acute sunburn and the risk of corneal damage. Eyes must be protected for up to 24 hours after ingestion of the psoralens. PUVA therapy may cause retinal damage in aphakic persons and is therefore contraindicated in these patients. Although skin cancer develops in 2% of patients on PUVA, it also occurs in patients on Goeckerman's regimen who have had intensive tar and ultraviolet B exposure. Fair-skinned people with long histories of exposure to ultraviolet irradiation are at

highest risk.

The retinoids, particularly acitretin (the major metabolite of etretinate), either alone or in combination with PUVA, also constitute an effective treatment for psoriasis. Acitretin is especially useful in the exfoliative and pustular varieties. Several major potential complications must be monitored in patients placed on retinoids. As a class, the retinoids are potent teratogens and should not be given to women of childbearing age who are not using adequate contraception. Acitretin, like other retinoids, can produce elevations in cholesterol and triglyceride levels, so dietary regulation may be necessary. In addition, because acitretin can induce hepatotoxicity, liver function tests should be performed before and at regular intervals during use of the drug. The half-life of acitretin is about 49 hours, considerably shorter than its parent compound of etretinate with a half-life of about 6 months. For HIV-positive patients with severe psoriasis, acitretin may be the best therapeutic strategy.

During acute attacks of pustular psoriasis, systemic corticosteroids have been the therapy of choice. Acitretin can also produce rapid remission or can be used for maintenance therapy after initial control has been achieved with systemic corticosteroids. Except in life-threatening pustular psoriasis, systemic corticosteroids have no place in the therapy of psoriasis; indeed, acute severe flare-ups of psoriasis can result when systemic corticosteroids are withdrawn ([Table 193.1](#)).

In view of the postulated immunologic mechanisms in psoriasis, it is interesting that cyclosporin A has been shown to be an effective treatment. The results of the clinical trials using low-dose (3 to 7 mg per kilogram) cyclosporin A are impressive, because the time required to achieve complete remission ranges from 1 to 4 weeks. The major adverse effects of cyclosporin A with short-term, low-dose usage include potential renal dysfunction and hypertension. The renal toxicity is usually reversible at low doses on discontinuing therapy; however, irreversible damage may occur with a prolonged treatment course. Patients who have previously received extensive phototherapy, particularly PUVA, must be monitored for the development of invasive squamous cell carcinomas of the skin. The use of cyclosporin A should be reserved for patients with recalcitrant, debilitating psoriasis when the benefits outweigh the potential risk of complications.

LICHEN PLANUS

Lichen planus (LP) is a common inflammatory dermatosis characterized by pruritic, angular, purple papules on the skin and small, white papules forming netlike patterns on mucosal surfaces.

ETIOLOGY AND PATHOGENESIS

The cause of LP is unknown, but a cell-mediated immune response appears to play a major role in its pathogenesis. Early LP lesions reveal increased CD4⁺ T cells in the dermal infiltrate; later lesions show CD8⁺ T cells in the epidermis. This pattern suggests that antigen presentation to helper T cells activates a cytokine response to recruit cytotoxic T cells, which results in damage to the keratinocytes of the epidermis. More recently, infection with hepatitis C virus has been found in association with LP in some cases. However, a significant causal relation has not been definitively established.

INCIDENCE AND EPIDEMIOLOGY

The incidence of LP is reportedly 0.1% to 1.4% in dermatology clinics. Most patients are between ages 30 and 60, with both sexes affected equally.

CLINICAL FEATURES

LP is a pruritic inflammatory dermatosis that affects the skin and mucous membranes. The flat-topped, polygonal, purple, scaly papules characteristic of LP appear most commonly on the trunk and the flexor surfaces of the extremities. Very fine, white reticulate lines on the surface of the papules, known as *Wickham's striae*, are a helpful diagnostic feature. The dorsal hands, flexor surfaces of the forearms, wrists, and ankles are areas of predisposition. Oral lesions on the lips or buccal mucosa, consisting of fine, lacy, or netlike reticulate patterns of small white papules or plaques, are present in over 50% of patients with cutaneous LP and may be the only finding in up to 25% of patients. In addition, the genitalia, nails, and scalp may be affected with specific forms of the disease. There are many variations in the morphology of LP, including hypertrophic, bullous, erosive, and atrophic types.

The differential diagnosis includes LP-like eruptions secondary to medications such as antimalarial agents, captopril, gold, methyldopa, penicillamine, phenothiazines, propranolol, tetracyclines, and thiazides. Chemical exposure to para-phenylenediamine in color photographic film developer can result in an eruption similar to LP. In graft-versus-host disease, an LP-like eruption may develop and can be distinguished histologically on skin biopsy. The lichen planus–lupus erythematosus overlap syndrome exhibits features of both disorders and may simply represent the coexistence of these two diseases.

LABORATORY FINDINGS

Skin biopsy, the only valuable diagnostic laboratory test for LP, reveals a classic “sawtooth” pattern to the epidermis, with hypergranulosis and hyperkeratosis at the surface. Keratinocyte degeneration at the lower epidermis results in eosinophilic or colloid bodies (e.g., Civatte bodies), which are positive for IgM antibody on direct immunofluorescence. Basal cell layer degeneration results in separation, or clefting, between the dermis and epidermis. Below the dermal–epidermal junction, a lichenoid or bandlike infiltrate of lymphocytes is present.

COURSE, THERAPY, AND PROGNOSIS

The onset of LP may be gradual or sudden. With acute, sudden eruptions, the course is usually shorter, and clearing may occur within several months. The papules in localized forms of LP usually resolve within 6 to 18 months, resulting in hyperpigmentation at the sites of involvement. In the more generalized forms, the eruption may persist for several years or longer. Involvement of the mucous membranes also prolongs the course.

Moderate to severe pruritus is reported by most patients. Koebner's phenomenon, similar to that seen with psoriasis, results in new papules of LP at sites of trauma to the skin.

Topical or intralesional corticosteroids are effective treatment for most cases of localized lesions of LP. Antihistamines are also beneficial in relieving pruritus. For patients with more widespread involvement, oral corticosteroids may be required to control severe pruritus and to slow or halt progression of the disease. Oral LP may be treated with topical corticosteroids in combination with an adhesive base such as Orabase for better adhesion to the mucous membranes. In particularly recalcitrant cases, retinoids, cyclosporin A, and photochemotherapy all have been used with varying success.

LP recurs in 10% to 20% of patients; recurrence is more common after generalized eruptions. The erosive and hypertrophic types are particularly difficult to treat and may also result in a protracted course or recurrence.

PITYRIASIS ROSEA

Pityriasis rosea (PR) is a common, acute, inflammatory skin eruption that manifests as oval, erythematous, scaly papules and plaques. It begins with a single red, scaly “herald patch” followed by a generalized eruption. The course of the disease is self-limited, and it is of unknown origin.

ETIOLOGY AND PATHOGENESIS

Many studies have attempted to identify an infectious agent responsible for the PR eruption, which has a similar onset, course, and resolution to a viral exanthem. However, no conclusive evidence for this mechanism has ever been obtained. A PR-like eruption has been reported to be caused by numerous drugs, particularly captopril and gold therapy. Barbiturates, metronidazole, isotretinoin, and several other medications all have been implicated as well. An immune mechanism has been postulated in the pathogenesis of PR. HLA-DR⁺ helper T lymphocytes and keratinocytes have been found in the cellular infiltrate of the inflammatory plaques, suggesting a cellular immune reaction.

CLINICAL FEATURES

The classic presentation of PR involves the onset of a single red, oval patch, commonly on the trunk and several centimeters in diameter. This initial lesion, the herald patch, precedes the generalized eruption by 1 to 2 weeks. The herald patch is usually scaly at the borders, with clearing toward the center of the lesion. The generalized eruption that follows is distributed over the trunk, abdomen, neck, and proximal extremities, with sparing of the palms and soles. Typical lesions are pink, oval, 1- to 2-cm thin plaques or patches with an inwardly pointed collarette of scale. Individual oval lesions may be oriented along their long axes in line with the skin tension lines of the trunk, creating a "Christmas tree" pattern characteristic of PR. The herald patch may resolve before the secondary generalized eruption, which generally subsides after 1 to 3 months without treatment. Mild to severe pruritus is noted in up to 75% of patients with PR. Resolution of the inflammatory patches may result in hypo- or hyperpigmentation.

The differential diagnosis of PR may include widespread superficial tinea infections, nummular eczema, drug eruptions, and, most important, secondary syphilis. Tinea can be excluded by mycology culture or potassium hydroxide examination for hyphae. Nummular eczema is much more persistent than PR and is characteristically annular with thicker, scaly plaques. Drug eruptions can be difficult to distinguish, particularly if they are related to the medications mentioned previously. Secondary syphilis can be differentiated by the presence of scaly, erythematous palmar and plantar papules, a history of a genital chancre, and a positive serologic test for syphilis.

LABORATORY FINDINGS

Biopsy of the characteristic oval patch reveals a spongiotic dermatitis with a lymphocytic infiltrate and patchy parakeratosis. Extravasated red blood cells into both the dermal papillae and epidermis may be seen. There are no helpful blood tests to identify this disorder, although elevated white blood cell counts have been reported.

MANAGEMENT

Because PR is generally self-limited within 6 to 8 weeks, symptomatic relief with topical midpotency corticosteroids and emollients may be beneficial. Ultraviolet B light therapy has been used with success but has also been reported to result in greater postinflammatory changes. Avoiding irritation of the lesions is helpful in preventing further pruritus. Recurrence occurs in less than 2% of patients.

CHAPTER 194: INFECTIONS OF SKIN

GARY L. DARMSTADT

[Bacterial Infections](#)
[Fungal Infections](#)
[Candidal Infections](#)

BACTERIAL INFECTIONS

MECHANISM OF PYOGENIC BACTERIAL INFECTION

Skin microflora is composed primarily of resident bacteria that are attached to the skin and are present in relatively stable numbers and transient flora that attach and cause disease only when the integrity of the skin is disturbed. The most important of the transient bacteria are the group A *Streptococcus pyogenes*; (GABHS) and *Staphylococcus aureus*.

IMPETIGO

Clinical Findings

Nonbullous impetigo accounts for more than 70% of cases of impetigo. Lesions of nonbullous impetigo usually begin on skin that has been traumatized. A vesicle or pustule forms initially and develops rapidly into a honey-colored, crusted plaque. Regional adenopathy is found in up to 90% of patients, and leukocytosis is present in approximately 50%. Without treatment, lesions generally resolve spontaneously without scarring within about 2 weeks.

Bullous impetigo manifests most commonly with flaccid, transparent bullae on the face, buttocks, trunk, perineum, and extremities. Rupture of bullae occurs easily, leaving a narrow rim of scale at the edge of a shallow, moist erosion. Surrounding erythema and regional adenopathy usually are absent.

Complications

Cellulitis has been reported in approximately 10% of patients with nonbullous impetigo but rarely follows the bullous form. Lymphangitis, suppurative lymphadenitis, guttate psoriasis, and scarlet fever may occasionally follow streptococcal disease. Infection with nephritogenic strains of GABHS may result in acute poststreptococcal glomerulonephritis. The most commonly affected age group is school-age children 3 to 7 years old. Impetigo-associated epidemics of poststreptococcal glomerulonephritis are caused by M groups 2, 49, 53, 55, 56, 57, and 60. Strains of GABHS associated with endemic impetigo in the United States have little or no nephritogenic potential. The clinical character of impetigo lesions does not differ between those that lead to poststreptococcal glomerulonephritis and those that do not. Acute rheumatic fever does not occur after impetigo.

Etiology

S. aureus is the predominant organism of nonbullous impetigo in the United States. Staphylococci usually spread from the nose to normal skin and then may colonize and possibly infect the skin. The staphylococcal types that cause nonbullous impetigo usually are not from phage group II, the group associated with scalded skin and toxic shock syndromes. GABHS are implicated in the development of some lesions of nonbullous impetigo. In contrast to what happens with *S. aureus* infection, the skin is colonized directly with GABHS an average of 10 days before impetigo develops. Several serotypes of GABHS, termed "impetigo strains," are found most frequently in lesions of nonbullous impetigo and are different from those that cause pharyngitis.

Bullous impetigo is always caused by coagulase-positive *S. aureus*; lesions of bullous impetigo are a manifestation of localized staphylococcal scalded skin syndrome and develop on grossly intact skin.

Diagnosis and Optimal Management

Diagnosis of impetigo is usually made on clinical grounds. Culture of fluid from an intact blister should yield the causative organism. When the patient appears ill, blood cultures should also be obtained.

Mupirocin applied three times daily for 7 to 10 days is equal to or greater in effectiveness and with fewer side effects than oral erythromycin ethylsuccinate for 7 to 10 days for treatment of localized, uncomplicated impetigo. Mupirocin may be preferable in areas with a high prevalence of erythromycin-resistant strains of *S. aureus*. In patients with widespread or deep involvement, including cellulitis, furunculosis, abscess formation, or suppurative lymphadenitis, systemic therapy with a β -lactamase-resistant oral antibiotic (e.g., cephalexin, dicloxacillin) should be prescribed. If a satisfactory clinical response is not achieved within 7 days, a culture should be taken by swabbing beneath the lifted edge of a crusted lesion. If a resistant organism is detected, an appropriate antibiotic should be given for an additional 7 days.

ECTHYMA

Clinical Findings

Ecthyma resembles nonbullous impetigo in onset and appearance but gradually develops into a deeper, more chronic infection. The initial lesion is a vesicle that erodes through the epidermis into the dermis to form a crusted ulcer. Lesions occur most commonly on the legs. Predisposing factors include pruritic lesions, such as insect bites, scabies, or pediculosis, which are subject to frequent scratching; poor hygiene; and malnutrition. Complications include lymphangitis, cellulitis, scar formation, and, rarely, poststreptococcal glomerulonephritis.

Etiology

The causative agent of ecthyma is usually GABHS. *S. aureus* is also cultured from most lesions but is probably a secondary pathogen.

Optimal Management

Crusts should be softened by warm compresses and removed. Systemic antibiotic therapy, as for impetigo, is indicated.

Ecthyma Gangrenosum

Ecthyma gangrenosum is a descriptive term for a necrotic ulcer covered with a gray-black eschar. Classically, it is a sign of *Pseudomonas aeruginosa* sepsis and usually occurs in immunosuppressed patients. The lesion begins as a red or purpuric macule that vesiculates and then ulcerates. There is a surrounding rim of pink to violaceous skin. The punched-out ulcer develops raised edges with a dense, black, depressed, crusted center. Clinically similar lesions may also develop as a result of infection with other bacilli, such as *Pseudomonas cepacia*, *Xanthomonas maltophilia*, *Escherichia coli*, *Serratia marcescens*, and *Aeromonas hydrophila*, and with *Candida* species. Blood cultures and skin biopsy for culture should be obtained, and empirical intravenous broad-spectrum antibiotic therapy, including antipseudomonal agents, should be initiated as soon as possible.

STAPHYLOCOCCAL SCALDED SKIN SYNDROME

Clinical Findings

Staphylococcal scalded skin syndrome occurs predominantly in infants and children younger than 5 years. A wide range of presentations may occur, from localized bullous impetigo to generalized cutaneous involvement with systemic toxicity. Onset of the rash may be preceded by malaise, fever, and cutaneous tenderness. Scarletiform erythema develops diffusely and is accentuated in flexural and periorificial areas. The conjunctivae are inflamed and occasionally become purulent, but oral mucosal surfaces are spared. In severe cases, sterile, flaccid blisters and erosions develop diffusely. Circumoral erythema is prominent, as is radial crusting and fissuring around the eyes, mouth, and nose. At this stage, areas of epidermis may separate in response to gentle shear force (Nikolsky's sign). Secondary problems of cutaneous superinfection and cellulitis, sepsis, fluid and electrolyte disturbances, and pneumonia may cause increased morbidity. Desquamation follows cutaneous erythema by a few days, and healing occurs without scarring within approximately 2 weeks.

Etiology

Staphylococcal scalded skin syndrome is caused predominantly by phage group II staphylococci, particularly strains 71 and 55, which are present at localized sites of infection such as the nasopharynx, skin, urinary tract, and conjunctivae. The clinical manifestations of staphylococcal scalded skin syndrome are mediated by hematogenous spread of staphylococcal epidermolytic or exfoliative toxins A or B.

Diagnosis and Optimal Management

Intact bullae are consistently sterile, unlike those of bullous impetigo, but cultures should be obtained from all suspected sites of localized infection and from the blood to identify the source for elaboration of the epidermolytic toxins. The subcorneal, granular layer split can be identified on skin biopsy or by examination of the exfoliated corneal layer on a frozen biopsy specimen.

Systemic therapy should be initiated with a b-lactamase-resistant antistaphylococcal antibiotic. The skin should be cleansed with Burow's or Dakin's solution, and an emollient should be applied during the resolution phase.

FOLLICULITIS

Clinical Findings

Folliculitis is a superficial infection of the hair follicle caused most often by *S. aureus*. The lesions are typically small, discrete, dome-shaped pustules with an erythematous base, located at the ostium of the pilosebaceous canals. Favored sites include the scalp, buttocks, and extremities. Poor hygiene, maceration, and drainage from wounds and abscesses are predisposing factors.

Etiology and Optimal Management

The causative organism of folliculitis can be identified by Gram's stain and culture of purulent material from the follicular orifice.

Treatment for folliculitis includes topical antibiotic cleansers such as chlorhexidine or hexachlorophene. In chronic recurrent folliculitis, daily topical application of a benzoyl peroxide lotion or gel may facilitate resolution. Topical therapy is usually all that is required for mild cases, but more severe cases may require b-lactamase-resistant systemic antibiotics such as dicloxacillin or cephalexin.

Gram-Negative Folliculitis

Folliculitis due to gram-negative organisms occurs primarily in patients with acne vulgaris who have been treated long-term with broad-spectrum systemic antibiotics. A superficial pustular form, caused by *Klebsiella* species, *Enterobacter* species, *E. coli*, or *P. aeruginosa*, occurs around the nose and spreads to the cheeks and chin. A deeper, nodular form of folliculitis on the face and trunk is caused by *Proteus* species. Culture of infected follicles is necessary to establish the diagnosis. Treatment consists of incision and drainage of the deeper, larger cysts; topical antibiotics; or selection of an oral antibiotic based on the sensitivity profile of the pathogenic organism. For severe, recalcitrant cases, 13-*cis*-retinoic acid 1 mg per kilogram per day has been helpful.

Sycosis Barbae

Sycosis barbae is a deeper, more severe, recurrent, inflammatory form of folliculitis due to *S. aureus* infection, which involves the entire depth of the follicle. Erythematous follicular papules and pustules develop on the chin, upper lip, and angle of the jaw, primarily in young black men. Papules may coalesce into plaques, and healing may occur with scarring. Those affected are frequently found to be *S. aureus* carriers. Treatment with warm saline compresses and topical antibiotics such as mupirocin usually clears the infection. More extensive, recalcitrant cases may require therapy with b-lactamase-resistant systemic antibiotics, as well as elimination of *S. aureus* from sites of carriage.

FUNGAL INFECTIONS

TINEA VERSICOLOR

Clinical Findings

Tinea versicolor often begins with perifollicular macules that enlarge to form confluent, scaling patches, most commonly on the neck, upper chest, back, and upper arms. The lesions are typically reddish-brown in whites; in blacks, they may be either hypopigmented or hyperpigmented. Pruritus is variable but usually minimal. Involved areas do not tan after sun exposure.

Etiology

Tinea versicolor is a chronic infection of the stratum corneum caused by the dimorphic yeast *Malassezia furfur*. Names used previously to identify the causal organism are *Pityrosporum ovale* and *Pityrosporum orbiculare*. *M. furfur* is part of the normal flora, predominantly in the yeast form and particularly in areas of skin that are rich in sebum production. Predisposing factors include a warm, humid environment; excessive sweating; occlusion; high plasma cortisol levels; immunosuppression; malnourishment; and genetically determined susceptibility. Tinea versicolor is most prevalent in adolescents and young adults.

Diagnosis and Optimal Management

A potassium hydroxide (KOH) preparation of scrapings is diagnostic of tinea versicolor, demonstrating groups of thick-walled spores and numerous short, thick, angular hyphae, resembling "spaghetti and meatballs."

Given that *M. furfur* is a normal human saprophyte, the organism is not eradicated from the skin after treatment. Consequently, the disorder tends to recur in predisposed persons. Appropriate topical therapy may include twice-daily application of one of the following for 2 to 4 weeks: selenium sulfide 2.5% lotion; 25% sodium hyposulfite or thiosulfate lotion; lotions, ointments, or creams containing 3% to 6% salicylic acid; or miconazole, clotrimazole, ketoconazole, or terbinafine cream. Recurrent episodes continue to respond promptly to these agents. Oral therapy may be more convenient and may be achieved successfully with ketoconazole or fluconazole 400 mg, repeated in 1 week, or itraconazole 200 mg per day for 5 to 7 days.

DERMATOPHYTE INFECTIONS

Dermatophyte infections of the stratum corneum, hair, or nails are caused primarily by *Trichophyton*, *Microsporum*, and *Epidermophyton* species. The severity of

disease tends to be greater in persons with diabetes mellitus, lymphoid malignancies, immunosuppression, and states with high plasma cortisol levels such as Cushing's syndrome. Local factors that predispose to infection include trauma to the skin, hydration of the skin with maceration, occlusion, and elevated temperature. Some degree of immunity is acquired by most infected people and may be associated with a delayed hypersensitivity response.

Tinea Capitis

Tinea capitis is a dermatophyte infection of the scalp, most often seen in children and due to infection with *Trichophyton tonsurans* and *Microsporum canis*. In *M. canis* infections, the spores are distributed in a sheathlike fashion around the hair shaft (ectothrix infection), whereas *T. tonsurans* produces an infection within the hair shaft (endothrix). Endothrix infections such as those caused by *T. tonsurans* can create a pattern known as "black dot ringworm," characterized by multiple, small, circular patches of alopecia in which hairs are broken off close to the hair follicle. Another clinical variant presents with diffuse scaling and minimal hair loss secondary to traction. A severe inflammatory response produces elevated, boggy, granulomatous masses (kerions), which are often studded with sterile pustules. Permanent scarring and alopecia may result.

In *Microsporum*-infected lesions, a characteristic bright green fluorescence is seen at the base of each hair on examination with the Wood lamp, whereas lesions caused by *T. tonsurans* fail to fluoresce. Microscopic examination of a KOH preparation of infected hair from the active border of a lesion discloses tiny spores surrounding the hair shaft in *Microsporum* infections and chains of spores within the hair shaft in *T. tonsurans* infections. Fungal culture is the most reliable method for diagnosis of tinea capitis. A specific causal diagnosis of tinea capitis may be obtained by planting broken-off infected hairs on Sabouraud's dextrose agar; growth of the dermatophyte may take 2 weeks or more.

Oral administration of griseofulvin microcrystalline is recommended for all forms of tinea capitis. Treatment may be necessary for 8 to 12 weeks or more and should be terminated only after fungal culture shows negative results. Itraconazole or terbinafine are useful in instances of griseofulvin resistance, intolerance, or allergy. Adult household contacts of infected children may be asymptomatic carriers and should be treated with ketoconazole shampoo daily until the infected child is clear clinically.

Tinea Corporis

Dermatophyte infection of the glabrous skin, excluding the palms, soles, and groin, can be caused by most of the dermatophyte species, although *Trichophyton rubrum* and *Trichophyton mentagrophytes* are the most prevalent causal organisms.

The most typical clinical lesion begins as a dry, mildly erythematous, elevated, scaly papule or plaque. The lesion spreads centrifugally as it clears centrally to form the characteristic annular lesion recognized as "ringworm." Some lesions may contain grouped pustules. Most lesions clear spontaneously within several months, but some become chronic.

Microscopic examination of KOH wet mount preparations and cultures should always be obtained when fungal infection is considered.

Tinea corporis usually responds to treatment with a topical antifungal agent in the imidazole or allylamine families, or cyclopirox olamine twice daily for 2 to 4 weeks. Itraconazole or terbinafine have produced excellent results, in many cases with a relatively short 1- to 2-week course of therapy.

Tinea Cruris

Dermatophyte infection of the groin occurs most often in adolescent boys and men and is usually caused by infection with *Epidermophyton floccosum* or *T. rubrum*, but occasionally by *T. mentagrophytes*.

The initial lesion is a small, raised, scaly, erythematous patch on the inner aspect of the thigh, which spreads peripherally, often developing multiple tiny vesicles at the advancing margin. It eventually forms bilateral, irregular, sharply bordered patches with hyperpigmented, scaly centers. In some cases, the infection may spread beyond the crural region. The penis is usually not involved in the infection, which is an important sign differentiating it from *Candida* infection. Pruritus may be severe initially but abates as the inflammatory reaction subsides. Bacterial superinfection must be excluded when there is a severe inflammatory reaction. *Tinea cruris* is more prevalent in obese people and in those who perspire excessively and wear tight-fitting clothing.

The patient should be advised to wear loose cotton underwear. Topical therapy with an imidazole or allylamine antifungal agent is recommended for severe infection, especially because these agents are effective in mixed candidal-dermatophytic infections. Pure dermatophytic infection may also be treated with tolnaftate.

Tinea Pedis

Dermatophyte infection of the toe webs and soles of the feet is caused primarily by *T. rubrum*, *T. mentagrophytes*, and *E. floccosum*. Most commonly, the lateral toe webs (third/fourth and fourth/fifth interdigital spaces) and the subdigital crevice are fissured, and the surrounding skin is macerated. Severe tenderness, itching, and a persistent foul odor are characteristic. Chronic infection is multifactorial, and involves overgrowth of bacterial flora, including *Micrococcus sedentarius*, *Brevibacterium epidermidis*, and gram-negative organisms. Diffuse hyperkeratosis and mild erythema of the soles of both feet and the palm of one hand is more refractory to treatment and tends to recur. A number of factors, such as occlusive footwear and warm, humid weather, predispose to infection. Tinea pedis may be transmitted in shower facilities and swimming pool areas.

Occasionally, a secondary skin eruption, referred to as a *dermatophytid* or "id" reaction appears in sensitized people and has been attributed to circulating fungal antigens derived from the primary infection. The eruption occurs most frequently on the extremities, especially the lower legs, and is characterized by grouped papules and vesicles and occasionally by sterile pustules. Id reactions are most often associated with tinea pedis but also occur with tinea capitis.

Simple measures such as avoidance of occlusive footwear, careful drying between the toes after bathing, and the use of an absorbent antifungal powder may suffice for management of milder infections. Topical antifungal therapy is curative in most cases. Several weeks of therapy may be necessary; low-grade, chronic infections, particularly those caused by *T. rubrum*, may be refractory. In such patients, oral itraconazole or terbinafine therapy may effect a cure, but recurrences are common.

Tinea Unguium

Dermatophyte infection of the nail plate occurs most often in people with tinea pedis but may occur as a primary infection. It can be caused by a number of dermatophytes, of which *T. rubrum* and *T. mentagrophytes* are the most common. The most superficial form of tinea unguium (white superficial onychomycosis) is often caused by *T. mentagrophytes* infection; it is manifested by irregular, single or multiple white patches on the surface of the nail unassociated with paronychia inflammation or deep infection. More commonly, *T. rubrum* causes a more invasive, subungual infection (distal subungual onychomycosis) that is initiated at the lateral distal margins of the nail and often preceded by mild paronychia. The nail initially develops a yellowish discoloration and slowly becomes thickened, brittle, and loosened from the nail bed.

Subungual debris and thin shavings of the infected nail should be examined microscopically with KOH and cultured. Repeated attempts may be required to demonstrate the fungus.

The long half-life of itraconazole in the nail has led to promising trials of intermittent short courses of therapy such as 400 mg per day, 1 week per month for 2 to 4 months.

CANDIDAL INFECTIONS

Candida albicans is not a member of the normal skin flora, but may colonize the skin, as well as the alimentary tract and the vagina as a saprophytic organism. Certain environmental conditions, notably elevated temperature and humidity, are associated with an increased colonization of the skin. Many bacterial species inhibit the growth of *C. albicans*, and alteration of the normal flora by use of antibiotics may promote overgrowth of the yeast.

INTERTRIGINOUS CANDIDOSIS

Intertriginous candidosis occurs most often in the axillae and the groin, under the breasts, under pendulous abdominal fat folds, in the umbilicus, and in the gluteal cleft. Typical lesions are confluent, moist, denuded, erythematous plaques with an irregular, macerated border. Satellite lesions are characteristic and consist of small vesicles or pustules on an erythematous base. With time, intertriginous candidal lesions may become lichenified, dry, scaly plaques. The lesions develop on skin subjected to irritation and maceration. Candidal superinfection is more likely to occur under conditions that lead to excessive perspiration, especially in the obese and in those with underlying disorders such as diabetes mellitus.

Interdigital candidosis commonly presents with fissures between the fingers of people whose hands are constantly immersed in water. Similar lesions between the toes may be secondary to occlusive footwear.

PERIANAL CANDIDOSIS

Perianal dermatitis is caused by irritation of the skin from occlusion, constant moisture, and poor hygiene. Superinfection may occur with *C. albicans*, especially in those who are receiving oral antibiotic or corticosteroid medication. The involved skin becomes erythematous, macerated, and excoriated, as with candidal intertrigo. Application of a topical antifungal agent (e.g., imidazole, allylamine, cyclopirox olamine, polyene) in conjunction with improved hygiene is usually effective for treatment of intertriginous or perianal candidosis.

CANDIDAL PARONYCHIA

Candidal paronychia is characterized by tenderness, erythema, and edema at the posterior nail fold. Purulent material is discharged occasionally. If the lesion becomes chronic, the nail may be invaded secondarily and become brittle and thickened, initially in the proximal portion but subsequently over the entire nail plate. The nail may manifest a brownish discoloration and prominent transverse ridges or grooves, or it may be completely destroyed. Associated infection with *Pseudomonas* species imparts a green color to the nail plate.

C. albicans can usually be cultured from the posterior nail fold and can often be identified on a KOH preparation of nail scrapings. Effective management includes keeping the finger as dry as possible and applying a topical antifungal agent three times daily for weeks to months until the nail plate grows out normally.

CHAPTER 195: BULLOUS DISEASES OF SKIN AND MUCOUS MEMBRANES

MARK C. UDEY

[Pemphigus](#)
[Bullous Pemphigoid](#)
[Dermatitis Herpetiformis](#)

Bullous diseases of skin and mucous membranes, although uncommon, are particularly significant because patients with these disorders may experience considerable morbidity from the disease process itself or as a consequence of therapy. These conditions are characterized by clinically apparent vesicles, bullae (blisters), erosions, or crusts when lesions are present on skin, and erosions when lesions are present on mucous membranes. In considering bullous diseases, it is useful to differentiate between the rare, inherited, noninflammatory mechanobullous diseases that are seen at birth or early in life (termed *epidermolysis bullosa*) and the more common, acquired, immune-mediated blistering disorders that form the basis for the discussion in this chapter. Disorders typified by microscopic (often subclinical) intraepidermal vesicles are termed “eczema” (or dermatitis) and are considered in other chapters.

PEMPHIGUS

The term “pemphigus” refers to several disorders that result from decreased adhesion between keratinocytes. Lesions of pemphigus vulgaris result because suprabasal keratinocytes fail to adhere to basal cells (keratinocytes that are anchored to the epidermal basement membrane) and to each other. In contrast, pemphigus foliaceus is a manifestation of the failure of the most superficial keratinocytes (cells of the granular layer) to adhere to underlying suprabasal cells. Lesions of paraneoplastic pemphigus may reflect more complex adhesive defects. Pemphigus vulgaris is an unremitting disease characterized by erosive lesions of oral and other mucous membranes, and blisters and erosions on skin. Pemphigus foliaceus is characterized by crusted lesions and rarely involves mucous membranes. Paraneoplastic pemphigus is characterized by severe stomatitis, conjunctival erosions, and polymorphic skin lesions and occurs in patients with known (usually lymphoid) neoplasms. These disorders are important to recognize because they cause significant morbidity and mortality. Before the use of glucocorticoids, pemphigus vulgaris was frequently a fatal disease. Patients with paraneoplastic pemphigus rarely recover despite aggressive therapy.

ETIOLOGY AND PATHOGENESIS

The cause of pemphigus is unknown. In the case of pemphigus vulgaris, genetic predisposition may be an important causal factor. Pemphigus vulgaris (but not pemphigus foliaceus) is more common among people of Jewish or Mediterranean descent. Among patients with pemphigus vulgaris, the frequency of human leukocyte antigen (HLA)-DR4 and DRw6 haplotypes is markedly increased. Furthermore, essentially all patients with the DR4 haplotype share a rare allele (DRB1*0402) that encodes the b chain of one of the HLA-DR antigens. Similarly, patients with the DRw6 haplotype share an allele (DQB1*0503) that encodes a b chain of HLA-DQ antigens. Although genetic predisposition is not known to play a role in the pathogenesis of pemphigus foliaceus, one form (fogo selvagem or “wild fire”) is endemic in inland river valleys of rural Brazil, where an arthropod has been implicated as a vector (an agent that predisposes to development of disease) in transmission of disease. Paraneoplastic pemphigus may develop as a consequence of cancer-associated immune dysregulation.

Lesions of pemphigus vulgaris, pemphigus foliaceus, and paraneoplastic pemphigus are caused by IgG antibodies that react with adhesion molecules called *desmogleins*. These cadherin-like transmembrane glycoproteins localize in desmosomes of stratified squamous epithelial cells, where they likely constitute an important adhesive mechanism. Antibody titers may correlate with disease activity in individual patients. Anti-desmoglein 1 antibodies in sera of patients with pemphigus foliaceus and anti-desmoglein 3 antibodies in patients with pemphigus vulgaris and paraneoplastic pemphigus cause blisters after adoptive transfer into newborn mice. Pemphigus vulgaris sera often also contain anti-desmoglein 1 antibodies, but these antibodies do not cause lesions in adoptive transfer studies. Pemphigus has also been described in neonatal children born to mothers with pemphigus as a result of passive transfer of pathogenic autoantibodies in utero. In this setting, the disease improves with disappearance of the maternally derived autoantibodies in the postnatal period. Some desmoglein 3–derived peptides that stimulate T-cell clones expanded from the peripheral blood of pemphigus vulgaris patients bind specifically to major histocompatibility complex (MHC) class II antigens encoded by the genes that appear to predispose to development of disease. Patients with paraneoplastic pemphigus have circulating antibodies that react with several members of the plakin family of desmosomal plaque proteins as well as desmoglein 3. The multiple reactivities present in the sera of these patients may contribute to the morphologic variation in paraneoplastic pemphigus lesions.

INCIDENCE AND EPIDEMIOLOGY

Sporadic pemphigus is an uncommon disease primarily of middle-aged and elderly people, although younger people can also be affected. Among Jews, pemphigus vulgaris is more common than pemphigus foliaceus. Pemphigus vulgaris and foliaceus are similarly infrequent in non-Jewish populations. In contrast to sporadic disease, endemic pemphigus foliaceus (fogo selvagem) frequently affects children and adolescents. Pemphigus foliaceus has been reported with increased frequency in patients treated with penicillamine, captopril, and structurally related drugs, and a number of patients with pemphigus foliaceus and thymic abnormalities (including thymoma) have been described. Paraneoplastic pemphigus is a rare disorder, which usually develops in association with lymphoid neoplasms.

CLINICAL FINDINGS

Generalized blisters and erosions are the clinical hallmarks of pemphigus. Considerable burning and pain may be present in lesional skin. Cutaneous pemphigus lesions may manifest as vesicles, blisters, erosions, or crusts. Patients with pemphigus vulgaris commonly present with oral erosions, and almost all patients have oral lesions at some time during the course of their disease. Conjunctivae, genital mucosae, and the esophagus may also be involved. In contrast, mucosal lesions are uncommon in pemphigus foliaceus. Cutaneous lesions of pemphigus vulgaris are typically erosive. When present, blisters do not have a prominent inflammatory component, may be flaccid, and are fragile. During periods of disease activity, blisters may be extended with gentle lateral traction (positive Nikolsky's sign). The scalp represents an area of common involvement in pemphigus vulgaris, but lesions are often present on the trunk and extremities. Scalp lesions and lesions in intertriginous areas may have a vegetative appearance. Mucosal predominant disease apparently occurs in patients with only anti-desmoglein 3 antibodies, whereas patients with mucosal and skin lesions produce antibodies reactive with desmoglein 1 and desmoglein 3. Cutaneous lesions of pemphigus foliaceus are more crusted than those of pemphigus vulgaris and intact blisters may be infrequent. Lesions of pemphigus foliaceus commonly are present in a seborrheic distribution (central chest, back, and face) and may remain localized for years. Mucosal lesions are rarely seen.

The differential diagnosis of pemphigus vulgaris includes other immune-mediated blistering diseases such as pemphigus foliaceus, bullous pemphigoid, erythema multiforme (Stevens–Johnson syndrome), drug eruptions, and other less common diseases. The differential diagnosis of pemphigus foliaceus includes pemphigus vulgaris, impetigo, and other bullous and pustular diseases. Patients with paraneoplastic pemphigus exhibit painful, recalcitrant erosions of oral and other mucous membranes and polymorphic cutaneous lesions. Cutaneous lesions of paraneoplastic pemphigus may resemble those of sporadic pemphigus, erythema multiforme, or even papulosquamous disorders.

LABORATORY FINDINGS

Laboratory features of pemphigus are distinctive. Routine histopathologic sections of biopsy specimens obtained from lesional skin reveal an intraepidermal separation immediately above the basal keratinocyte layer (suprabasal cleft formation) without evidence of abnormal keratinocyte differentiation in the case of pemphigus vulgaris, and a subcorneal cleft in the case of pemphigus foliaceus. Biopsies from patients with paraneoplastic pemphigus show intraepidermal separations and prominent, often lichenoid, inflammation in the dermis.

The histopathologic diagnosis of pemphigus should be confirmed by searching for immunoreactants in the skin and sera. Most patients have deposits of IgG on the surfaces of keratinocytes in perilesional as well as nonlesional skin. In addition, circulating autoantibodies can be detected and quantitated. Pemphigus vulgaris and pemphigus foliaceus autoantibodies cannot be differentiated with certainty by indirect immunofluorescence. Sera from patients with paraneoplastic pemphigus react with keratinocytes and also desmosomes in other tissues (such as rodent urinary bladder epithelia).

OPTIMAL MANAGEMENT

Without therapy, pemphigus vulgaris is a progressive, life-threatening disease. Extensive oral lesions may preclude adequate caloric intake, and widespread cutaneous lesions predispose to sepsis. The diagnosis of pemphigus foliaceus portends a somewhat better prognosis, although extensive untreated disease can also be fatal. Paraneoplastic pemphigus is resistant to therapy. Systemic glucocorticoid therapy is the mainstay of treatment for pemphigus. Prednisone (0.5 to 2 mg per kilogram per day) is used to achieve control, although higher doses may be required. The initial goal of therapy is to suppress the formation of new lesions. After control has been achieved, prednisone doses are decreased as the disease activity permits. Alternate-day dosing with prednisone is preferred if control can be maintained. Drugs such as azathioprine and cyclophosphamide are frequently used as steroid-sparing agents, especially in elderly patients with intercurrent medical problems. Mycophenolate mofetil has recently been reported to be efficacious, and other drugs such as gold salts and cyclosporine (and related agents) may also have a role. Plasmapheresis in conjunction with glucocorticoid and immunosuppressive therapy has been used in the treatment of patients with severe disease. Remissions can occur, but are not the rule. Topical or intralesional glucocorticoids may be of benefit in the treatment of pemphigus foliaceus if disease is localized.

BULLOUS PEMPHIGOID

Bullous pemphigoid is an uncommon disease of elderly people characterized by tense blisters and vesicles with a prominent inflammatory component. Pruritus is a common manifestation of active disease; mucous membrane involvement is not. Lesions result because basal keratinocytes fail to adhere to the epidermal basement membrane. In otherwise healthy patients, bullous pemphigoid is not a life-threatening disease.

ETIOLOGY AND PATHOGENESIS

The cause of bullous pemphigoid is unknown, but the pathogenesis of lesion development is relatively well understood. Sera from patients with bullous pemphigoid contain IgG autoantibodies that commonly react with a hemidesmosomal component (the 230-kd bullous pemphigoid antigen; BPAG1) that is homologous to desmoplakin, an intracellular component of desmosomes. Many sera also react with a transmembrane protein that has homology to collagen (the 180-kd bullous pemphigoid antigen; BPAG2; type XVII collagen). In neonatal mice, rabbit anti-murine BPAG2 antibodies cause lesions similar to those that occur in patients with pemphigoid. The matrix metalloproteinase gelatinase B (MMP-9) also appears to play a role in lesion formation in this experimental model. Complement components are universally present in the perilesional skin of bullous pemphigoid patients, and complement-dependent recruitment of neutrophils into lesional skin is required for blister formation in the bullous pemphigoid mouse model.

CLINICAL FINDINGS

Characteristic lesions of bullous pemphigoid are tense blisters or vesicles with surrounding erythema. Early lesions may resemble urticaria; late lesions may manifest as erosions. Common sites of involvement include the trunk and flexor surfaces of extremities. Lesions are localized to the legs in some patients. A few patients have oral erosions at some time during the course of their disease. Pruritus is a common feature of bullous pemphigoid, and increased pruritus may herald an exacerbation. It is important to differentiate bullous pemphigoid from cicatricial pemphigoid. Although skin lesions may be indistinguishable, cicatricial pemphigoid is a mucosal-predominant disease characterized by desquamative gingivitis (marginal gingival erosions) and frequent conjunctival erosions that may result in scarring and blindness. Acquired epidermolysis bullosa can mimic bullous pemphigoid as well as cicatricial pemphigoid. Several common disorders that must be distinguished from bullous pemphigoid include erythema multiforme, drug eruptions, and acute contact dermatitis. Linear IgA bullous dermatosis is less common and can be distinguished from bullous pemphigoid on the basis of immunofluorescence studies. Herpes gestationis is a rare bullous disease of pregnant and postpartum women that is a variant of bullous pemphigoid.

LABORATORY FINDINGS

Biopsy of a newly formed vesicle or blister reveals a subepidermal separation with a prominent underlying polymorphous inflammatory infiltrate that is often eosinophil-rich. The blister fluid itself may also contain inflammatory cells (including eosinophils). Immunoreactants (including complement components and, in most cases, IgG) are present in a linear pattern along the basement membrane of perilesional skin, and most patients also have circulating autoantibodies. The sensitivity of indirect immunofluorescence testing can be increased if NaCl-split human skin, in which an epidermal-dermal separation is induced, is used as the substrate. Cicatricial pemphigoid, acquired epidermolysis bullosa, and linear IgA bullous dermatosis all can be differentiated from bullous pemphigoid using clinical criteria in conjunction with a combination of these techniques. Autoantibody titer does not correlate well with disease activity in patients with bullous pemphigoid.

OPTIMAL MANAGEMENT

Although bullous pemphigoid may remit, most patients are affected for several years or longer. Topical fluorinated glucocorticoids are not usually of benefit in the treatment of bullous pemphigoid unless disease is localized. Most patients respond well to prednisone, 0.5 to 1.5 mg per kilogram per day. However, because patients are often elderly and may have intercurrent medical illnesses, unwanted side effects of systemic corticosteroid therapy are a serious problem. Azathioprine and cyclophosphamide are commonly used as steroid-sparing agents. Dapsone may also be of benefit in some patients. Therapy with broad-spectrum antibiotics (including tetracycline and erythromycin) or niacinamide may be helpful. In most patients, bullous pemphigoid is not a life-threatening disease. Thus, it is important to minimize the side effects of systemic immunosuppressive therapy.

DERMATITIS HERPETIFORMIS

Dermatitis herpetiformis is an uncommon chronic disease typified by the appearance of intensely pruritic vesicles on extensor surfaces of the extremities, sacrum, buttocks, back, and neck. It affects men and women with equal frequency and is rare in blacks.

ETIOLOGY AND PATHOGENESIS

The cause of dermatitis herpetiformis is unknown, and the pathogenesis of lesion formation is not well understood. Focal collections of IgA and complement can almost always be demonstrated at the tips of dermal papillae in involved as well as uninvolved skin, but the role that these immunoreactants play in lesion development is unknown. Most patients with dermatitis herpetiformis have subclinical gluten-sensitive enteropathy that can be demonstrated by small-bowel biopsy. In addition, patients who can adhere to a strict gluten-free diet often experience amelioration of their cutaneous symptoms. HLA-B8, HLA-DR3, and HLA-DQw2 antigens are present in 80% to 90% of patients with dermatitis herpetiformis. Dermatitis herpetiformis may represent a cutaneous manifestation of an IgA-predominant immune response directed at antigens encountered in the gastrointestinal tract of genetically predisposed people.

CLINICAL FINDINGS

Dermatitis herpetiformis is a distinctive disorder characterized by frequently excoriated, intensely pruritic papules and vesicles on the elbows, knees, scalp, back, sacrum, and buttocks. Lesions may occur individually or in groups. It frequently presents in young and middle-aged adults, but children may also be affected. The differential diagnosis of dermatitis herpetiformis includes scabies, acute eczematous dermatitis, erythema multiforme, pemphigoid, and linear IgA bullous dermatosis. Although subclinical gluten-sensitive enteropathy is almost universally present, symptomatic gastrointestinal disease is uncommon.

LABORATORY FINDINGS

Biopsies of early lesions reveal collections of neutrophils in the tips of dermal papillae with subepidermal cleft formation, and perivascular lymphohistiocytic inflammation in the dermis. Late lesions reveal more extensive subepidermal separation and may be difficult to differentiate from linear IgA bullous dermatosis, bullous pemphigoid, and acquired epidermolysis bullosa. Direct immunofluorescence testing of perilesional or normal skin is diagnostic and shows deposition of IgA and complement components in a granular pattern in the tips of dermal papillae. Circulating immunoreactants are not routinely detected.

OPTIMAL MANAGEMENT

Although dermatitis herpetiformis is a chronic disease with a remitting and relapsing course, the prognosis is excellent. Therapy with dapsone and related drugs has a

uniquely favorable effect on the disease course. Institution of dapsone (100 to 150 mg per day) often results in cessation of lesion formation and decreased pruritus in less than 24 hours. Patients who adhere to a strict gluten-free diet often require lower doses of medication or may not need drug therapy at all. Nonsteroidal anti-inflammatory drugs may exacerbate dermatitis herpetiformis.

CHAPTER 196: ATOPIC AND CONTACT DERMATITIS

TERESA A. BORKOWSKI AND MARK C. UDEY

[Atopic Dermatitis](#)
[Contact Dermatitis](#)

ATOPIC DERMATITIS

Atopic dermatitis is a chronic, relapsing, inflammatory dermatosis with lesions characterized by pruritus, erythema, and lichenification. It occurs most frequently in patients with a personal or family history of allergic disease and comprises one leg of the atopic triad (asthma, allergic rhinoconjunctivitis, and atopic dermatitis).

INCIDENCE AND EPIDEMIOLOGY

Atopic dermatitis affects 5% to 10% of children and is slightly more prevalent in boys than girls (1.2:1). There is no racial predisposition to atopic dermatitis within a geographic area. Approximately 60% of patients experience onset of symptoms within the first year of life, and 85% have disease symptoms by 5 years of age. The onset of atopic dermatitis in late adulthood is unusual.

ETIOLOGY AND PATHOGENESIS

Atopic dermatitis is a familial and, most likely, polygenic disease. Although the cause is unknown, the frequent coincidence of atopic dermatitis and allergic rhinitis or asthma suggests that IgE-mediated hypersensitivity may be involved in disease pathogenesis. Approximately two-thirds of patients have a family or personal history of asthma or allergic rhinitis, and 80% have elevated levels of serum IgE that may correlate with disease activity. In some pediatric patients, food allergens reproducibly induce acute pruritus in lesional skin. Atopy has been linked to polymorphisms in genes encoding the high-affinity IgE and β_2 -adrenergic receptors, as well as interleukin-4 (IL-4) gene regulatory regions.

Studies of immunologic abnormalities in atopic dermatitis may provide insight into disease pathogenesis. Cutaneous immune responses to environmental antigens are Th2 (IL-4-secreting T cell) predominant in atopic skin, and responses to infectious agents are blunted during periods of disease activity. Epicutaneous patch tests to allergens frequently show increased numbers of allergen-specific (Th2 cells) in atopic dermatitis patients. IL-4 enhances IgE production and suppresses production of the Th1 cytokine interferon (IFN)- γ . A relative deficiency in Th1 immunity may account for the attenuated delayed type hypersensitivity responses to contact and viral antigens that are characteristic of atopic dermatitis and may explain the increased susceptibility of patients to cutaneous viral infections such as herpes simplex and molluscum contagiosum.

Aberrant immune responses could reflect abnormalities in T cells or antigen-presenting cells. Atopic epidermal Langerhans' cells (members of the dendritic cell lineage) express high levels of the high-affinity IgE receptor and may play a role in the initiation (or perpetuation) of Th2-predominant responses to allergens. Excessive production of prostaglandin E₂ (PGE₂) by atopic monocytes may also foster Th2 responses by inhibiting IFN- γ production.

CLINICAL FINDINGS

The most consistent feature of atopic dermatitis is pruritus, often accompanied by generalized xerosis (dry skin). Acute skin lesions are erythematous patches and papules, often with excoriation, vesiculation, and crusting. With persistent scratching, acute lesions evolve into lichenified patches that are characteristic of chronic atopic dermatitis. Papulovesicular and lichenified lesions may be present in the same patient. Atopic dermatitis typically involves the flexural areas of the extremities and neck in older children and adults. Extensor surfaces of the extremities are more frequently involved in 2- to 10-year-old children, and infants often develop lesions on the cheeks, scalp, and buttocks. In severe cases, involvement may be generalized, resulting in exfoliative erythroderma. The clinical course is chronic with periodic exacerbations and remissions. Most patients experience a decrease in disease severity by adulthood.

Associated clinical features include Dennie–Morgan folds (transverse creases below the lower eyelids), hyperlinear palms, and keratosis pilaris (keratotic follicular papules on the extensor surfaces of arms and legs). Patients with severe atopic dermatitis may be at increased risk for cataracts.

Infection with *Staphylococcus aureus* is a common complication of atopic dermatitis, and disease exacerbation may result. Impetiginized lesions manifest as crusting and sometimes vesiculation. Crusting and vesiculation in a patient with atopic dermatitis may also result from herpes simplex infection. Patients with severe atopic dermatitis are predisposed to generalized herpes simplex (eczema herpeticum or Kaposi's varicelliform eruption). Patients may present with malaise, fever and lymphadenopathy, and disseminated papulovesicular (or papulopustular) lesions that may become hemorrhagic or evolve into painful punched-out erosions. Secondary bacterial infection is common. Eczema herpeticum is a potentially life-threatening complication of atopic dermatitis and warrants immediate treatment with antiviral and antibacterial agents. Concern regarding the possibility of ocular involvement should prompt immediate evaluation by an ophthalmologist.

LABORATORY FINDINGS

No serologic tests are diagnostic of atopic dermatitis. However, 80% of patients exhibit elevated levels of serum IgE. Skin and radioallergosorbent tests are often positive but may not correlate with clinical symptoms. Skin biopsies of acute lesions of atopic dermatitis display epidermal hyperplasia, microvesicles and intracellular edema, and a primarily dermal mononuclear cell infiltrate comprising lymphocytes, monocytes, and macrophages with occasional neutrophils or eosinophils. Chronic lesions show hyperkeratosis with variable intracellular edema and a mononuclear cell infiltrate. Chronic lesions may also contain increased numbers of mast cells.

OPTIMAL MANAGEMENT

Adequate skin hydration is an essential component of therapeutic regimens for atopic dermatitis, regardless of the severity of the disease. Frequent soaking baths followed by the immediate application of fragrance-free emollients are helpful in most cases. When pruritus is moderate to severe or interrupts sleep, oral antihistamines may be necessary. Topical corticosteroids are indicated when inflammation is present. In general, the least potent effective topical corticosteroid should be used, and potency or total dose should be tapered as soon as possible to prevent cutaneous thinning secondary to chronic use. Absorption may lead to systemic side effects in young children treated with potent topical corticosteroids and in older persons with extensive involvement. Application of potent topical corticosteroids to facial or periorbital skin may predispose to cataract formation. Flare-ups of atopic dermatitis are often associated with secondary *S. aureus* infections, and appropriate antibiotic therapy is usually efficacious.

During severe flare-ups of atopic dermatitis, oral corticosteroid therapy may be warranted. Systemic corticosteroids should be used judiciously, however, because prolonged remissions will not result and an alternative chronic therapy with its attendant side effects will be required. Ultraviolet light therapy, methotrexate, cyclosporine, and azathioprine may be useful for difficult-to-treat patients. Investigational drugs include IFN- γ and phosphodiesterase inhibitors. Children (not adults) may benefit from evaluation for food and inhalant allergies.

CONTACT DERMATITIS

Contact dermatitis is an eczematous dermatitis that develops as a consequence of exposure to an external and usually noninfectious agent. Two varieties of contact dermatitis exist: primary irritant dermatitis, which is not immunologically mediated and occurs in almost all who are exposed, and allergic contact dermatitis, which is antigen-specific and occurs only in those who have been previously sensitized.

ETIOLOGY AND PATHOGENESIS

Primary irritant dermatitis results when substances disrupt the barrier function of the stratum corneum and elicit cutaneous inflammatory responses by causing injury to underlying epidermal and perhaps dermal constituents. Irritant responses can be induced in most people, but the threshold for injury may vary considerably. Examples of common irritants include acids, alkalis, detergents, and organic solvents. In contrast, allergic contact dermatitis develops only in those who have been exposed and become sensitized to a particular agent, and then only after reexposure.

Allergic contact dermatitis is a clinically important example of a delayed-type hypersensitivity phenomenon. The events leading to development of allergic contact dermatitis can be divided into the sensitization and elicitation phases. The process begins when antigen penetrates the stratum corneum and encounters resident Langerhans' cells or similar dendritic cells in the dermis. After an incompletely understood activation process, these class II major histocompatibility complex antigen-bearing cells migrate to regional lymph nodes, where the initial presentation of antigen to T cells probably occurs. After clonal expansion and differentiation, some antigen-specific memory T cells circulate systemically. During subsequent exposure to antigen, antigen associated with epidermal cells (including Langerhans' cells and perhaps keratinocytes) is presented locally to sensitized T cells, evoking proinflammatory cytokine release and perhaps T-cell proliferation within the skin. Antigen-nonspecific elements (macrophages, other lymphocytes, and perhaps basophils, mast cells, and eosinophils) are also recruited to the involved area by cytokines and chemoattractants to participate in the inflammatory response.

Primary irritant dermatitis, which is extremely common, often results from the improper or excessive use of detergents or organic solvents. True allergic contact dermatitis, although seen less frequently, is also common. Frequent contact sensitizers include *Rhus* antigen (a pentadecylcatechol found in poison ivy, oak, and sumac), para-phenylenediamine, nickel, rubber compounds, ethylenediamine, certain local anesthetics (such as benzocaine), chromate, and neomycin.

CLINICAL FINDINGS

The typical primary lesions of acute allergic contact dermatitis are papulovesicles with surrounding erythema, often occurring in linear patterns as a result of direct exposure to antigen. Weeping and crusted lesions develop and may become secondarily infected. Lesions of chronic contact dermatitis exhibit prominent scaling and lichenification.

The most helpful features in determining the cause of contact dermatitis are patient history and physical examination. For example, nickel dermatitis is commonly seen in areas where metal and skin are apposed (e.g., in association with snaps, buckles, watchbands, and earrings). Beauticians with hand dermatitis may be sensitive to para-phenylenediamine in hair dyes. This chemical, which is also used in leather processing, photographic work, and rubber manufacture, cross-reacts with azo- and aniline dyes, printing inks, and several medications, including benzocaine, procaine, para-aminobenzoic acid, hydrochlorothiazide, and sulfonamides. An eczematous dermatitis involving exclusively the waistline or the dorsum of the feet suggests rubber sensitivity. Chromates used in cement may cause contact dermatitis of the dorsa of the hands in construction workers but spare the feet, particularly in workers who wear impermeable protective boots.

LABORATORY FINDINGS

The closed patch test is most commonly used to identify the allergen in allergic contact dermatitis. A nonirritating concentration of the compound is applied to the patient's skin in an area with no preexisting dermatitis. The test material is then covered by an occlusive dressing for 48 hours, after which the dressing and the compound are removed and the skin examined for redness, edema, and vesicles. In every case, the reaction caused by the test substance should be compared with that elicited by vehicle alone. Patch test results are most useful when they are obtained under standard conditions, replicated, and interpreted in a clinical context. The most common chemical allergens and the preferred testing concentrations can be found in Fisher's classic text (see [Bibliography](#)).

OPTIMAL MANAGEMENT

For localized contact dermatitis, moist compresses and simple drying antipruritic lotions (e.g., calamine lotion) applied several times daily suffice. Potent topical corticosteroids may also decrease pruritus and inflammation. Systemic antihistamines decrease pruritus and may provide symptomatic relief. Topical antihistamines and anesthetics should be avoided because of their sensitizing potential. For widespread contact dermatitis, a short course of systemic corticosteroids should be used. Relatively high doses of prednisone (0.75 to 1.5 mg per kilogram per day) are given initially and then tapered off over 14 days. Severe cases may require a more protracted course, but chronic systemic corticosteroid therapy is inappropriate.

If the substance causing contact dermatitis can be identified, avoidance is the simplest therapy. If the agent is an irritant, reexposure under modified conditions (shorter time, less frequent intervals, or lower concentrations) can sometimes be tolerated. True sensitization to a chemical, however, essentially precludes its use unless exposure areas can be shielded (e.g., with gloves). Barrier creams or ointments usually are not effective.

CHAPTER 197: URTICARIA AND ERYTHEMA MULTIFORME

CHRISTOPHER M. BARNARD

[Urticaria and Angioedema](#)
[Erythema Multiforme: Stevens–Johnson Syndrome and Toxic Epidermal Necrolysis](#)

URTICARIA AND ANGIOEDEMA

Allergic urticaria and angioedema are manifestations of an immediate hypersensitivity reaction resulting from the antigen-driven release of vasoactive products from IgE-sensitized mast cells (and perhaps basophils). Complement-mediated urticaria, hereditary or acquired, may result from serum complement abnormalities. Identical reactions also can result from direct mast cell degranulation through nonimmunologic mechanisms.

ETIOLOGY AND PATHOGENESIS

A variety of triggering mechanisms can result in mast cell degranulation ([Chapter 6](#)). Among these are IgE-mediated immediate hypersensitivity reactions, complement-dependent immune complex–induced release of vasoactive mediators, and release resulting from modulation of arachidonic acid metabolism by certain drugs (aspirin or other nonsteroidal anti-inflammatory agents). Stimuli such as pressure, exercise, and cold also may provoke mast cell degranulation, but a discussion of the physical urticarias is beyond the scope of this chapter.

Allergic urticaria develops only in persons who previously have encountered and formed IgE (reaginic) antibodies directed against the offending antigen (e.g., drug, venom, food). Mast cells and basophils concentrate IgE on their cell surfaces through specific receptors that bind the Fc fragment of IgE with high affinity, becoming sensitized to antigen. When individual IgE molecules are cross-linked on the surface of mast cells by multivalent antigen, a multitude of biochemical events occurs that rapidly culminates in the release of preformed (e.g., histamine) and newly synthesized (e.g., leukotrienes) vasoactive mediators and chemoattractants. Urticarial skin lesions then result from local vasodilatation and extravascular fluid accumulation (edema) with minimal cellular infiltrate.

INCIDENCE AND EPIDEMIOLOGY

Urticaria and angioedema are among the most common skin disorders and occur with the highest incidence in young adults. Although 15% to 20% of the population may have urticaria during their lifetime, it is probable that only a small percentage of this group has true allergic urticaria. Nonimmunologic urticaria is perhaps more common. For example, among agents that directly cause degranulation of mast cells, radiologic contrast media produce urticaria in 5% to 8% of the population, and aspirin, nonsteroidal anti-inflammatory agents, and tartrazine may cause reactions in 1% to 2%.

CLINICAL FEATURES AND LABORATORY FINDINGS

The lesions of urticaria (hives) can be polymorphic. Faintly erythematous well-circumscribed edematous papules (wheals), annular lesions, and polycyclic lesions all are typical ([Fig. 197.1](#)). Often, an erythematous halo (flare) surrounds the raised portion of the lesions. Urticarial lesions usually are pruritic and transient, disappearing over a 12- to 24-hour period. Alternatively, an individual lesion may appear to migrate. Persistent urticarial lesions with purpura or residual hyperpigmentation should undergo biopsy to exclude urticarial vasculitis. Angioedema represents a deeper dermal or subcutaneous edematous reaction and may occur with or without urticaria. The face, tongue, and extremities are the most commonly involved areas with angioedema; however, laryngeal edema with respiratory symptoms may occur and require immediate intervention.

FIGURE 197.1. Urticaria.

Skin biopsy reveals dermal edema and a variable perivascular infiltrate of mononuclear cells and eosinophils. Specific antigen IgE-mediated sensitivity may be revealed by scratch tests, intradermal skin testing, or radioallergosorbent tests (RAST). Patients with chronic urticaria (persisting for 2 to 6 months) should be evaluated not only for allergic problems, such as food, drug, pollen, and insect sting sensitivity, but also for other underlying causes. Some of the more common factors in the last category are occult infection (e.g., dental abscess, sinusitis, helminth infestation); physical urticaria (e.g., pressure, cold, light, cholinergic); and collagen vascular diseases. The workup should be systematic and complete to avoid repeated partial evaluations.

COURSE, THERAPY, AND PROGNOSIS

Acute urticaria usually resolves in less than 6 weeks. Although identification and elimination of the specific causative agent are desirable, these are not always possible. In about 70% of patients with chronic urticaria, a specific cause cannot be elucidated, and avoidance or elimination of a specific agent is not possible. Antihistamines are useful in the treatment of urticaria, regardless of its duration or cause. Many H₁ antagonists are available, and individual patients may tolerate or respond to certain drugs better than to others. Nonsedating H₁ antagonists, such as cetirizine, loratadine, fexofenadine, or astemizole, may be especially useful as first-line therapy. Concomitant administration of astemizole with erythromycin, ketoconazole, or itraconazole poses a rare, but potential, risk of serious cardiovascular side effects. Cetirizine, a metabolite of hydroxyzine, is a potent, nonsedating, selective H₁ antagonist with a rapid onset of action and the unique ability to inhibit eosinophil chemotaxis. Cetirizine appears to be the most efficacious of the nonsedating histamine H₁ antagonists currently available. An H₁ antagonist in combination with an H₂ antagonist may be efficacious in cases in which the same H₁ antagonist alone has been ineffective. Doxepin, a highly potent H₁ and H₂ antagonist, is a tricyclic antidepressant that is effective in controlling chronic idiopathic urticaria complicated by agitated clinical depression at relatively low doses. The sedating H₁ antihistamines, hydroxyzine and diphenhydramine, are helpful in reducing restlessness and anxiety in addition to controlling urticaria and facilitating sleep at night. Ketotifen, a mast cell stabilizer and H₁ antagonist, is effective in refractory cases of cholinergic urticaria but still awaits approval for use in this country. It is best to continue an effective regimen for 1 or 2 weeks after control has been achieved before decreasing dosages or changing the frequency of administration. Short courses of systemic corticosteroids may be appropriate in severe cases, but the side effects of chronic corticosteroid therapy outweigh the benefits.

ERYTHEMA MULTIFORME: STEVENS–JOHNSON SYNDROME AND TOXIC EPIDERMAL NECROLYSIS

Erythema multiforme is a spectrum of acute, self-limited, cutaneous and mucosal inflammatory syndromes, the hallmark of which is a persistent erythematous, annular, target lesion.

ETIOLOGY AND PATHOGENESIS

A wide variety of agents have been implicated in the cause of erythema multiforme. The most common of these are infections and drugs. Drugs commonly associated with erythema multiforme major and minor include sulfonamides (and sulfonamide derivatives), phenylbutazone, phenytoin, and the penicillin derivatives. Two infectious agents, recurrent herpes simplex and *Mycoplasma*, cause most cases of infection-associated erythema multiforme. Physical agents (e.g., x-radiation), immunizations and hyposensitizations, malignancies (e.g., carcinoma, lymphoma), contact allergies (e.g., as part of a vigorous response to poison ivy or poison oak), and various autoimmune diseases also have been associated with erythema multiforme, but not as frequently. Although specific pathogenic mechanisms remain to be defined, erythema multiforme appears to be an immunologically mediated syndrome. For example, typical lesions of erythema multiforme have been induced with intradermal injections of formalin-killed herpes simplex virus. In addition, viral antigens have been demonstrated in circulating immune complexes and in perilesional deposits of immunoreactants in patients with herpes simplex virus-associated erythema multiforme.

INCIDENCE AND EPIDEMIOLOGY

Erythema multiforme occurs in about 0.2% of patients with dermatologic disorders and in 0.01% to 0.1% of hospital inpatients. Most patients are 20 to 40 years of age, but children and elderly also may be affected. Recurrent episodes of erythema multiforme are common and may be associated with episodes of recurrent herpes simplex virus.

CLINICAL FEATURES AND LABORATORY FINDINGS

Erythema multiforme has been divided into major (involving skin and mucous membranes, such as Stevens–Johnson syndrome and toxic epidermal necrolysis) and minor (involving only one surface) forms. In reality, a continuum of disease exists. Often, lesions become acute after a prodrome of fever, malaise, and sore throat. Diagnostic lesions are typical erythematous, annular, target lesions with concentric rings of color and a symmetric distribution ([Fig. 197.2](#)). Bullae often develop in the center of target lesions and evolve into erosions that eventually crust. Mucosal involvement, particularly of the mouth or conjunctiva, occurs in up to 50% of patients. Widespread bulla formation, often on a background of large erythematous plaques, can result in the loss of substantial amounts of the epidermis.

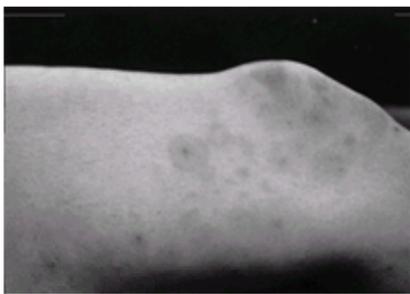

FIGURE 197.2. Erythema multiforme.

Stevens–Johnson syndrome, or erythema multiforme major, represents the intermediate form of the disease and is more likely to be triggered by drugs than by infectious agents. At least two mucosal surfaces (e.g., oral, labial, conjunctival, anogenital) must be involved in addition to the usual cutaneous findings of erythematous targetlike or bullous lesions to make the diagnosis of Stevens–Johnson syndrome. The mucosal lesions may precede the cutaneous erythema or bullae and can be painful in contrast to the skin lesions, which usually are nontender.

Toxic epidermal necrolysis probably is the most extreme form of erythema multiforme major ([Fig. 197.3](#)). This entity usually is caused by drugs and occurs in adults. It is characterized by the acute onset of generalized cutaneous inflammation with bulla formation that may involve most of the body surface. Oral and conjunctival involvement is common, and involvement of the respiratory tract, gastrointestinal tract, and vaginal mucosa is not unusual. Patients with toxic epidermal necrolysis often are febrile and toxic-appearing and complain of skin tenderness.

FIGURE 197.3. Toxic epidermal necrolysis.

The diagnosis of erythema multiforme is based primarily on clinical findings. Skin biopsy shows a predominantly mononuclear cell infiltrate with a variable number of neutrophils and eosinophils around blood vessels and the dermal–epidermal junction, with vacuolization of the basal cell layer. Subepidermal edema is characteristic, and bulla formation may occur. Widespread full-thickness epidermal necrosis is characteristic of toxic epidermal necrolysis. Frozen-section examination of the sloughed skin, combined with cytologic examination (Tzanck preparation) of the denuded base or frozen-section examination of a punch biopsy specimen, may aid in the rapid diagnosis of this life-threatening disorder. Tissue sections in the staphylococcal scalded skin syndrome reveal intraepidermal separation beneath the granular layer, whereas full-thickness epidermal necrosis with separation at the dermal–epidermal junction is characteristic of drug-induced toxic epidermal necrolysis. In addition, cytologic examination of cells from the denuded surface shows keratinocytes in the case of staphylococcal scalded skin syndrome and inflammatory cells in drug-induced toxic epidermal necrolysis.

Depending on the symptoms and severity of the disease, other laboratory studies may be indicated. The leukocyte count may be elevated. Patients with respiratory symptoms should undergo a chest radiograph to search for *Mycoplasma pneumoniae*.

COURSE, THERAPY, AND PROGNOSIS

Both minor and major erythema multiforme are self-limited, the former resolving in 1 to 2 weeks and the latter in 3 to 6 weeks. If the oral involvement is severe, food and fluid intake may be compromised. Ophthalmologic (keratitis and perforation) and respiratory (obstruction or pneumonia) problems and progression to toxic epidermal necrolysis with associated fluid and protein loss, internal organ involvement, and predisposition to septicemia are major complications. Death may occur in up to 20% of patients with severe erythema multiforme major and in up to 50% of patients with toxic epidermal necrolysis.

The mainstay of therapy is nutritional and fluid support and local care (compresses or whirlpool baths) to provide gentle debridement and prevent infection. Erythema multiforme major with widespread bullae formation and toxic epidermal necrolysis probably can be treated most effectively in a burn unit, where requirements for

aggressive fluid and nutritional support are recognized and local care is routine.

Systemic corticosteroid therapy for erythema multiforme is controversial. If prednisone is given early in the course of the illness, mortality may be diminished. The use of high doses of corticosteroids (e.g., prednisone, 1 to 2 mg per kilogram per day) in toxic epidermal necrolysis can decrease morbidity and may halt progression of cutaneous inflammation, but may not alter the high mortality rate seen in severely affected patients. For patients with recurrent erythema multiforme secondary to recurrent herpes simplex infection, chronic oral administration of acyclovir in suppressive doses has been helpful.

CHAPTER 198: APPROACH TO THE MANAGEMENT OF SKIN CANCER

SUSAN M. SWETTER

[General Incidence and Epidemiology](#)
[Basal Cell Carcinoma](#)
[Squamous Cell Carcinoma](#)
[Primary Cutaneous Melanoma](#)
[Metastatic Melanoma](#)

GENERAL INCIDENCE AND EPIDEMIOLOGY

Skin cancer is best divided into two groups: melanoma and nonmelanoma. Nonmelanoma skin cancer includes basal cell carcinoma (BCC) and squamous cell carcinoma (SCC), and it accounts for more than one-third of all cancers in the United States, with over 1 million cases detected annually. Melanoma, on the other hand, develops in over 44,000 Americans each year, and approximately 7,300 will die from metastatic disease.

BASAL CELL CARCINOMA

EPIDEMIOLOGY AND CLINICAL FINDINGS

Basal cell carcinoma arises from basal keratinocytes of the epidermis and adnexal structures. It is the most common skin cancer in humans and is primarily induced by ultraviolet B irradiation. Unlike SCC, BCC has no precursor lesion. It typically presents as a “pearly” or translucent, telangiectatic papule, although several distinct morphologic and histologic subtypes exist.

Superficial BCC is usually an erythematous, thin plaque on the trunk and extremities and may clinically resemble SCC in situ (Bowen's disease), psoriasis, or nummular eczema. Nodular BCC has the classic appearance of translucent, rolled borders and possible ulceration. Infiltrative BCC may appear as a depressed or ulcerated plaque and tends to behave more aggressively with a higher local recurrence rate if incompletely excised. Skin biopsy establishes the diagnosis and specific subtype of BCC.

OPTIMAL MANAGEMENT

Primary surgical excision is the mainstay of treatment for BCC. Surgical margins of 2 to 3 mm show cure rates over 95%. Larger clinical lesions, aggressive-growth subtypes, and lesions located in areas of higher local recurrence (nasolabial folds, preauricular and posterior auricular areas, and inner canthi) are excised with wider surgical margins (5 to 10 mm) or by means of Mohs' micrographic surgery.

Superficial BCC is confined to the epidermis and may be adequately treated with curettage and electrodesiccation, liquid nitrogen cryotherapy, or topical 5-fluorouracil, although recurrence rates are slightly higher compared with primary surgical excision. Most BCC is cured after surgery or destructive therapy. Recurrent tumors respond similarly to therapy, although cure rates tend to decrease with each unsuccessful procedure.

Mohs' micrographic surgery is indicated for recurrent tumors, large tumors (larger than 2.5 cm in diameter), tumors with poorly defined clinical margins, and those with aggressive histologic features, as just described. Mohs' micrographic surgery allows intraoperative assessment of tumor margins to ensure complete excision. In addition, it is a tissue-sparing technique that provides maximum tissue preservation in cosmetically sensitive areas such as the face.

Metastatic BCC is extremely rare, occurring in less than 1 per 4,000 cases (0.003% to 0.55% of all patients). Metastatic tumors occur most commonly on the scalp, head, and neck and are usually detected more than 10 years after treatment of the primary tumor. The most common site of metastasis is the regional lymph nodes, with lung, bone, and liver also possible. Metastatic BCC carries a poor prognosis, with average survival of 1.5 years after diagnosis and despite aggressive therapy.

SQUAMOUS CELL CARCINOMA

EPIDEMIOLOGY AND PRECURSOR LESIONS

Squamous cell carcinoma is the second most common form of skin cancer in whites, occurring in over 160,000 Americans each year. SCC arises from epidermal keratinocytes, as do its precursor lesions. Common precursor lesions for invasive nonmucosal SCC include actinic keratoses (AKs) and SCC in situ (Bowen's disease). AKs occur on sun-exposed sites as scaly or hyperkeratotic, erythematous papules. Although only a small percentage of AKs progress to invasive SCC (less than 0.2%), patients with numerous preexisting AKs are at significantly greater risk for development of SCC over a lifetime. Therefore, AKs are treated prophylactically with either liquid nitrogen cryotherapy or topical 5-fluorouracil. The regular use of sunscreen may also result in regression of AKs.

Bowen's disease typically presents as a well-demarcated, erythematous, thin plaque on sun-exposed sites of the body, although it may occur on nonexposed sites as well (e.g., on the glans penis as *erythroplasia of Queyrat*). An estimated 5% of untreated SCC in situ progresses to invasive SCC over many years, and thus treatment is similar to that for AKs. Therapeutic options include cryotherapy, topical 5-fluorouracil, curettage and electrodesiccation, or excision for recurrent lesions.

RISK FACTORS AND CLINICAL FINDINGS

Risk factors for SCC include fair complexion, increased ultraviolet B exposure, and decreased host immunity. Immunosuppressed organ transplantation patients have shown a significantly greater risk for development of cutaneous SCC with an increased likelihood for regional and distant metastasis. SCC typically presents as an erythematous, scaly papule, nodule, or plaque and may have central ulceration.

OPTIMAL MANAGEMENT

Treatment for invasive SCC is similar to that for BCC and includes excisional surgery, cryosurgery, topical chemotherapy, and radiation therapy. No uniform recommendation exists for surgical margins, although 3 to 5 mm is generally considered adequate for small, well-defined lesions. Wider margins may be necessary for large or histologically aggressive tumors, and Mohs' micrographic surgery is often performed in these cases.

Metastasis from cutaneous SCC occurs in 3% to 10% of cases, with increased incidence on mucosal surfaces and in immunosuppressed patients. Eighty-five percent of metastases from cutaneous SCC occur in the regional lymph nodes, with liver, lung, bone, and brain metastases also reported. Five-year survival rates remain low (14% to 39%).

Because approximately 50% of patients with nonmelanoma skin cancer have new primary lesions in the first 5 years after treatment, careful follow-up with regular skin examinations is recommended. In addition, sun protection and the use of sunscreens may help to prevent new precancerous and cancerous lesions.

PRIMARY CUTANEOUS MELANOMA

EPIDEMIOLOGY AND PRECURSOR LESIONS

By the year 2000, an estimated 1 in 75 Americans will develop melanoma over the course of a lifetime. Despite the increased incidence of melanoma, the case-based fatality rate has steadily fallen over the past 50 years, presumably because of earlier detection and treatment of thinner melanomas, which lack the potential to metastasize. Melanoma may arise de novo or from precursor melanocytic lesions, including congenital melanocytic nevi, common acquired melanocytic nevi,

dysplastic nevi (also referred to as "atypical moles"), and melanoma in situ (lentigo maligna, superficial spreading melanoma in situ, and acral lentiginous melanoma in situ).

CONGENITAL MELANOCYTIC NEVI

Congenital melanocytic nevi are present at birth or within the first few months of life and are estimated to occur in 1% to 2% of newborns. Most nevi are small (less than 1.5 cm in diameter) and solitary. Giant congenital melanocytic nevi (larger than 20 cm in diameter) occur in approximately 1 in 20,000 newborns and show increased risk of developing into melanoma over a lifetime (5% to 15% lifetime risk). Because of the large size of these lesions, the presence of frequent "satellite" melanocytic nevi, and the fact that nevus cells may extend to the underlying muscle and fascia, complete surgical excision is difficult, if not impossible. In addition, an estimated 50% of melanomas in these patients develop in extracutaneous sites, so excision of pigmented skin alone may not affect melanoma risk, although it may have significant cosmetic and psychosocial benefits for the child.

The actual risk of malignant transformation in small (less than 1.5 cm) and intermediate-size (1.5 to 20 cm) congenital melanocytic nevi is not known, but appears to be no greater than the risk for common acquired nevi. In addition, progression to melanoma is extremely rare in the prepubertal period, unlike melanoma arising within giant congenital melanocytic nevi. Therefore, surgical excision of smaller congenital melanocytic nevi can be deferred until the second decade of life, or permanently, if the lesion is clinically stable or removal will result in cosmetic or functional impairment.

Acquired melanocytic nevi may develop from early childhood into the fourth decade. Increased numbers of common acquired nevi (more than 100) are a risk factor for the development of melanoma, and patients should be examined periodically as well as educated in the warning signs of malignant change (change in color, size, or diameter, or onset of itching or bleeding in preexisting moles).

Dysplastic Nevi/Atypical Moles

Dysplastic nevi were initially described in the late 1970s in families with large numbers of clinically atypical moles and an increased incidence of melanoma. They may develop throughout life, unlike common acquired nevi. Dysplastic nevi show larger size than normal melanocytic nevi (more than 6 mm in diameter), variegated pigmentation (tan, brown, pink), irregular borders, and topographic asymmetry (central raised portion). Although any or all of these clinical features suggest a dysplastic nevus, histologic examination is necessary for confirmation.

Patients with the rare *familial atypical mole/melanoma syndrome* have atypical moles and have two or more first-degree relatives with dysplastic nevi and a history of melanoma. The estimated lifetime risk in affected persons approaches 100% by the age of 70. However, dysplastic nevi also occur sporadically, in a nonfamilial form, in up to 10% of the general population, and the risk of malignant transformation in these persons is difficult to assess. Most congenital, common acquired, and clinically atypical moles do not progress to melanoma, and histologic studies have established that only 30% to 50% of cutaneous melanomas are associated with precursor nevi. Thus, atypical moles are best considered markers for increased melanoma risk, rather than precursor lesions that will progress to melanoma. For this reason, patients should be taught to examine their moles periodically and to seek medical attention for any suspicious changes in existing nevi.

Melanoma In Situ

Melanoma arises from melanin-producing cells of the basal layer of the epidermis. Superficial spreading melanoma, lentigo maligna melanoma, and acral lentiginous melanoma have an in situ phase of intraepithelial, radial growth that may last for months to years before progressing to more invasive, vertical growth within the dermis. Nodular melanoma, on the other hand, is characterized by lack of an in situ phase and is typically thicker at the time of diagnosis.

Clinical Findings

Superficial spreading melanoma is the most common subtype of melanoma, occurring in about 70% of cases. Superficial spreading melanoma presents most commonly on the trunk in men and women and on the legs in women as a flat or slightly elevated nevus, with variegated pigmentation or irregular borders. A history of recent change in the nevus (size, color, shape, or onset of bleeding or pruritus) is reported by 80% of melanoma patients at the time of diagnosis.

Nodular melanoma occurs in 15% to 20% of patients and also is most commonly seen on the legs and trunk. Rapid growth over weeks to months is characteristic. Nodular melanoma presents as a dark brown to black nodule, which may ulcerate and bleed with minor trauma.

Lentigo maligna melanoma makes up 4% to 15% of cutaneous melanoma. Like BCC and SCC, lentigo maligna melanoma is closely linked to cumulative sun exposure, and it is usually located on the head and neck of older people (mean age, 65 years). Lentigo maligna is the specific in situ precursor lesion, although only 5% to 8% are estimated to progress to invasive melanoma. In these cases, the precursor lesion is usually large (3 to 6 cm in diameter), present for at least 10 to 15 years, and shows areas of dark brown to black macular pigmentation or raised blue-black nodules.

Acral lentiginous melanoma is the least common subtype of melanoma, accounting for only 2% to 8% of melanoma in whites. However, it makes up a high percentage of melanoma in African Americans, Asians, and Hispanics (35% to 90%). It is typically located on the palms or soles or beneath the nail plate. Subungual melanoma manifests as diffuse nail discoloration or a longitudinal pigmented band within the nail plate and must be differentiated from a benign junctional melanocytic nevus of the nail bed, which may present similarly. Involvement of the proximal or lateral nail folds (Hutchinson's sign) is a hallmark of acral lentiginous melanoma.

If melanoma is suspected clinically, excisional biopsy with 2- to 5-mm margins should be performed to allow optimal histologic examination and estimation of prognostic features. The most important determinant of prognosis is tumor thickness (also known as Breslow depth). Increased tumor thickness confers a higher metastatic potential and thus a poorer prognosis ([Table 198.1](#)). Clark's levels measure tumor invasion anatomically and appears to affect prognosis only in thinner (less than 1 mm) melanomas. The melanoma staging system currently accepted by the American Joint Committee on Cancer (AJCC) incorporates tumor thickness and anatomical level of invasion, with the recommendation to follow Breslow depth over Clark's level when any discordance arises ([Table 198.2](#)). Revisions in the AJCC melanoma staging system to incorporate histologic ulceration and number of lymph nodes involved are currently underway.

Thickness of Tumor (mm)	8-Year Survival (%)
Melanoma in situ	100
<0.76 mm	93.2
0.76-1.69	85.6
1.70-3.60	59.8
>3.60	33.3

Radial growth phase tumors <1.0 mm in depth show 100% survival at 8 years.
Data from Clark WH Jr, Elder DE, Guerry DN, et al. Model predicting survival in Stage I melanoma based on tumor progression. *J Natl Cancer Inst* 1985;81:1893.

TABLE 198.1. CORRELATION OF TUMOR THICKNESS AND SURVIVAL RATE IN MALIGNANT MELANOMA (VERTICAL GROWTH PHASE)

Stage	Criteria
0	Primary melanoma in situ (Clark level 0)
Ia	Primary melanoma ≤ 0.75 mm thick and/or Clark level II (pT1, N0, M0)
Ib	Primary melanoma 0.76–1.5 mm thick and/or Clark level III (pT2, N0, M0)
IIa	Primary melanoma 1.51–4.0 mm thick and/or Clark level IV (pT3, N0, M0)
IIb	Primary melanoma >4.0 mm thick and/or Clark level V (pT4, N0, M0)
III	Regional lymph node and/or in-transit metastasis (any pT, N1 or N2, M0)
IV	Distant skin, nodal, or systemic metastasis (or any combination) (any pT, any N, M1)

Tumor thickness should take precedence over Clark level and be used for pT staging when differences arise, according to the American Joint Committee on Cancer Melanoma Committee. Data from American Joint Committee on Cancer. *Manual for Staging of Cancer*, 4th ed. Philadelphia, JB Lippincott, 1992:143.

TABLE 198.2. AMERICAN JOINT COMMITTEE ON CANCER/UNION INTERNATIONALE CONTRE LE CANCER pTNM STAGING SYSTEM FOR MALIGNANT MELANOMA (1988)

OPTIMAL MANAGEMENT

Surgery is the primary mode of therapy for localized cutaneous melanoma. Recommendations for surgical margins have evolved dramatically over the past century with the realization that wider margins for deep tumors do not prevent metastatic disease. Although narrow surgical margins (less than 1.5 cm) may result in a higher local recurrence rate (or "persistent disease") for thicker melanomas, they do not affect metastatic potential or survival rate. Five-millimeter surgical margins are recommended for melanoma in situ and 1-cm margins for melanomas up to 1 mm in depth (low-risk primaries). Randomized, prospective studies suggest that 2-cm margins are appropriate for tumors in the intermediate-risk group (1 to 4 mm in Breslow depth), although 1-cm margins have been proposed for tumors 1 to 2 mm thickness. Margins of at least 2 cm are recommended for cutaneous melanomas greater than 4 mm in thickness (high-risk primaries) to prevent potential local recurrence on the skin.

Elective Lymph Node Dissection

Prophylactic lymph node dissection for primary cutaneous melanoma of intermediate thickness was initially believed to confer a survival advantage for patients with tumors 1 to 4 mm in depth. However, subsequent prospective, randomized clinical trials have shown no survival benefit for elective lymphadenectomy for melanomas of varying thicknesses on the extremities and have shown marginal to no benefit for nonextremity melanomas.

The use of lymphatic mapping and the "sentinel node" biopsy has effectively solved the dilemma of whether to perform regional node dissection in the absence of clinically palpable nodes in patients with thicker melanomas (more than 1 mm in depth). This procedure involves preoperative radiographic mapping (lymphoscintigraphy) and biopsy of the initial draining regional node to assess for the presence of micrometastasis, in which case a therapeutic lymph node dissection is performed.

Adjuvant Therapy

Numerous trials of adjuvant chemotherapy, nonspecific, passive immunotherapy, radiation therapy, and biologic therapy have been performed to assess survival benefit in patients with localized cutaneous disease. No increase in patient survival has yet been found with these adjunctive therapies. Adjuvant interferon alfa-2b and various experimental melanoma vaccines show promise in persons with high-risk primary cutaneous melanoma.

METASTATIC MELANOMA

Metastatic melanoma may occur locally, within or around the primary site, in regional lymph node basins, or distally, including remote skin, lymph node, visceral, skeletal, or central nervous system sites. Initial sites of disease relapse are most frequently seen in the skin, subcutaneous tissue, and lymph nodes. In these cases, surgical excision of isolated metastasis may result in long-term survival (up to 61% reported). Regional lymph node metastasis is associated with a 36% to 40% 5-year survival rate, although adjuvant interferon- α and melanoma cell vaccines show promise in prolonging survival.

The prognosis for persons with untreated distant metastatic disease is extremely poor, with a median survival of only 6 to 9 months and a 5-year survival rate between 5% and 7%. Systemic chemotherapy is the mainstay of treatment, despite low response rates (less than 20%). Use of modified concurrent biochemotherapy (with interleukin-2 and interferon) has shown increased response rates in some randomized trials and is being further investigated. In addition, specific active immunotherapy with experimental melanoma-derived, autologous, peptide, and dendritic cell vaccines has been shown to mediate tumor regression and is being intensively studied. Despite advances in the treatment of metastatic disease, however, detection and treatment of cutaneous melanoma in its thin, early phase remains the best chance for cure.

CHAPTER 199: CUTANEOUS REACTIONS TO DRUGS

MARTIN VAZQUEZ

Diagnosis

Drug eruptions are a heterogeneous group of cutaneous reactions due to medications. Although difficult to determine, cutaneous drug reactions are reported to occur in 0.3% to 2.2% of hospitalized patients, with antibiotics accounting for at least 40% of reactions ([Table 199.1](#)). Morbilliform reactions and urticaria are the most common manifestations. Other reactions are angioedema, erythema multiforme, exfoliative dermatitis, photosensitivity, vasculitis, and erythema nodosum. Risk factors include increased number of medications and AIDS.

Drug	Reaction Rate*
Amoxicillin	52
Trimethoprim-sulfamethoxazole	34
Ampicillin	33
Sibodol	22
Semisynthetic penicillin	21
Penicillin G	19
Cephalosporins	21
Erythromycin	20
Dihydrochloride hydrochloride	19
Quinidine	13
Cimetidine	13

* Reaction rate per 1000 recipients.
(From Bigby M, Jick S, Jick H, et al. Drug induced cutaneous reactions: a report from the Boston Collaborative Drug Surveillance Program on 13,438 inpatients, 1975-1983. *JAMA* 1986; 256:3358, with permission.)

TABLE 199.1. ALLERGIC SKIN REACTION RATES

DIAGNOSIS

Mislabeling a dermatosis as a drug eruption may unnecessarily limit future use of specific medications. To help minimize this, the differential diagnosis should include dermatosis not associated with drug use, such as allergic contact dermatitis, viral exanthems, and atopic dermatitis.

Although no algorithm is universally practiced, the following approach is recommended:

1. Classify the morphology and pattern of the eruption (e.g., morbilliform, urticarial, palpable purpura), including associated symptoms. Features of cutaneous skin eruptions with potential morbidity include skin pain, necrosis, and blisters; confluent erythema; palpable purpura; mucosal involvement; angioedema; high fever and lymphadenopathy; and cardiopulmonary compromise.
2. Obtain a detailed history, including prescription and over-the-counter medications, eye drops, suppositories, topical medications, herbal treatments, and other remedies currently or recently taken.
3. List previous allergies to medications, because reexposure may have occurred.
4. Note the temporal relation between the onset of the eruption and the ingestion of the drug or drugs. Most cutaneous drug eruptions occur within 7 to 14 days after beginning a new medication.
5. Determine the probability that a suspected drug is causing a particular eruption based on reports (this may require reference to the medical literature).
6. The response to stopping medication (i.e., "dechallenge") needs to be followed. After discontinuation of the offending agent, resolution of the eruption may take as long as 4 to 6 weeks. In certain cases when the medication is strongly indicated for a given patient, rechallenge may be performed. This, however, is not usually recommended.

[Table 199.2](#) outlines important primary drug-induced cutaneous eruptions with their key clinical features, differential diagnoses, implicated drugs, and management principles. Only the statistically most common causative drugs are listed. The list is otherwise extensive, and consulting the referenced text is advised.

TABLE 199.2. PRIMARY CUTANEOUS DRUG ERUPTIONS

In general, treating through a drug eruption (i.e., continuation of a possibly offending drug) is advised only for life-saving medications for which there are no substitutes. However, this is contraindicated when evolving erythema multiforme, toxic epidermal necrolysis, or exfoliative erythroderma is suspected.

CHAPTER 200: DERMATOLOGIC DIAGNOSIS: FUNDAMENTALS FOR THE INTERNIST

JULIE ANNE WINFIELD

[Following the Dermatologic Clues](#)
[Illustrative Cases](#)

It is almost impossible to practice current internal medicine without some working knowledge of dermatology. These two specialties are very closely intertwined. Just as a dermatologist cannot fully treat a patient's cutaneous problem without a full understanding of the underlying disease process, neither can an internist ignore cutaneous findings as a clue to the patient's disease. The two specialties work hand in hand.

The first goal of this chapter on basic aspects of dermatologic diagnosis is to develop a common language of communication between the specialties of dermatology and internal medicine. Dermatology is a descriptive specialty and, by means of a common language to describe the entities found, provides internists with a valuable tool to aid in evaluation of their patients. This language also helps to "paint a picture," which will be very helpful in the communication between the two specialties. Keep in mind that a combined group of descriptors, along with a complete history, typically leads to a diagnosis or series of diagnostic possibilities.

Although dermatologists sometimes categorize lesions as primary (those that develop as part of the pathologic process, such as a vesicle of bullous pemphigoid) or secondary (those that derive or evolve from the primary lesions, such as a crusted excoriation resulting from scratching a vesicle), for the purpose of this chapter no such division will be made.

The goal here is to develop a small working common vocabulary that can be used in clinical circumstances ranging from bedside to long-range (even telemedicine) consultations to a problem-oriented algorithm.

Annular—occurring in a ring, such as in tinea corporis or a nodular annular lesion of sarcoidosis ([Fig. 200.1](#))

FIGURE 200.1. Annular: sarcoidosis. See [color figure 200.1](#).

Atrophy—loss of substance of the skin; in the epidermis (loss of skin markings) or in the dermis or subcutis, creating a hollowed-out appearance such as in lipoatrophy ([Fig. 200.2](#) , with blue-yellow discoloration and increase in visibility of vasculature, and necrobiosis lipoidica diabetorum ([Fig. 200.3](#))

FIGURE 200.2. Atrophy: lipoatrophy. See [color figure 200.2](#).

FIGURE 200.3. Atrophy: necrobiosis lipoidica diabetorum. See [color figure 200.3](#).

Bulla—an elevated fluid-filled lesion larger than 0.5 cm, such as in bullous pemphigoid ([Fig. 200.4](#))

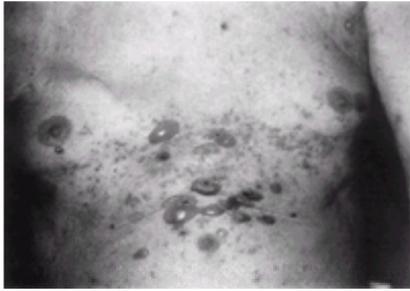

FIGURE 200.4. Vesicle and bulla: bullous pemphigoid. See [color figure 200.4](#).

Crust—a conglomeration of serum, blood, and inflammatory debris that develops after a spontaneous or induced break in the skin (scab), such as over an erosion or ulcer ([Fig. 200.24](#)) and in impetigo with characteristically “honey colored” crust

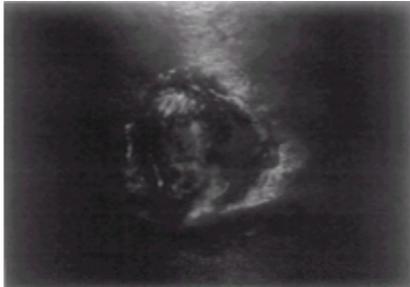

FIGURE 200.24. Ulcer: stasis ulcer with crusts. See [color figure 200.24](#).

Cyst—an often well-circumscribed, compressible lesion filled with semisolid material; most likely an epidermal cyst if a central punctum or pore is visible

Erosion—a well-circumscribed, often oval, moist lesion that results from a superficial break within the skin, most commonly resulting from a vesicle or blister, such as porphyria cutanea tarda ([Fig. 200.5](#))

FIGURE 200.5. Erosion: porphyria cutanea tarda. See [color figure 200.5](#).

Erythema—redness, as a primary event, as in nevus flammeus (stork bite) or as a secondary event, as in inflammation ([Color Fig. 200.7](#))

Exfoliative—diffuse shedding of scales (essentially involving the entire epidermis as an exfoliative dermatitis in erythrodermic psoriasis ([Fig. 200.6](#)), pityriasis rubra pilaris, and ichthyosis

FIGURE 200.6. Exfoliation: psoriasis. See [color figure 200.6](#).

Fissure—a linear, moist lesion that results from a superficial spontaneous break in the skin, as may result from underlying edema and inflammation in eczematous dermatitis of the hand ([Fig. 200.7](#))

FIGURE 200.7. Fissure: hand eczema with erythema. See [color figure 200.7](#).

Herpetiform—grouped or clustered lesions often on an erythematous base, as in herpes simplex ([Fig. 200.8](#))

FIGURE 200.8. Herpetiform: herpes simplex with umbilicated vesicles. See [color figure 200.8](#).

Hyperpigmentation—localized or generalized increase in pigmentation, as occurs in postinflammatory hyperpigmentation from an inflammatory process such as inflammatory acne lesion, eczema, and discoid lupus erythematosus ([Fig. 200.9](#))

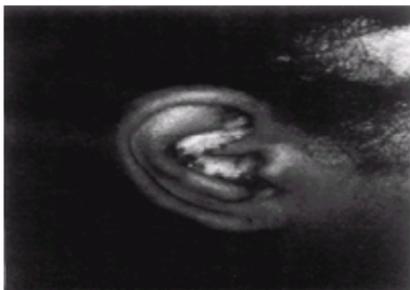

FIGURE 200.9. Hyperpigmentation/hypopigmentation: discoid lupus erythematosus with atrophic, hypopigmented center and hyperpigmented border. See [color figure 200.9](#).

Hypopigmentation—a decrease in normal pigmentation, again usually as a result of a chronic inflammatory process, such as discoid lupus erythematosus, eczema, or psoriasis ([Fig. 200.9](#))

Indurated—thickened, often plaquelike area, as seen in mycosis fungoides (cutaneous T-cell lymphoma) and scleroderma ([Fig. 200.10](#))

FIGURE 200.10. Indurated: scleroderma with diffusely shiny, taut skin. See [color figure 200.10](#).

Lichenification/lichenoid—proliferation of the keratinocytes and stratum corneum forming a thickened plaquelike structure as a result of chronic rubbing of the skin and occurring typically in chronic eczematous dermatosis ([Fig. 200.11](#)), but also in psoriasis and other pruritic conditions, as in lichen planus with the white Wickham striae overlying ([Fig. 200.15](#))

FIGURE 200.11. Lichenification: chronic eczematous dermatitis with hyperpigmentation. See [color figure 200.11](#).

FIGURE 200.15. Papule: lichen planus. See [color figure 200.15](#).

Linear—occurring in a line, as in contact dermatitis from poison ivy and in excoriation ([Fig. 200.12](#))

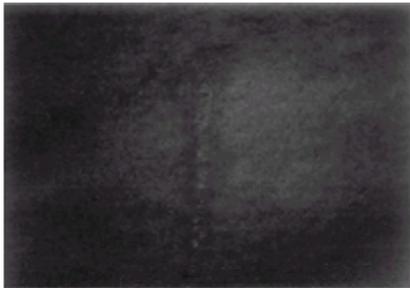

FIGURE 200.12. Linear: poison ivy contact dermatitis. See [color figure 200.12](#).

Macule—a circumscribed area of color change in normal skin without elevation or depression, as in vitiligo ([Fig. 200.13](#)) or a port wine stain

FIGURE 200.13. Macule: vitiligo. See [color figure 200.13](#).

Nodule—a palpable lesion deeper than a papule, often more than 2 cm in diameter, as in squamous cell carcinoma ([Fig. 200.14](#)) (Persistent nontender nodules are important signs of underlying systemic disease and should be considered for biopsy, also possibly sending half of a sterile biopsy specimen for culture if clinically indicated.)

FIGURE 200.14. Nodule: squamous cell carcinoma. See [color figure 200.14](#).

Papule—a raised palpable, often well-circumscribed lesion less than 0.5 cm in diameter (usually arising from surrounding tissue, not from deep within the skin like a nodule), as in lichen planus ([Fig. 200.15](#))

Plaque—a raised area larger than 0.5 cm, which may be the result of confluence of papules, as in plaque psoriasis or erythema nodosum ([Fig. 200.16](#))

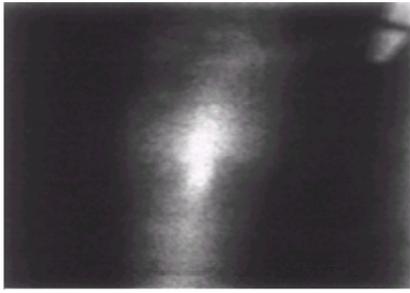

FIGURE 200.16. Plaque: erythema nodosum. See [color figure 200.16](#).

Polygonal—having discernible sides and angular corners, as in lichen planus ([Fig. 200.15](#))

Purpura—red-violet discoloration resulting from cutaneous hemorrhage, as in ecchymosis in autoerythrocyte sensitization ([Fig. 200.17](#)) and in petechiae (palpable purpura) in leukocytoclastic vasculitis ([Fig. 200.18](#))

FIGURE 200.17. Purpura/ecchymosis: autoerythrocyte sensitization. See [color figure 200.17](#).

FIGURE 200.18. Purpura/petechiae: leukocytoclastic vasculitis. See [color figure 200.18](#).

Pustule—a fluid-filled lesion that contains purulent exudate that may be white, yellow, or green, as in pustular psoriasis ([Fig. 200.19](#)). (A pustule surrounding a hair follicle with a central hair is called *folliculitis*. Also, many of the vesicular lesions of some viral diseases can secondarily become pustules, as in herpes and varicella. If indicated clinically, a Gram's stain and culture should be done to identify an infectious agent.)

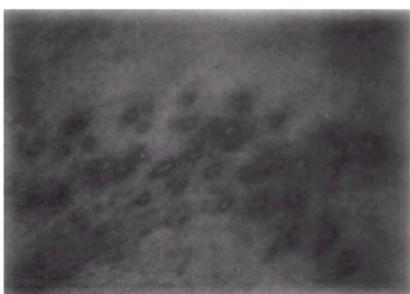

FIGURE 200.19. Pustule: pustular psoriasis. See [color figure 200.19](#).

Reticulated—a lacelike or network pattern, as in prominent vascular pattern in cutis marmorata

Scaling/desquamation—flesh-colored flakes of skin that represent the outermost terminally differentiated epidermis and may be enhanced as a primary event, as in ichthyosis ([Fig. 200.20](#)), or as a secondary event, as in chronic eczematous dermatitis ([Fig. 200.21](#)); also *scaly*.

FIGURE 200.20. Scale: X-linked ichthyosis. See [color figure 200.20](#).

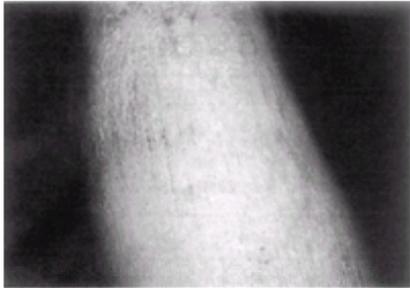

FIGURE 200.21. Excoriation: atopic dermatitis. See [color figure 200.21](#).

Serpiginous—moving in a curvilinear fashion, as in cutaneous larva migrans ([Fig. 200.22](#))

FIGURE 200.22. Serpiginous: cutaneous larva migrans. See [color figure 200.22](#).

Targetoid/iris—like a bullseye, a series of concentric rings, often with central clearing, as in erythema multiforme ([Fig. 200.23](#))

FIGURE 200.23. Target/iris: erythema multiforme. See [color figure 200.23](#).

Ulcer—a deep margined lesion that results from destruction of the epidermis and dermis, such as stasis ulcer ([Fig. 200.24](#))

Umbilicated—having a central dell or indentation suggesting a viral cause, as in molluscum contagiosum or herpes simplex ([Fig. 200.8](#))

Verrucous—having an irregular, rough, warty surface, as in seborrheic keratosis ([Fig. 200.25](#))

FIGURE 200.25. Verrucous: seborrheic keratosis. See [color figure 200.25](#).

The importance of the interplay of history, physical examination, and diagnostic techniques is illustrated best by several clinical cases studies. These case studies also show the way terms are used to make subtle distinctions between two problems of similar history or morphologic characteristics. The important points in the diagnostic process are described.

CASE STUDIES 1 AND 2

The history for Case 1 is helpful ([Table 200.2](#); [Fig. 200.28](#)). A respiratory tract infection treated with ampicillin with an abrupt onset of a pruritic eruption, suggests a drug allergy. The physical examination confirms a diffuse, maculopapular, erythematous (morbilliform) eruption. The blanching on diascopy suggests that there is no vasculitis. In contrast, for Case 2 ([Fig. 200.29](#)), despite the rapid onset, the history is relatively uninformative. Fatigue, excessive thirst, and frequent urination provide the only clues to the underlying problem. In this case, the physical examination is most important. It reveals red papules with yellow centers in rosettes that do not blanch on diascopy. These features are typical of eruptive xanthomas, a finding confirmed by biopsy. The final diagnosis was diabetes mellitus.

	Case 1 (Fig. 200.28)	Case 2 (Fig. 200.29)
History		
Onset	Rapid onset of trunk eruption 24 hours earlier	Same
General symptoms	None	Fatigue
Constitutional symptoms	None	None
Systemic illness	Respiratory tract infection 1 wk earlier	Excessive thirst, frequent urination
Medications	Ampicillin	None
Preliminary assessment	Drug allergy	Unknown
Examination		
General skin	Diffuse, erythematous macular and indurated lesions on trunk	Diffuse, erythematous papular lesions on trunk; some have faint yellow centers and coalesce into clusters or rosettes
Diascopy	Lesions blanch, leaving no erythema or dermal mottling	Lesions accentuated, resulting dermal mottling
Preliminary assessment	Drug allergy to ampicillin	Eruptive xanthomas secondary to diabetes mellitus
Special Techniques or Tests		
Prick blood glucose	Not done	Significantly elevated
Urea nitrogen	Not done	Significantly elevated
Skin biopsy	Not done	Compatible with eruptive xanthomas
Final Assessment	Drug allergy to ampicillin	Eruptive xanthomas secondary to diabetes mellitus

TABLE 200.2. CASES 1 AND 2: ERYTHEMATOUS ERUPTIONS OF THE TRUNK

FIGURE 200.28. Case 1—Drug allergy secondary to ampicillin. See [color figure 200.28](#).

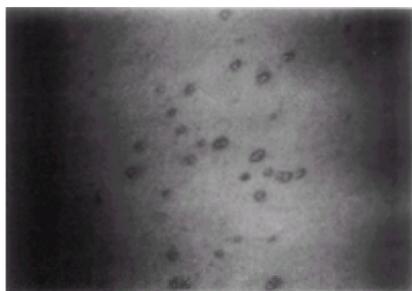

FIGURE 200.29. Case 2—Eruptive xanthomas secondary to diabetes mellitus. See [color figure 200.29](#).

CASE STUDIES 3 AND 4

Cases 3 and 4 illustrate how subtle differences in distribution can lead to the proper diagnosis ([Table 200.3](#); [Fig. 200.30](#) and [Fig. 200.31](#)). Except for the fatigue and arthralgia, the history for Case 3 is relatively unrevealing. The morphologic characteristics and the distribution of the lesions (in light-exposed areas, sparing the submental region) suggest lupus erythematosus. In contrast, the distribution of the lesions in Case 4 is typical of seborrheic dermatitis, because it involves the eyebrows, glabella, and nasolabial folds, but spares other light-exposed regions. In both cases, the sharp, scaly borders require at least the consideration of a superficial fungal infection (excluded by the negative potassium hydrochloride preparations). A skin biopsy for hematoxylin-eosin (H&E) and direct immunofluorescence, along with hematologic studies in Case 3 will confirm the diagnosis of lupus erythematosus.

	Case 3 (Fig. 200.30)	Case 4 (Fig. 200.31)
History		
Onset	Onset and slow progression of eruption of face during past month	Same
General symptoms	Fatigue, arthralgia	None
Constitutional symptoms	Constant only	None
Medications	None	None
Family history	Not helpful	Not helpful
Preliminary assessment	Positive light-induced eruption	None
Examination		
General skin	Sharply margined erythematous and plaques with peripheral scales on face and upper trunk, spare submental region and nasolabial folds	Sharply margined erythematous, red plaques of forehead, eyebrows, glabella, and nasolabial folds
Diascopy	Erythema blanches	None
Preliminary assessment	Lupus erythematosus or other light-related eruption	Seborrheic dermatitis, discoid lupus erythematosus, or drug toxic
Special Techniques or Tests		
KOH preparation	No hyaline element	None
AKB	Markedly positive	Negative
Skin biopsy	Compatible with lupus erythematosus	Not done
Final Assessment	Lupus erythematosus	Seborrheic dermatitis

KOH, potassium hydroxide; AKB, antinuclear antibody.

TABLE 200.3. CASES 3 AND 4: ERYTHEMATOUS ERUPTIONS OF THE FACE

FIGURE 200.30. Case 3—Systemic lupus erythematosus. See [color figure 200.30](#).

FIGURE 200.31. Case 4—Seborrheic dermatitis. See [color figure 200.31](#).

CASE STUDIES 5 AND 6

Cases 5 and 6 illustrate the problems of dealing with ulcerated nodules on extremities and elucidating whether there is an infectious basis ([Table 200.4](#); [Fig. 200.32](#) and [Fig. 200.33](#)). The history for Case 5 points to a joint problem of undetermined cause involving both hands, whereas the history of gardening and the ipsilateral spread of the lesions for Case 6 suggest an infectious basis. The physical findings provide strong evidence of this origin because sporotrichosis, nocardiosis, and atypical mycobacterial infections all can produce this picture. Typically, the potassium hydroxide preparation does not reveal the organism, but purulent drainage and tissue samples are adequate sources for culture. A biopsy for H&E can supply additional information for diagnosis. The key to Case 5 is the physical finding of tan and violaceous nodules overlying the metatarsophalangeal and proximal interphalangeal joints and the swelling of the proximal interphalangeal joints. These lesions, combined with the destructive arthritis, suggest multicentric reticulohistiocytosis. A skin biopsy would help confirm the diagnosis.

	Case 5 (Fig. 200.32)	Case 6 (Fig. 200.33)
History		
Onset	Slow onset and gradual progression to ulceration over months of both hands	Onset of nodules on hand 10 weeks after progression to chronic and acute spread on the arm of additional ulcerative nodules
General symptoms	Painful joints of the hands	None
Concomitant symptoms	None	None
Family history	None	None
Occupation	None	None
Activities	None	None
Previous treatment	None	None
Examination		
General skin	Multiple, poorly demarcated, violaceous and tan nodules over dorsal and lateral aspects of both hands and fingers, some ulcerated. No firm swelling of interphalangeal joints	Multiple, well-demarcated, ulcerated nodules on dorsal aspect of right hand and proximal to right elbow, left arm spared
Palpation	None	None
Special techniques on hands		
KOH preparation	None	None
Biopsy	None	None

PRESENTATION

Evaluation of the patient with lymphadenopathy or lymph node enlargement is common in clinical practice. The enlarged lymph node may have been noticed by the patient or discovered on routine physical examination by the physician. Lymph node enlargement may be a result of significant disease such as infection or malignancy. A careful history and physical examination and an understanding of the pathophysiology and differential diagnosis of lymph node enlargement are crucial in the evaluation of such patients.

PATHOPHYSIOLOGY

Lymph nodes are discrete organs of the lymphatic system ([Fig. 201.1](#)). Afferent lymphatics passively carry lymph that contains lymphocytes, macrophages, and antigens and sometimes carries microorganisms to the node for processing, passing through the subcapsular sinus to enter the cortex.

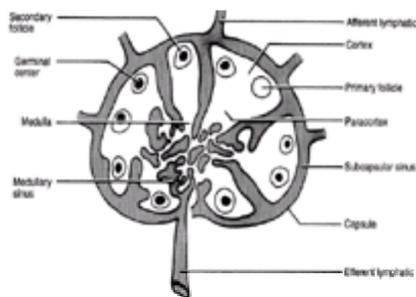

FIGURE 201.1. Structure of the lymph node.

The cortex consists of the primary and secondary lymphoid follicles. The primary follicles, which contain antibody-bearing B cells and T cells, give rise to secondary follicles after antigenic stimulation. Secondary follicles consist of an outer mantle zone of B cells and an inner germinal center, where macrophages, antigen-presenting dendritic reticulum cells, T cells, and B cells interact. This results in dramatic B-cell proliferation, differentiation, and antibody production.

The paracortex, found between the cortex and medulla, is the primary location for T cells in the node, with a predominance of the CD4 (helper or inducer T cell) phenotype. The paracortex also serves as the site where B cells, T cells, and macrophages, sometimes actively transporting antigens, reenter the node from the venous circulation through postcapillary venules.

The medulla, the innermost zone of the node, contains the medullary sinuses that converge on the hilum to form the efferent lymphatics. The lymph node architecture is well designed to facilitate its principal function: allowing the complex interaction of the cells of the immune system to process, respond to, and ultimately eliminate antigen. During the normal immune response, antigenic stimulation often results in lymphadenopathy from dramatic B-cell and T-cell proliferation and marked accumulation of lymphocytes and macrophages from increased blood flow to the node.

Lymphadenitis is the infiltration of inflammatory cells into the lymph node. Acute lymphadenitis results from direct microbiologic drainage; the nodes histologically demonstrate prominent germinal centers and neutrophilic infiltration, sometimes with abscess formation. Chronic lymphadenitis due to ongoing antigenic stimulation may manifest distinct histologic patterns. Follicular hyperplasia, resulting from various processes such as HIV infection or autoimmune disorders, manifests as marked enlargement and prominence of the germinal centers. In paracortical lymphoid hyperplasia such as that seen with some viral infections (e.g., Epstein–Barr virus) and in drug-induced reactions (e.g., from phenytoin), expansion of paracortical zones by means of immunoblastic proliferation results in a "pseudolymphomatous" pattern. Granulomatous lymphadenitis resulting from tuberculosis, sarcoidosis, and histoplasmosis typically results in lymphadenopathy.

Lymph node enlargement can result from the malignant transformation and proliferation of cells indigenous to the lymph node. Malignant lymphomas are neoplasms that arise from lymphocytes and their precursors. Lymphadenopathy can also result from infiltration of the node by leukemic cells. Many cancers of epithelial and sarcomatous origin metastasize to lymph nodes, where the milieu allows the neoplastic cells to thrive, resulting in nodal enlargement.

Lymph node enlargement may be caused by an accumulation of benign cells or substances in the node parenchyma. In some hereditary disorders such as lipid storage diseases, histiocytes laden with excess metabolites accumulate and result in nodal enlargement. In amyloidosis, the excessive deposition of the fibrillar protein can cause enlargement of the lymph node.

HISTORY AND PHYSICAL EXAMINATION

The history of the patient presenting with lymphadenopathy may provide clues to the cause of the lymph node enlargement. The age of the patient is important. In patients younger than 30 years of age, most cases of lymphadenopathy are benign and frequently are caused by infection. A typical example is the college-age student presenting with tender cervical nodes and fever who may have a viral upper respiratory infection, bacterial pharyngitis, or infectious mononucleosis. However, in patients older than 50 years, lymphadenopathy results from benign conditions only 40% of the time, and malignancy must be aggressively excluded. A careful review of risk factors for HIV infection, such as high-risk sexual activity or intravenous drug use, is important for the patient presenting with generalized lymphadenopathy of more than 3 months' duration. Symptoms accompanying the lymphadenopathy may also help the clinician formulate a differential diagnosis. Fever may be a component of infectious and malignant causes of lymphadenopathy. Fever and lymphadenopathy may be accompanied by signs of a localized infection such as pharyngitis. However, when ongoing low-grade fevers are accompanied by night sweats or weight loss, these constitutional symptoms suggest lymphoma, HIV infection, or tuberculosis.

Lymph nodes are best examined by palpating with the fingertips in a circular motion to determine the physical characteristics of the node. These characteristics include size, mobility of the lymph node versus fixation to underlying tissue, tenderness, and consistency. In adults, the normal lymph node is usually soft and can vary in size from a few millimeters for most regions to 1 cm in diameter for inguinal nodes. In acute infections, nodes may be tender, localized, and matted. Chronic infections may result in less tender, more generalized nodes. Lymphoma nodes are often large, rubbery, and nontender. Metastatic carcinoma results in localized, hard, fixed nodes. Only with experience does the clinician develop the ability to differentiate normal from abnormally enlarged nodes.

A thorough knowledge of the anatomical regions and drainage patterns of normal nodal groups is important (Fig. 201.2) because the location of the abnormally enlarged nodes can help the clinician to determine the diagnosis (Table 201.1). The cervical lymph nodes drain the head and neck. To examine the cervical nodes, the clinician can stand behind or in front of the patient. The submental nodes are located under the chin; submandibular nodes are found under the angle of the jaw. These nodes drain the mouth and the associated salivary glands. The anterior cervical nodes lie anterior to the sternocleidomastoid, and the posterior cervical nodes are posterior. The suboccipital nodes are located in the apex of the posterior cervical triangle. The preauricular and posterior auricular nodes are in front of and behind the pinna of the ear, respectively.

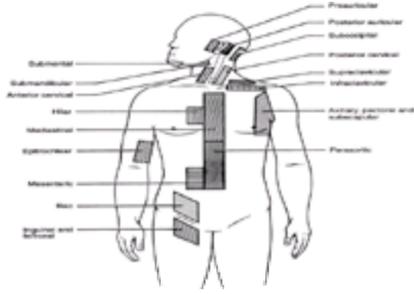

FIGURE 201.2. Anatomical lymph node regions.

Site of Enlargement	Typical Causes
Cervical	Infectious mononucleosis, bacterial or viral pharyngitis, metastatic head and neck carcinoma
Submental	Infection of the mouth and salivary glands
Submandibular	Infection of the mouth and salivary glands
Anterior cervical	Infection of the head and neck
Posterior cervical	Infectious mononucleosis, bacterial or viral pharyngitis, metastatic head and neck carcinoma
Suboccipital	Infection of the head and neck
Preauricular	Infection of the head and neck
Posterior auricular	Infection of the head and neck
Supraclavicular	Metastatic cancer, lymphoma
Axillary	Upper extremity infections, cat-scratch disease, lymphoma, metastatic breast carcinoma
Subscapular	Chest wall, breast, and intrathoracic structures
Pectoral	Chest wall, breast, and intrathoracic structures
Infraclavicular	Chest wall, breast, and intrathoracic structures
Epitrochlear	Chest wall, breast, and intrathoracic structures
Inguinal	Lower extremity and genitalia infections, sexually transmitted diseases, lymphoma, metastatic cervical or anal carcinoma
External iliac	Lower extremity and genitalia infections, lymphoma, metastatic cervical or anal carcinoma
Femoral	Lower extremity and genitalia infections, lymphoma, metastatic cervical or anal carcinoma
Hilar	Malignancy, other causes
Mediastinal	Malignancy, other causes
Mesenteric	Abdominal and pelvic infections, lymphoma
Pelvic	Abdominal and pelvic infections, lymphoma

TABLE 201.1. TYPICAL CAUSES OF LYMPHADENOPATHY ACCORDING TO THE ANATOMIC SITE OF ENLARGEMENT

In younger patients, cervical lymphadenopathy is common. Infectious mononucleosis frequently causes enlargement of posterior cervical nodes; bacterial or viral pharyngitis commonly results in enlargement of the anterior and posterior cervical nodes. Unilateral cervical node enlargement in an older patient, especially with a history of tobacco or alcohol abuse, may represent metastatic head and neck carcinoma.

In addition to draining head and neck structures, the supraclavicular nodes that lie posterior to the midclavicle drain the thorax and abdomen. Enlarged supraclavicular nodes may indicate a malignancy, such as lymphoma or metastatic cancer. *Virchow's node* refers to an enlarged left supraclavicular node as a result of metastatic gastrointestinal carcinoma.

Axillary lymph nodes are divided into central and lateral groups. The central axillary nodes are located near the middle of the axillary chest wall, with lateral groups along the upper humerus. These nodes are best examined by having the patient drop his or her arm in a relaxed position to the side of the body, allowing the examiner to more easily palpate the axilla by putting pressure against the chest wall and moving the examining hand downward from the apex. Axillary lymph nodes drain the upper extremity, chest wall, breast, and intrathoracic organs. Bilateral small, soft axillary nodes may be benign; tender unilateral enlarged nodes in this site may be the result of cat-scratch disease or upper extremity infections. Rubbery or firm nodes in the axilla may indicate lymphoma or metastatic breast carcinoma.

The chest wall, breast, and intrathoracic structures are also drained by the subscapular nodes that lie anterior to the latissimus dorsi, the pectoral nodes found beneath the lateral edge of the pectoralis major, and the infraclavicular nodes located under the distal clavicle. Epitrochlear nodes lie just proximal to the medial epicondyle of the humerus. These nodes may be difficult to examine, and they are best approached by palpating across this region in a posterior direction.

The inguinal lymph nodes located along the inguinal ligament drain the lower extremity and the genitalia. The external iliac and femoral nodes located in the femoral triangle drain structures in the pelvis. Benign inguinal lymph node enlargement is common, and small palpable nodes less than 1 cm in diameter are found in many patients. Sexually transmitted diseases such as syphilis and lymphogranuloma venereum may cause unilateral inguinal node enlargement. Progressive enlargement of inguinal lymph nodes or association with femoral or iliac lymphadenopathy suggests malignancy, such as lymphoma or metastatic cervical or anal carcinoma.

In addition to the superficial lymph nodes that may be palpated by the examiner, the history and physical examination may yield clues concerning lymphadenopathy in the deeper regions of the chest, abdomen, and pelvis. Hilar or mediastinal lymph node enlargement due to malignancy or other causes may produce symptoms caused by compression of thoracic structures. These include cough, dyspnea, and wheezing due to tracheobronchial compression; dysphagia due to esophageal compression; swelling of the face, neck, and arms due to superior vena cava or subclavian vein compression; and hoarseness due to recurrent laryngeal nerve compression. Mediastinal and hilar lymphadenopathy may also be discovered as a result of radiographic investigation (e.g., computed tomography [CT] scanning) of clinically evident superficial lymphadenopathy.

The abdomen and pelvis may harbor deep lymphadenopathy, such as that caused by lymphoma. Because of the physical characteristics of this cavity, large asymptomatic lymph node masses may arise in the retroperitoneum and pelvis. Occasionally, a large mesenteric or abdominopelvic lymph node mass may be palpable on physical examination. Clues to the presence of internal iliac or pelvic nodes include swelling of the lower extremities due to lymphatic or vascular compression by these nodes.

The spleen may be important in the evaluation of patients with lymphadenopathy. Splenomegaly that is tender may be seen in infectious mononucleosis syndromes. Patients with lymphoma and acute and chronic lymphocytic leukemia may manifest splenomegaly as well as lymphadenopathy. Infiltrative disease such as lipid storage diseases or amyloidosis may manifest with splenomegaly, as can autoimmune disease such as systemic lupus erythematosus.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

The ancillary workup of the patient with lymphadenopathy is often directed by the clinical setting and the data obtained from performing a thorough history and physical examination. There is no prescribed battery of tests that all patients should undergo. The clinician should carefully select ancillary testing based on the differential diagnosis. A complete blood count may be helpful for patients suspected of having infection or malignancy. The blood smear may provide important clues to a hematologic malignancy such as chronic lymphocytic leukemia or acute leukemia. The young patient suspected of infectious mononucleosis may have circulating atypical lymphocytes on a blood smear. However, this patient should also undergo a confirmatory Monospot (heterophile antibody) test. If suspected of a bacterial pharyngitis, a simple throat culture can be diagnostic. A patient with known risk factors for HIV infection can have generalized lymphadenopathy explained by performing a diagnostic serologic test for HIV. Serologic titers for other infectious agents such as cytomegalovirus or toxoplasmosis may be helpful. An elevated erythrocyte sedimentation rate is nonspecific and usually does not further a differential diagnosis. Titers for antinuclear antibody or rheumatoid factor may be

diagnostic for patients suspected of autoimmune illnesses.

Ancillary radiographic testing of the patient presenting with lymphadenopathy should be guided by the suspected diagnosis. A chest x-ray film and CT scans of the chest, abdomen, and pelvis may demonstrate lymphadenopathy in the deeper nodal groups and are especially useful for patients suspected of having lymphoma. However, many patients with superficial lymphadenopathy need no radiographic testing.

A lymph node biopsy is appropriate in several clinical situations. The patient with persistent, unexplained, localized, or generalized lymphadenopathy should undergo biopsy, especially if the node is firm, rubbery, or fixed. If lymphadenopathy is accompanied by fevers, night sweats, or weight loss and no source of infection is identified, a lymph node biopsy is indicated. Any patient suspected of having a malignant lymphoma should undergo immediate lymph node biopsy. In patients with a known malignancy, a lymph node biopsy may alter the therapeutic approach. For example, the patient with a gastric mass and a supraclavicular lymph node that is diagnostic of adenocarcinoma on biopsy might not need to undergo radical surgery. Lymph node biopsy can also be useful in the diagnosis of recurrent malignancy.

For patients with generalized lymphadenopathy, the largest node that is accessible should be biopsied to ensure that adequate tissue is available for pathologic diagnosis. Lymph nodes larger than 2 cm in diameter are preferred for biopsy. Abnormalities of inguinal lymph nodes are likely to represent reactive hyperplasia. Concern should be given to cosmetic issues; for example, the incisional scar from a resected axillary lymph node is less apparent than that from a node excised from the neck. Lymph node biopsy is diagnostic in about one half of the cases for which it is performed. Of the patients with a nondiagnostic biopsy, approximately 25% develop a disease, often a lymphoma, within 1 year. Patients with nondiagnostic biopsies need to be followed up closely and rebiopsy performed if nodes persist or worsen over time or if constitutional symptoms develop.

After the decision is made to perform a lymph node biopsy, the physician, surgeon, and pathologist need to communicate to be certain that the specimen is properly handled and appropriate testing performed ([Table 201.2](#)). An initial frozen section or "touch prep" histologic examination of the node may direct further studies. Patients who thought to have an infection such as tuberculosis should have the specimen properly cultured. The biopsied node should be delivered fresh to the pathology department, with instructions concerning the differential diagnosis of the suspected disorder.

1. Perform initial frozen section or touch prep histologic examination.
2. If infection is suspected, perform standard fixed histologic examination, as well as special stains and cultures for bacteria, fungus, or mycobacteria.
3. If malignancy is suspected, perform standard histologic examination, as well as immunohistochemical stains if needed.
4. If lymphoma is suspected, perform immunophenotyping (flow cytometry or immunohistochemistry) and, if needed to subclassify, cytogenetic analysis and immunoglobulin and T-cell receptor gene rearrangement studies.

TABLE 201.2. DIAGNOSTIC EVALUATION OF THE BIOPSIED LYMPH NODES

If a lymphoma is suspected, the diagnostic workup includes standard formalin fixation with histologic examination of the node and immunophenotyping by flow cytometry or immunohistochemistry. Freezing part of the specimen for potential molecular diagnostic studies such as analysis of immunoglobulin or T-cell receptor gene rearrangement is prudent. Fresh tissue can be analyzed for cytogenetic abnormalities, such as the translocation of chromosomes 14 and 18 seen in follicular lymphomas. If breast cancer is suspected, the node can be analyzed for estrogen and progesterone hormone receptor expression. In cases of malignancy of undetermined site, the fixed node can be processed for immunohistochemical analysis to help determine the site of origin. For example, a supraclavicular node that is histologically malignant and demonstrates cytokeratin and mucicarmine positivity on immunohistochemical stains suggests an adenocarcinoma, raising the possibilities of carcinoma of the lung, breast, or gastrointestinal tract.

Lymph node aspiration may occasionally be performed in lieu of a biopsy. Fine-needle aspiration (FNA) is particularly useful in diagnosing metastatic carcinoma or infectious lymphadenitis. FNA may be useful in diagnosing lymphoma in patients without easily accessible lymphadenopathy and in those who cannot tolerate an open biopsy. The major drawback of aspiration is obvious: no tissue is obtained for histopathologic review, which is critical in the classification of the lymphomas. Inconclusive results from FNA frequently necessitate open biopsy.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of lymphadenopathy is summarized in [Table 201.3](#). The diseases responsible for the enlargement of lymph nodes can be classified as infection, malignancy, inflammation, nonmalignant infiltration, endocrine abnormalities, and miscellaneous disorders including the histiocytoses.

TABLE 201.3. DIFFERENTIAL DIAGNOSIS OF LYMPHADENOPATHY

Infectious causes of lymphadenopathy are best approached by considering the types of infectious agents. Viral infections are important causes of lymphadenopathy. Epstein–Barr virus and cytomegalovirus can result in lymphadenopathy, as in the infectious mononucleosis syndromes ([Chapter 313](#) and [Chapter 314](#)). HIV is an important cause of lymphadenopathy ([Chapter 341](#)). Persistent generalized lymphadenopathy is a clinicopathologic entity in which the HIV-infected patient develops generalized lymphadenopathy, especially in the cervical, axillary, occipital, and inguinal regions. The development of persistent generalized lymphadenopathy may be a harbinger to progression to AIDS. Patients with HIV infection also have a markedly increased risk of malignant lymphoma, usually a high-grade non-Hodgkin's type. Rapidly progressive lymphadenopathy in the HIV-infected patient should alert the physician to the diagnosis of malignancy.

Acute bacterial infections such as that caused by *Staphylococcus* species may cause a suppurative lymphadenitis. Chronic bacterial infections may also result in enlargement of lymph nodes. Cat-scratch disease is caused by infection with a very small gram-negative bacillus. This disease occurs most commonly in children and young adults and manifests as enlargement of the superficial nodes that drain the site of entry of the organism. Although the patient's history may or may not give a clue of a recent cat bite, most affected patients live in homes with cats.

Lymphogranuloma venereum, caused by a chlamydial organism, results in enlarged matted inguinal lymph nodes that may become fixed to the skin and form sinuses. Syphilis is the most important spirochetal infection that results in lymphadenopathy. It is seen principally in the primary and secondary stages, often in the

inguinofemoral regions.

Mycobacterial infections such as tuberculosis can result in lymphadenopathy, especially in primary tuberculosis in which the nodes draining the portal of entry are enlarged. Endemic fungal infections may also result in lymphadenopathy. For example, histoplasmosis of the lung may be accompanied by hilar lymphadenopathy.

Parasitic infections may cause lymphadenopathy. *Toxoplasmosis gondii* infection, acquired by contamination with cat feces, may present with an enlarged node or group of nodes in the cervical, posterior auricular, suboccipital, or parotid regions that may persist for months. Biopsy demonstrates a distinctive histologic picture of follicular hyperplasia, clusters of epithelial histiocytes, and accumulation of monocytoid B cells in the nodal sinuses. Serologic confirmation should be obtained.

The malignant lymphomas comprise Hodgkin's disease and the non-Hodgkin's lymphomas ([Chapter 232](#) and [Chapter 233](#)). Hodgkin's disease most commonly begins as a painless enlargement of superficial lymph nodes, most frequently the cervical and supraclavicular nodes. The patient may also have involved mediastinal and hilar nodes found on the chest x-ray film. The patient may have classic "B" symptoms such as fever, night sweats, or weight loss. Non-Hodgkin's lymphoma may also manifest as painless lymphadenopathy. The clinical presentation of patients with non-Hodgkin's lymphoma depends on the histologic subtype.

Primary malignancies of the bone marrow may manifest with lymphadenopathy. For example, patients with acute lymphocytic leukemia may have extensive generalized lymphadenopathy or a large mediastinal mass. Patients with chronic lymphocytic leukemia often have generalized lymphadenopathy and splenomegaly. Waldenström's macroglobulinemia is a disease of the older patient characterized by lymphadenopathy, splenomegaly, and a monoclonal IgM protein spike.

Abnormally enlarged lymph nodes may result from malignant infiltration by metastatic cancer. These nodes are usually hard and may be fixed. A variety of adult tumors can metastasize to superficial lymph nodes. Malignant melanoma and carcinomas of the breast, lung, and stomach are most likely to produce lymphadenopathy that is clinically evident. Occasionally, a lymph node biopsy demonstrates a poorly differentiated malignancy ([Chapter 226](#)). The clinician relies on the pathologist for performing immunohistochemical, flow cytometric, and molecular diagnostic studies to determine the diagnosis. It is crucial to differentiate lymphoma from metastatic carcinoma, because the prognosis and treatment are different.

Lymphoid hyperplasia may occur in a variety of inflammatory disorders. Autoimmune diseases such as systemic lupus erythematosus, rheumatoid arthritis, and Sjögren's syndrome may manifest with generalized lymphadenopathy. Angioimmunoblastic lymphadenopathy affects mainly elderly persons and is characterized by generalized lymphadenopathy often associated with fever, hepatosplenomegaly, Coombs'-positive hemolytic anemia, and polyclonal hypergammaglobulinemia. Some patients have a history of an autoimmune illness, but, in most, the disease arises de novo. This benign disease may transform into malignant lymphoma.

Patients with organ transplants maintained on immunosuppressant therapy may develop post-transplantation lymphoproliferative syndrome ([Chapter 23](#)). This disorder may present with generalized lymphadenopathy and constitutional symptoms. It is often caused by Epstein-Barr virus infection and can resolve with the discontinuation of immunosuppressants; however, some cases are rapidly progressive and may require chemotherapy.

Lymphoid hyperplasia and lymphadenopathy may be a result of drug reaction, such as to phenytoin, hydralazine, and allopurinol.

Nonmalignant infiltration of the lymph node may result in lymphadenopathy. Amyloidosis ([Chapter 235](#)) may have lymphadenopathy as a prominent symptom. The fibrillar protein material may be deposited in lymph nodes and other organs. This disorder may be associated with malignancy or inflammatory disorders or may be primary. Occasionally, enlarged nontender lymph nodes are the first manifestation of the disease. In lipid storage diseases such as Gaucher's and Niemann-Pick disease ([Chapter 12](#)), lipid-laden histiocytes accumulate in the lymph nodes, resulting in enlargement. This most commonly occurs in the abdomen, and patients may have associated involvement of the liver and spleen.

Nonmalignant thyroid disorders may involve lymphadenopathy. Patients with Graves' disease or Hashimoto's thyroiditis occasionally have associated lymphadenopathy. Pathologically, these nodes demonstrate reactive hyperplasia.

Although most patients who present with lymphadenopathy have an infectious, neoplastic, or inflammatory disorder, there are miscellaneous disorders of unclear cause that result in prominent lymphadenopathy. Patients with sarcoidosis ([Chapter 373](#)) may present with bilateral hilar lymphadenopathy; patients may also have generalized peripheral lymphadenopathy. Castleman's disease, or giant follicular lymph node hyperplasia, is an idiopathic disorder that may manifest as localized or generalized lymphadenopathy. Frequently, mediastinal or hilar nodes are involved. Patients with the multicentric subtype of the disease may present with a rapidly progressive course that may lead to death.

Kawasaki's disease, or mucocutaneous lymph node syndrome, is seen in children and young adults. This disease is characterized by fever, conjunctivitis, a desquamative truncal exanthem, and cervical lymphadenopathy. Patients may develop a fatal coronary arteritis.

Lymphomatoid granulomatosis ([Chapter 374](#)) is characterized by the infiltration of the vessels of various organs by atypical lymphocytes and macrophages. Lungs, skin, and the central nervous system are most frequently affected. Forty percent of cases have mediastinal lymphadenopathy, but only 10% of cases have peripheral node enlargement. A significant proportion of these patients develop a malignant lymphoma, often of the T-cell phenotype.

The histiocytic disorders include an interesting array of diseases that may present with prominent lymphadenopathy. These diseases include benign and malignant proliferation of the two main classes of histiocytes: antigen-presenting cells such as Langerhans' cells and antigen-processing histiocytic cells, including monocytes and macrophages. The Langerhans' cell histiocytoses (formerly known as histiocytosis X) includes three syndromes of reactive histiocytic proliferation: eosinophilic granuloma, a benign disease that may present in children or adults, often with only a localized bone lesion; multifocal eosinophilic granuloma including the Hand-Schüller-Christian disease, manifesting in young children with a triad of exophthalmus, diabetes insipidus, and lytic bone lesions; and disseminated Langerhans' cell histiocytosis or Letterer-Siwe disease, a disease of infants, with fever, lymphadenopathy, hepatosplenomegaly, rash, and cytopenias.

Dermatopathic lymphadenitis occurs in patients with chronic skin disorders such as exfoliative dermatitis. These patients develop enlargement of superficial lymph nodes that pathologically demonstrate paracortical expansion of the antigen-presenting interdigitating reticulum cells. The lymphadenopathy may regress with appropriate treatment of the skin condition. Dermatopathic lymphadenopathy may also be associated with mycosis fungoides and cutaneous T-cell lymphoma. Malignant transformation of lymph node reticulum cells may rarely occur. These uncommon malignancies usually manifest as localized lymphadenopathy and frequently recur after chemotherapy.

Persons with benign proliferative disorders of antigen-processing cells such as macrophages also present with lymphadenopathy. Sinus histiocytosis with massive lymphadenopathy or Rosai-Dorfman disease occurs predominantly in young adults, who present with fever, leukocytosis, and bulky matted lymphadenopathy, often in the cervical region. The reactive hemophagocytic syndromes occur in the setting of infectious and neoplastic conditions, and patients may present with enlargement of lymph nodes in addition to pancytopenia and hepatosplenomegaly. In familial erythrophagocytic lymphohistiocytosis, a rare autosomal recessive disorder, patients presenting with lymphadenopathy, hepatosplenomegaly, pancytopenia, and frequently with fatigue and fever demonstrate a unique pathologic finding: phagocytized red blood cells in the bone marrow or lymph nodes.

Histiocytic medullary reticulosis is characterized by lymphadenopathy, hepatosplenomegaly, and constitutional symptoms, and a biopsy demonstrates proliferation of histiocytes and immature monocytoid cells. Kikuchi's disease, or histiocytic necrotizing lymphadenitis, is a benign, self-limited disease that occurs throughout the world. This disorder usually affects those younger than 40 years of age, and patients present with fever and symptoms of a flulike illness. The lymphadenopathy of this disorder may be generalized or, more commonly, localized to the cervical region. Pathologically, proliferation of histiocytes and immunoblasts is demonstrated, with marked necrosis and karyorrheatic debris.

Malignant disorders of mononuclear phagocytes include acute monocytic leukemia and true histiocytic lymphoma. The latter is an uncommon subtype of non-Hodgkin's lymphoma, in which patients present with lymphadenopathy as well as bone, skin, and gastrointestinal tract involvement.

Vascular transformation of the sinuses (nodal angiomatosis or stasis lymphadenopathy) may occur in any age group and can manifest as localized or generalized lymphadenopathy, although usually this is an incidental finding in lymph nodes surgically obtained for other reasons. Pathologically, the lymph node sinuses demonstrate expansion and sclerosis with vascular proliferation.

Young adults with inflammatory pseudotumor of lymph nodes may present with constitutional symptoms and lymphadenopathy of the superficial and deep groups.

Pathologically, the connective tissue elements of the node such as the hilum, trabeculae, and capsule demonstrate proliferation of spindled histiocytes and fibroblasts, as well as vascular proliferation. This disease demonstrates spontaneous remission in most cases.

STRATEGIES FOR OPTIMAL CARE

MANAGEMENT

The management of the patient with unexplained lymphadenopathy is based on an understanding of the pathophysiology of lymph node enlargement and clinical expertise in obtaining a history, performing a physical examination, and obtaining a differential diagnosis–directed ancillary battery of tests. If an infectious cause is strongly suspected, a period of observation or a trial of antimicrobial therapy can be instituted. HIV testing should be considered for patients with persistent generalized lymphadenopathy. However, if the nodes manifest characteristics suggesting malignancy or if unexplained lymphadenopathy persists, patients should undergo biopsy (Fig. 201.3).

FIGURE 201.3. Algorithm for the evaluation of lymphadenopathy. Empiric antibiotics or corticosteroids should not be given. If biopsy performed, coordinate with the surgeon and pathologist to ensure proper processing of specimen.

EVIDENCE LEVEL: C. Expert Opinion.

COMPLICATIONS AND PITFALLS

Several important errors may be made in evaluating a patient with lymphadenopathy. The unjustified use of antibiotics should be avoided. If the physician strongly suspects an infectious cause of the enlarged lymph nodes or if the diagnosis is established, prompt institution of specific antibiotics is indicated. However, the use of antibiotics in an attempt to treat unexplained lymphadenopathy delays diagnosis and is costly. It also places the patient at risk of having a drug reaction. Patients suspected of infectious mononucleosis should not be given antibiotics such as ampicillin because of a high incidence of rash, and lymph node biopsy should be avoided in these patients because the pathology of the lymph node may mimic that of malignant lymphoma.

The empiric use of corticosteroids should also be avoided. Unexplained lymphadenopathy demands an explanation, and empiric corticosteroid therapy can distort lymph node histopathology by its lympholytic effect. Corticosteroids can occasionally worsen infection.

The biopsy of a lymph node is important in the diagnosis of unexplained lymphadenopathy. However, lymph node biopsy may have potential problems that should be avoided. The physician, surgeon, and pathologist must communicate clearly concerning suspected causes of lymphadenopathy. Inappropriate handling of the specimen, such as submitting the entire node in fixative, which may preclude potentially important immunophenotyping and molecular analysis, or forgetting to send the tissue for appropriate cultures may result in nondiagnostic biopsies.

If a “watch and wait” approach is indicated, patients should be monitored closely (e.g., every 2 to 4 weeks), because unexplained, persistent lymphadenopathy or increasing enlargement of nodes requires biopsy. Patients with nondiagnostic biopsies need careful observation, because some will develop clinically significant disease over time. HIV testing should be considered for patients with nondiagnostic biopsies that have persistent generalized lymphadenopathy.

Indications for HOSPITALIZATION

Most patients with lymphadenopathy undergo evaluation and treatment as outpatients. However, patients with rapidly enlarging lymphadenopathy accompanied by significant symptoms, such as bulky mediastinal adenopathy and shortness of breath, and patients with debilitating constitutional symptoms require hospital admission for close observation, support, and diagnostic evaluation. Occasionally, patients require admission for the diagnostic biopsy of enlarged deep nodes, such as those in the retroperitoneum or thorax.

Indications for REFERRAL

Most cases of lymphadenopathy are managed by the primary care physician. Referral to a general or plastic surgeon for lymph node biopsy is often made by the internist. Sometimes, referral to an oncologist or hematologist is indicated, especially if the diagnosis of malignancy is strongly suspected.

COST-EFFECTIVENESS

To be cost-effective, a diagnostic approach should be based on data obtained from the history and physical examination. Often, these clinical clues direct an efficient workup that may include laboratory or radiographic imaging. However, indiscriminate testing should be avoided. Not every patient with lymphadenopathy needs expensive studies such as CT scanning. The decision to perform a lymph node biopsy can provide a prompt histologic diagnosis, precluding costly and often nondiagnostic testing.

ANATOMY AND FUNCTION

The spleen is the largest lymphoid organ in the body; in a healthy adult, it weighs between 75 and 100 g. The organ is located in the left upper quadrant, protected anteriorly, laterally, and posteriorly by the lower portion of the rib cage.

The spleen consists of a fibrous capsule and radiating fibrous trabeculae that enclose the white and red pulp ([Fig. 202.1](#)). The splenic vasculature and the intricate meshwork of splenic reticulum provide a unique environment for the primary function of the spleen—filtration—which results in removal of aging and defective erythrocytes, antigens, and microorganisms from the blood. Accessory spleens, which result from the failure of the spleen to develop into a single tissue mass, have been reported in 14% to 30% of patients.

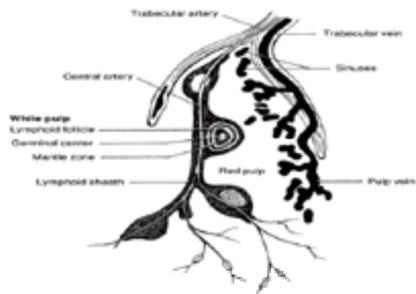

FIGURE 202.1. The structure of the spleen.

Arterial blood enters the spleen through the splenic artery, a branch of the celiac artery. Most blood from the splenic central and trabecular arterioles flows into the sinuses and cords, which are lined with macrophages. Blood from the red pulp sinuses and cords empties directly into the splenic venous system. The major venous drainage of the spleen is the splenic vein, which joins the superior mesenteric vein to form the portal vein.

The spleen is conventionally divided into three zones: the white pulp, the red pulp, and the marginal zone, which is located between the red and white pulp. The white pulp is further subdivided into a T-cell domain (predominantly CD4⁺ helper T lymphocytes), which surrounds the central arteriole and forms the periarteriolar lymphoid sheath, and a B-cell domain, which comprises the follicles and perifollicular mantle zone. Similar to the lymph node, the follicles are inactive or activated, the latter being associated with germinal center formation. The white pulp is responsible for the immunologic functions of the spleen. It contains a concentration of immunologically active cells, captures circulating antigens, provides an arena for their interaction, and is a major site for the production of opsonizing IgM antibody. The marginal zone, another predominantly B-cell layer in the periphery of the white pulp, contains the sinuses that filter material from the white pulp and blends into the red pulp area.

The red pulp occupies the largest portion of the spleen, and it is within the red pulp that the primary function of the spleen, filtration of defective or foreign cells, is carried out. The principal sites of red blood cell entrapment in the spleen are fenestrations in the wall of splenic sinuses, where blood from the splenic cords of the red pulp enters the venous circulation. Blood cells must squeeze through small slits in the cord lining before returning to the venules. Aging changes the biophysical properties of the red cell, making splenic entrapment of the red blood cells that have circulated for 105 to 120 days more likely. Damaged, defective, and aging erythrocytes are less deformable and are therefore retained in the cords, where they are phagocytized by splenic macrophages. During the course of a day, approximately 20 mL of aging red blood cells are removed.

Pitting, the ability of the spleen to remove particulate inclusions from red cells without destroying the cell itself, is also performed by these phagocytes. This pitting function removes Howell–Jolly bodies (nuclear remnants), Heinz bodies (denatured hemoglobin), and erythrocytic parasites such as *Plasmodium*. *Culling* refers to phagocytosis by splenic macrophages of abnormal whole red blood cells that have been damaged physically or immunologically.

The spleen also serves as a reservoir for platelets. One-third of the total platelet pool is normally sequestered in the spleen, but the role of the spleen in the final removal of normal platelets has not been precisely defined. Additional functions of the spleen include removal of bacteria from the circulation, especially pneumococci, and production of blood components if the bone marrow is unable to meet demands (i.e., extramedullary hematopoiesis). The spleen plays an important role in the generation of an immunologic response to certain pathogens.

PATHOPHYSIOLOGY

Although many conditions are associated with splenic enlargement or splenomegaly, limited types of pathologic mechanisms cause splenomegaly. Splenomegaly can result from infiltration of the spleen by reactive lymphoid cells or proliferating macrophages due to inflammation or infection or from infiltration by neoplastic cells in hematologic malignancies. Infiltration of the spleen with abnormal material, as in amyloidosis or Gaucher's disease, can produce splenomegaly. Hypertrophy or hyperplasia of the spleen usually is caused by reticuloendothelial hyperplasia resulting from underlying hematologic disorders such as hereditary spherocytosis and thalassemia or from extramedullary hematopoiesis in primary bone marrow disorders. Vascular congestion as a result of decreased venous drainage due to portal hypertension is associated with an increase in the size of the spleen and is called *congestive splenomegaly*. Splenomegaly can result from space-occupying lesions such as cysts, abscesses, or hemangiomas.

The pathologic action of the spleen—the reduction of circulating blood elements—has been attributed to three possible mechanisms: excessive splenic cellular elements (e.g., phagocytes), splenic production of an antibody that results in the destruction of hematopoietic cells, and overactivity of splenic function, leading to accelerated removal of any or all of the circulating blood elements. This action, referred to as *hypersplenism*, results in anemia, leukopenia, or thrombocytopenia, alone or in combination. The cytopenias associated with hypersplenism are the result of splenic pooling in the enlarged spleen with resultant sequestration of platelets, red blood cells, and granulocytes.

HISTORY AND PHYSICAL EXAMINATION

Disorders of the spleen usually are part of a generalized pathologic disorder, and the initial presentation depends on the underlying disease. The most common symptom directly related to the spleen is pain in the left upper quadrant. Pain may result from stretching of the splenic capsule or from splenic infarction, which is most commonly seen in patients with sickle cell anemia. A persistent dull ache or fullness in the left upper quadrant is often reported by patients with a massively enlarged spleen. Patients with disorders of the spleen may also present with signs and symptoms of shock due to splenic rupture and resultant intraperitoneal bleeding. Rupture of the spleen is most frequently associated with penetrating trauma, nonpenetrating trauma, or operative trauma, and rupture occasionally complicates

severity of cytopenias does not correlate with the degree of splenic enlargement. Because the splenomegaly and hypersplenism are secondary pathologic processes, treatment usually is directed toward the underlying condition. However, splenectomy often corrects persistent and significant cytopenias.

Not all left upper quadrant masses are related to splenomegaly. Other causes of a left upper quadrant mass include gastric or colon tumors and pancreatic or renal cyst or tumors.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

Splenomegaly is common, but a palpable spleen in an adult is almost always clinically significant and requires evaluation. In general, diagnostic tests to evaluate splenomegaly are not performed on the spleen itself; they are oriented toward diagnosis of disease states that result in splenomegaly. However, a determination of splenic size can begin with a plain abdominal radiograph that may demonstrate an enlarged splenic shadow. Computed tomography (CT), ultrasonography, and magnetic resonance imaging (MRI) of the left upper quadrant can depict the spleen, define abnormalities in size and shape, and delineate parenchymal pathology. Radioisotopic scanning with a technetium Tc 99m sulfur colloid scan is another technique, although less sensitive than CT or MRI, to determine the size and shape of the spleen and to look for defects suggesting tumors, cysts, or extrasplenic masses displacing the spleen. This test can also be used as an indicator of splenic function.

The major laboratory abnormalities associated with splenomegaly are determined by the underlying disease. The most valuable laboratory tests in the differential diagnosis of splenomegaly are the complete blood cell count and a differential count, examination of the peripheral blood smear, and liver function tests. Bone marrow aspiration and biopsy are often useful in the diagnosis of leukemia, lymphoma, lipid storage disorders, and disseminated fungal and mycobacteria infections. For patients presenting with anemia, Coombs' test and hemoglobin electrophoresis are sometimes useful. Hemolytic anemia is detectable by routine laboratory tests for anemia and for hemolysis, including a reticulocyte count and determinations of serum bilirubin and serum haptoglobin levels. Erythrocyte counts may be elevated in patients with polycythemia vera, but in most presentations, the erythrocyte count is normal or decreased. Leukocyte counts may be elevated (e.g., in chronic leukemias), normal, or decreased (e.g., in Felty's syndrome, hairy cell leukemia). Platelet counts also may vary; they are often increased in patients with polycythemia vera or normal or decreased in patients with idiopathic thrombocytopenic purpura (ITP). In cases of primary marrow failure, the spleen may be enlarged and undergo myeloid metaplasia in an effort to generate more cells to compensate for the abnormal marrow.

For patients with fever, blood and bone marrow cultures are valuable, as are the tests for viral disease with specific viral titers. Laboratory abnormalities consistent with liver dysfunction or radiologic evidence of esophageal varices suggest portal hypertension. Serologic tests for collagen vascular diseases may be useful. Because many conditions associated with splenomegaly also cause lymphadenopathy, biopsy of a palpable lymph node often discloses the cause of the splenomegaly. When systemic symptoms accompany splenomegaly, but no lymphadenopathy is found, a laparotomy with biopsies of the liver and lymph nodes is sometimes indicated, as is splenectomy itself.

STRATEGIES FOR OPTIMAL CARE

The most common emergency indication for splenectomy is traumatic or iatrogenic splenic rupture. The medical indications for splenectomy include two broad categories: diagnostic splenectomy and splenectomy to alleviate the consequences of splenomegaly, principally cytopenias. Splenectomy is a part of the staging laparotomy in patients with Hodgkin's disease; however, with improvements in radiologic imaging, this is no longer routinely performed. Occasionally, splenectomy is indicated to establish the diagnosis of isolated splenomegaly. More recently, laparoscopic splenectomies have been performed, which appear to have advantages over the open operation.

Splenectomy is useful for symptom control in patients with CML and hairy cell leukemia. Although the overall survival rates for patients with CML treated with splenectomy are not different from those treated without splenectomy, removal of the spleen usually makes patients more comfortable and makes management somewhat easier by reducing transfusion requirements. Splenectomy is an effective treatment for patients with CLL in selective clinical situations, including patients with extensive splenomegaly that is refractory to chemotherapy and patients with autoimmune cytopenias as a complication of CLL.

HIV infection is associated with thrombocytopenia that is similar to classic ITP. However, unlike results for patients with classic ITP, splenectomy has been highly effective in producing a sustained increase in platelet counts in approximately 90% of HIV-infected patients. Although the data are limited, most reported series show no significant increase in the incidence of infection after splenectomy in patients with AIDS nor acceleration in the clinical progression of AIDS.

Splenectomy is indicated for the management of autoimmune hemolytic anemia in patients who fail to respond to corticosteroids. Approximately 50% to 60% of patients with autoimmune hemolytic anemia have an excellent response to splenectomy. Cytopenias associated with hypersplenism are frequently corrected by splenectomy. Splenomegaly associated with increased destruction of red blood cells, as in hereditary spherocytosis, responds dramatically to splenectomy.

The main contraindication to splenectomy is marrow failure, because the enlarged spleen is the only source of hematopoietic cells for these patients. It is critically important in the setting of an enlarged spleen and cytopenias to differentiate extramedullary hematopoiesis from increased cell destruction. Hypersplenism is suggested by a cellular marrow and signs of increased peripheral destruction (e.g., reticulocytes, band forms, and large platelets). Extramedullary hematopoiesis is suggested by the presence of bizarre erythrocyte sizes and shapes.

The main complication associated with splenectomy is the risk of infection, particularly by encapsulated bacterial organisms. The precise reason for enhanced susceptibility to infection in asplenic patients or in patients with splenic dysfunction is not entirely clear, but a variety of immunologic defects have been reported. These include diminished responses to intravenous immunization with particular antigens; defects in the production of antibodies to T-cell-independent antigens, such as the polysaccharide components of the bacterial capsules; a deficiency in tuftsin, a phagocytosis-promoting peptide; decreased serum levels of IgG and IgM; and an inability to remove opsonized bacteria from the bloodstream. As a consequence, patients who have had splenectomy have an increased risk of septicemia with encapsulated bacteria, including *Streptococcus pneumoniae*, *Neisseria meningitidis*, and *Haemophilus influenzae*. Septicemia in these patients is characteristically fulminant.

The risk of serious infection depends somewhat on the cause of the abnormal splenic function, the age of the patient, and the presence of other immunologic abnormalities. Patients who have undergone splenectomy after trauma have a lower risk of infection. Because septicemia is more common in children and adolescents, it is reasonable to delay splenectomy for hematologic disorders in very young children. Infection occurs most frequently within the first 3 years after splenectomy. Patients with sickle cell anemia are functionally asplenic as a result of repeated infarctions and are particularly susceptible to *Salmonella* infections. Patients who have had splenectomy are also more susceptible to the parasitic disease, babesiosis, which is caused by *Babesia microti*; such patients should avoid areas where this parasite is endemic (e.g., Cape Cod, Massachusetts). Splenectomy does not appear to enhance the risk of nonbacterial infections.

All patients undergoing splenectomy should receive as prophylaxis a pneumococcus vaccine and a vaccine against *H. influenzae*, if available. Vaccination is best performed about 10 days before elective splenectomy and preoperatively in traumatized patients in whom splenectomy is anticipated.

After splenectomy, characteristic changes in blood composition occur. Howell-Jolly bodies are found in almost all patients, and siderocytes, nucleated red blood cells, and Heinz body inclusions are common as a result of the loss of the pitting and culling functions of the spleen. Splenectomy results in an increase in platelets, which sometimes reach levels greater than 1 million cells per cubic millimeter. Postsplenectomy thrombocytosis is often transient but may persist. In patients with marked thrombocytopenia before splenectomy, the platelet count often returns to normal within 2 days, but peak levels may not be reached for 2 weeks. The white blood cell count usually is elevated the first day and may remain persistently elevated for several months.

CHAPTER 203: APPROACH TO THE PATIENT WITH A MEDIASTINAL MASS

KEVIN R. FOX

[Presentation](#)
[History and Physical Examination](#)
[Laboratory Studies and Diagnostic Tests](#)
[Differential Diagnosis](#)
[Strategies for Optimal Care](#)
[Cost-Effectiveness](#)

PRESENTATION

The mediastinum is the anatomic space that separates the left and right pleural sacs of the thorax. The development of a mediastinal mass may occur in any of the compartments of the mediastinum. The traditional anatomic compartmentalizations of the mediastinum are varied; the division of the mediastinum into three compartments—*anterior*, *middle*, and *posterior*—simplifies the diagnostic process for the internist or medical oncologist ([Fig. 203.1](#)).

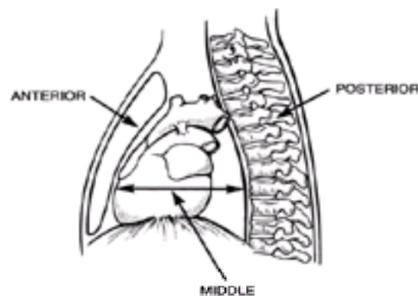

FIGURE 203.1. Anatomic subdivision of the mediastinum.

The *anterior* mediastinum contains the thymus gland, fat, and lymph nodes. The *middle* mediastinum, which encompasses the superior mediastinum at the thoracic inlet, includes the trachea with its bifurcation, aortic arch and great vessels, subcarinal and paratracheal nodes, pericardium, heart, and upper esophagus. The *posterior* mediastinum includes most of the esophagus, the descending aorta, the nerve chains of autonomic origin, and lymph nodes. The presentation of a mediastinal mass varies greatly from one patient to another, given the wide array of potentially affected structures and the wide variety of benign and malignant illnesses that may involve the mediastinum. Mediastinal masses usually are manifestations of diseases that have a predilection for one of the three mediastinal compartments and are thereby differentiated from diseases that involve two or more mediastinal compartments, such as acute and chronic mediastinitis, hemorrhage, or pneumomediastinum.

An understanding of the clinical presentation of mediastinal masses is best derived from a review of the broad differential diagnosis associated with these masses ([Table 203.1](#)). Approximately one-half of mediastinal masses are asymptomatic and are found incidentally at chest radiography performed for different reasons. Of the asymptomatic masses, approximately 10% prove to be malignant. The other 50% of mediastinal masses are heralded by symptoms that are largely of two types. The first type is a direct manifestation of the mass itself; the second type is a systemic manifestation of the malignant disease the mass represents. Fifty percent of masses associated with symptoms ultimately prove to be malignant. One-third of all mediastinal masses, regardless of presentation, are malignant.

Anterior Compartment	Middle Compartment	Posterior Compartment
Thymoma and benign thymic disorders	Gen-ovl tumors	Neurogenic tumors
Gen-ovl tumors	Teratoma	Lymphoma
Thyroidoma	Teratocarcinoma	Non-Hodgkin's lymphoma
Teratocarcinoma	Seminoma	Neuroblastoma
Seminoma	Lymphoma	Blaschoviruses
Thyroid gland and thyroid tumors	Hodgkin's disease	Medullary cysts
Lymphoma	Non-Hodgkin's lymphoma	Bronchogenic
Hodgkin's disease	Medullary cysts	Enteric
Non-Hodgkin's lymphoma	Bronchogenic	Thyroid duct
Epine	Pericardial	Esophageal cancer and diverticula
Soft-tissue tumors	Enteric	Aortic aneurysms and vascular malformations
Benign tumors	Neurofibroma	Soft-tissue tumors
Sarcoma	Granulomatous disease	Benign tumors
Pericardial cysts	Aneurysms and vascular malformations	Sarcoma
Lymph nodes enlarged by benign conditions	Epine	
Parathyroid tumors		

TABLE 203.1. DIFFERENTIAL DIAGNOSIS OF MEDIASTINAL MASSES ACCORDING TO LOCATION

HISTORY AND PHYSICAL EXAMINATION

The patient may report symptoms directly caused by the tumor mass. Chest pain, cough, and dyspnea may be caused by impingement of masses on neural, tracheobronchial, pericardial, or vascular structures, and symptoms may vary in duration of onset. Stridor is particularly ominous and implies tracheal compromise, constituting a potential medical emergency. Hemoptysis may imply bronchogenic carcinoma giving rise to malignant mediastinal adenopathy and may be an important clue in directing the diagnostic evaluation. Hoarseness implies paralysis of the recurrent laryngeal nerve in its course through the mediastinum, and dysphagia suggests intrinsic esophageal abnormality or extrinsic compression of the esophagus and directs attention to the posterior mediastinum. Dyspnea, cough, and head pain or fullness that occur while the person is supine may herald superior vena cava obstruction and imply a pathologic condition in the middle mediastinum.

Systemic symptoms of a malignant mediastinal tumor may predominate in the clinical presentation. Fever, weight loss, and night sweats are the classic B symptoms that may accompany Hodgkin's disease or non-Hodgkin's lymphoma, or they may rarely accompany other malignant lesions such as lung cancer or thymoma. Thyrotoxicosis, symptoms of weight loss, agitation, and irritability may be a manifestation of an enlarged, substernal thyroid gland. Because most malignant tumors of the posterior mediastinum are of neurogenic origin, a few patients have the hypertensive crises of pheochromocytoma or the episodic flushing and diarrhea of carcinoid-like tumors. Myasthenia gravis and its attendant symptoms of weakness, dyspnea, and double vision are present at diagnosis among a small percentage of patients with thymoma. A history of tobacco abuse and passive exposure to cigarette smoke always should be sought.

The physical examination is directed toward signs that may lend evidence to the diagnosis, make feasible diagnosis by relatively noninvasive means, or serve as harbingers of cardiopulmonary compromise that necessitates emergency hospitalization. Examination of the vital signs should seek unexplained tachycardia, pulsus alternans, or an increase in the pulsus paradoxus, all of which in addition to the mediastinal mass may suggest pericardial involvement. Careful examination of the neck may disclose auscultatory signs of stridor or tracheal deviation, which may constitute emergency airway obstruction. Marked enlargement of the thyroid may be the only physical finding that accompanies substernal thyroid that becomes apparent as a superoanterior mediastinal mass. The characteristic facial swelling and dilatation of the superficial veins of the neck, thorax, and scalp that are signs of the superior vena cava syndrome occur among patients with lung cancer or, less often, lymphoma.

Perhaps nowhere can the physical examination benefit the patient more than in establishing sites for diagnosis that do not require invasive thoracic procedures. A thorough lymph node examination of the neck, supraclavicular fossae, and axillae may disclose lymphadenopathy and a site for biopsy. This approach is particularly relevant for patients with Hodgkin's disease, because most patients with mediastinal disease also have cervical or supraclavicular lymphadenopathy. Careful examination of the testes of young men with anterior mediastinal masses may disclose a testicular mass associated with a germ cell tumor of the mediastinum. A thorough neurologic examination always should be performed; weakness and oculomotor dysfunction may suggest myasthenia gravis if the patient has thymoma and may increase the risk of invasive diagnostic surgical procedures.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

ROUTINE EVALUATION

Routine laboratory studies and various tumor markers are not fail-safe substitutes in establishing the diagnosis of mediastinal masses. Because most patients with such masses ultimately undergo invasive diagnostic or therapeutic procedures, routine evaluation of serum electrolytes, a complete blood cell count, liver function tests including lactate dehydrogenase determination, and coagulation studies should be undertaken. Measurements of b-human chorionic gonadotropin (b-hCG) and a-fetoprotein (AFP) can be justified in the care of any patient younger than 40 years with an anterior mediastinal mass. Whether the elevation of one or both of these markers obviates tissue diagnosis is controversial. Because germ cell tumors represent a minority of mediastinal masses, it is usually prudent to proceed with the diagnostic evaluation rather than waiting for the results of these assays.

In rare instances laboratory evaluation circumvents invasive biopsy procedures. This occurs occasionally for patients with lymphoblastic lymphoma, a relatively uncommon high-grade lymphoma of the non-Hodgkin's type with a predilection for the mediastinum. This lymphoma sometimes manifests itself with circulating lymphoblasts detectable on a peripheral blood smear. For this reason, a young patient with a mass in the anterior mediastinum should undergo careful examination of the peripheral blood film by an experienced hematopathologist. If any suspicion of such malignant lymphocytosis is raised, oncologic consultation for bone marrow aspiration and biopsy should be obtained immediately.

Patients with malignant posterior mediastinal masses usually have tumors of neural origin, which may include pheochromocytoma or carcinoid-like tumors. Measurements of urinary catecholamines or 5-hydroxyindoleacetic acid are useful if either of these diagnoses is suspected on the basis of clinical presentation.

RADIOLOGIC EVALUATION

For almost every patient the mass of interest is first found on posteroanterior and lateral chest radiographs. However, the requisite diagnostic study for every patient with a mediastinal mass is contrast-enhanced computed tomographic (CT) scanning of the chest. This study should be performed with intravenous contrast and oral contrast media; oral contrast medium better delineates the esophagus. The CT scan should extend from the thoracic inlet to the most caudal extent of the posterior diaphragmatic recesses.

The value of thoracic CT scanning cannot be understated. The scan localizes the mediastinal mass and directs further diagnostic studies. It can help differentiate vascular abnormalities, benign collections of fat, cysts, and hiatal hernias, and it may allow the evaluation to cease if these anomalies necessitate no therapeutic intervention. The proximity of masses to critical vascular structures, large airways, and the pericardium is easy to evaluate.

Magnetic resonance imaging (MRI) should not be considered a substitute for CT scanning of the mediastinum. MRI is more expensive and more inconvenient for the patient than is CT scanning, and it provides the same information. MRI is justified when no form of iodine-containing contrast material can be safely administered to a patient in preparation for CT scanning. MRI of the thoracic spine should be considered if a patient with a posterior mediastinal mass has back pain in a radicular distribution or has CT evidence of foraminal invasion by the mass. These findings herald epidural space involvement by tumor and may alter surgical strategy. Other diagnostic studies rarely are indicated before the biopsy procedure. A barium swallow examination is indicated if the patient has dysphagia and the CT scan suggests an esophageal mass or malformation.

DIFFERENTIAL DIAGNOSIS

[Table 203.1](#) provides a comprehensive list of diagnostic possibilities based on the anatomic location of the mass of interest. Some confusion in organizing such a list may occur with the inclusion of the "superior" mediastinum in the anterior or middle mediastinal compartments. Such rigid adherence to anatomic lines is relatively impractical, because many diseases occur in more than one of these arbitrarily designated compartments.

The relative frequency of primary mediastinal tumors can be derived from review of the records of large groups of patients and is shown in [Table 203.2](#). At least one-half of mediastinal neoplasms among adults are thymoma, lymphoma, and germ cell tumors, which are likely to be situated in the anterior or middle mediastinum. When anterior mediastinal masses are considered separately, thymoma predominates, followed by lymphoma, germ cell tumors, and masses and tumors of thyroid and parathyroid origin ([Table 203.2](#)).

Tumor	Overall Frequency (%)	Anterior Compartment Frequency (%)
Thymoma and thymic lesions	19	47
Lymphoma	13	23
Germ cell tumors	11	15
Soft-tissue tumors	7	<10
Endocrine tumors and masses	6	16
Neurogenic tumors	21	<1

TABLE 203.2. RELATIVE FREQUENCY OF MEDIASTINAL TUMORS

Hodgkin's disease is more likely to manifest itself with a mediastinal mass than is non-Hodgkin's lymphoma. Approximately 60% of patients with Hodgkin's disease have mediastinal masses as part of their clinical presentations; this is more than twice the frequency of patients with such masses caused by non-Hodgkin's lymphoma. Lymphoblastic lymphoma and diffuse large-cell lymphoma constitute most types of non-Hodgkin's lymphomas associated with such masses.

The neurogenic tumors that predominate in the posterior mediastinum compose a broad array of rare tumor types that may arise from nerve tissue or from the nerve sheath. Neurofibroma, neurilemoma, schwannoma, pheochromocytoma, and paraganglioma may be encountered in the posterior mediastinum. Many of these lesions are benign and nonfunctional, and they are easily managed by means of surgical extirpation.

STRATEGIES FOR OPTIMAL CARE

DIAGNOSTIC MANAGEMENT

The approach to a patient with a mediastinal mass culminates in the invasive procedure that carries the greatest likelihood of establishing the diagnosis with the least morbidity. The CT finding of fat, a benign-appearing cyst, or a vascular anomaly or aneurysm generally necessitates no further intervention, although referral to a cardiothoracic surgeon may be warranted for final diagnostic and therapeutic intervention.

CHAPTER 204: APPROACH TO THE PATIENT WITH SUPERIOR VENA CAVA SYNDROME

JANICE P. DUTCHER

[Presentation](#)
[Pathophysiology](#)
[History and Physical Examination](#)
[Laboratory Studies and Diagnostic Tests](#)
[Differential Diagnosis](#)
[Strategies for Optimal Care](#)

PRESENTATION

Superior vena cava syndrome usually is a subacute process caused by slow obstruction of the superior vena cava within the mediastinum. Physical findings that suggest the diagnosis include facial swelling and engorgement of the veins of the neck or chest wall. The earliest symptoms are dyspnea and tachypnea. There also may be hoarseness, tongue swelling, nasal congestion, or headache. Chest pain and cough may accompany this syndrome ([Table 204.1](#)). In rare instances there may be hemodynamic compromise with hypotension and severe dyspnea. These patients may have syncope when suddenly supine.

Sign or Symptom	Percentage of Patients Affected (n = 370)
Venous distention, neck	66
Dyspnea	63
Venous distention, chest	54
Facial swelling or edema	46-50
Cough	24
Cyanosis	20
Plethora of face	19
Arm swelling or edema	14-18
Chest pain	15
Dysphagia	9

TABLE 204.1. PHYSICAL FINDINGS AND SYMPTOMS OF SUPERIOR VENA CAVA SYNDROME

PATHOPHYSIOLOGY

The development of superior vena cava syndrome usually is insidious as obstruction progresses, leading to engorgement of veins that feed into the superior vena cava and decreasing venous return to the heart. Venous thrombus may develop progressively within the superior vena cava. The most common cause of this obstructive process is an intramediastinal malignant tumor that produces external compression with or without direct extension into the vena cava. Because superior vena cava syndrome may be the initial presentation of a previously undiagnosed malignant tumor, the management of symptoms and the diagnosis of underlying disease are important. Superior vena cava syndrome may be a manifestation of recurrent or metastatic tumor or occasionally indicate a nonmalignant process.

HISTORY AND PHYSICAL EXAMINATION

The patient frequently has no symptoms and first notices the engorged veins on the chest and neck or facial swelling. Some patients report increasing dyspnea and tachypnea or even chest pain ([Table 204.1](#)). Because the most common cause of the syndrome is a malignant tumor (in 78% to 86% of series), lung cancer being the most common cause (65% of cases in one series), a history of cigarette smoking often is obtained, as is a history of prior chronic pulmonary disease. Because recurrent metastatic cancer can cause superior vena cava syndrome, a history of prior malignant disease should be obtained.

Physical examination confirms venous engorgement of the superficial veins of the chest and neck and possibly edema of the face and arms. In severe cases, there may be cyanosis. Examination of the lungs may reveal the distant breath sounds of a patient with chronic obstructive pulmonary disease, the unilaterally absent breath sounds of a patient with a pleural effusion, or normal findings. The cardiac examination reveals normal heart sounds, but sinus arrhythmias are common among this patient population.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

The most important diagnostic study is chest radiography, the result of which often suggest the cause of the problem, showing mediastinal widening or a hilar mass (80%) ([Fig. 204.1](#)). There may be a pleural effusion. The radiograph occasionally appears normal. Other laboratory tests that may be helpful include those for serum electrolytes, arterial blood gases, and serum lactate dehydrogenase. A computed tomographic (CT) scan of the chest obtained with contrast is important in assessing the extent of the mass. The scan also may demonstrate the apparent absence of central blood vessels caused by obstruction. If the differential diagnosis of superior vena cava syndrome is uncertain, a venogram through the upper extremity can help confirm the diagnosis when the clinical findings are subtle.

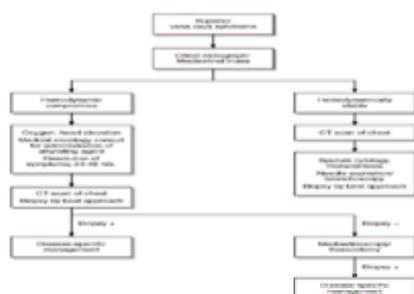

FIGURE 204.1. Algorithm for the evaluation of superior vena cava syndrome, utilizing chest radiography.

DIFFERENTIAL DIAGNOSIS

Despite the potential clinical significance of the signs and symptoms, the diverse causes of superior vena cava syndrome make it imperative to obtain a precise pathologic diagnosis to direct disease-specific treatment. Rarely are the symptoms immediately life threatening. The three most common tumors that cause superior vena cava syndrome are small-cell cancer of the lung, non-small-cell cancer of the lung, and non-Hodgkin's lymphoma. Less commonly, mediastinal germ cell tumors, malignant thymoma, and Hodgkin's disease can produce superior vena cava syndrome, as can metastatic cancers such as breast cancer involving the mediastinal lymph nodes.

Most patients with superior vena cava syndrome have a readily apparent hilar or mediastinal tumor with superior mediastinal widening revealed on a chest radiograph. In the case of primary lung cancer, sputum cytologic analysis often is diagnostic and can help differentiate the histologic subtype, allowing caregivers to specify the treatment approach. For patients who also have a pleural effusion, such as those with lung cancer or lymphoma, thoracentesis with cytologic evaluation of the fluid may provide a histologic diagnosis. If results of neither of these modalities help confirm the diagnosis, bronchoscopy with biopsy or CT-guided fine-needle aspiration or core biopsy should yield a diagnosis in cases of lung cancer or germ cell cancer ([Fig. 204.1](#)). However, needle biopsy usually does not provide enough information for diagnosis of lymphoma and yields an inadequate pathologic specimen.

A surgical procedure may be necessary to obtain sufficient tissue for an accurate pathologic diagnosis of the type of tumor causing compression. Procedures that must be considered include mediastinoscopy and mediastinotomy (paramediastinal incision or Chamberlain procedure). The approach used is based on the level of concern about engorged mediastinal vessels. An indication of severity may be obtained from the CT scan. Open biopsy with direct visualization of the vessels often is safer than mediastinoscopy and may be the procedure of choice. Mediastinoscopy, however, can be safely performed in more subtle clinical situations.

In some cases, biopsy can be performed on other sites of disease to obtain a pathologic diagnosis. For example, in the case of small-cell carcinoma or lymphoma, bone marrow biopsy may demonstrate systemic involvement and provide a diagnosis. For patients with palpable supraclavicular lymph nodes, biopsy often yields a diagnosis.

The other cause of superior vena cava syndrome that can develop among patients with known malignant disease is venous thrombosis due to the presence of a central venous catheter, such as an access device. This can also be associated with cardiac pacemakers. This cause should be considered in the evaluation of a patient with superior vena cava syndrome, an access device, and no apparent mediastinal tumor. Although thrombolytic agents may be helpful early in the thrombotic process, this complication usually necessitates removal of the catheter in conjunction with anticoagulation to prevent embolization. A nonmalignant and rare cause of superior vena cava compression to be considered in the differential diagnosis is idiopathic mediastinal fibrosis or histoplasmosis.

STRATEGIES FOR OPTIMAL CARE

MANAGEMENT

In the care of a patient with superior vena cava syndrome, the goals are to relieve symptoms and to obtain a histologic diagnosis. Initial symptomatic relief can be obtained with bed rest with head elevation and oxygen administration ([Fig. 204.1](#)). This reduces cardiac output and decreases venous pressure. The diagnostic evaluation previously described then proceeds as expeditiously as possible.

If the clinical situation is considered an emergency because of hemodynamic compromise, every attempt should be made to obtain a correct histologic diagnosis, and the most direct approach to obtaining tissue should be considered. If emergency treatment is deemed necessary before biopsy, irradiation should be avoided because it adversely affects the integrity of the tissue at subsequent biopsy. An alternative approach to induce rapid decompression of the vena cava that has a high likelihood of preservation of the histologic features of the tumor at biopsy is administration of a single, large dose of an alkylating agent. This approach should be used only to relieve life-threatening signs and symptoms and only under the guidance of a medical oncologist. It is exceedingly rare that such an emergency situation would arise.

After obtaining an accurate diagnosis of the cause of new-onset superior vena cava syndrome, which presumably is caused by a malignant tumor, management involves complete staging of the disease followed by disease-specific therapy. Non-small-cell lung cancer frequently is localized to the chest and mediastinum. However, small-cell cancer or lymphoma frequently is systemic and necessitates a comprehensive diagnostic evaluation followed by chemotherapy. Radiation therapy to the mediastinal tumor is to the management of most of these diseases. When superior vena cava syndrome is a manifestation of a known previously managed malignant tumor, irradiation usually is the therapy of choice. In the care of patients with recurrent obstruction after radiation, placement of an expandable wire stent or balloon angioplasty has been successful in maintaining patency.

COMPLICATIONS AND PITFALLS

The most common complication is inability to obtain a histologic diagnosis in the apparent urgency to manage superior vena cava syndrome. Careful assessment of hemodynamic status determines the rapidity with which the diagnostic evaluation must be concluded. A careful history interview and physical examination and rapid biopsy of lymph nodes, bone marrow, or mediastinal mass leads to rapid diagnosis and treatment. Complications of mediastinal biopsy have led to hesitancy in pursuing mediastinoscopy in the setting of dilated intrathoracic blood vessels. However, biopsy guided by CT scanning usually can be accomplished safely, as can an open biopsy. Concern about the safety of mediastinoscopy or the efficacy of needle biopsy for a given patient should prompt immediate consideration of open biopsy with direct visualization to enable acquisition of adequate tissue for diagnosis.

An additional potential complication of superior vena cava syndrome is tracheomalacia, which may develop from prolonged tracheal compression by the mediastinal mass. This may lead to complications such as trauma, edema, or rupture of the trachea during intubation for anesthesia. During extubation, there may be tracheal collapse with acute respiratory distress. These potential complications must be considered when patients are undergoing diagnostic surgical procedures.

In the care of patients for whom superior vena cava syndrome is a manifestation of a recurrent malignant tumor, the situation may be more ominous, because primary therapy already may have been exhausted. Such patients are at much greater risk for local complications from invasion of adjacent structures such as the trachea, esophagus, and pericardium. If not previously used, radiation therapy is the therapy of choice for such local complications.

Patients with superior vena cava syndrome usually need to be admitted to the hospital for assessment of hemodynamic status, diagnostic evaluation including biopsy, and initial treatment with radiation therapy or chemotherapy. After the acute problem resolves, completion of the diagnostic evaluation and therapy can be accomplished on an outpatient basis.

Indications for HOSPITALIZATION

Patients with malignant superior vena cava syndrome should be treated by experienced medical oncologists, who can direct the diagnostic evaluation and intervene with chemotherapy if necessary. Thoracic surgeons familiar with the anatomic features of engorged vessels and the physiologic mechanisms of this syndrome are consulted if biopsy of a supraclavicular node or the mediastinum is anticipated.

COST-EFFECTIVENESS

Despite the drama of the initial clinical presentation, newly diagnosed lymphoma, germ cell cancer, and in some cases, small-cell lung cancer are potentially curable, and the appropriate pathologic diagnosis and management can return otherwise healthy persons to their optimal level of activity.

CHAPTER 205: APPROACH TO THE PATIENT WITH A PALPABLE MASS AND/OR AN ABNORMAL MAMMOGRAM

HELEN PASS, MARK HELVIE AND SOFIA D. MERAJVER

[Pathophysiology](#)
[Approach to a Patient with Abnormal Findings at Clinical Breast Examination](#)
[Approach to a Patient with an Abnormal Mammogram](#)

The advent of mammographic screening for early detection of breast cancer among women older than 40 years has been shown in randomized trials to decrease mortality from this disease 15% to 30%. As the number of women undergoing screening increases, larger numbers of clinically occult radiographic abnormalities of the breast are being evaluated. The increase in the practice of routine monthly breast self-examination and yearly clinical breast examination likewise leads to early detection of palpable abnormalities of the breast. The evaluation of an abnormal mammogram and a palpable mass is focused on establishing the distinction between breast cancer and a multitude of nonmalignant conditions. The evaluation centers on the triad of physical examination, radiologic evaluation, and tissue sampling. Because delays in diagnosis of breast cancer are likely to have an adverse effect on the quality and length of life of the patient, the algorithms described herein are specifically designed to execute an efficient and cost-effective evaluation in light of the untoward consequences of a missed cancer diagnosis.

PATHOPHYSIOLOGY

The normal breast tissue of an adult is highly heterogeneous to palpation and radiologic imaging throughout life. Among premenopausal women, changes in the hormonally responsive ducts and lobules during the menstrual cycle are reflected in cyclical differences in the findings at physical examination of the breasts. Individual differences in the proliferative capacity of the epithelial tissue of the breast and the abundance of fibrous connective tissue are reflected in density on mammograms and affect the sensitivity and specificity of this imaging modality. Use of exogenous estrogens (oral contraceptives, hormone replacement therapy, fertility treatments), lean body mass, diet, and heredity all are thought to contribute to the fibroglandular content of breast tissue and to mammographic density. Given the intrinsic heterogeneity of breast tissue appreciated during both physical and radiologic examinations, criteria have been developed to help clinicians discern malignant causes of masses and mammographic abnormalities.

APPROACH TO A PATIENT WITH ABNORMAL FINDINGS AT CLINICAL BREAST EXAMINATION

It is estimated that at some point in her life one of every two women will see a physician for a breast problem. Although breast cancer is the most common malignant tumor among U.S. women, 80% to 90% of clinical evaluations for breast disorders are for benign conditions. Thus the goal of the evaluation after abnormal findings have been obtained at clinical breast examination is to avoid missing the diagnosis of malignant disease while providing reassurance if the diagnosis is a benign condition.

HISTORY AND PHYSICAL EXAMINATION

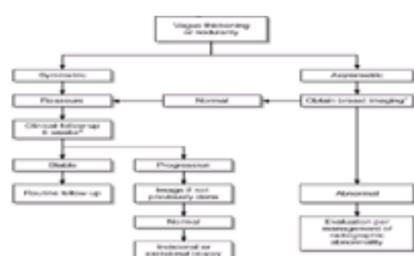

Evaluation begins with a history interview and physical examination to identify the patient's area of concern (if the abnormality was discovered at self-examination) and to assess the clinician's degree of suspicion of malignancy. The initial impression whether the abnormality represents a vague area of thickening or nodularity as opposed to a true dominant mass should be recorded.

Salient points of history about the mass or abnormality are the timing of appearance with respect to the menstrual cycle, rate of change, associated signs such as redness, pruritus, or nipple discharge (which may no longer be present), history of trauma, and present hormone and other drug use. Family history, previous breast biopsy, reproductive history, and hormonal exposures help place the present mass or abnormality in the context of the patient's breast cancer risk profile.

Accurate interpretation of the findings at clinical breast examination can be challenging. In a study of concordance for the need for biopsy, diagnostic accuracy was 73% among four experienced surgeons in examinations of 15 patients with malignant lesions. Therefore, in the evaluation of a palpable breast mass, the diagnostic triad of physical examination, mammography, and fine-needle aspiration biopsy (FNA), known as the *triple test*, should be used. In Europe successful use of the triple test for many years has decreased the need for excisional biopsy. When results with all three diagnostic components are benign, the triple test has a greater than 99% positive predictive value for benign disease. Nevertheless, for many practitioners, the safest and most expeditious method of practice is excisional biopsy of any breast mass. The triple test is useful only for the evaluation of a dominant mass, because FNA is unreliable in the evaluation of thickening or nodularity.

ALGORITHM FOR THE EVALUATION OF BREAST THICKENING OR NODULARITY

The initial step in the evaluation of diffuse thickening or nodularity is to compare the affected site with the mirror image area of the opposite breast ([Fig. 205.1](#)). Symmetrical areas are seldom pathologic, and reassurance with follow-up clinical evaluation is appropriate. Postmenopausal women should undergo a follow-up examination in 6 weeks, and premenopausal women on day 5, 6, or 7 (follicular phase) of the menstrual cycle. If at reexamination, the area is clinically stable, the patient should undergo routine follow-up examinations according to her health maintenance schedule. If the area seems to progress in this period, further evaluation with mammography, ultrasonography of the breast, or both depending on the patient's age, and referral to a breast specialist should be obtained. A radiologic abnormality with only a vaguely palpable abnormality should be managed by means of image-guided biopsy (see later). A distinct, palpable abnormality (dominant palpable mass) should be evaluated further (see later).

1. Age < 30. Consider ultrasonography.
2. Age > 30. Obtain diagnostic mammogram if ultrasonography is equivocal.
3. Consider excisional biopsy if ultrasonography is equivocal.

FIGURE 205.1. Algorithm for the assessment of thickening or nodularity of the breast. The objective is to focus the invasive diagnostic assessment on asymmetric findings and to provide adequate short-term follow-up care to ensure stability of symmetric findings.

EVIDENCE LEVEL: C. Expert Opinion.

Persistent asymmetric thickening or nodularity should be evaluated by means of breast imaging. If findings at radiologic assessment are normal and are concordant with the findings at physical examination, a 6-week clinical follow-up examination is indicated. Any patient with an abnormality that shows progression at the short-term follow-up examination should be referred for biopsy. Patients with stable areas may be treated conservatively with reinforcement of breast self-examination and education about the need to return before the next scheduled health maintenance evaluation if the area changes.

The most common cause of nodularity, especially when the nodule is tender, is fibrocystic changes. Among younger women, the upper outer quadrants and axillary tail are common areas of these changes. Older women often have a bilateral thickened ridge along the inframammary folds. Symmetry and stability over time help

avoid overaggressive evaluation of these frequent findings.

ALGORITHM FOR THE EVALUATION OF A DOMINANT PALPABLE BREAST MASS

The initial step in the evaluation of a dominant palpable mass is to determine degree of suspicion (Fig. 205.2). Breast cancer generally becomes apparent as a hard, nontender, irregular mass; it is impossible, however, to rule out cancer on the basis of clinical evaluation alone. A premenopausal patient may be observed if the clinician has low index of suspicion regarding malignancy of the lesion. The patient should be reexamined on day 5, 6, or 7 of her next menstrual cycle. A dominant mass that persists through one cycle requires further evaluation (see below).

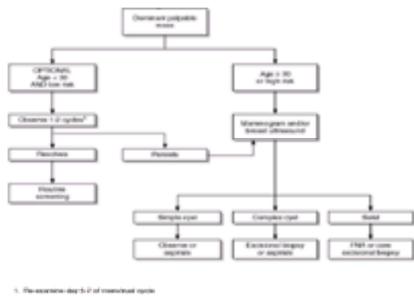

FIGURE 205.2. Algorithm for assessment of a palpable dominant breast mass. The objective of this evaluation is to differentiate benign and malignant causes with the triad of physical examination, imaging, and tissue sampling.
EVIDENCE LEVEL: C. Expert Opinion.

For a dominant mass that persists through one menstrual cycle or a lesion that the primary care provider is concerned is not a simple cyst, additional evaluation and referral to a breast specialist are indicated. Urgent radiologic evaluation (within 1 week) followed by FNA is appropriate. There are advantages to performing imaging studies first. Even when performed by experienced physicians, FNA results in tissue disruption and hematoma formation that may interfere with mammography or ultrasonography. If a malignant lesion is diagnosed through FNA, mammography still is needed to evaluate the remainder of the breast parenchyma and the contralateral breast. Negative mammographic findings in the setting of a clinically dominant mass should not delay biopsy because 10% of breast cancers are mammographically occult. If, however, imaging is delayed one needs to consider proceeding with FNA in the interest of timely assessment.

A clinician's skill and experience with FNA should guide whether aspiration is performed in the primary care setting or referral to a breast care specialist is obtained. FNA is a simple office procedure that requires readily available equipment (a 10 cc syringe, 22 gauge needle, and cytology solution). The most significant risk of FNA performed by an inexperienced practitioner is that the FNA may yield an inadequate sample, thereby delaying diagnosis. Repeat FNA, possibly under image guidance, or excisional biopsy should be obtained by a breast specialist after FNA does not provide enough information for diagnosis. Other potential side effects of FNA include hematoma and, rarely, pneumothorax. In general, unless the clinician is very experienced, it is recommended that FNA be performed by a breast care specialist.

If a cyst is suspected after clinical examination (smooth, mobile, possibly tender mass) or documented at ultrasonography, FNA can be both diagnostic and therapeutic. Observation alone may be chosen only if a lesion meets all of the sonographic criteria for a simple cyst. The lesion must be a round, well-circumscribed, smooth-walled structure that is anechoic (with- out internal echoes) and is enhanced through transmission. If the lesion does not meet all of these criteria, is painful, or interferes with performance of an adequate examination, FNA should be performed. The abnormal area should be well localized in case excisional biopsy is necessary after cyst aspiration. Indications for excisional biopsy after cyst aspiration include the recovery of grossly bloody or turbid cyst fluid, the presence of residual mass after aspiration, or recurrence of a cyst in the same location two or three times after aspiration. A follow-up physical examination always should be performed 2 to 3 months after cyst aspiration. Cytologic analysis of clear, straw-colored fluid is neither necessary nor helpful. If, however, the character of the fluid is atypical, cytologic analysis must be performed.

DIAGNOSTIC PITFALLS

Unlike that of a cyst, FNA of a solid mass produces little or no fluid. Aspiration of a solid lesion requires more skill than simple cyst aspiration to obtain an accurate diagnosis. Nevertheless FNA of a solid mass is less invasive than excisional biopsy and allows rapid diagnosis. If malignant growth is diagnosed, treatment may be reduced to a one-step operative procedure with frozen-section confirmation. Any patient for whom an FNA reveals atypical or insufficient sampling should be referred for biopsy without delay. Concordance must be established among the physical examination, imaging, and FNA results because the false-negative rate of FNA has been reported to range between 0.4% and 35% with a much lower false-positive rate of 0.17%. False-negative FNA results are most often caused by inadequate tissue sampling, aspiration of a tumor less than 1 cm in diameter, or tumors with a large degree of fibrosis. A critical element of FNA that produces enough information to confirm a diagnosis is the availability of a skilled cytopathologist.

In summary, a palpable abnormality must be adequately explained through a multimodality approach. It is impossible to rule out cancer on clinical or radiologic grounds alone, and two-thirds of women with breast cancer have no identifiable risk factors. Therefore radiologic or pathologic assessment or both must be obtained for any dominant palpable abnormality. Even when performed correctly, the triple test is only 99% accurate; thus patients who are unwilling to accept a 1% false-negative rate should undergo open biopsy. Referral to a breast care specialist should be initiated when the diagnostic requirements exceed the skills or experience of the clinician.

APPROACH TO A PATIENT WITH AN ABNORMAL MAMMOGRAM

EVALUATION OF THE MAMMOGRAM

The primary purpose of mammography is detection of clinically occult breast cancer at an early stage. Mammographic evaluations frequently are categorized as *screening* or *diagnostic*. Screening mammography is performed on women who do not have symptoms and generally includes two views (crandio-caudal and mediolateral oblique) of each breast. The goal of screening mammography is detection, not characterization of an abnormality. Diagnostic mammography is performed on patients who have abnormal screening mammograms, palpable clinical findings, or complex surgical or medical histories. Diagnostic mammography often entails additional mammographic views and adjunctive modalities such as ultrasonography. Correlation with physical findings is essential. The goal of diagnostic mammography is to characterize a potential mammographic abnormality. After completion of diagnostic mammography for a patient who has no symptoms, a final assessment is rendered regarding the need for biopsy or follow-up mammography. Evaluation after abnormal mammographic results are obtained is summarized in Fig. 205.3.

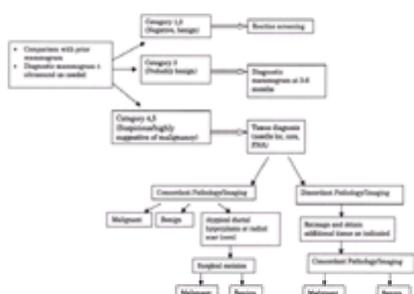

FIGURE 205.3. Algorithm for assessment after abnormal mammographic results are obtained. The objective of this evaluation is to help identify lesions that have moderate or high probability of being malignant and to assist in the procurement of accurate tissue diagnosis. (Adapted from *National Comprehensive Cancer Network breast cancer screening guidelines*, version 1. Rockledge, PA: National Comprehensive Cancer Network, 1999, with permission.)

EVIDENCE LEVEL: B. Adapted from the NCCN Breast Screening Guideline.

Mammographic images are obtained by means of passing low-energy x-rays (25 to 28 kilovolts peak [kVp]) through a compressed breast onto an image receptor, typically film. The resolution of mammography is higher than that of almost all other medical imaging systems. Since the passage of the Mammography Quality Standards Act (MQSA) in 1992, all mammographic facilities and personnel have been federally regulated. The U.S. Food and Drug Administration provides yearly on-site inspection of mammographic equipment, quality processes, and personnel. Interpreting radiologists are required to provide documentation of continuing education, tracking of positive results, and demonstration of minimal yearly interpretative volume (480 studies). MQSA also regulates reporting of mammographic findings.

Interpretation of mammograms depends on perception or detection of an abnormal finding and characterization of an abnormality once detected. Mammographic analysis entails skillful, thorough evaluation of high-quality images by a trained and experienced radiologist. There is a high rate of interobserver variation. Double reading by two independent radiologists may improve sensitivity. Once an abnormality is detected with a screening study, additional diagnostic images usually are needed before final characterization. Five to ten percent of women who undergo screening need additional evaluation of potential abnormalities found at screening. Most women who need additional evaluation have normal results and can return to undergoing routine screening examinations without biopsy.

Magnification views with smaller focal spots define the number and morphologic features of microcalcification particles. *Spot compression views* and *angled views* are used to assess the margins of masses. *Incremental mammographic views* are used to determine whether a potential abnormality seen on only one view truly represents a three-dimensional mass or is merely a summation shadow found on one view. Comparison with older mammograms is important for interpretation of the mammographic stability of findings.

Although it is relatively sensitive in the detection of breast cancer, like physical examination of the breast, mammography lacks specificity. The overall positive predictive value when biopsy is recommended generally is reported to be 15% to 30%. There is considerable variation in this number depending on factors such as the interpreting physician and the population screened. The false-negative rate for mammography in the presence of a palpable finding is approximately 10%. Desirable outcome goals of screening mammography defined by the U.S. Department of Health and Human Services include a positive predictive value of 25% to 40%, more than 50% of found cancers being stage 0 or I, more than 30% of found cancers being minimal cancer, and less than 25% of women having positive axillary lymph nodes.

To standardize mammographic reporting and improve communication, the American College of Radiology developed the Breast Imaging Reporting and Data System (BIRADS). The BIRADS final assessment categories were adopted by the MQSA beginning in 1999. All final mammographic interpretations must be assigned to one of six categories ([Table 205.1](#)). Category 1 and 2 assessments are normal or benign findings for which routine care is recommended. Category 4 and 5 assessments indicate a probability of malignancy high enough that biopsy is warranted. Category 3 assessments ("probably benign") indicate findings that have a very low probability of malignancy. Experienced centers have reported the probability of malignancy of category 3 lesions to be 1% to 2%. Women receiving category 3 mammographic assessment are counseled to undergo short-term follow-up mammography, usually in 3 to 6 months. It is assumed that a corresponding physical abnormality does not exist. Informed patients or their physicians unwilling to accept this very low risk for malignancy may be referred for surgical consultation. Category 0 is used only to describe abnormal screening mammograms awaiting further diagnostic investigation. The Food and Drug Administration requires that as of 1999 patients receive a written summary mammographic report directly from the radiologist.

1. Negative
2. Benign
3. Probably benign
4. Suspicious
5. Highly suggestive of malignancy
0. Incomplete, need additional imaging evaluation

(Source: From American College of Radiology. *Breast Imaging Reporting and Data System*, 3rd ed. Reston, VA: American College of Radiology, 1998, with permission.)

TABLE 205.1. FOOD AND DRUG ADMINISTRATION AND AMERICAN COLLEGE OF RADIOLOGY BIRADS FINAL ASSESSMENT OF MAMMOGRAPHIC FINDINGS

MAMMOGRAPHIC CHARACTERISTICS OF BREAST CANCER

Approximately 90% of cancers manifest themselves as microcalcifications or masses on mammograms. Microcalcifications may be the sole manifestation of breast cancer, especially ductal carcinoma in situ. Microcalcifications with a high probability of representing malignant growth include fine, irregular particles in a ductal pattern with linear forms. Small foci of clustered pleomorphic calcifications have a moderate probability of representing a malignant tumor. Intermediate-probability microcalcifications may be a manifestation of carcinoma or fibrocystic change. Certain calcifications, such as those associated with degenerating fibroadenoma, ductal ectasia, or microcystic adenosis, can be ascertained to be benign on the basis of the specific appearance.

The detection of masses with indistinct or spicular margins suggests the presence of malignant growth ([Fig. 205.4](#)). The margins relate to extension of tumor or fibrosis at the margins of the breast carcinoma. Circumscribed round or oval masses are most frequently benign lesions such as fibroadenoma or a cyst. Circumscribed carcinoma, although unusual, cannot be excluded with mammography. Less common mammographic manifestations of carcinoma include areas of asymmetric density, architectural distortion, or developing density from year to year.

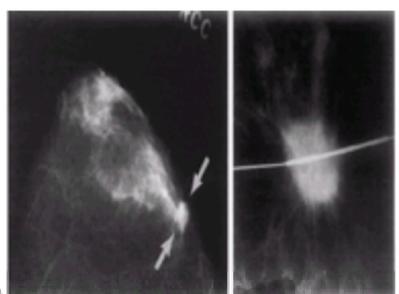

FIGURE 205.4. **A:** Craniocaudal mammogram shows a 1 cm spicular nonpalpable mass (*arrows*) in the lateral aspect of the breast. **B:** Specimen radiograph of excised tissue shows spicular margins to better advantage. Metallic hook wire (*white line*) had been placed to guide surgical excision. Invasive carcinoma was diagnosed by means of pathologic examination of this specimen.

ULTRASONOGRAPHY AS AN ADJUNCT IN THE EVALUATION OF AN ABNORMAL MAMMOGRAM

Ultrasonography is used to further characterize a mammographic mass. The primary role of ultrasonography is to differentiate a fluid-filled cyst from a solid mass. Geographic correlation between the mammographic mass and ultrasound finding is essential. Masses fulfilling criteria for a simple cyst, such as smooth-walled, circumscribed, anechoic masses with increased through transmission, are classified as benign and necessitate no further management unless they are painful ([Fig. 205.5](#)). Solid masses usually require tissue biopsy because ultrasonography cannot conclusively differentiate benign from malignant solid masses. Ultrasonography also is used for imaging examinations of women with palpable findings even in the absence of mammographic abnormality to differentiate a solid from a cystic mass. This is especially helpful to women with dense breasts. Normal findings of a sonographic evaluation in the presence of a palpable mass does not exclude carcinoma; clinical management is needed.

FIGURE 205.5. Ultrasound image obtained to characterize a mass found on a mammogram. Image shows a simple cyst with smooth margins and anechoic (*black*) center with enhanced through transmission.

TISSUE DIAGNOSIS OF AN ABNORMAL MAMMOGRAPHIC LESION

Biopsy options for women with nonpalpable category 4 or 5 assessments include wire localization with open surgical biopsy, image-directed core-needle biopsy, and less commonly FNA with cytologic analysis. Needle localization procedures involve the placement of a localizing needle and a hook wire at the site of the mammographic abnormality. The procedure is performed with mammographic or sonographic guidance. Open surgical biopsy is performed by means of excision of tissue around the hook wire. A specimen radiograph of the excised tissue obtained with mammographic technique confirms successful removal before pathologic analysis ([Fig. 205.4B](#)). Core biopsy of nonpalpable lesions gained wide acceptance in the 1990s. This method involves placing a core breast biopsy needle (11 to 14 gauge) into a breast abnormality with the patient under local anesthesia and obtaining repeated samples. Image guidance may be accomplished with either stereotactic mammography or ultrasonography. The sensitivity and specificity of core-needle biopsy are reported to be higher than 95%. Because core biopsy is a sampling technique, lesions are not typically completely excised. Areas of atypical ductal hyperplasia or radial scarring should be surgically re-excised because some patients are found to have associated carcinoma. Core biopsy specimens showing ductal carcinoma in situ are, in a minority of cases, found to contain invasive carcinoma when more tissue is excised. The results of all biopsies must be correlated with the mammographic findings. Discordant results between mammographic and pathologic evaluations necessitate imaging in 4 to 6 weeks and possible re-excision.

DIAGNOSTIC PITFALLS

Breast density or composition influences the sensitivity of mammography. A very dense mammographic pattern occurs when the breast composition is primarily fibroglandular and has minimal adipose tissue. In extremely dense breasts, carcinoma may be masked or camouflaged by the overlying dense tissue, which markedly limits mammographic sensitivity. A fat density pattern, however, allows higher sensitivity. Breast density varies from person to person and may be increased with hormone replacement therapy.

Mammography cannot be used to rule out breast cancer in a patient with a palpable finding. Because patients may derive false assurance from a normal mammographic report in the presence of a palpable finding, it is the clinician's responsibility to ensure that these patients have complete evaluation. After thorough diagnostic evaluation, sound clinical and surgical judgment is needed to integrate the palpable findings with the imaging results. Any patient with clinically suspect findings should be referred for surgical consultation regardless of the breast imaging results.

UNCOMMON PRESENTATIONS

The symptoms of approximately 3% to 5% of breast cancers are erythema, edema, and peau d'orange. After 1 week of unsuccessful antibiotic treatment, these patients should undergo immediate mammography and biopsy of either the affected skin or a mammographic abnormality if one is detected. These patients should be considered to have inflammatory breast cancer and urgently referred to the care of a surgical oncologist to expedite diagnosis and initiation of chemotherapy.

Nipple discharge is a relatively common presenting symptom of breast disease and is most often of nonneoplastic causation. The evaluation for nipple discharge centers on discerning whether benign or malignant neoplasia is the cause, because both are likely to necessitate surgical intervention to excise a neoplasm or to control the symptoms. Serous, serosanguineous, bloody, or watery discharge is evaluated with mammography to find an associated mass or calcification, which increases the likelihood of neoplasia as an etiologic factor. Unilateral and spontaneous discharge, confinement to one duct at expression of the breast, association with a mass, and male sex are characteristics used by the surgeon to decide on intervention. Bloody discharge is most often caused by intraductal papilloma. Persistent nipple discharges that exhibit any of the characteristics listed warrant referral to a breast specialist. Bilateral galactorrhea unexplained by lactation or pregnancy is assessed by means of prolactin level, visual field testing, and computed tomography or magnetic resonance imaging of the sella turcica region to ascertain the presence of a pituitary adenoma. Other causes of bilateral galactorrhea, such as hypothyroidism and syndromes associated with amenorrhea, generally are best evaluated by an endocrinologist.

An isolated enlarged axillary node should be considered for biopsy if the node is not easily movable, is larger than 2 cm in diameter, or appears other than benign on a mammogram in the absence of other mammographic abnormalities. If adenocarcinoma is diagnosed in an isolated lymph node, special stains for estrogen and progesterone receptors and mucin should be performed on the biopsy specimen, and serum tumor markers (cancer antigens CA 27.29, CA 125, and CA 19-9 and carcinoembryonic antigen [CEA]) should be evaluated to help identify the organ of origin of the cancer.

Although risk for breast cancer increases with age, breast cancer does occur among the very young. A family history of breast or ovarian cancer or known *BRCA* mutation carrier status are major risk factors for early-onset breast cancer. Women with a family history of breast or ovarian cancer who have a palpable mass or abnormal mammogram should undergo aggressive diagnostic evaluation, regardless of age. Mammographic screening generally is begun when a woman is 5 years younger than the family member who had the earliest case of breast cancer. Women who have undergone radiation therapy to the chest for lymphoma or another condition before they are 20 years of age also are at high risk for bilateral breast cancer and need special consideration. These women should start mammographic screening by 25 years of age. Abnormalities found at physical examination or mammography should be thoroughly evaluated.

Breast cancer rarely develops in pregnant or lactating women. An asymmetric, enlarging mass should be evaluated, even in the absence of unusual risk factors, because breast cancers that arise under these conditions tend to grow rapidly and thus carry a poor prognosis. There is no known contraindication to mammographic evaluation or tissue sampling of a suspicious mass in a pregnant or lactating patient.

[Differential Diagnosis](#)
[Strategies For Optimal Care](#)
[Cost-Effectiveness](#)

PRESENTATION

The initial symptom of cancer of the testis typically is a scrotal mass. The mass may be tender or painless. Many patients first notice the mass after minor trauma, and the injury commonly is considered by the patient the cause of the mass. In reality, the injury draws attention to the mass, or the abnormal testis is more susceptible to trauma. In the past, some men were reluctant to seek medical attention when they noticed a scrotal mass. This delay still occurs, but it does seem that various public education efforts have been responsible for a heightened awareness of testicular cancer. Similar efforts have led to more awareness by primary physicians and earlier consideration of the presence of testicular neoplasia.

HISTORY AND PHYSICAL EXAMINATION

A logical approach to the initial evaluation of a scrotal mass is imperative. The patient should be questioned carefully about his symptoms, including duration, the presence of pain, fever, dysuria, urethral discharge, a history of trauma, and antecedent urologic conditions, particularly a history of an undescended testis or prior scrotal or inguinal operation. The age of the patient is important, because the likely diagnosis varies according to age. Other symptoms that should be sought include those specifically related to potential areas of metastatic spread of testicular cancer. These include back pain, which indicates retroperitoneal nodal involvement, dyspnea or cough, weight loss, or gynecomastia, which indicates tumor production of human chorionic gonadotropin (hCG).

Physical examination of the scrotum carefully delineates the size and character of the mass and its consistency. A normal testis is ovoid, smooth, tense, and sensitive to pressure. A normal epididymis is posterior to the testis and is separated from the testis by a thin groove. It is flaccid and slightly sensitive to palpation. The relation of the mass to the testis, epididymis, and spermatic cord is critical. A mass clearly separable from the testis suggests epididymitis, and a mass within the parenchyma of the testis suggests neoplasia.

Transillumination of the mass should be attempted. Masses that readily transilluminate are cystic and not likely to be malignant. Masses that do not transilluminate and are not clearly separable from the testis should be assumed to be neoplastic until proved otherwise. Other important aspects of the physical examination include palpation for an abdominal mass, organo- megalia, and inguinal or supraclavicular lymphadenopathy.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

The choice of laboratory and radiographic studies is dictated by the findings derived from the history and physical examination. If a neoplasm is suspected, testicular ultrasonography should be considered. Ultrasonography can better define the anatomic structures in the scrotum, show specifically whether the mass is cystic, and show whether the mass is of testicular or paratesticular origin. [Figure 206.1](#) is a testicular ultrasound scan that shows a hypoechoic parenchymal testicular mass. This patient underwent radical inguinal orchiectomy; it was confirmed that the lesion was a malignant germ cell tumor of the testis.

FIGURE 206.1. Ultrasound scan of the testis shows a well-defined, hypoechoic mass, proven at orchiectomy to be a nonseminomatous testicular tumor.
EVIDENCE LEVEL: C. Expert Opinion.

Diagnostic studies should include determination of the tumor markers b-hCG and a-fetoprotein (AFP). These marker levels are useful only if elevated; an elevated b-HCG or AFP level in this clinical situation confirms the diagnosis of a neoplasm of testicular germ cell origin. However, normal marker levels in no way exclude malignancy. Patients with testicular seminoma usually have normal levels of markers, and many patients with germ cell tumors other than seminoma have normal marker levels, particularly if the tumor is localized to the testis. Neoplasms that rarely involve the testis or paratesticular structures, such as lymphoma, stromal tumors, or sarcoma, do not have elevated levels of germ cell tumor markers. Other diagnostic tests that may be appropriate include urinalysis and smear and culture of urethral discharge, if present.

DIFFERENTIAL DIAGNOSIS

The critical issues that define the differential diagnosis for a given patient are duration and severity of the symptoms, whether the scrotal mass is of testicular or paratesticular origin, and whether the mass is cystic or solid. Differential diagnostic considerations and a decision tree are shown in [Fig. 206.2](#). Scrotal masses of acute onset and associated with severe symptoms usually are acute epididymitis or testicular torsion. Differentiating these two processes may be quite difficult for an acutely ill patient. Although malignant neoplasms of the testis may be thought by the patient to be of abrupt onset, the severity of the illness is not ordinarily that of these two conditions.

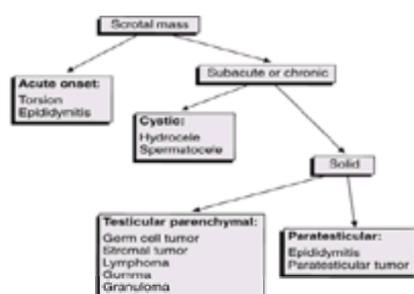

FIGURE 206.2. Differential diagnosis of a scrotal mass.
EVIDENCE LEVEL: C. Expert Opinion.

Cystic masses revealed with transillumination or ultrasonography usually are hydroceles. Hydroceles may surround the testis (except the posterior aspect) or may be localized to the spermatic cord. Some have a relatively acute onset. Some acute-onset hydroceles may be reactive in nature and may be associated with a testicular tumor. If this is the case, ultrasonography can help confirm the presence of a testicular mass.

The most common misdiagnosis of testis tumor is epididymitis. This differential diagnosis occasionally may be difficult. At examination, the epididymis is thick, tense, and tender. The groove between the testis and epididymis is obliterated, and the epididymis fits over the posterior aspect of the testis like a crescent. Unless a diagnosis of epididymitis is certain, the patient should be reexamined after a brief course of antibiotics. If the enlargement is not resolving, the diagnosis of epididymitis may be erroneous, and inguinal exploration should be considered.

STRATEGIES FOR OPTIMAL CARE

MANAGEMENT

The choice of diagnostic studies is dictated by the clinical findings. The management of a testicular mass thought to be a neoplasm is outlined in [Chapter 222](#). In brief, results of inguinal exploration and orchiectomy confirm the diagnosis and initiate therapy.

COMPLICATIONS AND PITFALLS

A testicular neoplasm must not be erroneously diagnosed as a benign condition. As discussed in [Chapter 222](#), these tumors are sometimes rapidly progressive, and the likelihood of cure correlates strongly with tumor stage and volume at diagnosis.

Indications for REFERRAL

Low-grade epididymitis ordinarily does not necessitate urologic consultation, and many causes of scrotal masses, such as hydrocele, spermatocele, and varicocele, usually necessitate no specific management. Testicular tumors do necessitate urologic consultation, and acute, severe epididymitis and testicular torsion are urologic emergencies.

COST-EFFECTIVENESS

The widespread availability of testicular ultrasonography has added to the cost of the evaluation of a scrotal mass. However, the information gained from such a procedure may have a substantial effect on the treatment of these patients, and the study frequently is justified in the diagnostic evaluation of many patients. The most costly aspect of the evaluation of these patients is erroneous diagnosis of a lesion that proves to be a testicular tumor. The resultant delay in diagnosis may mandate much more aggressive therapy and reduce the likelihood of cure.

PRESENTATION

Because of the widespread ability to measure prostate-specific antigen (PSA), it is not uncommon for male patients to request assistance in the interpretation of a serum PSA level. Although many patients with prostate cancer have only an abnormal elevation in PSA level, an isolated elevation in PSA is not enough information to confirm a diagnosis of prostate cancer. A thorough understanding of the interpretation of this serum marker is needed to appropriately advise patients.

Patients also may have urinary symptoms, including frequency, urgency, decreased flow, nocturia, urinary tract infection, or signs of prostatic inflammation. These symptoms may be caused by both benign and malignant causes of prostatic enlargement that lead to obstruction of urinary flow. Measurement of PSA and digital rectal examination (DRE) are commonly used in the initial evaluation of these symptoms. DRE is mandatory for patients with urinary symptoms and should be a component of the routine physical examination of any male patient older than 40 years. Palpation of the entire prostate sometimes is difficult, but most men can be thoroughly examined by an experienced clinician. The presence of a prostate nodule or abnormally firm prostate gland mandates further evaluation.

PATHOPHYSIOLOGY

Prostate-specific antigen is a 34 kd glycoprotein with serine protease activity. Its main biologic role appears to be liquefaction of coagulated semen after ejaculation. PSA has also been shown to activate growth factors; the implication is that PSA has a regulatory role in epithelial growth in the prostate. PSA is produced almost exclusively by prostatic epithelial cells. In the setting of neoplasia or inflammation, breakdown of epithelial barriers causes release of PSA into the blood stream, where it is complexed to circulating proteins. Total PSA levels roughly correlate with prostate volume.

Prostate cancer is typically multifocal in distribution throughout the gland. Although an index lesion often is present, even these areas typically contain more than one histologic grade of tumor and often are mixtures of tumor with benign prostatic hyperplasia (BPH). Most tumors arise in the peripheral zone of the gland, and a minority occur in the transitional and central zones. The peripheral zone is easily accessible because this is the portion of the gland typically palpated during DRE. Unfortunately, many tumors become clinically significant before a palpable nodule or area of induration develops.

HISTORY AND PHYSICAL EXAMINATION

The first element of the history and physical examination is a discussion of urinary symptoms. Voiding dysfunction such as decreased stream and nocturia suggest enlargement of the prostate gland. These findings may be associated with benign conditions, particularly in the absence of a palpable abnormality. Dysuria, hematuria, and hematospermia are relatively rare as initial signs of prostate cancer and should prompt a thorough evaluation of the urinary tract, including excretory urography and cystoscopy. Both prostatitis and benign enlargement of the gland may elevate serum PSA level.

Family history is an important historical element. Evidence suggests that only 9% of prostate cancers are caused by inherited factors. Men with first- and second-degree relatives with prostate cancer are at increased relative risk for prostate cancer, particularly if the relative was found to have prostate cancer at a young age. Race and ethnicity also appear to be important factors. African American men have a higher incidence and death rate of prostate cancer than do white men. Familial risk also appears to be more important among African American men. Race and ethnicity also play a role through environmental and dietary exposures. The clearest indication of this is increased risk for prostate cancer among Asian men immigrating to the United States. Asians typically have low levels of clinically significant prostate cancer; however, this rate increases in subsequent generations after immigration.

Documentation of current medications is a critical component of the history. The 5 α -reductase inhibitor finasteride decreases serum PSA levels as much as 50%. Patients taking exogenous androgens to manage sexual dysfunction and symptoms associated with aging may have an elevated PSA level. Phytoestrogens are present in a number of commonly used nutritional supplements, including soy products and some herbal preparations. These may have the effect of lowering PSA levels.

Urologic instrumentation such as catheterization or cystoscopy may cause an elevated PSA. Prostate biopsy can markedly elevate serum PSA; a 4 to 6 week period is needed after biopsy before a baseline PSA level is determined. Ejaculation and strenuous exercise also have been reported to cause transient increases in serum PSA level.

Although patients presenting with metastatic disease are becoming rare with the advent of widespread PSA testing, a thorough review of systems and physical examination are necessary for patients with an elevated PSA level or a prostate nodule. All patients should undergo DRE. A normal prostate has two lobes, a median crease, and easily palpable lateral lobes. The seminal vesicles usually are not palpable. A normal prostate gland has a firm, rubbery consistency commonly likened to the thenar eminence of the palm. Areas of induration and nodules are hard. The presence of these features, obliteration of any of the normal landmarks, or any asymmetry is a sign of prostate carcinoma. It is important to record the location, character, size, and margins of any palpable abnormality and its relation to any of the normal landmarks. An enlarged gland with a normal consistency typically is associated with a benign condition such as BPH.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

An abnormal finding at DRE is a clear indication for measuring PSA if this has not already been done. Although there are several assays for serum PSA, the most commonly used is the Tandem-R assay, which has a normal range of less than 0.2 to 3.9 ng per milliliter. Ultrasensitive PSA assays have been developed that allow detection of PSA levels as low as 0.01 ng per milliliter, but the usefulness of such information is not known. Assays also have been developed to differentiate free PSA from PSA bound to circulating serum proteins.

The definitive diagnostic procedure for patients in this setting is transrectal ultrasound (TRUS)-guided needle biopsy of the prostate gland. Performed by an experienced examiner and after appropriate preparation, this diagnostic study has minimal morbidity. When no palpable abnormality is found at DRE and no lesion is clearly seen on a TRUS scan, sextant biopsy in which all portions of the gland are sampled is also performed. When an abnormality can be palpated or seen on an imaging study, specific biopsy of the abnormal area is also performed. By itself TRUS biopsy is nonspecific as a screening modality, although it does allow estimation of prostate volume, which may be useful in estimating PSA density (see later).

TRUS biopsy is an outpatient procedure that is generally well tolerated. A Fleet enema and prophylactic oral antibiotics usually are given before the procedure. Patients with indications for full intravenous prophylactic antibiotic coverage, such as artificial heart valves or a prosthesis, or anticoagulation for cardiac conditions need more extensive intervention before TRUS biopsy. Complications of this procedure include a relatively low risk for urosepsis, a 1% to 2% risk for urinary retention caused by swelling, and possible hematuria and local discomfort. Bleeding typically is not a problem, although patients taking nonsteroidal anti-inflammatory agents should discontinue these 1 week before the biopsy is performed. Radionuclide bone scans and pelvic imaging such as computed tomography or magnetic resonance imaging are appropriate before pathologic diagnosis only when the PSA level is markedly elevated or abnormal findings at physical examination suggest dissemination of disease.

DIFFERENTIAL DIAGNOSIS

An elevation in serum PSA level is not enough information to confirm a diagnosis of prostate cancer. Men with BPH, prostatitis, prostatic infarction, or urologic manipulation and those who exercise strenuously can have an elevated PSA level. In rare instances elevations in serum PSA level have been associated with undifferentiated cancers such as breast cancer.

A palpable nodule found at DRE may be caused by infarction or inflammation, nodular BPH, or an earlier biopsy. Tenderness at DRE suggests ongoing inflammation or infection. Induration, asymmetry of the gland, or obliteration of the typical landmarks is more often associated with the presence of a malignant tumor than with a benign condition. The differential diagnosis of conditions associated with an elevated PSA level or palpable abnormality at DRE is summarized in [Table 207.1](#).

Elevated Prostate-Specific Antigen	Prostate Nodule
Prostate cancer	Prostate cancer
Benign prostatic hyperplasia	Benign prostatic hypertrophy (nodular)
Prostatitis	Prostatitis (granulomatous)
Prostatic infarction	Prostatic infarction
Urologic manipulation	Previous biopsy
Exercise (minimal)	
Ejaculation (minimal)	
Other malignant lesion (rare)	

TABLE 207.1. DIFFERENTIAL DIAGNOSIS

STRATEGIES FOR OPTIMAL CARE

The most important decision to be made concerns the timing of biopsy of the prostate. This decision must take into account the overall condition of the patient. Establishing a diagnosis of localized prostate cancer for a patient whose life span is limited because of comorbid conditions may be of minimal benefit. These factors ideally are considered before serum PSA is measured. Most patients and physicians, however, do not consider how the information will be used until after the value is obtained. Screening is controversial. Several groups, including the American Cancer Society and American Urologic Association, recommend screening for men older than 50 years (40 years for men with a family history of prostate cancer and for African Americans). The American College of Physicians and other groups do not recommend screening given the lack of evidence that screening influences mortality from prostate cancer. Despite these conflicting recommendations, many men have PSA levels measured, and a large percentage have elevations in these levels. Data from several clinical series indicate that as many as 20% of men who have PSA levels measured have elevated values and that as many as 25% of these men undergo further evaluation. Most of the cancers detected in this way are clinically significant. Even in the setting of a T1c lesion (TNM staging system; elevated PSA level, normal DRE findings), 85% to 95% of cases of cancer detected are of clinically significant volume. Studies suggest that most cancers detected through screening are potentially harmful, confined to the organ, and potentially curable.

An isolated elevated PSA level in a patient who has no symptoms is problematic. The criteria used to refer these men for biopsy is a major issue. PSA cutoff levels at 4 and 10 ng per milliliter provide the best levels of sensitivity and specificity. Patients with levels less than 4 ng per milliliter are at very low risk for prostate cancer, whereas those with levels greater than 10 ng per milliliter are at high enough risk to justify biopsy in most instances. Decisions for the patient with a PSA level between 4 and 10 ng per milliliter remain problematic. Several strategies have been developed to refine this approach.

AGE-SPECIFIC REFERENCE RANGES FOR SERUM LEVEL OF PROSTATE-SPECIFIC ANTIGEN

The prostate gland enlarges with age, and prostatic inflammation is most common among older men. Because of these factors more tissue is available to produce PSA, and there is more leakage of PSA into the circulation. Older men without prostate cancer therefore have higher PSA levels than do younger men. Several studies have examined age-specific PSA ranges. With lower ranges of PSA for men younger than 60 years, sensitivity for detection of prostate cancer increases. Analyses have suggested that the effect of using the lower range will be limited and that there will be only a 2% to 4% increase in the rate of detection of curable cancer. The number of additional younger men who would undergo biopsy was not predicted. In contrast, wider PSA reference ranges for older men increase the specificity for detecting prostate cancer. The increased specificity would cause a decrease in the number of these men referred for biopsy. Analysis of one large practice suggested that this broader range would cause a 6% decrease in biopsy rate. Less than 1% of men who actually had cancer would not have been referred for biopsy, and most of these had well-differentiated organ-confined cancers that posed little threat to their lives. Other analyses have suggested that as many as 10% of organ-confined cancers would not be detected with use of the age-specific ranges for older men. Race also has been incorporated into this approach. Mean serum PSA concentrations are significantly higher among African American men in both populations with and without cancer, and these levels increase with age. The age-specific reference ranges for both whites and African Americans are shown in [Table 207.2](#).

Age Range (yr)	Appropriate PSA Range (ng/mL)	
	Whites	African Americans
40-50	0.0-2.5	0.0-2.0
51-60	0.0-3.5	0.0-4.0
61-70	0.0-5.5	0.0-4.5
>70	0.0-6.5	0.0-5.5

TABLE 207.2. AGE-SPECIFIC REFERENCE RANGES FOR PROSTATE-SPECIFIC ANTIGEN (PSA)

FREE AND PROTEIN-BOUND PROSTATE-SPECIFIC ANTIGEN

Prostate-specific antigen circulates in both free and protein-bound forms, with approximately 70% bound to serum proteins, primarily a1-antichymotrypsin. Patients with prostate cancer have a lower percentage of free PSA than do patients with BPH. Results of initial studies suggest that a free PSA percentage less than 18% suggests the presence of prostate cancer and may increase the specificity of PSA testing. The combination and potential interactions of free PSA percentage and the age-specific reference ranges have not been evaluated, although at least one study has shown that free PSA values are not age dependent.

PROSTATE-SPECIFIC ANTIGEN DENSITY AND VELOCITY

Prostate-specific antigen density is an attempt to differentiate BPH from prostate cancer by means of assessing PSA production per unit volume of the prostate gland. The ratio between serum PSA level and prostate volume as estimated with TRUS suggests that patients with a PSA density greater than 0.15 have a much greater rate of having detectable cancer. Prostate volume is difficult to determine in clinical practice, making this a less than useful measure.

PSA velocity relies on serial measurements of PSA to determine the rate of rise of PSA level over time. Data suggest that patients with organ-confined prostate

cancer have a rise of approximately 0.5 ng per milliliter per year compared with 0.18 ng per milliliter per year among men with BPH. Unfortunately, the variability in the PSA assay itself often approaches the level of change associated with the presence of malignancy. This and variability among laboratories performing the assay make using the assay somewhat difficult.

Indications for REFERRAL

The most important decision concerns referral of patients for biopsy. The decision to proceed with evaluation ideally is made before the PSA level is measured, because only patients who will benefit from the diagnosis of or current therapy for prostate cancer should undergo biopsy. Once PSA has been measured and shown to be elevated, it is unlikely that the evaluation will stop short of biopsy of the prostate gland. Patients with PSA values greater than the age-specific ranges might benefit from TRUS-guided biopsy whether or not an abnormality is found at DRE. Any patient in generally good medical condition who has a palpable nodule should be referred for biopsy. Patients with symptoms of urinary outflow obstruction and either a normal or elevated PSA level who can tolerate therapy should consult with a urologist. A strategy for the detection of early prostate cancer is outlined in [Table 207.3](#).

Prostate-Specific Antigen	Digital Rectal Examination	Action
Normal age specific	Negative	Annual PSA and DRE
Elevated age specific	Negative	TRUS: biopsy-visualized lesions and sextant biopsy
Any	Positive	TRUS: biopsy-visualized and palpable lesions and sextant biopsy

PSA, prostate-specific antigen; DRE, digital rectal examination; TRUS, transrectal ultrasonography.

TABLE 207.3. DETECTION OF EARLY PROSTATE CANCER FOR APPROPRIATE PATIENTS

COST-EFFECTIVENESS

Economic grounds often have been used to criticize the use of measurement of PSA in prostate cancer screening. A comparison of the cost of PSA screening with that of mammographic screening for breast cancer shows that prostate cancer compares quite favorably. On average, the cost per case of prostate cancer detected is approximately \$3,000 compared with \$15,000 for each case of breast cancer detected. The main difference is that screening for breast cancer has been shown to reduce mortality, whereas no similar data exist for prostate cancer. Data addressing this question will be available at the completion of large, randomized screening trials within the next few years.

PRESENTATION

The word *adnexa* is the plural of *adnexum*, which means “connected part” or “appendage.” In gynecology, the term *adnexa* is used to include the ovaries, the fallopian tubes, the broad ligament, and the structures in it that are derived from embryonic remnants of the wolffian ducts or from peritoneal inclusions. Any one of these structures can be called an *adnexum*, but this term is seldom used.

The most common presentation of an adnexal mass is the incidental finding of a tumor adjacent to the uterus during a routine pelvic examination of a woman who has no symptoms. An adnexal mass also may become apparent with pelvic or abdominal pain. These may be caused by complications of the mass, such as torsion, infection, or hemorrhage, or symptoms due to pressure on adjacent organs. The symptoms may depend on the origin of the adnexal mass. Menstrual disorders such as menorrhagia or dysmenorrhea due to ovarian endometrioma or pelvic inflammatory disease (PID) may prompt the pelvic examination that elicits the mass. Bowel symptoms such as diarrhea, constipation, or the passage of mucus or blood may lead to the discovery of an adnexal mass due to diverticulitis or colon cancer. Urinary symptoms such as dysuria, hematuria, or incontinence may occur if the mass originates in the urinary tract.

PATHOPHYSIOLOGY

An adnexal mass may arise from the gynecologic organs themselves or be caused by disease in adjacent anatomic structures. Most adnexal masses are of gynecologic origin, arising from the ovary, fallopian tube, broad ligament, or uterus. The various gynecologic conditions that can account for the finding of an adnexal mass are listed in [Table 208.1](#). Adnexal masses also can originate in the intestine, urinary tract, abdominal wall, or retroperitoneum ([Table 208.2](#)).

Structure	Mass
Ovary	Functional cyst Follicle cyst Corpus luteum cyst Theca lutein cyst Neoplasm Benign Malignant Endometrioma Inflammatory disease Adhesive disease (subacute or chronic infections)
Fallopian tube	Tuboovarian abscess Pyosalpinx Hydrosalpinx Ectopic pregnancy Neoplasm Carcinoma Sarcoma
Broad ligament	Choriocarcinoma Cyst from wolffian duct remnants Gartner duct cyst Peritoneal inclusion cyst Malignant tumor of the broad ligament
Uterus	Pedunculated or intraligamentous leiomyoma Pregnancy in horn of bicornuate uterus

TABLE 208.1. GYNECOLOGIC ADNEXAL MASSES

Structure	Mass
Intestine	Feces or gas Diverticulitis Enteritis Pelvic appendicitis Carcinoma of the colon
Urinary tract	Distended bladder Bladder neoplasm or calculus Pelvic kidney
Abdominal wall	Hematoma Abscess Desmoid tumor
Retroperitoneal cavity	Lymphoma Sarcoma Teratoma

TABLE 208.2. NONGYNECOLOGIC ADNEXAL MASSES

During the reproductive years, the most common adnexal enlargement found at pelvic examination is a functional cyst of the ovary. These non-neoplastic cysts form as a result of minor aberrations in the normal process of ovulation. If ovulation does not occur (anovulatory cycle), the follicle continues to enlarge and may reach a size of 10 cm or more in diameter, resulting in a follicular cyst. Less commonly, a functional cyst may arise from the corpus luteum. Formation of the corpus luteum is a normal postovulatory event. On occasion, however, the corpus luteum may become palpably enlarged because of hemorrhage, and a corpus luteum cyst forms. Because normal corpus lutea are cystic, the term *corpus luteum cyst* should be reserved for those larger than 3 cm in diameter. Functional ovarian cysts of either follicular or luteal origin usually regress spontaneously within one or two menstrual cycles.

If the ovarian follicle is overstimulated by excess luteinizing hormone, as occurs in Stein–Leventhal (polycystic ovary) syndrome, or by excess human chorionic gonadotropin (hCG), as occurs with hydatidiform mole, theca lutein cysts form. These cysts resolve spontaneously when the underlying pathophysiologic process has been corrected. While present, however, the cysts must be differentiated from primary adnexal neoplasms or other adnexal disorders.

The most important concern in finding an adnexal mass is that it might represent a malignant neoplasm. Most adnexal neoplasms are of ovarian origin. Neoplasms of the fallopian tube and parametrium are rare. Ovarian neoplasms can be cystic or solid. The most common benign cystic tumors are serous cystadenoma, mucinous cystadenoma, and cystic teratoma. Malignant epithelial tumors of the ovary usually are serous or mucinous cystadenocarcinoma. Less common histologic types are endometrioid, clear-cell, or mixed epithelial tumors. The common benign solid ovarian tumors are fibroma, adenofibroma, thecoma, and Brenner tumor. All usually are firm to palpation. Solid malignant ovarian neoplasms usually are primary adenocarcinoma of the ovary. Metastatic lesions to the ovary usually originate in the uterus, gastrointestinal tract, or breast.

Endometriosis is a frequently encountered gynecologic cause of an adnexal mass. The hallmark of this disease is ectopic endometrial tissue. Although endometriosis may be found in distant sites such as the pleura and gastrointestinal tract, it is most commonly found on peritoneal surfaces in the pelvis. Endometriotic implants on the ovarian surface may coalesce and form a hemorrhagic cyst known as *endometrioma*. These cysts have a complex, loculated appearance on ultrasound scans and therefore may mimic ovarian cancer.

PID commonly becomes apparent as a tender adnexal mass. This may be the result of a tuboovarian abscess, hydrosalpinx, or chronic adhesions and scarring from resolved PID. Uterine disease also can manifest itself as an adnexal mass—pedunculated, intraligamentous, or cervical leiomyoma. Ectopic pregnancy in a

rudimentary or well-developed horn of a bicornuate uterus also can become apparent as a palpable adnexal mass.

Although most adnexal masses are of gynecologic origin, it is important for the clinician to be cognizant that masses in the region of the adnexa may originate in the intestine, urinary tract, abdominal wall, or retroperitoneal cavity. Feces or gas in the colon or a distended neurogenic bladder may mimic an adnexal mass of ovarian origin. It is prudent to ensure that the patient has evacuated her bowel and voided before a pelvic examination for a suspected adnexal tumor. Diverticulitis, appendicitis, inflammatory bowel disease, and tumors arising in the intestine are examples of gastrointestinal disorders that cause a mass in the region of the adnexa. Urinary tract disease, including bladder calculus and neoplasia of the kidney, ureter, bladder, or urethra, also may cause an apparent adnexal mass. A pelvic kidney from congenital malformation or transplantation may be palpable in the adnexal region. Abdominal wall masses (hematoma, abscess, hernia, or desmoid tumor) can develop caudad to the umbilicus and may be diagnosed as adnexal masses. The most common tumors of retroperitoneal origin that may cause adnexal masses are lymphoma, sarcoma, or teratoma.

HISTORY AND PHYSICAL EXAMINATION

Because of the wide array of gynecologic and nongynecologic diseases that can be responsible for the clinical finding of an adnexal mass, a comprehensive gynecologic and medical history is mandatory. Most ovarian neoplasms, unless advanced, are not associated with pain or menstrual disturbances. The association of pain with a mass in the region of the adnexa suggests torsion, infection, leiomyomatous degeneration, PID, or endometriosis. Rapidly growing germ cell tumors of the ovary can cause pain from stretching of the ovarian capsule. Menstrual disorders such as oligomenorrhea, dysmenorrhea, or menorrhagia also should alert the clinician to the possibility of the presence of a functional ovarian cyst, endometriosis, leiomyoma, granulosa cell tumor, or ectopic pregnancy. Because masses in the adnexal region may be caused by intestinal or urinary tract disease, the history interview must elicit any symptoms pertaining to these systems. A history of nausea, vomiting, anorexia, constipation, diarrhea, or the passage of blood through the rectum may be relevant. Disturbances in micturition may point to urinary tract disease. In rare instances hematuria or blood in the stool may be caused by endometriotic implants involving the wall of the bladder, colon, or rectum.

The physical examination should include general medical surveillance, a breast examination, examination for enlarged supraclavicular nodes, and abdominal examination for masses, ascites, or organomegaly. The initial identification of an adnexal mass usually is made by means of pelvic examination. During the pelvic examination, the location, consistency, size, laterality, and tenderness of the mass are assessed. These facts should be interpreted in the context of the age of the patient to formulate an appropriate differential diagnosis. The pelvic examination must include both vaginal and rectovaginal examinations. The latter affords the best assessment of the rectum, posterior pelvis, and parametrium. Stool on the glove should be examined for occult blood. Cross contamination from vaginal blood must be avoided. If tenderness or fever is present, cervical cultures for gonorrhea and chlamydia should be obtained.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

A pregnancy test (urine or serum b-hCG) should be performed whenever there is a mass in the adnexal region of a woman of reproductive age. If b-hCG level is elevated, it must be assumed that the patient is pregnant. Patients with an adnexal mass in addition to an elevated b-hCG level should be immediately referred to an obstetrician–gynecologist for further treatment. Evaluation of these patients may lead to the diagnosis of ectopic pregnancy, theca lutein cyst associated with gestational trophoblastic disease, ovarian choriocarcinoma, embryonal carcinoma, or endodermal sinus tumor of the ovary. All these are life-threatening conditions without timely diagnosis and treatment. However, the most likely diagnosis is physiologic enlargement of the corpus luteum during the first trimester of a normal intrauterine pregnancy. Because many of these patients may have normal pregnancies, the use of diagnostic studies with ionizing radiation should be avoided.

Pelvic ultrasonography is a safe and useful diagnostic test. In most cases, it can be used to determine the position, size, and structure of an adnexal mass. Transvaginal ultrasonography provides enhanced resolution of the adnexa compared with transabdominal sonography. Therefore, use of the transvaginal probe has become a routine component of ultrasound examination of the pelvis. In addition to size and location, knowledge of the internal morphologic features of the mass are critical for diagnosis. Benign follicle cysts have distinct borders with little or no internal septation. Cysts with a complex internal architecture that might include septa, solid components, papillary formations, and vessels present a diagnostic challenge. Gas-fluid levels suggest tuboovarian abscess, pelvic abscess, or ruptured viscus. A pelvic hematoma in the vicinity of the adnexa is likely to have a more homogeneous appearance. Benign cystic teratoma (dermoid cysts) often exhibit a highly specific sonographic findings. Benign ovarian teratomas typically have both cystic and solid components. The former usually contains oily and sebaceous material, whereas the latter may include bone, teeth, and hair. Certain sonographic findings suggest ovarian cancer. These include a high proportion of solid areas, a complex internal structure with thick septa separating cystic loculations, papillary formations, and the presence of ascites. Color-flow Doppler analysis of the vessels within an adnexal mass can provide additional information regarding the likelihood of malignancy.

Computed tomography (CT) of the abdomen and pelvis can be helpful in confirming the presence of a pelvic mass and is useful for assessment of the retroperitoneal cavity. Magnetic resonance imaging (MRI) is expensive and rarely provides information beyond that obtained with CT. A simple radiographic examination of the abdomen and pelvis may be useful in detecting the teeth of a benign cystic teratoma or calcifications within a degenerating uterine leiomyoma. When gastrointestinal symptoms are elicited, sigmoidoscopy or contrast radiographic studies of the gastrointestinal tract are indicated. Urinary tract symptoms may warrant cystoscopy and intravenous pyelography.

Tumor markers may be used to aid in diagnosis. The level of cancer antigen CA 125 may be elevated in epithelial ovarian cancer. Germ cell tumors may be associated with elevations in serum b-hCG or a-fetoprotein level. Sex cord–stromal tumors of the ovary, granulosa cell tumor, and Sertoli–Leydig cell tumor may produce excess estrogens and androgens, respectively. Steroid cell tumors are exceedingly rare neoplasms that may produce androgens, estrogens, progestins, or corticosteroids. In rare instances patients with steroid cell tumors of the ovary have Cushing's syndrome.

Some physicians advocate serum CA 125 measurement as a screening test for ovarian cancer. However, CA 125 determination has an unacceptably low positive predictive value even when a reference value is selected to provide relatively low sensitivity. Therefore, serum CA 125 determination is not a valid screening test for ovarian cancer. It is, however, an appropriate component of the evaluation for an adnexal mass. Markedly elevated levels of serum CA 125 (more than 200) have a positive predictive value of more than 75% and therefore usually indicate the presence of epithelial ovarian cancer. However, moderately elevated levels (less than 200) are common in association with benign ovarian tumors, endometriosis, PID, and pregnancy. Level of CA 125 also may be elevated in association with pancreatitis, cirrhosis, peritonitis, peritoneal tuberculosis, or malignant disease of the pancreas, lung, breast, or colon. Conversely, some instances of ovarian cancer (as many as 25%) may not elevate serum CA 125 level. An elevated peripheral white blood cell count (WBC) and erythrocyte sedimentation rate may support the diagnosis of PID.

DIFFERENTIAL DIAGNOSIS

Arriving at a precise diagnosis is important because many adnexal masses may respond to nonsurgical management (e.g., functional ovarian cysts, tuboovarian abscess, or endometriosis), whereas others necessitate surgical removal (e.g., benign or malignant neoplasms or ectopic pregnancy). The differential diagnosis of an adnexal mass includes all the conditions listed in [Table 208.1](#) and [Table 208.2](#). A careful and thorough history interview is necessary to support a differential diagnosis. An adequate history must include a menstrual history, bowel and bladder function, and any symptoms of direct or referred pain, abdominal bloating, nausea, vomiting, or diarrhea.

Physical examination aids in diagnosis when special attention is paid to the abdominal and pelvic findings. In most cases, laboratory studies and special diagnostic tests are needed, including a pregnancy test, complete blood cell count, pelvic ultrasonography, and possibly a CT of the abdomen and pelvis. If the history and physical findings point to a possible gastrointestinal or urinary tract origin of the mass, laboratory studies and diagnostic tests aimed at these areas are warranted. When the cause of an adnexal mass is unclear after the aforementioned evaluation, diagnostic laparoscopy may be helpful. For example, laparoscopy enables one to differentiate readily between uterine leiomyoma and an ovarian neoplasm.

STRATEGIES FOR OPTIMAL CARE

MANAGEMENT

An algorithm for care of a patient with an adnexal mass is outlined in [Fig. 208.1](#). Before a pelvic examination, it is prudent to request that the patient void and evacuate. If a mass is felt and there is a possibility of retained feces, an enema may be necessary before a second examination. Adnexal masses that are not retained stool or urine necessitate further scrutiny. Postmenopausal or premenarchal women with a palpable adnexal mass have a reasonably high likelihood of having malignant pelvic disease and therefore should be referred to a gynecologic oncologist for additional evaluation. This evaluation would probably include pelvic

ultrasonography and serum CA 125 measurement. For women of reproductive age urinary b-hCG should be measured. If the test result is positive, the patient is either pregnant (highly likely) or has a b-hCG–secreting neoplasm (rare) that is probably of gynecologic origin. The adnexal mass may represent normal corpus luteum, which often is palpable during the first trimester of a normal pregnancy or during ectopic pregnancy. If any of these diagnoses is likely, the patient should be referred to a gynecologist.

FIGURE 208.1. Algorithm for management of an adnexal mass. *b-hCG*, b-human chorionic gonadotropin; *BSO*, bilateral salpingo-oophorectomy; *CDC*, Centers for Disease Control and Prevention; *ECT*, ectopic pregnancy; *GCT*, germ cell tumor; *GTD*, gestational trophoblastic disease; *HIV*, human immunodeficiency virus; *IUP*, intrauterine pregnancy; *TAH*, total abdominal hysterectomy; *TOA*, tuboovarian abscess.

EVIDENCE LEVEL: C. Expert Opinion.

If the urine pregnancy test result is negative, transvaginal ultrasonography should be performed. If the adnexa appear normal, an evaluation workup for tumor of other pelvic structures should be undertaken. A simple ovarian cyst 5 cm or less in diameter in a nonpregnant woman of reproductive age probably is functional. These cysts are likely to resolve spontaneously. Repetition of the pelvic examination and ultrasonography in 6 weeks is reasonable. Ultrasonically simple cysts that persist for more than 10 to 12 weeks should be surgically removed to exclude malignant growth and prevent the development of adnexal torsion.

If the pelvic ultrasound scan depicts an adnexal mass with irregular borders or a complex internal architecture (septa, papillary formations, cystic and solid components), then medical or surgical intervention is likely to be needed. Often an experienced ultrasonographer is able to discriminate between infectious (tuboovarian abscess), benign (endometrioma, cystic teratoma), and malignant (ovarian carcinoma) conditions with fair accuracy. However, there is considerable overlap in the appearance of complex adnexal masses. Overall, approximately 70% of multilocular solid ovarian masses are malignant. The other 30% are likely caused by infection (tuboovarian abscess) or endometriosis (endometrioma). Both these nonmalignant diagnoses occur almost exclusively among women of reproductive age. Therefore, a complex adnexal mass in a premenarchal or postmenopausal woman is highly likely to be malignant. Malignant ovarian tumors should be managed by a gynecologic oncologist. Standard management of ovarian cancer involves surgical staging and cytoreduction. Preoperative evaluation usually includes complete blood cell count, serum chemical analysis, measurement of CA 125, barium enema radiography, and abdominal and pelvic CT with oral and intravenous contrast. The management of ovarian cancer is discussed in [Chapter 221](#).

Complex adnexal masses in women of reproductive age that are associated with tenderness during pelvic examination or a fever likely represent a tuboovarian abscess. Blood, urine, and cervical cultures should be performed for gonorrhea and chlamydia. Serologic testing for syphilis and HIV infection also are indicated. Antibiotic therapy in accordance with treatment guidelines of the Centers for Disease Control and Prevention should be initiated during the wait for culture results ([Table 208.3](#)). Persistent symptomatic tuboovarian abscess refractory to combination antibiotic therapy may necessitate surgical management. The operation usually includes exploratory laparotomy, total abdominal hysterectomy, and bilateral salpingo-oophorectomy.

Inpatient Treatment
Regimen A
Cefoxitin 2 g i.v. every 6 hr or cefotetan 2 g i.v. every 12 hr
Doxycycline 100 mg i.v. or by mouth every 12 hr
Regimen B
Clindamycin 900 mg i.v. every 8 hr
Gentamicin loading dose 12 mg/kg i.v. or i.m. followed by maintenance dose (1.5 mg/kg) every 8 hr
Either regimen should be given for at least 48 hr after clinical improvement.
Doxycycline (100 mg by mouth two times per day) or clindamycin (450 mg by mouth five times per day) should be continued for a total of 10 to 14 days.
Outpatient Treatment
Cefoxitin 2 g i.m., probenecid 1 g by mouth, or ceftriaxone 250 mg i.m.
plus
Doxycycline 100 mg by mouth two times per day or tetracycline 500 mg by mouth four times per day for 10 to 14 days.

TABLE 208.3. 1989 CDC TREATMENT GUIDELINES FOR PELVIC INFLAMMATORY DISEASE

Findings at pelvic ultrasonography may suggest that the adnexal mass is not of ovarian origin. Leiomyomas uteri (fibroid tumors) are a common finding in the region of the adnexa. These masses appear solid and usually do not require medical or surgical intervention even if quite large (5 cm in diameter or more). However, any adnexal mass, cystic or solid, in a premenarchal or postmenopausal woman mandates further investigation. Adnexal neoplasms are more commonly malignant among premenarchal patients. Management usually leads to surgical exploration for staging and cytoreduction by a gynecologic oncologist.

COMPLICATIONS AND PITFALLS

The important pitfalls in the care of patients with adnexal masses involve either being too aggressive, as in managing functional ovarian cysts surgically, or being too conservative and delaying surgical management of an adnexal mass that may be malignant. The key to avoiding such errors is thorough evaluation with early and accurate diagnosis. The likelihood that an adnexal mass is a malignant neoplasm is highly age dependent. In cases that elude diagnosis with noninvasive tests, diagnostic laparoscopy often is a reasonable approach. The patient must be adequately informed that the procedure may be converted to exploratory laparotomy depending on the intraoperative findings.

A woman of reproductive age with complex adnexal masses presumed to be tuboovarian abscesses may have ovarian cancer. Pain or fever may be associated with an ovarian cancer when tumor necrosis, ovarian torsion, chronic PID, or intestinal obstruction from carcinomatosis is present. These clinical scenarios may further blur the distinction between an underlying infectious and a malignant condition.

Indications for HOSPITALIZATION

Any patient with an adnexal mass that might be malignant should be hospitalized for exploratory laparotomy with possible surgical staging and cytoreduction. Women of reproductive age who have complex adnexal masses believed to be tuboovarian abscesses associated with pain or fever should be hospitalized for appropriate intravenous antibiotic therapy. Most adnexal masses resulting from other causes may be managed in an outpatient setting. Hospitalization might be needed only if surgical intervention is needed. However, in many of these cases, laparoscopic removal of small (likely benign) adnexal masses may be performed in a same-day surgery unit.

Indications for REFERRAL

The need for surgical intervention or obstetric care is a common indication for referral of a patient with an adnexal mass. Any woman of reproductive age who has a positive urine b-hCG test result and an adnexal mass should be referred to an obstetrician–gynecologist. A normal intrauterine pregnancy or diagnosis and management of ectopic pregnancy are likely outcomes. However, a premenarchal or postmenopausal woman with an elevated b-hCG level should be referred to a gynecologic oncologist for evaluation of a probable malignant tumor. A persistent simple adnexal cyst in a woman of reproductive age is an indication for referral to an obstetrician–gynecologist. Surgical removal by means of laparoscopy or laparotomy usually is appropriate. A postmenopausal or premenarchal woman with an adnexal mass should be referred to a gynecologic oncologist. Exploratory laparotomy for surgical staging and cytoreduction often is needed.

COST-EFFECTIVENESS

The evaluation and management of an adnexal mass may be cost-effective without diminution in the quality of patient care. Appropriate selection of patients with adnexal masses for outpatient medical and surgical management will result in substantial cost savings. Appropriate selection of diagnostic imaging studies for these patients also may further reduce costs.

We are in the midst of a technological explosion. With MRI, CT, and ultrasonography, noninvasive imaging of the deepest recesses of the body can be performed. Although these advanced, expensive imaging modalities often are invaluable for diagnosis and surveillance of an adnexal mass, they may greatly increase health care costs and afford little benefit over lower-cost alternatives. Inappropriate use may be caused by failure to select the least expensive test that provides adequate diagnostic information. For example, use of MRI instead of ultrasonography for surveillance of a simple ovarian cyst in a woman of reproductive age is inappropriate. Costs may be increased by frequent use of inappropriate imaging tests for documentation of a persistent adnexal cyst. Combination of expensive imaging modalities that provide overlapping diagnostic information (CT and MRI) often is inappropriate.

Too often a postmenopausal woman with a large pelvic mass and greatly elevated CA 125 level is referred to a gynecologic oncologist after normal results are obtained at pelvic ultrasonography, CT, and MRI. A strong argument can be made that the findings at pelvic examination alone mandate hospitalization and exploratory laparotomy. For this hypothetical patient, limiting the evaluation to CT of the abdomen and pelvis, barium enema radiography, mammography, and measurement of CA 125 and carcinoembryonic antigen (CEA) provides more useful diagnostic information. This battery of tests would discriminate with acceptable accuracy between tumors arising in the gynecologic organs, intestine, urinary tract, breast, or retroperitoneum at lower overall cost than would laparotomy.

Benign processes that become apparent as adnexal masses also may be diagnosed and managed in a cost-effective way. Tuboovarian abscess often is diagnosed with a combination of assessment of vital signs, pelvic examination, cervical culture, blood culture, and pelvic ultrasonography. CT, MRI, and nuclear isotope scans are expensive and usually are unnecessary. The appropriate selection of outpatient as opposed to inpatient surgical management of adnexal masses may greatly reduce costs. Women of reproductive age who have persistent simple ovarian cysts often are excellent candidates for laparoscopic surgery in a same-day surgical unit.

CHAPTER 209: APPROACH TO THE PATIENT WITH AN ABNORMAL PAPANICOLAOU SMEAR

ANDREW W. MENZIN AND STEPHEN C. RUBIN

[Pathophysiology](#)
[History and Physical Examination](#)
[Laboratory Studies and Diagnostic Tests](#)
[Strategies For Optimal Care](#)
[Cost-Effectiveness](#)

In the 1940s, Dr. George Papanicolaou introduced techniques for interpreting cytologic specimens from the vagina and cervix to detect cervical cancer and its precursors. More than 50 years later the Papanicolaou (Pap) smear is the prime example of cancer prevention through community-based screening programs. Epidemiologic data from British Columbia reveal a threefold decrease in the incidence of cervical cancer during the three decades after institution of widespread use of Pap smears. In the United States, an 80% decrease in the incidence of cervical cancer and a fall in the death rate occurred during the same period. Although cervical cancer ranks as the second most common cancer among women worldwide, it is only seventh most common in countries with established screening programs. Almost 50 million Pap smears are performed each year in the United States. As a screening test, the Pap smear is performed on women who do not have symptoms. Through a joint effort of the American College of Obstetricians and Gynecologists (ACOG), the American Cancer Society, and several other organizations, recommendations have been outlined to guide primary care physicians in screening for cervical cancer ([Table 209.1](#)).

Annual pelvic examination and Pap smear for
All women who have been sexually active
All women who have reached the age of 18 years
After three consecutive normal and satisfactory^a Pap smears performed on a yearly basis, the interval between Pap smears may be extended (e.g., from 1 to 3 years) at the discretion of the physician and on the basis of the patient's risk factors.

^aSee Table 209.2.

TABLE 209.1. GUIDELINES FOR CERVICAL CANCER SCREENING

PATHOPHYSIOLOGY

The normal cervix is covered with nonkeratinized squamous epithelium. The cervical canal is lined with mucinous columnar cells. The transition between these epithelial types is the squamocolumnar junction. The region in which the columnar epithelium is gradually covered and replaced by squamous epithelium is called the *transformation zone*. Metaplastic change is a normal finding in this area, but most cases of cervical neoplasia also are found in the transformation zone.

Intraepithelial neoplasia precedes cervical cancer. The mean age of a patient at diagnosis of cervical cancer is 54 years. Carcinoma in situ is generally detected in women in their early forties. Dysplastic lesions usually occur among women in their twenties and thirties. However, a consistent trend toward earlier development of preinvasive and invasive lesions has been observed.

Preinvasive and invasive forms of cervical neoplasia are associated with sexual contact. Women who abstain from intercourse are thought not to be at risk. Specific associations include young age at first intercourse, a large number of partners, and relations with partners who have been promiscuous. Changing sexual practices may be responsible in part for the increasing incidence of preinvasive cervical neoplasia.

Investigators are searching for a transmittable agent that is passed during intercourse. Most of the known sexually transmitted diseases have at one time been implicated, included gonorrhea, syphilis, chlamydia, and trichomonas vaginalis. Considerable work has targeted the role of herpes simplex virus 2 (HSV-2). Women with preinvasive and invasive disease are more likely to have HSV-2 serum antibody titers. Though HSV-2 DNA and antigens have been detected in cervical neoplastic specimens, the prevalence rates have been low. Doubt exists about the role of HSV-2 as the primary causative agent in cervical neoplasia.

More extensive and convincing information implicates the human papillomavirus (HPV), the most common sexually transmitted infection. HPV DNA can be demonstrated in more than 90% of intraepithelial and invasive lesions. Considerable molecular evidence is emerging to support the notion that HPV actively participates in the oncogenic cascade of cervical epithelium. Epidemiologic data also support this association.

Other factors may play a role. Immunosuppressed patients, such as those taking steroids or those with AIDS, are at increased risk for preinvasive and invasive cervical neoplasia. Cigarette smoking increases a woman's risk; nicotine metabolites have been detected in the cervical mucus. Use of oral contraceptive also may play a role, as may deficiencies in vitamins A and C.

HISTORY AND PHYSICAL EXAMINATION

The Pap smear is only one component of cancer screening and prevention. Before a cytologic sample is obtained, a detailed history should be obtained and a physical examination performed. During the pelvic examination, careful, systematic inspection and palpation with accurate documentation allow proper assessment and interpretation of subsequent tests, including cytologic sampling.

The reliability of any screening test is related to the ability to obtain proper samples for analysis. Much effort has been directed at development of the optimal technique to obtain a Pap smear. Samples should not be obtained during the menses. Specimens are obtained before a manual examination is performed. Using a wooden spatula and a moistened endocervical cotton swab or brush, the examiner samples the portio and canal of the cervix to include cells from the transformation zone. The use of an endocervical brush has improved the sampling of endocervical cells, reducing the rate of unsatisfactory smears. The endocervical brush is safe for use during pregnancy.

Cytologic specimens must be transferred to a glass slide, and fixative is applied immediately to avoid air-drying artifacts, which can occur even in a matter of seconds. This effect of delayed fixation can severely limit accuracy and confound diagnosis. Endocervical and ectocervical sample material may be placed on a single slide without altering cytologic interpretation. Techniques with a liquid dispersion medium into which the cytologic sample is placed are becoming widely available. This process removes some of the background artifact before the final smear is produced. Although the background can obscure the underlying cytologic processes, it also can aid in interpretation of these processes. Though available, the technique has not been embraced by all cytopathologists or clinicians.

Despite an overall sensitivity of more than 90% with these sampling techniques, the false-negative rate remains in the range of 20%. In an effort to decrease false-negative rates, re-screening programs have gained acceptance. Whether performed manually or with computer assistance (Papnet), re-screening efforts supplement the quality-control criteria applied to Pap smear evaluation.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

The criteria for describing cytologic findings have evolved considerably since Papanicolaou proposed a five-category system. However, a lack of reproducibility has

with ASCUS and low-grade smears. An NCI-sponsored clinical trial also is underway to examine use of molecular markers to identify neoplastic lesions among women whose Pap smears contain atypical glandular cells of undetermined significance. The results of these studies may improve the cost-effectiveness of Pap smear evaluation algorithms.

Management after review of all diagnostic results is outlined in (Fig. 209.2). If findings at cytologic, colposcopic, and histologic assessment agree, a treatment plan is developed. If the diagnostic information is not in agreement, particularly if histologic confirmation of a high-grade abnormality is not obtained, further diagnostic evaluation with cervical cone biopsy is appropriate. Other indications for conization are given in Table 209.3. Usually performed in an outpatient surgical setting, conization may require regional or general anesthesia. Complications include bleeding (10% or less of patients), which may occur perioperatively or after 10 to 14 days, when the cervical eschar is shed; cervical stenosis, caused by scarring of the external cervical shed; and subsequent pregnancy loss related to an incompetent cervix caused by excision of large volumes of tissue. Conization remains the standard of care for the histologic diagnosis of cervical neoplasia.

FIGURE 209.2. Algorithm for evaluation of an abnormal Pap smear. LEEP, Loop electrosurgical excision procedure. (Modified from Giuntoli RL, Atkinson BF, Ernst CS, et al. *Atkinson's correlative atlas of colposcopy, cytology, and histopathology*. Philadelphia: JB Lippincott, 1987:233.)

EVIDENCE LEVEL: B. Reference: Cervical cytology: evaluation and management of abnormalities. ACOG Technical Bulletin 1993;183:1-8.

Unsatisfactory colposcopy (failure to completely visualize the squamocolumnar junction or a cervical abnormality)
 Identification and evaluation of early invasive carcinoma (micro-invasion)
 Excision of a lesion that extends into the endocervical canal
 Cellular abnormality found on specimen from endocervical curettage
 Glandular neoplasia identified at cytologic or histologic sampling
 Disparity between cytologic, colposcopic, and histologic (biopsy) results

TABLE 209.3. INDICATIONS FOR CONE BIOPSY

The management of subclinical HPV infection (abnormalities detected only at cytologic or histologic examination) emphasizes the reality that eradication of the virus is not possible. Ablative or excisional intervention is reserved for more severe abnormalities. The patient should be informed that the abnormality may persist or regress intermittently. Follow-up examinations at 6- to 12-month intervals are recommended because of the association between the presence of HPV and cervical neoplasia.

In longitudinal studies of the natural history of CIN, mild lesions (CIN 1) have a greater propensity for spontaneous regression (approximately 60%) than do CIN 2 and 3 lesions. These more severe abnormalities have significantly higher rates of progression to carcinoma in situ and invasive cancer when left untreated. Therefore, only the low-grade lesions of HPV or mild dysplasia are considered for expectant management.

When the decision is made to proceed with intervention for a dysplastic lesion, several options are available. These modalities include cryotherapy, laser vaporization, electrosurgical excision, or hysterectomy. Although each of these procedures is effective in almost 90% of cases, lesions can recur. Recurrence tends to be more frequent with larger, more severe, and multifocal lesions.

CRYOSURGERY

Rapid freezing followed by thawing of the cervix leads to lysis of the epithelial cells. With the double-freeze technique (freeze 3 minutes, thaw 5 minutes, freeze 3 minutes) with carbon dioxide or nitrous oxide, an ice ball forms that should extend 4 to 5 mm beyond the edges of the cryoprobe. Failures are more frequent with large lesions not covered completely by the probe, higher-grade lesions, and those that involve cervical glands the depth of which may be beyond the perimeter of the ice ball. This technique is not appropriate for lesions that extend into the endocervical canal. Cramping is common during the procedure. A watery discharge usually occurs for several weeks after therapy. Cervical stenosis may occur in as many as 5% of cases as the cervix heals, and the squamocolumnar junction frequently assumes an endocervical location.

LASER VAPORIZATION

Carbon dioxide lasers can be used to destroy dysplastic and HPV lesions and to perform cone biopsies. Vaporization is carried to a depth of 5 to 7 mm, which includes the gland crypts, and should extend beyond the colposcopic area of abnormality. The procedure, like cryosurgery, may be performed on an outpatient basis with local or regional analgesia and minimal cramping. Cervical stenosis occurs less frequently with this technique, and the squamocolumnar junction usually remains visible. The primary disadvantages of laser surgery for cervical dysplasia include the high cost and the lack of histologic specimens for analysis and confirmation (unless conization is performed).

ELECTROSURGICAL EXCISION

A loop electrosurgical excision procedure (LEEP), or large-loop excision of the transformation zone, has been used for excision of cervical lesions and for in-office cone biopsy. With the patient under local anesthesia, a thin wire loop connected to a generator is passed through cervical tissue to remove the entire transformation zone. A blend of cutting and coagulation current minimizes the bleeding complications, which occur in 1% to 2% of procedures. For additional hemostasis, the base of the site is cauterized. This procedure may destroy residual dysplastic cells that remain after excision and reduce recurrence. LEEP has become widely practiced. Because deeper endocervical tissue can be removed, this technique may replace operative conization in certain cases. The success of LEEP is directly related to the cost-effectiveness of the equipment compared with that of laser technology, to the availability of a histologic specimen produced with minimal cauterization artifact, and to ease of use and safety. Cervical stenosis is unusual (less than 1% of cases), and healing typically is associated with easy identification of the squamocolumnar junction.

HYSTERECTOMY

When childbearing has been completed, women with high-grade dysplasia may choose hysterectomy. The procedure also can be used to treat patients with recurrent disease or those with lesions not otherwise amenable to less invasive procedures. Even after "definitive" treatment with hysterectomy, surveillance for lower genital

tract dysplasia is important because of the field effect of intraepithelial and invasive neoplasia.

COST-EFFECTIVENESS

Economic issues are increasingly affecting patterns of care. The guidelines for management after abnormal findings are obtained at cytologic examination of the cervix are no exception. The appropriate interval between Pap smears is at the forefront of this debate. Data from Europe suggest that although screening decreases the incidence of cervical cancer, the benefit improves little as the interval between smears is shortened from 3 years to 2 years to 1 year (90.8%, 92.5%, 93.5%, respectively). This information comes from a population whose demographics differ from those in the United States, and it is predicated on complete compliance throughout the study population. Current guidelines from the ACOG remain those in [Table 209.1](#).

The algorithm in [Fig. 209.2](#) is under review on economic grounds. In an effort to reduce the expenditure on colposcopy and cervical biopsies, consideration is being given to evaluation with repeat cytologic smears only for low-grade lesions. A study by Flannely et al. cautioned against this plan. They reported a high prevalence of severe dysplasia among women whose initial Pap smear revealed only mild or moderate dysplasia.

“See and treat” is a proposed management plan for patients with an abnormal Pap smear. In one visit, colposcopy and LEEP are performed if dysplasia is confirmed by the colposcopic impression. The advantages of a reduced number of visits, fewer treatment failures due to lack of compliance, and elimination of the expense and delay from colposcopic biopsy are championed. Concerns about inappropriate use, excessive treatment of many women because of the stated inaccuracy of colposcopic impressions, and the potential long-term sequelae of more excisional procedures make this treatment option still investigational.

The cornerstone of optimal care with regard to cervical cancer screening is communication and education. Patients need to be informed about the indications for screening and subsequent treatment options. When abnormalities exist on a Pap smear, communication between the clinician and the cytopathologist may clarify ambiguities.

[Cost-Effectiveness](#)

PRESENTATION

Patients with cancer metastatic to bone may have disability from pain and loss of function caused by pathologic fractures or impending fractures through lytic lesions. The initial presentation usually is pain but may be the classic presentation of a fracture; the exact clinical manifestations depend on the site. Development of increasing bone pain in a patient with known cancer of a type that frequently produces lytic metastases in bone, such as breast cancer, renal cell cancer, lung cancer, or multiple myeloma, should suggest fracture. In contrast, although they have bone pain, patients with prostate cancer usually have blastic lesions in bone that are much less likely to fracture.

PATHOPHYSIOLOGY

Metastatic bone disease occurs most frequently in the axial skeleton and lower extremities, affects weight-bearing structures, and often limits activity. The bones most often affected by metastatic cancer include the vertebrae, pelvis, femur (especially the hip), and skull. The upper extremity is much less commonly involved (10% to 15% of cases). Despite the frequency of bony involvement by metastatic cancer, pathologic fractures requiring surgical intervention occur among only approximately 10% of patients with metastatic bone disease. However, such fractures are much more likely to occur in the weight-bearing bones.

The strength of a bone depends on the continuity of the cortex and on the underlying medullary structure. A lytic metastatic lesion of a long bone usually destroys the cortex and the underlying bone. Evaluations of the biomechanical strength of bone have shown that a defect the length of which is less than the diameter of the bone decreases strength 70%, but a defect larger than the diameter of the bone (most common) produces a 90% reduction in strength. Predictions of the types of lesions in long bones that will fracture are based on clinical factors such as anatomic site, pain pattern, type of lesion, and size of lesion ([Table 210.1](#)) and show an 81% risk for fracture in lesions larger than two-thirds of the diameter of the bone and greater risk in lower extremities than in upper extremities.

Variable	Score		
	1	2	3
Site	Upper limb	Lower limb	Peritrochanter
Pain	Mild	Moderate	Functional
Lesion	Blastic	Mixed	Lytic
Size ^a	<1/3	1/3-2/3	>2/3

^a In relation to the diameter of the bone.

TABLE 210.1. SCORING SYSTEM FOR PATHOLOGIC FRACTURES

HISTORY AND PHYSICAL EXAMINATION

The initial history is that of the events surrounding the fracture. Often there is no trauma, but the stress of normal activity leads to fracture through the weakened bone. A history of known malignant disease in such a patient, particularly one of the four types previously listed, should prompt a potential diagnosis of fracture, not just pain from bony involvement by tumor. Physical examination may reveal the classic findings of a hip fracture, obvious dislocation of a shoulder, or minimal alteration in structure, as in a patient with collapse of the thoracic vertebrae.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

Radiographs are the most useful studies for evaluating fractures. Computed tomography (CT) or magnetic resonance imaging (MR) sometimes help to differentiate progressive bone involvement from fracture. However, patients with a high likelihood of having cancer metastatic to bone should be examined periodically before symptoms occur to identify areas of involvement. These areas usually can be found with a bone scan followed by radiography of areas of increased isotope uptake. CT or MRI can be used to delineate the degree of bone destruction, particularly in the pelvis. In the case of myeloma, a bone survey is much more helpful than a bone scan, because the lack of osteoblastic reaction in this disease produces no areas of isotope uptake on a bone scan, but the usual lytic disease and osteoporosis are obvious on radiographs. Radiographs of patients with prostate cancer frequently demonstrate blastic rather than lytic lesions, and these are much less likely to cause fractures. Cancer antigen CA 27.29 is a tumor marker used in following metastatic bone disease from breast cancer; measurement of this marker can be useful in assessing response to therapy for bone disease.

DIFFERENTIAL DIAGNOSIS

If the chief symptom is sudden onset of bone pain with loss of function and clinical findings of fracture–dislocation, the diagnosis is based on examination and radiographic results. If the patient is known to have malignant disease, the fracture is almost certainly pathologic. If the patient has no known malignant disease, but the radiograph shows a lytic lesion and a fracture, biopsy or other evaluation is necessary to provide a tissue diagnosis. For a patient with less obvious physical findings but increasing bone pain, as in the back or pelvis, CT or MRI may be necessary to differentiate progressive bone disease or spinal cord compression from a fracture.

STRATEGIES FOR OPTIMAL CARE

MANAGEMENT

The role of surgical intervention in metastatic bone disease has increased because of improved orthopedic techniques and systemic treatment approaches to many of these tumors. Patients are living longer, and function must be maintained. The tumors that most commonly involve bone are also those that are most likely to heal after intervention with a combined-modality approach.

Newer materials such as polymethyl methacrylate (PMMA) function as bone cement and can be used to replace and stabilize large segments of abnormal bone. Because abnormal bone does not heal through a pathologic fracture, replacement with PMMA and external or internal fixation with metal hardware provides stabilization and time for healing. In many cases, irradiation may enhance bone healing in areas of normal bone surrounding the previous lesion. The technique curettage of tumor, defect filling with PMMA, and fixation is called *composite osteosynthesis*, and it is used to manage fractures of the long bones. The metal

component is a bone plate placed parallel to the bone and attached to normal bone with screws or an intramedullary rod that provides fixation of the healing cavity. These procedures are most commonly used to repair damaged long bones ([Fig. 210.1](#)).

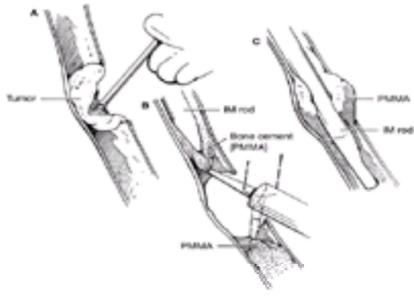

FIGURE 210.1. Diaphyseal reconstruction for metastatic cancer. Long bones (femur and humerus) with metastatic tumors of the shafts (diaphysis) are reconstructed by means of intramedullary (IM) rod fixation combined with application of polymethyl methacrylate (PMMA). **A:** Curettage of tumor. **B:** Placement of PMMA proximal and distal to the site of the tumor or fracture or both in addition to filling the tumor defect. **C:** Stable fixation depends on this combined fixation. Small diaphyseal tumors can be managed prophylactically with fluoroscopic control without opening of the fracture site.

With newer techniques and materials, it is possible to replace extensive bone involved with metastatic disease in the hip area, including hemijoint replacement, and provide enough support to allow walking. Depending on the site of tumor in the trochanteric region, other prosthetic devices may be used with PMMA. Lesions in the pelvis are managed with local irradiation and sometimes with embolization without surgery. These types of restorative approaches are particularly important because they allow rapid return of function without the disability of prolonged bed rest.

Vertebrectomy through anterior or posterior approaches to manage metastatic cancer in isolated vertebrae is becoming common; PMMA is used for replacement and rods for stabilization. Careful preoperative assessment makes this operation an alternative method to preserve function. Embolization of vertebral tumors followed by radiation therapy or surgery also has been effective in the short term. All such interventions eventually depend on the effectiveness of systemic treatment.

In breast cancer, treatment with systemic therapy (hormones or chemotherapy) frequently is beneficial for generalized bone disease. Irradiation usually is effective in treating patients with localized, painful lesions. Surgical management is indicated for pending or actual fractures, particularly in weight-bearing bones. For patients with breast cancer with bone-only disease, aggressive management of skeletal metastases is indicated to maintain function to the greatest degree possible over the course of several years. Bisphosphonates have been found to be effective in preventing new bone problems and in reducing the development of new lesions. This has been shown in breast cancer and myeloma, both diseases with generalized bony involvement. Prolonged treatment is indicated. The results for other bone-tropic tumors are not known.

Patients with renal cell cancer also are likely to have bony metastases, particularly in the pelvis and vertebrae. Surgical intervention is somewhat more difficult because of the location and because of the vascular nature of the tumor. In large pelvic tumors, vascular embolization sometimes is indicated to reduce blood flow, shrink the tumor, and obtain pain relief. Irradiation of this tumor is effective in about 50% of cases, and effective treatment promotes bone healing. The goals of managing bone disease are to maintain function as long as possible and to reduce pain. Surgical stabilization of lesions in weight-bearing bones usually is indicated to allow walking.

In lung cancer, skeletal metastases rarely lead to pathologic fractures, in part because bone lesions are fewer and usually are managed successfully with radiation therapy. Because of the blastic nature of the bone metastases in prostate cancer, fractures also are rare.

COMPLICATIONS AND PITFALLS

The most important complication of pathologic fractures among patients with metastatic cancer is permanent loss of function. Fractures can lead to medical problems that progressively impair function and disable the patient. Attempts to improve function with surgical intervention are not always successful, but risks and benefits must be assessed on a case by case basis, determined by each patient's clinical and functional status and the potential to relieve pain and suffering and maintain function.

Indications for HOSPITALIZATION

A patient with a new fracture of the lower extremity needs hospitalization to assess the extent of injury and to provide initial pain relief. If the decision is to pursue a surgical approach, an experienced orthopedic surgeon or neurosurgeon should be consulted.

COST-EFFECTIVENESS

As techniques improve and surgical morbidity lessens, the benefit of preventing and managing fractures among patients with otherwise good prognoses outweighs the risk of surgery. Aggressive assessment and maintenance of function become the goals in the management of bone metastases in keeping with the overall status of the patient's underlying disease. Even with limited intervention, there is opportunity to relieve pain and suffering. After appropriate intervention, patients with isolated fractures and an indolent course of disease may continue to function for years with abnormal bone lesions.

CHAPTER 211: APPROACH TO THE PATIENT WITH ANEMIA

THOMAS P. DUFFY

[Presentation and Pathophysiology](#)
[Differential Diagnosis](#)
[Strategies for Optimal Care](#)

PRESENTATION AND PATHOPHYSIOLOGY

Anemia is a reduction in normal red blood cell (RBC) mass within the body. It is found with measurement of the hematocrit and hemoglobin content of peripheral blood samples. Hematocrit was originally determined by means of centrifugation of a sample of whole blood within a capillary tube; the hematocrit represented the ratio of packed RBC volume to plasma volume within the tube after centrifugation. Alterations in either component affected the ratio, plasma volume changes elevating or depressing a stable red cell volume. Hematocrit now is derived from the calculated product of electronically generated values for RBC number and the average size or mean corpuscular volume (MCV) of the RBCs; the hemoglobin content of the same sample is measured with a chromogenic assay performed with the electronic counter.

Normal values have been established for these hematologic measurements through the study of large populations of healthy controls. The values vary according to atmospheric pressure and gender. Ambient oxygen pressure accounts for elevated RBC mass at high altitudes, and gender differences exist because of the contribution of androgens to erythropoiesis. The normal hematocrit for a man is $47\% \pm 7\%$, and that for a woman is $42\% \pm 5\%$. A lower hematocrit or a hemoglobin level less than 13.5 g per deciliter for men or 12 g per deciliter for women constitutes anemia unless there is disproportionate expansion in plasma volume. This circumstance occurs with the “physiologic” anemia or hydremia of pregnancy, in which an increase in plasma volume outdistances a parallel increase in RBC volume. Overexpanded plasma volume is the explanation for anemia for some athletes, and it contributes to the anemia associated with dysproteinemia and splenomegaly.

Finding the cause of anemia is grounded in a logical sequence derived from knowledge of the cycle of erythropoiesis within the body. RBC mass is kept constant by means of matching RBC production with destruction of senescent RBCs. The body's RBC mass is maintained within circumscribed limits by a negative-feedback stimulatory mechanism the set point of which responds to the oxygen tension of blood perfusing the kidneys. Erythropoietin (EPO), the critical humoral component in the loop, is a glycoprotein released from peritubular cells of the kidneys in amounts determined by the oxygen tension of blood. A fall in this level, whether caused by hypoxemia or by anemia, results in increased secretion of EPO in an attempt to increase RBC production to compensate for the reduced availability of oxygen. EPO directly stimulates the proliferation and differentiation of erythroid precursors, leading to erythroid hyperplasia of the bone marrow. The presence of the hormone accelerates release of increased numbers of young RBCs, or reticulocytes, from the marrow. The normal cycle of erythropoiesis requires coordination of EPO stimulation with the necessary precursor cells and building blocks in a conducive microenvironment to maintain production. Normal RBC structure and function determine the life span of an RBC. Lesions in any component of this cycle may cause anemia of variable severity.

If shortened RBC survival causes anemia, as occurs with bleeding or hemolysis, an intact EPO feedback mechanism causes increased secretion of EPO. The EPO surge leads to erythroid hyperplasia, amplification of the marrow erythroid pool, and release of increased numbers of reticulocytes from the marrow. Measurement of an elevated reticulocyte count identifies an insult outside the marrow as the source of anemia ([Table 211.1](#)). This elevated reticulocyte count indicates that the marrow is attempting to respond to a peripheral lesion that has caused anemia. An inadequate reticulocyte count implicates an abnormality within the marrow or EPO deficiency as the cause of the anemia. Because reticulocyte count allows a division of anemic states into the two broad categories of medullary or extramedullary causes, counting reticulocytes is an essential initial step in the evaluation of any patient with anemia ([Fig. 211.1](#)).

Characteristics	Lesion in the Marrow	Lesion outside the Marrow
Site of lesion	Stem cell disorders (e.g., aplasia, leukemia, myelodysplastic syndrome); building block disorders (e.g., Fe, B ₁₂ , folate deficiencies); erythropoietin deficiency	Blood loss; hemolytic; hypersplenism
Reticulocytosis ^a	Absent	Present
Type of anemia ^b	Hyporegenerative	Hyperregenerative

^a Absolute reticulocyte count is calculated as % reticulocytes \times red blood cell count, given in millions of cells/mm³. Reticulocytosis is defined as $>100,000/\text{mm}^3$.
^b Anemia is defined as a hematocrit less than 40% for men and less than 37% for women.

TABLE 211.1. HYPOREGENERATIVE AND HYPERREGENERATIVE ANEMIA

FIGURE 211.1. Algorithm for the approach to the care of a patient with anemia.
EVIDENCE LEVEL: C. Expert Opinion.

For an anemic patient with an elevated reticulocyte count, pursuit of the cause of this hyperregenerative anemia entails an investigation for evidence of hemolysis or bleeding. Because the final common pathway in all types of hemolytic anemia involves alterations in RBC structure, examination of a peripheral blood smear for any morphologic abnormalities is the single most important task in the diagnosis of hyperregenerative anemia. The focus in determining the cause of a reticulocytopenic or hyporegenerative anemia is the marrow, the presumed site of deficient production of RBCs. Bone marrow examination provides a window onto this aspect of erythropoiesis, although serum measurements of essential factors such as iron, folate, and vitamin B₁₂ may provide enough information to prove the existence of the lesion without a painful bone marrow examination. Radioimmunoassay can be used to measure EPO levels to complete the information necessary to address the cause of hyporegenerative anemia. A low EPO level in the presence of anemia indicates this humoral deficiency as a cause of the anemia.

A second broad categorization of anemia is based on the size of RBCs. This value is generated with a Coulter electronic counter as part of the standard blood count. On the basis of RBC size, anemia can be classified as microcytic (MCV less than 80 fL), macrocytic (MCV greater than 95 fL), or normocytic (MCV of 80 to 95 fL) ([Table 211.2](#)). The microcytic types of anemia originate in iron or hemoglobin deficiencies; most macrocytic anemia is caused by folate and vitamin B₁₂ deficiencies. The normocytic types of anemia have more heterogeneous origins; they include all types of hemolytic anemia and the EPO-deficient states. All types of anemia are initially normocytic, because the original normocytic RBC population outnumbers the burgeoning abnormal cell population and is only slowly diluted by abnormal cells

of a different size.

Microcytic Anemia (MCV < 80 fL)	Normocytic Anemia (MCV = 80 to 95 fL)	Macrocytic Anemia (MCV > 95 fL)
Iron deficiency Anemia of chronic disease Thalassemia Sideroblastic anemia	Initial stage of all types of anemia Erythropoietin deficiency Anemia of chronic disease Stem cell disorders Myelofibrotic anemia Endocrine disorders Dysproteinemia	Megaloblastic anemia Vitamin B ₁₂ or folate deficiency Myelodysplasia Purine or pyrimidine metabolism abnormalities Acromegaly Liver disease Hypothyroidism Reticulocytosis Red blood cell agglutination

MCV, mean corpuscular volume of erythrocytes.

TABLE 211.2. CATEGORIZATION OF ANEMIA ACCORDING TO SIZE OF RED BLOOD CELLS

An additional measurement generated by the electronic counter is RBC distribution width (RDW), a visual display of the range of RBC sizes. This is an important determination for patients with more than one population of RBCs, a circumstance that occurs after transfusion and in mixed-deficiency types of anemia. A combination of folate and iron deficiencies is a not uncommon cause of anemia during pregnancy and in alcoholic states; this mixed deficiency may generate a normal MCV although microcytic and macrocytic RBCs are present. The RDW allows recognition of this dual population of RBCs and the contribution of a mixed lesion to a normocytic anemia.

The electronic counter also measures white blood cell (WBC) and platelet counts as part of a complete blood cell count. Reduction in all three cell lines constitutes the condition called *pancytopenia*. This entity is caused by a defect in a shared precursor cell, such as a deficiency of stem cells in aplastic anemia or a lesion in nucleic acid metabolism in megaloblastic processes. Pancytopenia also may be caused by hypersplenism, a state in which an enlarged spleen prematurely removes cells from the peripheral blood. Recognition of anemia as a component of a more generalized process of pancytopenia necessitates recasting of the differential diagnosis to explain the trilineage reduction; a lesion in the stem cell usually is found in this situation.

The initial approach to the problem of anemia requires information derived from the electronic counter-generated complete blood cell count (hematocrit, hemoglobin level, MCV, WBC count, platelet count, RDW), reticulocyte count, and examination of a peripheral blood smear ([Fig. 211.1](#)). The reticulocyte count allows assignment of the anemia to a hyporegenerative or hyperregenerative process, that is, whether the cause is within or outside the marrow. The MCV of the RBCs is a second determinant that allows characterization of the anemia as microcytic, macrocytic, or normocytic anemia on the basis of cell size. These measurements dictate the evaluation necessary to identify the specific cause of anemia.

DIFFERENTIAL DIAGNOSIS

MICROCYTIC ANEMIA

All microcytic types of anemia involve a deficiency in hemoglobin synthesis within the developing RBC. Because hemoglobin production requires coordinated synthesis of heme and globin, deficiencies in either of these two components of hemoglobin may produce microcytic RBCs. Absolute lack of iron is the leading cause of deficient hemoglobin synthesis, although abnormalities in iron transport (e.g., anemia of chronic disease) or heme synthesis (e.g., sideroblastic anemia) also may cause a reduction in RBC hemoglobin content and size.

Differentiation of the varied causes of microcytic anemia is possible by means of direct inspection of marrow iron stores or measurement of serum iron indices. Because iron deficiency anemia does not occur until mobilization of marrow iron stores is complete, the absence of iron in a bone marrow specimen is the absolute determinant of iron deficiency anemia. Marrow stores of iron are paralleled by serum levels of ferritin, a storage form of iron that circulates in small amounts in the peripheral blood. Radioimmunoassay can be used to measure ferritin levels, which can substitute for the marrow examination in uncomplicated instances of iron deficiency anemia. Serum levels of iron and its transport protein, transferrin, also mirror the availability of iron for hemoglobin synthesis; a decrease in serum iron level and elevation of transferrin level to that associated with transferrin saturation of less than 15% are evidence that a deficiency of iron is rate limiting for hemoglobin synthesis.

All other causes of microcytic anemia represent deficient hemoglobin synthesis (sideropenic anemia) in the face of adequate to increased amounts of iron stores. In the anemia of chronic disease, the vector of iron delivery is directed away from its specific target of the developing RBC, and iron becomes closeted within reticuloendothelial cells. This reorientation of iron transport is a reaction to the effect of cytokines released in response to the challenge of infection, inflammation, or malignancy within the body. Iron-deficient erythropoiesis in the anemia of chronic disease represents a form of nutritional immunity in which a small amount of hemoglobin synthesis is sacrificed while invading microorganisms and malignant cells are deprived of iron, an essential nutrient for all cellular growth and proliferation. Iron indices in the anemia of chronic disease reveal a low serum iron level and a low transferrin level. Transferrin saturation also may be reduced, although not usually to levels as low as those associated with iron deficiency anemia. Serum ferritin level, a mirror of iron stores, is increased in the anemia of chronic disease and differentiates this form of microcytic anemia from iron deficiency anemia.

Iron accumulation characterizes the sideroblastic types of anemia. Iron accumulates on and around the mitochondria of developing RBCs within the marrow. All sideroblastic types of anemia share this morphologic feature, which requires bone marrow examination for identification. Iron accumulates in this location because sideroblastic types of anemia represent a defect in protoporphyrin ring synthesis, a multistep process that occurs in the mitochondria surrounding the nucleus of the developing RBC; this feature determines the “ringed” designation of this type of anemia, because the mitochondria are distributed in necklace-like manner around the nuclei of the RBCs.

Near-total saturation of transferrin with an elevated serum iron level occurs in sideroblastic types of anemia; elevated ferritin levels are additional evidence of this iron-overload state. Iron stains of the marrow readily show the ringed distribution of iron or siderotic granules around the erythroblast nucleus. The causes of these types of anemia include inherited deficiencies of enzymes essential in protoporphyrin ring synthesis and lesions resulting from toxins, such as alcohol, and drugs, such as chloramphenicol and isoniazid. Sideroblastic anemia is a component of myelodysplastic syndromes, which may presage an ultimate transformation into leukemia.

Another major cause of microcytic anemia, thalassemia, is a more prominent consideration when microcytic anemia occurs among persons of Mediterranean ancestry. Defective globin chain synthesis of various degrees determines the severity of this inherited form of faulty hemoglobin synthesis. Hemoglobin electrophoresis, family documentation of similar anemia, and globin chain synthesis ratios can help ascertain whether a person has this form of microcytic anemia.

The cause of a hypochromic microcytic anemia may be identified with a trial of iron therapy. When modest microcytic or normocytic anemia is found, correction of the anemia after ferrous sulfate administration confirms the role of iron deficiency in producing the anemia. The response of an iron-deficient patient to iron therapy is manifested initially in reticulocytosis that occurs 5 to 7 days after initiation of therapy. Measurement of ferritin before iron therapy provides an essential baseline value for iron stores that can be used to gauge replenishment of these stores.

Identification of iron deficiency as the source of anemia is only the initial step in managing the problem. This type of anemia commonly is caused by a malignant tumor; anemia may be the initial sign that unmasks a lesion, often in the gastrointestinal tract, that is still localized and potentially curable. A physician who discovers iron deficiency incurs the responsibility to investigate and define the source of blood loss that has produced the iron deficiency.

MACROCYTIC ANEMIA

Macrocytic anemia can be categorized according to the presence or absence of megaloblastic hematopoiesis; the latter condition is a morphologic manifestation of

nuclear–cytoplasmic asynchrony caused by a disorder in DNA synthesis in hematopoietic elements. Deficiencies in folate or vitamin B₁₂ metabolism are the most frequent causes of a megaloblastic state. Measurement of serum vitamin B₁₂ and RBC folate provides a means of documenting the contribution of these substances to macrocytic anemia (Fig. 211.1). Drugs such as zidovudine and methotrexate induce megaloblastic anemia by interfering with nucleic acid synthesis.

A megaloblastic lesion is not restricted to cells of the erythroid lineage alone, and involvement of all three cell lines within the marrow leads to varying degrees of pancytopenia in the peripheral blood. Disordered DNA synthesis causes markedly ineffective hematopoiesis; the involved cell lines self-destruct within the marrow. The marked elevation in serum lactate dehydrogenase levels that occurs in megaloblastic states is caused by this intramedullary death of hematopoietic precursor elements. Another characteristic of megaloblastic processes is an alteration in WBC structure. Hypersegmentation of polymorphonuclear cells is the earliest peripheral blood manifestation of a megaloblastic process. Examination of a peripheral blood smear for neutrophils containing more than five lobes is a critical component of the evaluation of macrocytic anemia.

Megaloblastic maturation is not restricted to vitamin deficiencies or to the effects of drugs. Inherited abnormalities in purine and pyrimidine metabolism also may compromise nucleic acid synthesis as a rare cause of megaloblastic anemia. Less pronounced megaloblastic transformation accompanies the myelodysplastic–myeloleukemic disorders in which alterations in nuclear function are attributable to acquired chromosomal or genetic abnormalities.

Megaloblastic types of anemia, especially those caused by folate or vitamin B₁₂ deficiency, are associated with the most exaggerated macrocytosis. An MCV of more than 115 fL usually is the result of a vitamin deficiency rather than of myelodysplasia. If a megaloblastic process is believed to be the cause of anemia, therapy with both vitamins should be initiated after measurement of baseline serum vitamin B₁₂ and RBC folate levels. Vitamin B₁₂ and folate should be administered until the specific deficiency is identified, because the morphologic alterations in hematopoiesis with vitamin B₁₂ and folate deficiency are indistinguishable from one another. Vitamin B₁₂ deficiency also causes a neurologic disorder characterized by the loss of vibratory and position sensation in the lower extremities, and such neurologic findings help to support the diagnosis of vitamin B₁₂ deficiency.

Nonmegaloblastic macrocytic types of anemia may have multiple causes. Liver disease, hypothyroidism, and alcoholism independent of any vitamin deficiency cause macrocytic anemia through poorly understood mechanisms that increase the RBC membrane surface. Because these macrocytic types of anemia do not involve the other hematopoietic elements, pancytopenia is not a feature, as it is in megaloblastic macrocytic states. Hypoplastic and aplastic types of anemia may produce a slight increase in MCV. Another cause of macrocytosis is the elevated reticulocyte count that accompanies hemolytic anemia. The elevation in MCV is explained by the increased size of the reticulocytes. Spurious macrocytosis often exists in the presence of cold agglutinins or cryoglobulins. These cold-reactive plasma proteins cause agglutination of RBCs in the electronic counter, producing a false reading of increased RBC size. Heating the blood sample helps unmask this contribution to macrocytosis.

NORMOCYTIC HYPOREGENERATIVE ANEMIA

Normocytic types of anemia with no compensatory reticulocytosis may be caused by a primary defect within the marrow or represent a secondary process from an absolute or functional deficiency of EPO. Renal disease is commonly complicated by anemia through the latter pathway, as is the anemia of chronic disease, which may be normocytic or microcytic, caused by cytokine-mediated suppression of the EPO pathway. Measurement of EPO may document the contribution of this deficiency to anemia, and a recombinant form of EPO is available to reverse the process.

Mature RBCs represent a final step in the differentiation that has its shared origin with WBCs and platelets in stem cells within the marrow. In aplastic and hypoplastic types of anemia, stem cell deficiencies give rise to a parallel reduction in peripheral counts. Selective elimination of erythroid precursors, as occurs with parvovirus infection of the marrow and immune disorders produces pure RBC aplasia. Infiltrative disorders of the marrow caused by tumor, infection, or fibrosis cause myelophthytic anemia, which has leukoerythroblastic blood features of teardrop-shaped RBCs and nucleated RBCs as well as some immature WBCs revealed on the peripheral blood smear. Malignant hematologic diseases also are complicated by normocytic anemia as the malignant process suppresses the production of normal marrow elements.

NORMOCYTIC HYPERREGENERATIVE ANEMIA

Hemolytic types of anemia are normocytic or slightly macrocytic if marked reticulocytosis is present. The two broad categories of hemolytic anemia are inherited and acquired (Table 211.3). An important clue to the presence of inherited hemolytic anemia is a family history of anemia or a history of chronic anemia. Lesions of the RBC membrane, abnormalities in the enzymatic pathways necessary for energy metabolism within the RBC, and defects in hemoglobin structure and function produce the inherited hemolytic types of anemia. The acquired forms are predominantly immune in origin, whereas RBC trauma is another mechanism of hemolysis (microangiopathic anemia). Infectious organisms may parasitize the RBC, as in malaria, or secrete substances that disrupt the RBC membrane, as in clostridial sepsis. Severe liver and kidney disease may be complicated by hemolytic anemia. Hypersplenism also leads to shortened RBC survival, often with leukopenia and thrombocytopenia.

Inherited Forms	Acquired Forms
Membrane abnormalities	Membrane abnormalities
Spherocytosis	Paroxysmal nocturnal hemoglobinuria
Pyruvate kinase deficiency	Spher cell anemia (e.g., liver disease)
Elliptocytosis	Immune hemolytic anemia
Elliptocytosis	Autoimmune hemolytic anemia
Hemoglobinopathies	Drug-induced anemia
Abnormal variants (e.g., hemoglobin S, C)	Immune hemolytic anemia
Defective synthesis (e.g., thalassemia)	Immune hemolytic anemia
Unstable hemoglobins	Immune hemolytic anemia
Red blood cell enzyme deficiencies	Immune hemolytic anemia
Glucose-6-phosphate dehydrogenase	Immune hemolytic anemia
Pyruvate kinase	Immune hemolytic anemia

TABLE 211.3. TYPES AND CAUSES OF HEMOLYTIC ANEMIA

The shortened RBC survival in hemolytic anemia can be quantified with chromium-labeling techniques that allow calculation of RBC half-life and document the role of the spleen in sequestering RBCs. More indirect evidence of hemolysis is the hyperbilirubinemia that often accompanies the excessive breakdown of RBCs by hemolysis. Hemolysis frequently is expressed in alterations of RBC structure. Examination of a peripheral blood smear still is the most important and productive pursuit in the evaluation of a patient with hemolytic anemia (Fig. 211.1).

Hyperregenerative anemia is not synonymous with hemolysis, because marrow that responds to bleeding or to administration of a missing nutrient displays reticulocytosis. Withdrawal of a toxin such as alcohol may be followed by reticulocytosis. The clinical setting in which reticulocytosis occurs strongly influences the importance of these contributions to anemia.

STRATEGIES FOR OPTIMAL CARE

Although laboratory findings define anemia, it is often only by integrating hematologic data with the clinical signs and symptoms and history that the correct diagnosis can be made. The family history, social and travel history, and history of occupational exposures may contain vital information and clues to the cause of anemia. Laboratory data from previous hospitalizations or examinations may help in placing a current episode of anemia into perspective. Anemia frequently is not the primary lesion but is a manifestation of an underlying disorder. Anemia often serves as a “sickness index” of the body that calls attention to the primary disorder and narrows the diagnostic possibilities on the basis of the type of anemia.

CHAPTER 212: APPROACH TO THE PATIENT WITH LEUKOPENIA

LAURENCE A. BOXER

[Presentation](#)
[Pathophysiology](#)
[History and Physical Examination](#)
[Laboratory Studies and Diagnostic Tests](#)
[Differential Diagnosis](#)
[Strategies for Optimal Care](#)
[Cost-Effectiveness](#)

Leukopenia is defined as a reduction in total white blood cell count to less than 4,000 cells per microliter. *Neutropenia* is an absolute blood neutrophil count (total leukocyte count per microliter multiplied by the percentage of neutrophils and bands) more than two standard deviations below the normal mean. Normal neutrophil levels should be stratified for age and race. For whites, the lower limit for normal neutrophil count is 1,500 cells per microliter, and it may reflect a reduction in neutrophils and lymphocytes. Blacks have somewhat lower neutrophil counts, and the lower limit of normal is approximately 1,200 cells per microliter. These relatively low counts among blacks probably reflect a relative decrease in neutrophils in the storage compartment of the bone marrow.

Individual patients may be characterized as having mild neutropenia with cell counts of 1,000 to 1,500 per microliter, moderate neutropenia with counts of 500 to 1,000 per microliter, or severe neutropenia with counts less than 500 per microliter. This stratification is useful in predicting the risk for infection, because only patients with severe neutropenia have increased susceptibility to life-threatening infections.

Normal lymphocyte count for adults is 1,000 to 4,900 cells per microliter. Approximately 80% of normal adult blood lymphocytes are CD3+ T lymphocytes, and almost two thirds of blood T lymphocytes are CD4+ (helper) T lymphocytes. Most patients with lymphocytopenia have reductions in the absolute number of T lymphocytes and reductions in numbers of CD4+ T lymphocytes in particular. The average absolute number of CD3+ T lymphocytes in normal adult blood is 1,800 per microliter, ranging from 1,000 to 2,300 per microliter. The average absolute number of CD4+CD3+ T lymphocytes is 1,100 per microliter, ranging from 300 to 1,300 per microliter. The average absolute number of cells of the other main T-cell subgroup, CD8+CD3+ T lymphocytes, is 600 per microliter, ranging from 100 to 900 per microliter. Lymphocytopenia is defined as a total lymphocyte count of less than 2,000 per microliter, but among children the lower limit of normal is less than 1,500 per microliter.

PRESENTATION

Persons with neutrophil counts lower than 500 per microliter are at substantially greater risk for infection, largely from their own endogenous flora, but colonization with various nosocomial organisms also occurs. Some patients with isolated chronic neutropenia with an absolute neutrophil count (ANC) of fewer than 200 cells per microliter do not have many serious infections, probably because the rest of the immune system remains intact. In contrast, patients with neutropenia caused by acquired disorders of production, such as patients receiving cytotoxic therapy, immunosuppressive drugs, or irradiation, particularly as management of malignant disease, are more likely to contract serious bacterial infections because the overall immune system is compromised.

Leukopenia associated with neutropenia and accompanied by monocytopenia and lymphocytopenia often is more serious than neutropenia alone. The integrity of the skin and mucous membranes, the vascular supply to tissue, and the nutritional status of the patient also influence risk for infection. The most frequently occurring types of pyogenic infections among patients with profound neutropenia cause a fever higher than 101°F, cutaneous cellulitis, abscesses (including liver), furunculosis, pneumonia, and septicemia. Stomatitis, gingivitis, perirectal inflammation, colitis, sinusitis, and otitis media also may occur.

Isolated neutropenia does not heighten a patient's susceptibility to parasitic, viral, or fungal infections or to bacterial meningitis. The most common pathogens isolated from patients with neutropenia are *Staphylococcus aureus* and gram-negative organisms. The usual signs and symptoms of local infection and inflammation, such as exudate, fluctuation, and regional lymphadenopathy, are generally less evident among patients with than among those without neutropenia because of the inability of a patient with neutropenia to form pus. However, the neutropenic patient can feel pain at a site of infection.

PATHOPHYSIOLOGY

Attempts have been made to classify neutropenia on a pathophysiologic basis, such as disorders of production, maturation, accelerated use, or a combination of these mechanisms. Unfortunately, kinetic methods of characterizing neutropenia are not sufficiently refined to allow unambiguous delineation. The neutropenic disorders are classified herein according to whether there appears to be an intrinsic defect in the myeloid progenitors or whether neutropenia is caused by factors extrinsic to marrow myeloid cells ([Table 212.1](#)).

Secondary Neutropenia Caused by Factors Extrinsic to Bone Marrow Myeloid Cells (Common Disorders)
Bone marrow replacement by malignant tumor, fibrosis, granuloma, Gaucher's cells
Neutropenia following irradiation, cytotoxic chemotherapy, or immunosuppression
Neutropenia associated with folate or vitamin B ₁₂ deficiency
Alcoholism
Infection
Autoimmune neutropenia
T _H lymphoproliferative disease
Drug-induced neutropenia
Hypersplenism
Neutropenia Arising from Intrinsic Defects in Myeloid Cells or Their Precursors (Rare Disorders)
Cyclic neutropenia
Severe congenital neutropenia (Kostmann's syndrome)
Idiopathic neutropenia including benign neutropenia
Neutropenia associated with dysgranulopoiesis
Syndrome-associated neutropenia (e.g., Shwachman-Diamond syndrome, cartilage hair hypoplasia, Chediak-Higashi syndrome, spherulosis congenita, glycogen storage disease type 1b)
Myelodysplasia
Paroxysmal nocturnal hemoglobinuria

TABLE 212.1. CLASSIFICATION OF NEUTROPENIA

Acute neutropenia often develops when there is rapid neutrophil use and impaired production. Cytotoxic drugs are particularly likely to induce neutropenia because of the high proliferative rate of neutrophil precursors and the rapid turnover of blood neutrophils. Chronic neutropenia usually arises from reduced production or excessive splenic sequestration of neutrophils.

HISTORY AND PHYSICAL EXAMINATION

Evaluation begins with a thorough clinical history to establish the onset of neutropenia; the type, frequency, and severity of infections; drug, animal, or toxic exposures; and family history of recurrent infection or unexplained infantile deaths. The examiner also assesses the locations of infections and complications of these infections, the means by which infections were documented, the presence or absence of a symptom-free interval, including febrile episodes, the microbiologic report on any isolates, and the response to antibiotic therapy.

The physical examination may provide clues to the basis of the underlying condition that predisposes the patient to recurrent infections. Height and weight measurements of children are essential to identify failure to thrive or recent weight loss. Other important physical findings include scarred tympanic membranes and postnasal drip or cervical adenopathy, which suggests chronic respiratory infection. Recurrent cough, wheezing, or chest deformity suggests pulmonary disease. Lymphadenopathy, hepatosplenomegaly, pallor, wasting, or recent weight loss suggest systemic disease. Gingivitis and oral ulcers often accompany chronic neutropenia. Documentation of fever is important, but taking the rectal temperature of a patient with neutropenia should be avoided to avoid injury to the rectal

mucosa and spread of bacteria to the circulation.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

In the appropriate setting, the diagnosis of neutropenia is not difficult. Isolated absolute neutropenia has a limited number of causes ([Table 212.1](#)). The duration and severity of neutropenia greatly influence the extent of laboratory evaluation. Patients with chronic neutropenia since infancy and a history of recurrent fever and chronic gingivitis should have white blood cell counts and differential counts obtained three times a week for 6 weeks to evaluate the periodicity that suggests cyclic neutropenia. Bone marrow aspiration and biopsy should be performed on selected patients to aid in diagnosis and to assess cellularity. Additional marrow studies, such as cytogenetic analysis and special stains for detecting leukemia and other malignant disorders, should be performed for patients who might have intrinsic defects in myeloid cells or their progenitors and for patients who might have malignant disease. Selection of additional laboratory tests is based on the duration and severity of neutropenia and the findings at physical examination ([Fig. 212.1](#)).

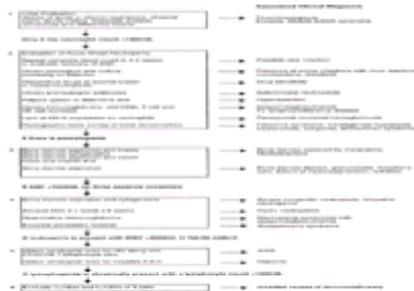

FIGURE 212.1. Algorithm for the evaluation of a patient with leukopenia. ANC, absolute neutrophil count; WBC, white blood cell count.

EVIDENCE LEVEL: B. Reference: Dr. Laurence A. Boxer. Guidelines for evaluation for patients with neutropenia: Severe Chronic Neutropenia International Registry Guidelines.

The presence of antineutrophil antibodies is associated with immune neutropenia. A variety of known neutrophil antibody assays have been used to evaluate suspected autoimmune neutropenia, but all assays directly measure antibody on the patient's own neutrophils or indirectly measure antibody in the patient's serum.

DIFFERENTIAL DIAGNOSIS

NEUTROPENIA CAUSED BY FACTORS EXTRINSIC TO MARROW MYELOID CELLS

Secondary neutropenia is caused by factors extrinsic to bone marrow myeloid cells.

BONE MARROW REPLACEMENT

Bone marrow replacement with leukemia, myeloma, lymphoma, or metastatic solid tumors (e.g., breast, prostate) that infiltrate the bone marrow may produce leukoerythroblastic peripheral blood smears. Tumor-induced myelofibrosis may further accentuate the neutropenia. Myelofibrosis also can be caused by granulomatous infection, Gaucher's disease, or radiation therapy.

NUTRITIONAL DEFICIENCIES

Neutropenia is an early and consistent feature of megaloblastic anemia caused by vitamin B₁₂ or folate deficiency, although it is usually accompanied by macrocytic anemia and sometimes by mild thrombocytopenia. Alcohol may suppress the marrow and inhibit the response of the marrow to infection when patients have diseases such as pneumococcal pneumonia. Mild neutropenia can occur among patients with anorexia nervosa, but neutropenia is generally not a feature of kwashiorkor or starvation.

INFECTION

Transient neutropenia is commonly caused by viral infection ([Table 212.2](#)). Neutropenia associated with common childhood viral illnesses develops during the first 1 to 2 days of illness and may persist for 3 to 8 days. This usually corresponds to the period of acute viremia and may be related to virus-induced redistribution of neutrophils from the circulating to the marginating pool. Sequestration or increased neutrophil use after tissue damage by the viruses also may occur. Acute transient neutropenia often occurs during the early stages of infectious mononucleosis.

Bacterial	Rickettsial
Typhoid fever	Rocky Mountain spotted fever
Paratyphoid fever	Typhus fever
Tuberculosis (disseminated)	Rickettsial pox
Brucellosis	Fungal
Tuberculosis	Histoplasmosis (disseminated)
Gram-negative sepsis	Protozoal
Viral	Malaria
Infectious hepatitis	Leishmaniasis (kala-azar)
Infectious mononucleosis	
Influenza	
Measles	
Rubella	
Roseola	
Varicella	
Respiratory syncytial virus	
Dengue fever	
Colorado tick fever	
Yellow fever	
Sand-fly fever	
Plague	
Cholera	
Cytomegalovirus	
Lymphocytic choriomeningitis virus	
Human immunodeficiency virus, type 1	

TABLE 212.2. INFECTIONS ASSOCIATED WITH NEUTROPENIA

Chronic neutropenia often accompanies infection with HIV-1 associated with AIDS. Neutropenia associated with AIDS arises from a combination of impairment of neutrophil production and the accelerated destruction of neutrophils by antibodies. Neutropenia also may be associated with bacterial, protozoal, rickettsial, and severe fungal infections. Sepsis is a particularly serious cause of neutropenia.

DRUG EFFECTS

Drugs can induce severe neutropenia through immune, toxic, or hypersensitivity reactions ([Table 212.3](#)). Drug-induced neutropenia should be differentiated from that associated with viral infection and from the severe neutropenia that occurs after administration of large doses of cytotoxic drugs or after radiation therapy. Drug-induced neutropenia may be asymptomatic despite the presence of absolute neutropenia, especially among patients whose blood cell counts are regularly monitored during drug therapy. The annual incidence of drug-induced neutropenia is 3.4 cases per 1 million persons. The incidence of drug-induced neutropenia rises precipitously with age; only 10% of cases occur among children and young adults, and more than 50% of cases develop among older persons. Idiosyncratic reactions are unpredictable and occur with administration of drugs such as chloramphenicol.

Characteristic	Immune Form	Toxic Form	Hypersensitivity Form
Analgesic drug	Aspirin, propylthiouracil, penicillin	Phenothiazine	Penicillin, phenobarbital
Time to onset	Days to weeks	Weeks to months	Weeks to months
Clinical appearance	Acute, often explosive system	Often asymptomatic or indolent onset	May be associated with fever, rash, lymphadenopathy, hepatitis, nephritis, pneumonitis, or aplastic anemia
Rechallenge	Prone to recur with small test dose	Latent period, high doses required	Latent period, high doses required
Laboratory findings	Antibody test results positive	Evidence of direct toxicity to cells	Evidence of metabolic-mediated damage to cells

TABLE 212.3. IMMUNE, TOXIC, AND HYPERSENSITIVITY-MEDIATED NEUTROPENIA

Clinical observation and laboratory studies have suggested that drug-induced neutropenia has at least three underlying mechanisms. Acute hypersensitivity drug reactions may last for only a few days, but chronic idiosyncratic reactions may last for months or years. Immune-mediated neutropenia usually lasts for 1 week. After neutropenia occurs, the most important therapeutic measure is withdrawal of all drugs that are not essential, particularly drugs that might be myelotoxic.

Immune neutropenia is associated with the presence of circulating antineutrophil antibodies and may occur in isolation or with associated disease ([Table 212.4](#)). The antibodies may mediate neutrophil destruction by means of complement-mediated lysis or splenic phagocytosis of opsonized neutrophils. Antineutrophil antibodies cause transfusion reactions and may cause a variety of neutropenic disorders in later life. Lymphoproliferative neutropenia may be associated with the presence of circulating large granular lymphocytes (suppressor Tg cells). Because reliable methods to measure neutrophil-specific antibodies or to assess neutrophil survival in vivo have been difficult to develop, the pathophysiologic and clinical importance of these antibodies among patients who might have an immune disorder frequently remains unclear.

Systemic lupus erythematosus
 Seropositive rheumatoid arthritis
 Felty's syndrome
 Sjogren's syndrome
 Immune thrombocytopenic purpura
 Coombs'-positive autoimmune hemolytic anemia
 Chronic active hepatitis
 Hypogammaglobulinemia
 Dysgammaglobulinemia (hyper IgM)
 Lymphoproliferative disease
 Graves' disease
 Hashimoto's thyroiditis
 Cyclical neutropenia and T_H lymphocytosis
 Infectious mononucleosis
 Hodgkin's disease
 Pure white cell aplasia

TABLE 212.4. AUTOIMMUNE NEUTROPENIA

Splenic enlargement is associated with a variety of disorders (see [Chapter 202](#)). The neutropenia often is accompanied by moderate thrombocytopenia and anemia. In some cases, splenectomy may be necessary to restore neutrophil count to normal, but splenectomy predisposes the patient to infection by encapsulated organisms and should be used sparingly in treating neutropenic patients.

INTRINSIC DEFECTS IN MYELOID PROGENITORS

Neutropenia uncommonly is caused by intrinsic defects in myeloid cells or their progenitors.

CONGENITAL NEUTROPENIA

Cyclic neutropenia is a rare congenital granulopoietic disorder. It may be inherited in an autosomal dominant manner and is characterized by regular, periodic oscillations in the number of peripheral neutrophils from normal to neutropenic values. The mean oscillatory period is 21 ± 3 days. During the neutropenic phase, most patients have oral ulcers, stomatitis, or pharyngitis associated with lymph node enlargement. Serious infections occur occasionally and may lead to pneumonia, recurrent ulceration of the oral, vaginal, and rectal mucosa, and death. Pneumonia and chronic periodontitis often occur, and sepsis may arise from *Clostridium perfringens* infection. Cyclic neutropenia arises from a regulatory abnormality involving early hematopoietic precursor cells, but the exact nature of the defect remains unknown.

Severe congenital neutropenia, also called *Kostmann's syndrome*, is a rare disorder characterized by an arrest in myeloid maturation at the promyelocyte stage of the bone marrow, resulting in an ANC of less than 200 cells per microliter. In the United States, this disorder occurs sporadically. Patients typically have monocytosis and eosinophilia. Beginning in early infancy, they have recurrent, severe pyogenic infections, especially of the skin, mouth, and rectum. Platelet count is normal, and these patients typically have anemia associated with chronic inflammatory disease. With supportive therapy alone, only a few patients with severe congenital neutropenia have survived to adolescence. Sixteen percent of patients now treated with granulocyte colony-stimulating factor (G-CSF) have had acute myelogenous leukemia or myelodysplasia associated with monosomy 7 and revealed at cytogenetic analysis of the bone marrow.

CHRONIC IDIOPATHIC NEUTROPENIA

Chronic idiopathic neutropenia is a group of uncommon, poorly understood disorders involving committed stem cells of the myeloid series. Normal numbers of red cell and platelet precursors are present. The monocyte count often is moderately elevated. There is no splenomegaly. The degree of susceptibility to infection associated with chronic idiopathic neutropenia is roughly proportional to the blood neutrophil count, and patients with an ANC less than 500 cells per microliter are more susceptible to infection. Bone marrow examination shows a spectrum of abnormalities from normal cellularity to selective hypoplasia of the neutrophilic series. Neutropenia can be caused by bone marrow failure, as in rare syndrome-associated processes ([Table 212.1](#)). Neutropenia also is a prominent feature of myelodysplasia and is accompanied by megaloblastoid features in the bone marrow (see [Chapter 230](#)).

HEREDITARY AND ACQUIRED LYMPHOCYTOPENIA

Inherited causes of lymphocytopenia may be associated with inherited immunodeficiency diseases ([Table 212.5](#)). Inherited immunodeficiency disorders may be accompanied by a quantitative or qualitative stem cell abnormality that causes ineffective lymphocytopoiesis. Other conditions, such as Wiskott–Aldrich syndrome, may be accompanied by lymphocytopenia arising from accelerated destruction of T cells. A similar mechanism is present in patients with adenosine deaminase deficiency and purine nucleoside phosphorylase deficiency.

Acquired Causes
 Infectious diseases including AIDS, hepatitis, influenza, tuberculosis, typhoid fever, and sepsis
 Iatrogenic conditions after administration of immunosuppressive therapy, glucocorticoids, high-dose PUVA therapy, cytotoxic chemotherapy, irradiation, and thoracic duct drainage
 Systemic disease associated with autoimmune diseases, including systemic lupus erythematosus, myasthenia gravis, Hodgkin's disease, protein-losing enteropathy, renal failure, sarcoidosis, thermal injury, and aplastic anemia
 Dietary deficiency associated with ethanol abuse and zinc deficiency

Inherited Causes
 Aplasia of lymphopoietic stem cells
 Severe combined immunodeficiency associated with defect in IL-2 receptor γ -chain, deficiency of ADA or PNP, or unknown
 Ataxia telangiectasia
 Wiskott–Aldrich syndrome
 Immunodeficiency with thymoma
 Cartilage-hair hypoplasia
 Idiopathic CD4⁺ T lymphocytopenia

ADA, adenosine deaminase; PNP, purine nucleoside phosphorylase; IL-2, interleukin-2; PUVA, psoralen and ultraviolet A irradiation.

TABLE 212.5. CAUSES OF LYMPHOCYTOPENIA

Acquired lymphocytopenia defines syndromes associated with depletion of blood lymphocytes that are not caused by inherited diseases. AIDS is the most common infectious disease associated with lymphocytopenia. The lymphocytopenia is caused by destruction of CD4⁺ T cells infected with HIV-1 or HIV-2. Lymphocytopenia also may reflect impaired lymphocyte production and proliferation caused by destruction of the normal thymic or lymphoid architecture. Patients with AIDS or inherited dysfunction of lymphocytes have recurrent infections. They often have unusual responses to usually benign infectious agents, or they have infections with unusual organisms. *Pneumocystis carini* infection, cytomegalovirus infection, rubeola, and varicella often cause fatal pneumonia among these patients. Pneumonitis with any of these agents should suggest a potential immunodeficiency. These patients also have a higher incidence of malignant disease and autoimmune disorders. Other viral and bacterial diseases may be associated with lymphocytopenia ([Table 212.5](#)). In some instances of acute viremia, lymphocytes may undergo accelerated destruction from active infection with the virus, may be trapped in the spleen or nodes, or may migrate to the respiratory tract.

IATROGENIC AND AUTOIMMUNE LYMPHOPENIA

Iatrogenic lymphopenia is caused by cytotoxic chemotherapy, radiation therapy, and the administration of antilymphocyte globulin. During long-term treatment of patients with psoriasis with psoralen and ultraviolet irradiation, T lymphocytes may be destroyed. Glucocorticoids can cause lymphopenia through induced cell destruction. Systemic diseases associated with autoimmunity may lead to lymphocytopenia. These include systemic lupus erythematosus, rheumatoid arthritis, and myasthenia gravis. Conditions such as protein-losing enteropathy may be associated with lymphocyte depletion. An algorithm for the evaluation of a patient with leukopenia, neutropenia, or lymphopenia is presented in [Fig. 212.1](#).

STRATEGIES FOR OPTIMAL CARE

MANAGEMENT

The management of acquired, transient neutropenia characteristically associated with malignant disease, myelosuppressive chemotherapy, or immunosuppressive therapy differs from that of congenital or chronic forms of neutropenia. Among patients with acquired neutropenia, infection sometimes heralded only by fever is a leading cause of death. The clinician therefore must have a high index of suspicion. Early recognition and management of infection may be lifesaving.

Therapy for chronic neutropenia is dictated by the patient's history. For patients with benign neutropenia, including those with neutropenia after an acute viral illness without evidence of repeated bacterial infection or chronic gingivitis, no specific therapy is needed. For patients with life-threatening infection, broad-spectrum intravenous antibiotics should be started promptly.

Recombinant technology has produced effective therapy for severe congenital neutropenia, chronic symptomatic idiopathic neutropenia, and cyclic neutropenia. A randomized, controlled trial involving patients with severe chronic neutropenia in which recombinant human G-CSF (rhG-CSF) was administered subcutaneously at dosages ranging from 3.4 to 11.50 μg per kilogram per day, dramatic increases in neutrophil counts occurred among patients with these disorders, resulting in marked attenuation of infection and inflammation. Recombinant human G-CSF also has been used successfully in the treatment of some patients with drug-induced neutropenia whose neutrophil count did not increase after cessation of the offending drug.

The management of chronic autoimmune neutropenia is dictated by the patient's medical history. Many patients with autoimmune neutropenia have associated diseases or have drug-associated antibodies. Among patients with more severe neutropenia (less than 500 cells per microliter), infection may become an increasing problem. They often respond to prednisone (60 to 100 mg per day). A modest increase in blood neutrophil count occurs within 1 to 2 weeks after the initiation of therapy. The prednisone should be administered daily, followed in 1 month by alternate-day steroid therapy at a reduced dose (e.g., 20 to 30 mg per day). For patients with autoimmune neutropenia who have not had success with glucocorticoid therapy, results of several uncontrolled studies have shown responses with cytotoxic drugs such as cyclophosphamide, azathioprine, or vincristine, intravenous γ -globulin therapy, and plasmapheresis. The approach to the treatment of patients with Felty's syndrome remains controversial. Splenectomy has been the mainstay of therapy, but the ANC commonly increases only temporarily. Fortunately, some patients with Felty's syndrome have responded to rhG-CSF.

COMPLICATIONS AND PITFALLS

All of the long-term effects of rhG-CSF therapy remain unknown, but they do include a propensity for development of moderate splenomegaly. Some patients who have preleukemia disorders, such as severe congenital neutropenia and Shwachman–Diamond syndrome, while receiving rhG-CSF have had myelodysplasia or acute myelogenous leukemia. Such patients should be monitored with frequent blood counts and annual bone marrow cytogenetic analyses. If patients with preleukemia disorder do eventually have myelodysplasia or acute myelogenous leukemia, bone marrow transplantation is the only effective treatment. On a short-term basis, administration of rhG-CSF has been associated with elevation of serum lactate dehydrogenase, uric acid, and alkaline phosphatase levels. Some patients have had transient erythematous rashes, alopecia, thrombocytopenia, and vasculitis. These clinical complications resolved promptly after cessation of rhG-CSF therapy. Twenty percent of patients receiving rhG-CSF before the increase in the circulating neutrophil count have bone pain, which presumably reflects myeloid expansion. The pain is easily relieved with nonsteroidal anti-inflammatory drugs and usually lasts only 1 day.

Indications for HOSPITALIZATION

Patients with acute neutropenia (less than 500 cells per microliter) who are immunosuppressed should be hospitalized at the onset of fever (temperature greater than 38.2°C) and treated with broad-spectrum antibiotics after the diagnostic evaluation for the source of the fever (see [Chapter 267](#)). Patients with chronic neutropenia who have life-threatening infections also should be hospitalized and treated with broad-spectrum antibiotics. A patient with chronic neutropenia with a superficial infection or low-grade fever can be treated with oral antibiotics outside the hospital.

Indications for REFERRAL

All patients with chronic neutropenia who might have an intrinsic disorder of the myeloid or precursor cells should undergo bone marrow and cytogenetic analyses by a hematologist. A patient with severe congenital neutropenia found to have myelodysplasia or a cytogenetic abnormality is best treated by a hematologist. Patients with autoimmune neutropenia who do not respond to glucocorticoids also are probably best treated by a hematologist.

COST-EFFECTIVENESS

Therapy with rhG-CSF has proved to be cost-effective in the treatment of patients with severe congenital neutropenia or cyclic neutropenia, because these patients have fewer hospitalizations and need reduced amounts of intravenous antibiotics. Therapy with rhG-CSF is not cost-effective for patients with idiopathic neutropenia if the primary benefit is to prevent recurrent mouth ulcers and gingivitis. For many patients with idiopathic neutropenia, rhG-CSF can be administered every other day.

Therapy with rhG-CSF should be used primarily for patients with chronic neutropenia who have symptoms and have had recurrent infections.

CHAPTER 213: APPROACH TO THE PATIENT WITH THROMBOCYTOPENIA

DOUGLAS B. CINES

[Pathophysiology](#)
[History and Physical Examination](#)
[Laboratory Studies and Diagnostic Tests](#)
[Differential Diagnosis](#)
[Strategies for Optimal Care](#)

Advances in medical technology over the past two decades have markedly increased the frequency with which thrombocytopenia is detected. This has meant changes in both the typical presentation and the relative prevalence of predisposing disorders. Twenty years ago, thrombocytopenia, often severe, was typically diagnosed when a patient had bleeding. Today, with platelets included in automated blood cell counting, it is far more common for mild to moderate thrombocytopenia to be detected as an incidental finding, especially among patients admitted to a hospital for other conditions. Thus thrombocytopenia often is a clue to an underlying medical disorder in addition to being a risk factor for bleeding.

When it does occur, bleeding due to thrombocytopenia usually begins in the skin or mucous membranes. Spontaneous bleeding is rare at platelet counts greater than 30,000 per microliter. Risk for bleeding increases as the platelet count falls below 20,000 per microliter, at which point patients may begin to bruise easily. Spontaneous bruising and petechiae, generally starting in dependent areas, gingival bleeding after brushing, menorrhagia, and epistaxis become progressively more common if platelet count falls below 10,000 to 20,000 per microliter. At platelet counts less than 5,000 per microliter, persistent gastrointestinal bleeding may occur, and there is risk for spontaneous intracranial hemorrhage. Bleeding may occur at higher platelet counts when qualitative platelet defects, such as those caused by medications that impair platelet function, have been superimposed or when underlying anatomic defects that predispose to bleeding are present.

PATHOPHYSIOLOGY

Physiologic recruitment of platelets to sites of bleeding (see [Chapter 218](#)) does not by itself cause thrombocytopenia, because the bone marrow can increase platelet production about fivefold in otherwise healthy persons. Thrombocytopenia develops when there is a disequilibrium between platelet production, distribution, and destruction. This conceptual approach to understanding platelet function also provides a convenient means to categorize the disorders that cause thrombocytopenia.

IMPAIRED PLATELET PRODUCTION

Platelets are formed when the cytoplasm of mature megakaryocytes undergoes fragmentation. Megakaryocytes develop from pluripotent stem cells under the coordinate influence of several soluble peptides, including c-Mpl ligand (thrombopoietin) and interleukin-3, -6, -11, and possibly others (see [Chapter 256](#)). Conditions that cause physical or toxic injury to the megakaryocytes or their progenitors, that consume requisite growth factors, or that disrupt their interaction with the marrow stroma and vasculature may impair platelet production ([Table 213.1](#)). Examples include chemotherapy, ethanol ingestion, exposure to radiation, and viral infection (e.g., HIV, parvovirus) that can propagate within these cells. Platelet production is impaired in some patients with pernicious anemia or folate deficiency, in clonal disorders such as myelodysplasia and paroxysmal nocturnal hemoglobinuria, and in some congenital thrombocytopenic conditions, including those characterized by the production of abnormally large or small platelets.

Acquired
Marrow infiltration: metastatic cancer, hematologic malignant disease (e.g., leukemia, lymphoma, myeloma), myelofibrosis, Gaucher's disease, granulomatous processes, others
Aplastic anemia (idiopathic or immune), chemotherapy, radiation therapy
Amegakaryocytic thrombocytopenia (autoimmune; drug-induced, including chemotherapy, alcohol, thiazides; myelodysplasia; viral [e.g., congenital rubella, parvovirus infection, HIV infection])
Ineffective thrombopoiesis: folate and vitamin B₁₂ deficiency; paroxysmal nocturnal hemoglobinuria; myelodysplasia and other clonal hematologic disorders; iron deficiency (rare)
Congenital
Normal-size platelets: thrombocytopenia with absent radius, Wiskott-Aldrich syndrome and variants, miscellaneous autosomal dominant and recessive syndromes
Giant platelets: Bernard Soulier syndrome, May-Hegglin anomaly; Alport's syndrome and variants, miscellaneous types of autosomal dominant macrothrombocytopenia

TABLE 213.1. THROMBOCYTOPENIA DUE TO DECREASED PLATELET PRODUCTION

INCREASED PLATELET POOLING

About one-third of platelets exist in the splenic circulation, from which they emerge without discernible impairment of function. The size of this pool is roughly proportional to that of the spleen itself. Any disorder that causes clinically detectable splenic enlargement may reduce the number of circulating platelets. However, the life span of these platelets is not necessarily lessened, and bleeding is uncommon. In contrast, platelet clearance within the spleen may be accelerated in some of these conditions as well, a situation known as *hypersplenism*. It remains unclear why platelets are prematurely removed in hypersplenic conditions or why erythrocytes and leukocytes often are spared. The causes of splenomegaly and hypersplenism are considered in [Chapter 202](#).

INCREASED PLATELET DESTRUCTION

It is convenient to divide the causes of platelet destruction into immunologic and nonimmunologic disorders ([Table 213.2](#)).

Immune Platelet Destruction
Autoimmune thrombocytopenia
Idiopathic (occasionally accompanied by autoimmune hemolytic anemia)
Secondary autoimmune thrombocytopenia (e.g., chronic lymphoblastic leukemia, systemic lupus erythematosus, thyroid dysfunction, hypogammaglobulinemia, antiphospholipid syndrome, bone marrow transplantation)
HIV infection**
Drug-dependent immune thrombocytopenia
Posttransfusion purpura
Sepsis**
Neonatal autoimmune thrombocytopenia
Nonimmunologic Platelet Destruction
Disseminated intravascular coagulation
Cardiopulmonary bypass surgery
Sepsis**
Thrombotic thrombocytopenic purpura or hemolytic-uremic syndrome
Preeclampsia
Acute or hyperacute allograft rejection
Hemophagocytic syndrome* (postinfectious, neoplastic)
Hypersplenism
** Multifactorial thrombocytopenia due to decreased production and increased destruction involving both immunologic and nonimmunologic factors.

TABLE 213.2. THROMBOCYTOPENIA DUE TO INCREASED PLATELET DESTRUCTION

Immunologic Factors

Platelets can become the target of autoantibodies, alloantibodies, or immune complexes. In idiopathic autoimmune thrombocytopenia (ITP), platelets are sensitized by

autoantibodies directed to one or more cell-specific glycoprotein complexes, such as IIb/IIIa or Ib/IX/V. ITP is most common among children. Most patients are otherwise healthy, but ITP occurs with increased frequency among patients with systemic lupus erythematosus, primary antiphospholipid syndrome, chronic lymphocytic leukemia, hypogammaglobulinemia, and thyroid dysfunction, among others. Platelets coated with IgG antibodies are recognized by specific receptors expressed by tissue macrophages, leading to their internalization and destruction. Some antibodies also may bind to megakaryocytes, impeding a compensatory increase in platelet production. During pregnancy, IgG autoantibodies can cross the placenta and cause transient neonatal thrombocytopenia.

Posttransfusion purpura (PTP) is a rare disorder that affects primarily multiparous women or persons who have received previous transfusions. Affected persons have profound thrombocytopenia 1 to 2 weeks after exposure to a blood product containing platelet antigens that they lack, most commonly in the form of soluble antigens in the plasma that accompanies packed erythrocytes. PTP may be mediated by alloantibodies that destroy both the transfused platelets and, through undefined mechanisms, the host's platelets. Binding of immune complexes to platelets may accelerate platelet destruction in some patients with bacterial sepsis, during certain systemic viral infections, and after exposure to drugs such as heparin.

Nonimmunologic Factors

Platelets may be cleared more rapidly when they are activated or when macrophage function is stimulated. Such activation may initiate translocation of normally cryptic determinants (e.g., anionic phospholipids) to the cell surface, which can be recognized by macrophages. In disseminated intravascular coagulation (DIC), platelets are activated by thrombin and by traversing fibrin clots in the microcirculation. Platelets become activated at the interface between blood and artificial surfaces during cardiopulmonary bypass. In sepsis, activation may be caused by immune complexes or soluble microbial products. In thrombotic thrombocytopenic purpura (TTP), hemolytic-uremic syndrome (HUS), preeclampsia, and hyperacute allograft rejection, platelets may be activated as a result of endothelial cell injury. Seemingly normal platelets (as well as erythrocytes and granulocytes) may be subject to phagocytosis by splenic macrophages in hypersplenic conditions and in hemophagocytic syndrome, in which it is presumed that macrophages are "activated" by excessive production or an exuberant response to cytokines.

HISTORY AND PHYSICAL EXAMINATION

A directed history interview should establish the severity and duration of bleeding if present, identify anatomic lesions that may be predisposed to bleed, identify the presence of comorbid conditions known to cause thrombocytopenia, and include or exclude known causes of thrombocytopenia. Bleeding caused by thrombocytopenia ranges in onset, distribution, and severity from chronic, localized, and mild to acute, generalized, and profound. Bleeding may be superimposed on the clinical features of numerous other disorders (considered elsewhere).

Although most patients seek medical attention within days of the onset of bleeding, it is by no means uncommon for patients to have an exacerbation of intermittent or mild bleeding that had been present for several weeks, months, or even years. Some patients may recall an untoward frequency or severity of epistaxis in childhood. Others report severe menorrhagia or excessive bleeding after tooth extraction, giving birth, or other minor trauma or surgical procedures. Evidence of chronicity often is a valuable clue to the cause of thrombocytopenia. A diligent search must be conducted to find previous platelet counts or to identify events such as hospital admissions during which such a determination was likely to have been made. The patient should also be asked about family members who may have a history of excessive bleeding or bruising.

When bleeding is of recent onset, it is important to consider the possibility that thrombocytopenia is part of a multisystem disorder. Questions related to changes in the patient's general health, including fatigue, fever, and changes in weight, as well as a search for symptoms attributable to dysfunction of specific organs, may provide insight. A search should be conducted for specific factors known to cause thrombocytopenia, including prescribed and over-the-counter medications, especially those taken for the first time, resumed within the previous 3 weeks, or taken intermittently. Attention should be given to ingestion of alcohol, the use of illicit drugs, unusual dietary habits, or recent vaccinations or infections.

A separate category involves patients in whom thrombocytopenia is detected during the investigation of a thrombotic event. The specific disorders in which thrombosis and thrombocytopenia occur coincidentally are considered in detail below.

The physical examination is directed initially at assessment of the extent of bleeding and then at specific findings that favor or tend to exclude the more common causes of thrombocytopenia. The extent of cutaneous bleeding provides some guidance in gauging risk for internal bleeding. A thorough ophthalmologic examination is mandatory, as is examination of stool and urine for evidence of occult bleeding. Although no organ may be overlooked, because it may provide a clue to causation, special attention is paid to the liver, spleen, and lymphatic tissue.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

A complete blood cell count and analysis of the peripheral blood with a light microscope should be performed for every patient for several reasons. First, the presence of thrombocytopenia must be confirmed. Platelets from about 0.01% of all persons agglutinate in the presence of EDTA, the anticoagulant in which blood is collected routinely for automated blood counts. This phenomenon is caused by autoantibodies that bind to platelets only at concentrations of ionized calcium less than those that occur in vivo. The clumped platelets are ignored by automated counters, and falsely low values are obtained. The disparity between the number of platelets evident on a blood smear and the recorded value is readily evident by visual examination, as is the presence of platelet clumps. The patient's actual platelet count can then be determined in other anticoagulants or whole-blood specimens.

Second, examination of a peripheral blood smear may reveal abnormalities in the erythrocytes or leukocytes that provide clues to the cause of thrombocytopenia and that may indicate other clinical features necessitating immediate treatment. For example, the presence of schistocytes and nucleated red blood cells provide a clue to the presence of TTP. Leukoerythroblastic findings (immature granulocytes and nucleated erythrocytes) may suggest infiltration of the bone marrow. The blood smear may reveal myeloblasts, lymphoblasts, circulating lymphoma cells, large granular lymphocytes, or dysplastic changes indicative of a myelodysplastic disorder or atypical lymphocytes, suggesting a systemic viral disorder. Deficiencies of folate or vitamin B₁₂ produce characteristic changes in the erythroid and myeloid cells that occur early in the course of each disease.

Third, the size of the platelets may provide a clue to the cause of thrombocytopenia. Mean platelet volume increases more commonly in disorders that accelerate peripheral destruction, in those that infiltrate the bone marrow, and in myeloproliferative conditions such as essential thrombocythemia and agnogenic myelofibrosis or myeloid metaplasia. A predominance of giant platelets approaching or exceeding the size of erythrocytes may be a clue to hereditary thrombocytopenia.

Bone marrow aspiration and biopsy may be indicated when the cause of thrombocytopenia remains uncertain despite careful history taking, physical examination, and evaluation of the peripheral blood smear, especially when the thrombocytopenia is severe or progressive or when abnormalities in multiple cell lineages are present. The presence of a normal number, distribution, and appearance of megakaryocytes in the marrow suggests that platelet destruction or pooling or loss of platelets in the peripheral circulation is more likely, although these features do not exclude impaired production as a contributing feature. Examination of the bone marrow may reveal the extent of marrow cellularity and is therefore required to make the diagnosis of aplastic anemia or to identify the rare case of isolated megakaryocytic aplasia. Examination of the bone marrow also is necessary when an infiltrative or dysplastic process is suspected. In dysplastic conditions, there may be subtle alterations in megakaryocyte structure, including the presence of micro- or hypolobulated megakaryocytes; in myeloproliferative disorders, the megakaryocytes may be found in clusters. In a few patients, chromosomal abnormalities or clonal genetic rearrangements may be identified that are of diagnostic or prognostic importance.

In many patients with thrombocytopenia, a bone marrow examination is performed reflexively, without careful consideration as to its utility or necessity. The probability that bone marrow examination will help in making a diagnosis varies widely, depending on the cause of thrombocytopenia. Therefore, the decision to perform a bone marrow examination should be based on the likelihood that the suspected cause is one in which diagnostic morphologic abnormalities are likely to be found.

Other tests that should be ordered as part of the initial evaluation depend on the clinical setting. For example, among patients with sepsis or cancer, it may be appropriate to consider a diagnosis of DIC and to measure fibrin split products. In others, it may be appropriate to perform a more detailed biochemical evaluation of liver function and spleen size. No single paradigm for subsequent testing is suitable for all clinical situations. Tests useful to make the diagnosis of specific disorders are as follows.

DIFFERENTIAL DIAGNOSIS

IMPAIRED PLATELET PRODUCTION

Impairment of platelet production usually is part of a multilineage process, and bone marrow examination usually is needed for definitive diagnosis. The most common causes are aplasia (drug induced, autoimmune, myelodysplasia, congenital, paroxysmal nocturnal hemoglobinuria); infiltration (neoplastic, granulomatous, infectious, fibrosis, necrosis); nutritional (folate or vitamin B₁₂) (see [Chapter 243](#)); and clonal disorders, such as myelodysplasia or hypoproliferative leukemia (see [Chapter 229](#) and [Chapter 231](#)). Isolated amegakaryocytic thrombocytopenia is a rare condition caused by ethanol ingestion, antibody- or cell-mediated immune suppression, or myelodysplasia.

INCREASED SPLENIC SEQUESTRATION

Any disorder that enlarges the spleen increases the splenic pool of platelets and proportionately reduces the number of circulating platelets. Some disorders also accelerate platelet destruction within the spleen; the most prevalent example is portal hypertension due to cirrhosis. The specific disorders that cause splenomegaly and hypersplenism are discussed in [Chapter 202](#).

INCREASED PLATELET DESTRUCTION

Immunologic Causes

Idiopathic Thrombocytopenic Purpura

Idiopathic thrombocytopenic purpura is a diagnosis of exclusion. The diagnosis requires the absence of other hematologic abnormalities unless readily explained, such as iron deficiency anemia, and failure to detect other potential causes, such as drugs known to cause thrombocytopenia. Patients are in their usual state of health with the exception of bleeding, and the physical examination should reveal only petechiae or ecchymoses. Bone marrow analysis, if performed, should have entirely normal findings or show increased numbers of megakaryocytes. Although antibodies to individual platelet glycoproteins often are found, the positive and negative predictive values of such tests in clinical practice remain to be established. One of the associated disorders listed in [Table 213.2](#) may be present. HIV testing is indicated for patients at risk because the progress and approach to therapy differ among these patients and because of the social implications.

Drug-induced Thrombocytopenia

Prescribed, over-the-counter, and illicit drugs have become the most common causes of thrombocytopenia among patients who are not in hospitals or long-term care facilities. Although medications initiated within the 1 to 4 weeks before the patient seeks medical attention usually are responsible, all drugs should be suspected, especially when the medication is taken intermittently or was recently resumed. The list of medications implicated as causing thrombocytopenia is extensive. The utility of laboratory tests to include or exclude a diagnosis of drug-induced thrombocytopenia has been established only for heparin. Suspected medications should be discontinued or a chemically unrelated drug substituted whenever possible.

Posttransfusion Purpura

The diagnosis of PTP should be considered for any multiparous woman or any person who has undergone a transfusion who has severe thrombocytopenia 7 to 10 days after receiving a blood product containing platelet antigens. Most affected persons lack human platelet antigen HPA-1a, which is present on the platelets of 99% of the general population. A few cases have been attributed to other polymorphic antigens. The diagnosis should be suspected on clinical grounds but can be corroborated in many cases when the patient's serum lyses platelets from most donors. Antibody specificity can be established with a panel of platelets that lack individual alloantigens, and the genotype of the patient's platelets can be established on recovery with molecular biologic techniques.

Nonimmunologic Causes

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation is a complex coagulation disorder in which platelets and clotting factors are activated by thrombin and are then consumed. Most patients with DIC are gravely ill and have a fulminant bleeding diathesis when they come to medical attention. The most common cause is sepsis, but acute DIC also can follow massive trauma, thermal injury or trauma to the brain, and various obstetric disorders, including placental abruption, retention of fetal parts, and eclampsia. Patients with acute DIC have thrombocytopenia, consumption of coagulation proteins leading to prolonged prothrombin and partial thromboplastin times, and evidence of secondary fibrinolysis that entails rapid lysis of thrombi within the microvasculature. Schistocytes caused by residual fibrin clots are found on peripheral blood smears in about 25% of cases, but overt hemolysis is rare.

The diagnosis of acute DIC usually is obvious on the basis of the clinical signs and symptoms, profound thrombocytopenia, and prolonged clotting times. The diagnosis is confirmed when D-dimers are found in the patient's plasma; these represent the effect of sequential cleavage of fibrinogen by thrombin and plasmin. About 5% of patients have a more indolent disorder characterized by recurrent arterial or venous thrombi, generally in the setting of malignant disease. Elevation of fibrinogen and fibrin degradation products or D-dimers may be the only clue to diagnosis in these cases.

Thrombotic Thrombocytopenic Purpura

Thrombotic thrombocytopenic purpura is an uncommon disorder; the incidence is about 1 case among 500,000 persons per year. It is characterized by an onset over several days to weeks when a previously healthy person has fluctuating neurologic signs, fever, weakness, anorexia, or other gastrointestinal problems. TTP also may occur during or immediately after pregnancy, after a systemic viral illness, among patients with HIV infection, and among persons with underlying vascular disorders such as systemic lupus erythematosus or progressive systemic sclerosis. The neurologic signs and symptoms, such as headache, visual disturbances, seizures, and stupor, may wax and wane initially, but eventually they predominate in most cases. Some patients have myocardial or mesenteric ischemia or respiratory distress syndrome. Almost every patient has thrombocytopenia, and more than 90% have evidence of microangiopathic hemolytic anemia when they seek medical attention. Nucleated red blood cells disproportionate to the number of reticulocytes usually are evident in the peripheral blood smear, serum lactate dehydrogenase level usually is markedly elevated, and about one-half of patients have evidence of mild renal insufficiency, although urinalysis may show only hematuria and proteinuria.

The signs and symptoms of TTP are caused by platelet thrombi that produce diffuse microvascular occlusion, a finding evident in histologic sections from affected organs. The disease may be caused by an autoantibody to an enzyme involved in the physiologic processing of ultralarge von Willebrand's factor multimers released from activated endothelium. Persistence of these ultralarge multimers may promote platelet agglutination. A deficiency of the processing enzyme may be present in some cases of familial or multiple relapsing disease. As yet, no laboratory test can be used to confirm or exclude a diagnosis of TTP. The diagnosis rests on the clinical and laboratory features. The diagnosis is progressively more difficult to confirm when fewer features are present, and a trial of therapy (see later) often is needed in atypical cases when the disorder is suspected.

Hemolytic-Uremic Syndrome

Patients with HUS have the signs and symptoms of renal failure. About 90% of cases occur among children after 6 months of age, typically several days to a week after a gastrointestinal disorder characterized by bloody diarrhea. The endemic form of the disease prevalent among children is generally caused by Shiga-like toxins (SLT) secreted by certain serotypes of *Escherichia coli* (O157:H7 accounts for half the cases in the United States) that damage glomerular endothelial cells and initiate platelet adhesion within the glomerular arterioles and capillaries. In the United States, HUS occurs episodically, especially among young children and persons living in nursing homes, through exposure to SLT-producing *E. coli* in food. HUS also occurs among some patients treated with mitomycin C, cyclosporine, quinine, or ticlopidine, after irradiation to the kidney, after pregnancy, and perhaps among women taking oral contraceptives. Autosomal dominant and recessive forms of the disease have been described that may be insidious in onset and refractory to treatment.

In endemic areas, the diagnosis of HUS is evident when a young child has renal insufficiency, thrombocytopenia (which may be mild or absent in one-third of cases), and microangiopathic hemolysis a week after a diarrheal illness. On occasion, however, extraglomerular manifestations predominate, including gastrointestinal pain or

bleeding, respiratory distress, and neurologic symptoms, making the differentiation from TTP difficult, especially among adults in nonendemic areas. Detection of SLT-1 in the stool or antibodies to SLT-1, or isolation and speciation of *E. coli* may be helpful in such settings.

Hemophagocytic Syndrome

Hemophagocytic syndrome is a rare disorder characterized by pancytopenia caused by phagocytosis of hematologic cells by macrophages. The disorder may follow diverse microbial infections and occurs among children with a genetic inability to contain Epstein–Barr virus infection and occasionally among patients with T-cell lymphoma or histiocytic malignant disease. Patients are generally profoundly ill from the underlying systemic inflammatory disorder. The diagnosis is confirmed when bone marrow aspiration biopsy or tissue section shows erythrophagocytosis or macrophages containing nuclear debris.

THROMBOSIS AND THROMBOCYTOPENIA

The differential diagnosis for patients with thrombosis and thrombocytopenia ([Table 213.3](#)) differs from that for patients with bleeding. TTP, HUS, and DIC are considered earlier. Sufficient platelets may be consumed within acutely rejected renal allografts to cause thrombocytopenia. Thrombocytopenia usually is a late finding in preeclampsia and rarely necessitates specific therapy, but sometimes it can precede other manifestations of the disease. When thrombocytopenia is severe or progressive or persists longer than 3 to 5 days after delivery, additional diagnoses should be considered, including DIC, TTP, and HELLP syndrome (hemolysis, elevated liver function test results, and thrombocytopenia).

Heparin-induced thrombosis or thrombocytopenia;
Thrombotic thrombocytopenic purpura, hemolytic-uremic syndrome
Systemic lupus erythematosus
Primary antiphospholipid syndrome
Disseminated intravascular coagulation
Preeclampsia
Hyperacute renal allograft rejection
Paroxysmal nocturnal hemoglobinuria

TABLE 213.3. DISORDERS ASSOCIATED WITH SIMULTANEOUS ONSET OF THROMBOSIS AND THROMBOCYTOPENIA

Heparin-induced Thrombocytopenia and Thrombosis

About 1% of patients treated with heparin have thrombocytopenia, usually starting 5 to 7 days after therapy begins. Some of these patients have arterial or venous thrombosis, especially at sites of indwelling peripheral catheters. Patients also may have myocardial, cerebrovascular, or mesenteric infarction or pulmonary emboli. Heparin-induced thrombocytopenia and thrombosis (HIT) is more common among patients with cardiovascular disease, but it can occur in any setting. The diagnosis should be suspected when any patient receiving heparin (including subcutaneous heparin, infusion to maintain the patency of intravenous lines, and heparin-bonded central venous catheters) is found to have thrombocytopenia or a platelet count that decreases 40% to 50% without another explanation. Sera from most patients with HIT contain antibodies to complexes between heparin and platelet factor 4 that are presumed to cause platelet activation and possibly endothelial cell injury. Laboratory confirmation can be made in about 90% of cases either by means of measuring antibodies to heparin–platelet factor 4 complexes with enzyme-linked immunosorbent assay (ELISA) or by means of detecting heparin-dependent antiplatelet antibodies through the release of serotonin from normal platelets in the presence of the patient's plasma and heparin. The diagnosis is confirmed with a response to heparin withdrawal (see later).

Primary Antiphospholipid Syndrome

About 15% of patients with primary antiphospholipid syndrome have thrombocytopenia, which is generally mild and not associated with bleeding. Patients typically have arterial or venous thrombosis, which may be recurrent, in the absence of known risk factors. There may be a history of unexplained, recurrent spontaneous abortions, or the disorder may be found incidentally when the patient is found to have a prolonged partial thromboplastin time. Antiphospholipid (e.g., cardiolipin) antibodies may be found by ELISA or when they prolong phospholipid-dependent clotting (so-called lupus inhibitor or lupus anticoagulant). However, antiphospholipid antibodies also may be detected after various infections (e.g., HIV infection), after exposure to certain medications (e.g., phenothiazines), and in some persons who do not have symptoms. Antibodies to phospholipid-binding proteins such as β_2 -glycoprotein I, annexin V, or prothrombin may be more specific and play a role in pathogenesis through activation of platelets or through vascular injury.

Paroxysmal Nocturnal Hemoglobinuria

Paroxysmal nocturnal hemoglobinuria is a rare disorder in which patients may have episodes of intravascular hemolysis and hemoglobinuria. Hemolysis is caused by enhanced sensitivity of the erythrocytes to the lytic actions of complement caused by a deficiency of the complement regulatory proteins CD55 (decay-accelerating factor) and CD59 (membrane inhibitor of reactive lysis). Hemolysis is part of a general defect in the expression of proteins linked to cell membranes by a glycosyl-phosphatidylinositol (GPI) anchor caused by a deficiency in hematopoietic cells of an enzyme, α -1,6- *N*-acetylglucosaminyl-transferase, required for anchor synthesis. Thrombocytopenia, which occurs among about one-third of the patients, is part of a general impairment in hematopoiesis rather than being caused by accelerated platelet destruction. It is unclear which GPI-linked protein is responsible for impaired platelet production or why these patients are susceptible to thrombosis.

The diagnosis paroxysmal nocturnal hemoglobinuria should be suspected when the classic features of periodic hemolysis and hemoglobinuria are present, but it also should be considered in patients with arterial thrombi or venous thrombi at atypical sites (e.g., mesenteric, hepatic, or superior sagittal veins) and for patients with a hypoplastic bone marrow. The diagnosis is confirmed when the erythrocytes have enhanced sensitivity to complement-mediated lysis initiated by low-ionic-strength or acidic media. The diagnosis is made with greater precision when flow cytometry shows the erythrocytes or leukocytes have reduced expression of GPI-linked proteins.

STRATEGIES FOR OPTIMAL CARE

The first step in treating a patient with thrombocytopenia is to assess the magnitude and sites of bleeding or the risk for bleeding. Spontaneous bleeding is uncommon among otherwise healthy persons with platelet counts greater than 20,000 per microliter. The risk increases as the platelet count falls below this level. In general, hospitalization should be considered for patients with bleeding at sites other than the skin, patients with platelet counts less than 10,000 per microliter, and patients with platelet counts less than 20,000 per microliter who are perceived to be at increased risk for bleeding because of concomitant medical problems or social conditions (e.g., elderly patients living alone). Platelet counts of 50,000 to 100,000 per microliter generally are required for invasive and most surgical procedures (other than simple dental extractions), as are platelet counts in excess of 100,000 per microliter for patients undergoing cardiopulmonary bypass.

General measures that reduce the risk or severity of bleeding should not be overlooked. These include avoidance of trauma, including placement of central venous catheters, avoidance of medications that impair platelet function, control of hypertension, correction of medical problems that may predispose to bleeding (e.g., control of acid secretion for patients with a history of peptic ulcer disease), and red blood cell transfusions, which may improve platelet function. Administration of ϵ -aminocaproic acid, which inhibits fibrinolysis, may help reduce mucosal bleeding for patients with thrombocytopenia but should be avoided if there is evidence of DIC.

Platelet transfusions may be indicated to manage active bleeding outside the skin when the underlying cause of thrombocytopenia is not readily reversible. Transfusion also is indicated for prophylaxis in the care of patients at high risk of bleeding because of mucosal damage (e.g., patients with leukemia undergoing induction therapy) or those predisposed to bleed from identified structural lesions. Although platelet transfusion often is initiated when platelet counts fall below 20,000 per microliter, it appears safe to use a lower threshold (e.g., 10,000 per microliter) in the care of patients whose condition is clinically stable and afebrile.

Transfusion of platelets confers a higher risk for allergic, pyogenic, and infectious complications and graft-versus-host disease among immunocompromised persons than does erythrocyte transfusion, because multiple donors often are needed and because cytokines accumulate in the accompanying plasma. Mechanical depletion or irradiation of leukocytes and shortened storage time may decrease the incidence of noninfectious complications, but about 40% of patients still will develop alloantibodies that ultimately make them resistant to platelet support, even when HLA-matched platelets are used. Moreover, platelet transfusions are contraindicated in the management of TTP and HIT in the absence of life-threatening hemorrhage, because they may exacerbate the thrombotic manifestations with disastrous consequences. Therefore platelet transfusions should be used judiciously in the care of all patients while attempts are made to correct the underlying disease.

MANAGEMENT OF IMMUNE THROMBOCYTOPENIA

Idiopathic Autoimmune Thrombocytopenia

Idiopathic autoimmune thrombocytopenia among children is distinct from the disease of the same name among adults. Children commonly have severe thrombocytopenia and an abrupt onset of petechiae or purpura. Despite the sometimes florid onset, the disorder generally is self-limited. Platelet counts generally exceed 30,000 to 50,000 per microliter within a week, even in the absence of treatment. Complete remission within 6 to 12 months is the rule for more than 80% of children. Spontaneous intracranial hemorrhage is the main fear, but this complication is too uncommon for an effect of therapy to be proven.

Treatment with glucocorticoids or intravenous immunoglobulin (IVIG) lessens the number of days the platelet count is less than 20,000 per microliter, but the medical importance of this outcome is controversial. Therapy is indicated in the care of severely thrombocytopenic children who have a chronic course, those with diffuse or internal bleeding, and perhaps older adolescents, among whom the clinical course is less predictable.

Unlike children, adults rarely have a spontaneous remission. Therefore adults with bleeding are treated with prednisone (1 mg per kilogram per day). Between 50% and 70% of patients will respond to this treatment within 3 weeks with a rise in the platelet count to greater than 50,000 per microliter. Bleeding may stop within days, even before a rise in platelet count is detected. Patients with profound thrombocytopenia and bleeding and those who do not respond to prednisone should be treated with IVIG (1 g per kilogram per day for 1 or 2 consecutive days), which has a success rate greater than 80%. Platelet transfusions may be surprisingly successful in emergencies. Adults with platelet counts greater than 30,000 to 40,000 per microliter rarely need immediate treatment in the absence of concomitant hemostatic problems, trauma, or surgery.

Despite the success of initial therapy, most adults relapse when corticosteroids are withdrawn and within 3 to 4 weeks of IVIG administration. Therefore, most adults with platelet counts persistently below 40,000 to 50,000 per microliter are candidates for splenectomy, which has an initial success rate of about 60% to 70%. Patients should receive Pneumovax vaccine and vaccinations against *H. influenza* and meningococcus before the procedure, but a lifelong risk for sepsis remains.

Numerous options exist for treatment of patients with severe thrombocytopenia refractory to splenectomy. These include a search for an accessory spleen, use of danazol, use of vinca alkaloids, immunosuppression with azathioprine or cyclophosphamide, use of high-dose dexamethasone, reinstatement of the initial therapy with corticosteroids and IVIG at lower doses, and a combination of these approaches, among others.

Pregnancy presents a special problem. There is a weak correlation between maternal and fetal platelet counts, and there has been no demonstration that a maternal response to any therapy lessens the risk for severe neonatal thrombocytopenia. Fetal platelet count can be obtained by means of percutaneous umbilical blood sampling near term, but the need for this measurement and the benefits of cesarean section when fetal thrombocytopenia is found are unproven. Most hematologists currently do not favor either intervention for most patients.

Posttransfusion Purpura

The course of PTP can be prolonged and severe in the absence of therapy. IVIG has replaced plasmapheresis as the treatment of choice with a success rate greater than 90%. Some patients need a second course of treatment. Limitation of subsequent transfusions to antigen-negative cells is logical but unproven.

Drug-induced Thrombocytopenia

Management of drug-induced thrombocytopenia is to discontinue all nonessential medications for at least 3 weeks and to substitute chemically distinct medications when necessary. Some patients need ancillary measures like those used to manage ITP or PTP when thrombocytopenia is unusually severe or bleeding occurs.

MANAGEMENT OF NONIMMUNE AND THROMBOTIC THROMBOCYTOPENIA

Acute DIC has a high mortality because the prognosis of the underlying disorders is generally poor. Mortality is generally unaffected by heparin despite improvement in coagulation measurements. Heparin nevertheless is indicated in the treatment of patients with thrombotic complications and may prolong the life span of transfused platelets and fresh frozen plasma in specific instances.

TTP is uniformly fatal without therapy, but the mortality rate has been lowered to about 20% with the advent of plasmapheresis. The value of adding prednisone is uncertain. Plasmapheresis should be performed daily until platelet count and the serum lactate dehydrogenase level have returned to normal. Plasmapheresis should not be discontinued because the patient's condition appears clinically improved unless the results of these two laboratory tests corroborate the impression. It may take as long as 3 weeks of daily plasmapheresis to see improvement. About 15% of patients have a relapse within the first few weeks and another 15% sometime thereafter. Patients with relapses almost always respond to reinstatement of plasmapheresis, although a chronic relapsing course develops in a few. Failure to respond to plasmapheresis is ominous, but about 40% to 50% of such patients respond to splenectomy. Anecdotal responses have been reported with the use of cryosupernatant, vinca alkaloids, prednisone, antiplatelet drugs, staphylococcal protein A columns, IVIG, and immunosuppressive therapy.

There is no evidence that any intervention, including antibiotics, prevents the development of end-stage renal disease among children with postdiarrheal HUS. The evidence that plasmapheresis, or indeed any therapy, alters the course of atypical childhood or adult-onset HUS is far less convincing than it is for TTP.

IVIG has been proved to be of benefit in the care of some patients with hemophagocytic syndrome, which once was almost universally fatal. Anecdotal responses to cyclosporine have been reported.

The critical decisions in the management of HIT involve proper diagnosis and scrupulous avoidance of subsequent exposure to even small amounts of heparin. Risk for thrombosis decreases during the first 36 hours after heparin is discontinued, but it persists for several days among some patients. Improvement in platelet count generally takes 2 to 5 days. Management of preexisting or heparin-induced thrombi is a particular problem, because additional exposure to the drug exacerbates the thrombocytopenia and may precipitate new thrombotic events. Low-molecular-weight heparin should be avoided because most HIT antibodies are cross-reactive. The treatments of choice are the thrombin inhibitors lepirudin and danaparoid, a mucopolysaccharide complex with anti-factor Xa activity; approximately 7% of patients with HIT have antibodies that cross-react with danaparoid in vitro, but their clinical significance is uncertain. Ancrod, dextran, warfarin sodium, plasma exchange, antiplatelet agents, and iloprost (a prostacyclin analogue) have been used successfully in individual cases.

Therapy for primary antiphospholipid syndrome and thrombosis involves immediate and long-term anticoagulation. Immunosuppression may be added in refractory cases, and plasma exchange has been used in life-threatening circumstances. Heparin or antiplatelet drugs are used commonly to treat women with recurrent spontaneous abortion, although efficacy has yet to be proved through placebo-controlled trials.

Corticosteroids may ameliorate the rate of hemolysis for patients with paroxysmal nocturnal hemoglobinuria, but they have relatively little effect on platelet count among most patients. Danazol has been helpful in a few cases, but the mainstay of therapy is antithymocyte globulin and bone marrow transplantation.

undertaken. In the absence of neutrophils, an infected site contains necrotic ulcers. Important cutaneous microemboli and rashes may be present. Sinuses should be percussed for tenderness. A careful, noninvasive examination of the perirectal area should be performed. In the absence of adequate neutrophils, the findings of pneumonia may be subtle.

The physical examination should be an attempt to determine the cause of the pancytopenia. In many disorders, there may be no further physical findings. However, splenomegaly may indicate that pancytopenia has been caused by hypersplenism or a myelophthitic state with extramedullary splenic hematopoiesis. With massive splenomegaly, the spleen extends into the lower abdomen, and the examination should begin in the lower abdomen and carefully proceed cephalad. Massive splenomegaly occurs in Gaucher's disease, myelofibrosis, hairy cell leukemia, and lymphoma. Splenomegaly usually does not occur with aplastic anemia, acute nonlymphocytic leukemia, ineffective hematopoiesis, and myelodysplastic syndromes.

Lymphadenopathy may indicate the presence of lymphoma, acute or chronic lymphocytic leukemia, or metastatic carcinoma. Examination of the breasts should be performed, because pancytopenia may accompany metastatic breast carcinoma. Skin and joint findings suggesting collagen vascular disease or arthritis may indicate the presence of immunologically mediated pancytopenia.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

Laboratory studies are the most definitive aspect of the evaluation for pancytopenia ([Fig. 214.1](#)). An immediate and careful examination of a good-quality peripheral blood smear is mandatory. The complete blood cell count and differential count may indicate that some cell lines are more severely affected than others. Cell lines should be individually examined.

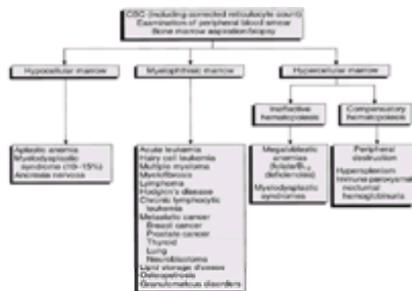

FIGURE 214.1. Algorithm for the evaluation of pancytopenia.
EVIDENCE LEVEL: C. Expert Opinion.

Erythroid macrocytosis may indicate ineffective hematopoiesis, as in vitamin B₁₂ or folate deficiency, or the defect may occur as leukoerythroblastosis in myelophthitic disorders. The latter condition may be associated with poikilocytosis, nucleated RBCs, and teardrop-shaped cells. Nucleated RBCs are findings of stress erythropoiesis. Although aplastic anemia is classified as normochromic normocytic anemia, macrocytosis indicative of terminal stress erythropoiesis may be present. Polychromatophilia is indicative of erythroid production.

Rouleaux formation may indicate lymphoma or multiple myeloma. Blasts may indicate an underlying leukemia or myelodysplastic syndrome. Hairy cell leukemia, chronic lymphocytic leukemia, and non-Hodgkin's lymphoma may be associated with the finding of circulating cells the presence of which is enough information to confirm a diagnosis. In some bone marrow failure syndromes, such as aplastic anemia, an absence of myeloid cells causes relative lymphocytosis. A leukoerythroblastic smear has a few immature myeloid cells in addition to the RBC changes. Pelger–Huet anomaly and hypogranulation of the myeloid cells suggest an underlying myelodysplastic syndrome. Hypersegmentation of polymorphonuclear leukocytes is associated with megaloblastic anemia. An almost normal differential count and percentage of myeloid cells may indicate peripheral destruction caused by hypersplenism. Decreased numbers of small platelets indicate decreased platelet production, and the presence of giant platelets is associated with a myelophthitic process or compensatory thrombopoiesis.

Most important, examination of the peripheral blood must include a reticulocyte count with a supravital stain for numeric assessment of erythroid production. For more accurate measurement of erythropoiesis, the reticulocyte count should be corrected for an abnormal hemoglobin level.

In all cases of pancytopenia, bone marrow aspiration and biopsy should be performed immediately after the peripheral blood examination. In conjunction with the peripheral blood findings, these studies can help identify the cause of the pancytopenia in most cases. Aspirate examination of individual cell lines and cells allows the diagnosis of malignant disease of the hematopoietic system, lipid storage disorders, megaloblastic anemias, and myelodysplastic syndromes. Metastatic cancer cells sometimes are found in the aspirate, although these findings are more frequent in core biopsy. Prussian blue stains may demonstrate the presence of the ringed sideroblasts indicative of the myelodysplastic syndromes. Examination of the aspirate should include flow cytometry, which may aid in the identification of clonal abnormal cell populations. Cytogenetic abnormalities are found in the congenital bone marrow failure syndromes, such as Fanconi's aplastic anemia, and in some types of leukemia and myelodysplastic syndrome.

Extremely important in the evaluation of pancytopenia is core bone marrow biopsy, especially if a hypocellular aspirate is obtained. The biopsy provides the only true estimate of bone marrow cellularity. Although hypocellular marrow usually is associated with aplastic anemia, the possibility of a hypocellular myelodysplastic syndrome must be considered, and the core biopsy should be carefully correlated with the aspirate biopsy and cytogenetic studies. Bone marrow biopsy allows the diagnosis of myelofibrosis and increases the yield of diagnosis of metastatic carcinoma, mycobacterial infection, lymphoma, and hairy cell leukemia. No specific marrow findings are associated with HIV infection, although some of the secondary consequences such as granuloma or lymphoma may be demonstrated in the marrow. Bone marrow aspiration and biopsy often establish the diagnosis among patients with an enlarged spleen, particularly if the splenomegaly is caused by an infiltrative disorder or extramedullary hematopoiesis.

Careful evaluation of the peripheral blood and bone marrow often establish the cause of the pancytopenia. The need for further laboratory testing is dictated by the results of these examinations.

STRATEGIES FOR OPTIMAL CARE

MANAGEMENT OF PANCYTOPENIA

The care of a patient with pancytopenia involves four simultaneous issues. The first two are complete evaluation of the underlying disorder and institution of appropriate treatment (see elsewhere). The third issue involves management of complications, which may represent a medical emergency. The fourth aspect involves prophylaxis of future complications of pancytopenia.

Patients with mild to moderate pancytopenia may need no immediate care other than diagnostic evaluation. A patient with fever and an absolute neutrophil count less than 500 per microliter should be considered to have a potentially life-threatening bacterial infection (see [Chapter 267](#)). Because infection in this setting may cause death within hours, numerous blood samples and samples from other appropriate lesions, secretions, and orifices should be cultured, and the patient should immediately receive broad-spectrum intravenous antibiotics. The choice of antibiotics may be dictated in part by accompanying signs and symptoms, and the choice varies somewhat from institution to institution. The choice of antibiotics should be adequate to manage a wide spectrum of bacterial infections. If a specific organism is subsequently identified, the antibiotic regimen may become more selective.

If the fever continues unabated, the possibility of *Staphylococcus epidermidis* or fungal infection should be considered. In the case of continued fever, constant attention should be directed at the clinical signs and symptoms, and additional cultures should be obtained. Given the life-threatening nature of this problem, the

immediate and aggressive approach to the neutropenic fever may well dictate whether the patient will survive the pancytopenia.

Prophylaxis of infection in the setting of neutropenia without fever or signs of infection is controversial. As neutrophil level decreases, susceptibility to infection may increase, and prophylaxis should be considered for patients with severe neutropenia. Attempts should be made to decrease the patient's exposure to potential sources of exogenous infection, including fresh fruit, vegetables, flowers, and plants, all of which may contain a heavy burden of soil organisms and fungal spores. Patients should be hospitalized in single rooms, and careful hand washing by hospital personnel may decrease acquisition of nosocomial infections. Patients with potential respiratory illnesses should avoid large crowds, and ill personnel should wear high-filtration masks.

The patient should be carefully examined for the presence of oral fungal infection and may be treated prophylactically with oral antifungal agents. Although some patients have been treated with prophylactic antibiotics, this must be undertaken with the knowledge that a selective infection, often with resistant organisms, may develop. Careful attention should be paid to personal hygiene that includes daily bathing with particular attention to intertriginous areas. Skin breaks should be avoided or promptly treated. A careful dental evaluation may be in order. In the setting of some causes of pancytopenia, the underlying disorder may cause an additional immunosuppressed state, leaving the patient susceptible to viral, fungal, and parasitic infections. Consideration should be given in these situations to *Pneumocystis carinii* prophylaxis.

Complete microbial isolation of the patient in a protective environment and decontamination of the gastrointestinal flora with nonabsorbable oral antibiotics are controversial. A patient with only mild to moderate neutropenia and immunosuppression does not need this type of treatment. Use of these limited facilities often is expensive, the procedure isolates the patient, and the oral antibiotics taste bad. Such facilities usually are limited to hematopoietic stem cell transplant recipients with prolonged severe neutropenia and immunosuppression.

MANAGEMENT OF HEMORRHAGE

Patients with pancytopenia most frequently have hemorrhage. A patient with hemorrhage and thrombocytopenia, especially with a platelet count less than 50,000 per microliter, should be treated with platelet transfusions (see [Chapter 213](#) and [Chapter 218](#)). Each platelet unit ideally causes an increment of 10,000 platelets per microliter per square meter of body surface area. An aggressive approach should be taken to life-threatening hemorrhage, especially in the gastrointestinal tract, oral cavity, retina, or central nervous system. Increased increments are found among patients who have undergone splenectomy, and less than ideal responses occur among patients with splenomegaly. Patients with sepsis, disseminated intravascular coagulation, microangiopathic states, and active bleeding may have blunted responses. Patients alloimmunized to HLA antigens or platelet-specific antigens may have little or no response and may need transfusions with HLA-compatible platelets. Alloimmunization may be caused by prior transfusions and pregnancies. Medications that interfere with platelet function should not be used. Myelodysplastic syndromes or myeloproliferative disorders may cause qualitative platelet dysfunction and increased bleeding. Coincidental congenital platelet dysfunctional disorders may require a higher platelet count for active bleeding or as prophylaxis.

Prophylaxis of hemorrhage is a more controversial issue. Activities conducive to trauma should be avoided, and for women of childbearing potential, menses should be suppressed. In many centers, a platelet count of 20,000 per microliter mandates a platelet transfusion, even in the absence of active bleeding. However, decisions to transfuse platelets prophylactically should be made on the basis of laboratory data and clinical assessment. For patients with active production of platelets but increased consumption, little value is derived from platelet transfusions, even in severe thrombocytopenia, except in rare circumstances. Patients who have stable thrombocytopenia because of decreased production in the absence of active bleeding probably need transfusions at levels less than 5000 per microliter or as preparation for an invasive procedure.

Suboptimal posttransfusion increments necessitate additional evaluation. In the absence of nonimmune reasons for a poor response, patients should be evaluated for alloimmunization by means of HLA antibody testing. Certain causes of pancytopenia, such as aplastic anemia, more frequently cause such sensitization. HLA-compatible donors should be sought, and transfusion of single-donor platelets treated with pheresis should be attempted. When results are appropriate, attempts should be made to use the same donor repeatedly. In the absence of an identified donor, a cross-match test should be performed to identify potential donors. Avoidance of alloimmunization among patients who need long-term platelet support is attempted through the judicious use of blood products and the use of leukocyte-depleted products.

Erythrocyte transfusions should be given after consideration of the clinical situation and the laboratory results. Younger patients with anemia that developed over long periods tolerate lower hemoglobin levels than do older persons. RBC transfusions among older persons with pancytopenia from megaloblastic anemia should be administered cautiously, because the blood volume may be expanded, and transfusions may precipitate congestive heart failure. Long-term transfusion may cause transfusion hemosiderosis, and iron chelation may have to be considered.

In the setting of pancytopenia, any transfusion must be administered judiciously, especially until it is established whether the patient has aplastic anemia. Transfusions, particularly in cases of aplastic anemia, may cause sensitization to non-HLA minor histocompatibility antigens, resulting in nonengraftment of transplanted hematopoietic stem cells. Transfusions from family members should be avoided. Because many of the conditions that cause pancytopenia may lead to therapy with hematopoietic stem cell transplantation, immediate evaluation of the patient's cytomegalovirus (CMV) history should be undertaken with measurement of CMV antibody. Before these results are obtained, patients should receive CMV-negative blood products if possible. If the patient is CMV-naive, CMV-negative products should be used. For patients with immunosuppressed states resulting from the underlying disease or its therapy, blood products should be irradiated to prevent potentially fatal transfusion-associated graft-versus-host disease.

Few of the conditions previously described necessitate use of exogenous hematopoietic cytokines. Under most circumstances, measured levels are appropriately elevated. In some disorders, granulocyte colony-stimulating factor or granulocyte-macrophage colony-stimulating factor can be detrimental because they stimulate the underlying hematopoietic malignant lesion. However, these cytokines have aided therapy for neutropenic infections. Although these agents have not been demonstrated to cure aplastic anemia, the infection rate appears to be diminished among responders. A variety of agents and combinations of agents are under study (see [Chapter 212](#) and [Chapter 213](#)).

[Differential Diagnosis](#)
[Strategies for Optimal Care](#)

PRESENTATION

An increase in hemoglobin concentration, hematocrit, or red blood cell (RBC) number may reflect a decrease in plasma volume or indicate an absolute increase in the number of RBCs. *Polycythemia* is the term used to designate an absolute increase in circulating RBC mass. Because a reduction in plasma volume with normal numbers of RBCs results in a relative increase in RBC mass, such clinical events have been called *relative polycythemia* or *spurious polycythemia*. The increased RBC mass can be primary (polycythemia vera), which defines an autonomous underlying mechanism, or secondary, indicating that the increase in RBCs is caused by an identifiable mechanism, tissue hypoxia, or increased production of erythropoietin (EPO).

PATHOPHYSIOLOGY

The forms of polycythemia ([Table 215.1](#)) have limited pathophysiologic mechanisms. In relative polycythemia, plasma volume is constricted, and RBC mass is normal or high normal. Although fluid loss is the acute cause, the pathogenesis of chronic relative polycythemia is unknown.

Clinical Pathophysiologic Mechanisms	Supportive Laboratory Findings
Dehydration	Decreased plasma volume
Diuretic use	Decreased plasma volume
Relative polycythemia	Increased hemoglobin, increased hematocrit, increased RBC count
Primary polycythemia (polycythemia vera)	Increased hemoglobin, increased hematocrit, increased RBC count, increased EPO
Secondary polycythemia	Increased hemoglobin, increased hematocrit, increased RBC count, increased EPO
High altitude	Increased hemoglobin, increased hematocrit, increased RBC count, increased EPO
Cardiopulmonary causes of hypoxia	Increased hemoglobin, increased hematocrit, increased RBC count, increased EPO
Aberrant sites of EPO production	Increased hemoglobin, increased hematocrit, increased RBC count, increased EPO
Increased responsiveness of erythroid progenitor cells to physiologic amounts of EPO	Increased hemoglobin, increased hematocrit, increased RBC count, increased EPO

TABLE 215.1. CAUSES OF POLYCYTHEMIA

In the absolute or true types of polycythemia, different pathophysiologic mechanisms exist. In (primary) polycythemia vera an autonomous clonal expansion of EPO-independent hematopoietic stem cells occurs. The autonomy is consistent with the evidence that polycythemia vera is a neoplastic disease. The growth advantage of the neoplastic clone appears to relate to alterations in the *bcl-2* oncogene family with deregulated and increased expression of *bcl-X* (an important inhibitor of apoptosis) in the EPO-independent clone. In the other forms of polycythemia, increased RBC production is caused by a physiologic increase in EPO secretion (e.g., high altitude, cardiopulmonary causes of hypoxia), a pathologic increase (e.g., aberrant sites of EPO production), or increased responsiveness of erythroid progenitor cells to physiologic amounts of EPO (e.g., familial, congenital lesions of the EPO receptor).

EPO is the normal regulator of RBC production, and cellular hypoxia is the primary stimulus to its production and release. EPO, the first identified cytokine, is an approximately 35-kd glycoprotein that is an obligatory growth factor for erythroid development. It is produced by interstitial cells of endothelial or fibroblast lineage, which are present primarily in the renal cortical peritubular site. Approximately 10% of EPO is extrarenal in origin, largely from the liver. Hypoxia stimulates prostaglandin release, which recruits new cells to produce EPO. The enhanced EPO production is caused by an increase in the number of these cells not from more EPO derived from extant cells.

The gene for human EPO is on chromosome 7. Renal interstitial cell hypoxia causes gene activation with increased transcription and messenger RNA (mRNA). A "hypoxic-responsive element" at the 3' tail of the gene appears to serve as the activator of transcription, and mRNA synthesis increases. EPO does not induce the hematopoietic stem cell to its primary commitment to the erythroid compartment. The mechanism for the initial commitment to a given cell lineage (e.g., erythroid, myeloid, megakaryocytic) is unknown. However, EPO receptors (approximately 200 per cell) are present on the erythroid progenitor cells, and as a result, EPO serves as a lineage-specific cytokine to enhance growth, differentiation, and amplification of these cells into the erythroid cell pool. Truncated mutations of the EPO receptors (particularly at exon 8, which encodes the c-terminal region) have been associated with familial (congenital) polycythemia. Hyperresponsiveness of erythroid progenitor cells to EPO has been shown to be caused by these mutations, although the true mechanism in this form of polycythemia may be altered signal transduction of downstream elements, such as *JAK2* and *STATS*.

The physiologic half-life of EPO is not known, but studies with transgenic mice that express the human EPO gene have shown that even a slight increase in hormone secretion sustained over a long period produces polycythemia. A pulse of EPO transforms undifferentiated erythroid-committed precursors to proerythroblasts, accelerates the cells in the maturation sequence, and causes reticulocyte formation within 5 days.

Any alteration in ambient oxygen content (e.g., high altitude), disorders associated with decreased arterial oxygen tension (e.g., cardiac or arteriovenous shunting), reduced oxygen-carrying capacity of the blood (e.g., elevated carboxyhemoglobin levels caused by smoking), or altered oxygen delivery to tissues (e.g., high-oxygen-affinity hemoglobin) increases EPO production and causes secondary polycythemia. In the absence of hypoxia, familial or acquired secondary polycythemia may be caused by aberrant or inappropriate EPO production ([Table 215.1](#)).

HISTORY AND PHYSICAL EXAMINATION

The clinical history can define some of the clinical states associated with elevated hemoglobin concentration. The familial forms of polycythemia (e.g., high-affinity hemoglobin, altered diphosphoglycerate) often are first recognized in adulthood when family members become dedicated blood donors. A smoking history is important, because cessation is a prerequisite for the delineation of other possible mechanisms.

Patients with relative polycythemia have definable clinical features. They are usually middle-aged white men with moderate obesity, hypertension, and a history of smoking and alcohol use. The symptoms commonly include nervousness, headaches, and dizziness. These patients have a high prevalence of thromboembolic cardiac and cerebral vascular episodes and often a family history of cerebral and cardiovascular disease.

The symptoms and signs of true polycythemia, such as headaches, vertigo, visual disturbances, and mental confusion, are caused by the increase in RBC mass and the concomitant increase in blood viscosity and total blood volume. Studies of residents of high altitudes have shown adaptive tolerance; few symptoms are expressed despite hemoglobin concentrations as high as 25 g per deciliter. The acclimatization process is associated with a shift to the right of the oxygen dissociation curve, which enhances the unloading of oxygen to the tissue. Because a variety of events can cause tissue hypoxia, the clinical correlations with elevated hemoglobin levels can be broad ([Table 215.1](#)).

LABORATORY STUDIES AND DIAGNOSTIC TESTS

The initial diagnostic evaluation for a patient with an elevated hemoglobin concentration, hematocrit, or RBC count is measurement of RBC mass. This should be done, ideally in the nonsmoking state, for men with a stable hematocrit higher than 51% and for women with a hematocrit higher than 48%. Unless the body habitus is unusual, an RBC mass of 36 mL per kilogram or greater for a man and 32 mL per kilogram for a woman is enough information to confirm a diagnosis of polycythemia. A more accurate expression of normal involves surface area; this is particularly critical in the diagnostic evaluation for obese patients.

Arterial blood gases and carboxyhemoglobin should be measured; methemoglobin should be measured in cases of cyanosis. Hypoxia with resultant increased EPO production occurs at an arterial oxygen saturation of less than 92% and a Pa O₂ of less than 65 mm Hg. Carboxyhemoglobin decreases oxygen-carrying capacity and must be directly measured; because this value increases during the course of smoke exposure, it is best obtained late in the day. A normal value for nonsmokers is 0.9 ± 0.5%. Levels in moderate smokers are in the range of 3% to 5%. Among heavy smokers, concentrations are in the range of 5% to 7%. Methemoglobin need not be measured unless cyanosis is present; concentrations greater than 1.5 g per deciliter are associated with cyanosis.

If high-oxygen-affinity hemoglobin is suspected, the oxygen dissociation curve and P₅₀ are measured. The classic pattern is a hyperbolic curve shifted to the left. Because most hemoglobin variants have normal electrophoretic patterns, peptide mapping and amino acid analysis may be needed for final diagnosis.

An EPO assay can be used in the differential diagnosis of polycythemia. Because much overlap exists between clinical entities, the physician must be cautious in interpreting results obtained from any single sample. The range among healthy persons is 4 to 16 (immunoradiometric method). Among most untreated patients with polycythemia vera it is less than 4 mU per milliliter or in the lower range of normal. Most patients with secondary polycythemia have a level in the high normal range or above. In polycythemia vera the EPO level is not greatly influenced by phlebotomy therapy. The basis for the reduced levels in polycythemia vera is unknown, but the reductions may be caused by down-regulation of normal EPO secretion. Spontaneous EPO-independent *in vitro* endogenous erythroid colony growth characterizes the peripheral blood (sample) in polycythemia vera. In secondary polycythemia an absolute EPO requirement exists for growth. In many parts of the world, this differential feature is included in the diagnostic criteria for polycythemia; such assays are not readily available in the United States.

DIFFERENTIAL DIAGNOSIS

The primary mechanisms of elevated hemoglobin level and the focused diagnostic tests are outlined in [Table 215.1](#). A sequential diagnostic approach is displayed in [Fig. 215.1](#). Measurement of RBC mass separates relative from absolute polycythemia. When the hematocrit is significantly greater than 60%, RBC mass is almost always abnormal; the measurement can be bypassed in certain cases.

FIGURE 215.1. Algorithm for evaluation of patient with an elevated hemoglobin level. Carboxyhemoglobin is measured only for smokers or when there is potential industrial exposure. Bone marrow culture to separate normal EPO-dependent growth from EPO-independent growth in polycythemia vera is of value, but relatively unavailable. A patient with a normal EPO level and no other findings should be considered for P₅₀O₂ measurement to identify very rare high-affinity hemoglobin, more than 40 of which are recognized. Long-standing myocardial failure also can produce these findings.

EVIDENCE LEVEL: C. Expert Opinion.

Because the most common cause of true polycythemia is decreased oxygen delivery, the next step in evaluation is measurement of arterial blood gases and carboxyhemoglobin. If the values are abnormal, the diagnosis is easily defined through evaluation of the causes of the low arterial oxygen tension or high carboxyhemoglobin or methemoglobin level.

If blood gases are normal, three diagnostic categories exist. The first is autonomous drive to hematopoiesis. Associated findings of splenomegaly and elevated platelet and white blood cell counts support this diagnosis. The second is defective oxygen delivery system to tissues (e.g., high-affinity hemoglobin, alteration in diphosphoglycerate binding). An oxygen dissociation curve and P₅₀ measurement are required for diagnosis of these lesions. Third, inappropriate secretion of EPO may cause polycythemia. A variety of organs have been implicated in cases of aberrant or inappropriate secretion of EPO, although most cases are caused by kidney or liver lesions. If no other specific symptoms or signs exist, it is wise to perform abdominal ultrasonography or computed tomography.

STRATEGIES FOR OPTIMAL CARE

MANAGEMENT

Relative Polycythemia

Although the RBC mass is not increased in relative polycythemia, risk for cardiac and cerebrovascular complications is increased. Because the pathophysiologic mechanisms are unknown, therapy is directed at weight reduction, cessation of alcohol use and smoking, control of hypertension, and an attempt at alteration of lifestyle. These supportive measures have produced an improved clinical outlook.

Secondary Polycythemia

Because secondary polycythemia is physiologic compensation, the proper clinical approach is to identify and manage the primary cause. This is particularly true for aberrant or inappropriate secretion of EPO, for which correction of the lesion often is curative. If repair of the primary lesion is impossible, the nature of the physiologic burden of the increased RBC mass must be considered. Clinical wisdom is that the increase in RBCs provides needed compensation for the underlying hypoxia-related disease and that therapy should not perturb this compensatory status.

Because blood viscosity is directly related to RBC mass, concern has focused on the potential cardiovascular burden. Work capacity improves after phlebotomy reduction of hematocrit from 63% to 48% among patients with secondary polycythemia. Patients with obstructive lung disease whose hematocrit is reduced to normal have a decrease in pulmonary artery pressure, total pulmonary vascular resistance, and right ventricular work. This supports the view that RBC production frequently overcompensates for physiologic needs and that a phlebotomy program using the patient's symptoms as therapeutic criteria is appropriate. Most patients with secondary polycythemia have maximum cardiopulmonary function with a hematocrit maintained in the range of 47% to 50%.

Polycythemia Vera

Because polycythemia vera evolves through seteral stages, therapy is focused on the critical clinical issues in the specific phase (see [Chapter 231](#)). In the pre-erythrocytic phase, histamine H₁- and H₂- blocking agents provide relief from the primary symptom of pruritus. Recombinant interferon-alfa also has been effective

in controlling pruritus. Phlebotomy therapy has substantially prolonged median survival time, and it is the primary therapeutic modality used during the erythrocytic phase, when RBC mass and whole-blood viscosity are mainly responsible for the clinical findings. The therapeutic target is a hematocrit of 44% to 50%.

Hydroxyurea has been used to reduce risk for phlebotomy-related thrombotic events during the initial 2 to 3 years of therapy. This chemotherapeutic agent appears to have the least mutagenic and leukemogenic potential of the vast number of agents tried. Recombinant interferon- α has proved effective at reducing RBC values. Iron deficiency does supervene during serial phlebotomy, but iron replacement should be avoided, because high iron levels stimulate RBC production. Patients with a high phlebotomy requirement or those who enter the proliferative phase, in which the associated thrombocytopenia poses clinical risk, should be treated with suppressive drugs. Hydroxyurea, anagrelide and interferon are effective (see [Chapter 231](#)).

The primary aims of therapy are to maintain platelet count at less than 500,000 per microliter and hematocrit at less than 48%. Late in the course of polycythemia vera, the clinical problems are related to the anemia and progressive splenomegaly of the postpolycythemic myeloid metaplasia phase. Transfusions and, for those with relatively low serum EPO levels, the use of EPO are supportive measures. For patients with late-stage leukemic transformation, the therapy is that used for any secondary acute leukemia.

COMPLICATIONS AND PITFALLS

The primary complication in the care of a patient with elevated RBC values is risk for cerebral ischemia or the cardiac arrhythmias or ischemia associated with a phlebotomy program. This is particularly true of patients older than 60 years, for whom the volume shifts may produce dramatic changes. Small-volume (100 to 200 mL) phlebotomy should be used, particularly when treatment begins; volume replacement increases safety. The primary diagnostic pitfall is failure to identify underlying polycythemia in a patient who has had recent bleeding and who has normal or borderline RBC values and a decreased mean corpuscular volume that provides evidence of iron-deficient erythropoiesis with a drive to increased RBC production.

[Lymphocytosis](#)

White blood cells (WBCs) are mobile agents of infectious surveillance and tissue repair. Each class of WBC, including neutrophils, monocytes, eosinophils, and lymphocytes, makes a distinctive contribution to host defense and repair. The production and regulated trafficking of each class of WBC, whether orchestrated by the bone marrow or by the lymph nodes, is extremely sensitive to acute and chronic demands produced by infection, inflammation, and injury. Elevation in the WBC count above the normal range, called leukocytosis, is extremely common. Careful and thoughtful evaluation of the patient with leukocytosis can provide great insight into the patient's health.

In evaluating the patient with leukocytosis, the clinician should ask three questions. First, which class or classes of WBCs are elevated: neutrophils, lymphocytes, monocytes, eosinophils, basophils, or monocytes? The causes of leukocytosis are quite distinctive, depending on which class of white cells is elevated, and pinpointing which class of cells is too numerous is the critical first step. Second, how high is the elevation? All normal ranges are really the mean plus or minus two standard deviations of a large population sampling, and in the course of a medical practice, many normal individuals with "abnormally" elevated WBC counts will be encountered. Conversely, the higher the WBC count, the less likely it is that the elevation is a normal Gaussian variation. Third, for how long has the particular subset of WBCs been elevated? The differential diagnoses of acute elevations of each class of leukocytes are different from those of chronic elevations, and lifelong elevations are distinctive altogether.

Once the clinician has determined the specific cell type that is elevated, the degree of elevation, and the chronicity of the problem, a specific list of likely differential diagnoses should be generated. With this list in hand, the next step is to review or repeat the history and physical examination of the patient, focusing on those features that can differentiate the specific diagnoses under consideration. It is frequently important to repeat the initial interview and examination because the clinician may not ask the critical questions or may miss a subtle physical finding without the elevated WBC count in hand. After this process is completed, the clinician reevaluates the list of likely diagnoses, effectively reorganizing the list from most to least likely.

With the newly organized list of differential diagnoses in hand, specialized tests can be ordered if necessary. These can include hematology cytochemical stains, such as leukocyte alkaline phosphatase; serologic tests for viral illnesses; flow cytometric analyses of circulating blood cells; and bone marrow aspiration. Results of the appropriate focused tests usually pinpoint the diagnosis. Following this evaluation algorithm leads directly and efficiently to accurate diagnoses ([Fig. 216.1](#)).

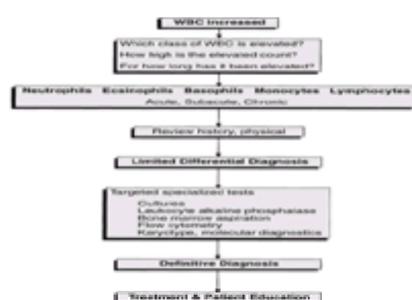

FIGURE 216.1. Algorithm for evaluation of the patient with leukocytosis.

NEUTROPHILIA

In the adult, the neutrophils usually constitute most of the circulating WBCs. What makes evaluation of neutrophilia interesting is that the neutrophils measured by phlebotomy are only 5% of the total body neutrophil pool at any one time, and they are being measured during only 2% to 3% of their lifetime, in rapid transit from the bone marrow to the tissues. Because the neutrophil count normally varies widely within a broad range, a single sampling can be confusing. A single circulating neutrophil count is a snapshot of one corner of a rapidly changing cellular population.

CONSTITUTIONAL NEUTROPHILIAS

Some individuals are totally normal but have neutrophil counts above the "normal range." Five percent of individuals tested have neutrophil counts above the mean plus two standard deviations (approximately 8,000 per cubic millimeter) in any laboratory. Although sometimes high neutrophil counts are found to be normal when repeated, in other individuals the neutrophil count is always high. Individuals have been followed for as long as two decades with elevated neutrophil counts, without known causes or consequences. Such *chronic idiopathic neutrophilia* can be an isolated occurrence in an individual or can rarely be hereditary. The only important caveat is that patients with otherwise obscure neutrophilia should have congenital asplenia excluded by ultrasonography.

Uncommon genetic disorders that are accompanied by neutrophilia include leukocyte adhesion deficiency, familial myeloproliferative disease, and Down's syndrome, but these are invariably diagnosed in childhood.

ACUTE ACQUIRED NEUTROPHILIA

Neutrophilia is an acquired disorder in most patients in whom it is detected. Because neutrophils are the infantry of the inflammatory and immune systems, frequently employed in any and all combat theaters, neutrophilia is a common finding with any infection, inflammation, injury, or stress. Acute or chronic bacterial infection, acute myocardial infarction (usually paralleling the rise and fall of aspartate aminotransaminase levels), pulmonary embolism, and trauma or surgery are probably the most common causes seen in clinical practice.

Although neutrophilia follows the stress of many surgical procedures temporarily, splenectomy can result in prolonged or even lifelong neutrophilia as high as 20,000 to 25,000 per cubic millimeter. Heat stroke, burns, hemolysis, diabetic ketoacidosis, acute thyrotoxicosis, and acute gout are additional stresses that often result in neutrophilia. A clinician discovering new-onset neutrophilia should carefully evaluate the patient for these common occurrences ([Table 216.1](#)).

Acute neutrophilia
 Infection (esp. bacterial)
 Trauma
 Tissue infarction: pulmonary embolism, myocardial infarction, stroke, cell crisis, burn
 Labor and delivery
 Hypoxia
 Drugs (esp. adrenergic agonists, corticosteroids, lithium, granulocyte-macrophage colony-stimulating factor)
 Diabetic ketoacidosis
Acute onset
 Renal failure, hepatic coma
 Hemolytic anemia
 Hemorrhage
Chronic but acquired neutrophilia
 Infections (esp. osteomyelitis, sinusitis)
 Vasculitis (esp. polyarteritis nodosa)
 Chronic pulmonary emboli
 Pericarditis, pleuritis
 Carcinomas, malignant lymphomas, Hodgkin's disease
 Chronic myelogenous leukemia
 Polycythemia vera
 Myelofibrosis and myeloid metaplasia
 Splenectomy
Life-long neutrophilia
 Chronic idiopathic neutrophilia
 Hereditary neutrophilia
 Aplasia

TABLE 216.1. COMMON CAUSES OF NEUTROPHILIA

Patients should be questioned about drug treatments that commonly cause neutrophilia, including epinephrine, corticosteroids, and lithium, as well as the recombinant pharmaceuticals granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF). Epinephrine releases into the circulation a sequestered pool of mature neutrophils that normally adhere to the vascular endothelium. Patients receiving subcutaneous epinephrine for bronchospasm, for example, develop neutrophilias in the range of 10,000 to 20,000 per cubic millimeter. Corticosteroids accelerate the release of neutrophils and bands from a large storage pool within the bone marrow, resulting in neutrophilia often accompanied by an increase in band forms. Lithium, usually prescribed for bipolar affective disorders, also raises the neutrophil count by an unknown mechanism. G-CSF and GM-CSF are parenteral pharmaceuticals that are prescribed by hematologists and oncologists, and their use should be easily identified.

SUBACUTE AND CHRONIC NEUTROPHILIA

For patients in whom neutrophilia is acquired but has a longer history or does not disappear when potential common causes are remedied, a more extensive and slightly different list of diagnoses needs to be considered. These include chronic infections, recurrent pulmonary emboli, vasculitis (especially polyarteritis nodosa), chronic pleuritis or pericarditis, Hodgkin's disease, and a variety of tumors, including carcinomas (especially bladder and pancreatic tumors) and lymphomas. Although acute myelogenous leukemia rarely presents with neutrophilia, circulating blasts with any mature neutrophil count necessitates bone marrow aspiration to rule out acute myelogenous leukemia. Persistently elevated neutrophil counts can be the presenting sign of chronic myelogenous leukemia or, if accompanied by elevations in platelet counts, eosinophils, basophils, or polycythemia vera.

In evaluating persistent neutrophilia, the clinician must review the patient's history, physical examination results, and laboratory studies for indexes of these infectious, inflammatory, and neoplastic conditions. In pursuing this differential diagnosis, the leukocyte alkaline phosphatase cytochemical stain of circulating WBCs is often most useful. The result is uniformly near zero in chronic myelogenous leukemia, and it is normal to elevated in reactive secondary neutrophilias and in polycythemia vera. If the result is low, bone marrow aspiration for karyotyping to detect t(9:22) or molecular diagnostic evaluation for the presence of abnormal P210 BCR/ABL mRNAs should be performed to confirm the diagnosis of chronic myelogenous leukemia. If the leukocyte alkaline phosphatase result is normal or elevated, specific measures to identify or rule out the causes of persistent reactive neutrophilia should be vigorously pursued because they are all serious.

EOSINOPHILIA

Rose-staining eosinophils (*eos* means "dawn," as in Homer's "rosy-fingered dawn") developed and persisted during evolution as a specialized mobile defense against parasites. They are induced to differentiate from multilineage myeloid progenitor cells in the bone marrow in response to interleukin-5 (IL-5) and interleukin-3 (IL-3) secreted by activated T cells. The contents of their fragile granules are extremely toxic, which accounts for their importance in penetrating and killing highly protected, encapsulated parasites. If eosinophils are inappropriately stimulated, these same granule contents irritate and deform the normal structures with which they come in contact, including vascular walls, endocardial surfaces, and mesenchymal tissues. Because of these effects, there is no such thing as benign persistent eosinophilia. Persistent eosinophilia signifies a serious parasitic infection or other serious disease that stimulates eosinophilia through generalized T-cell activation or a primary nonreactive hypereosinophilia, which is dangerous because of the toxic consequences of the eosinophils themselves.

Patients who present with eosinophilia (more than 450 cells per cubic millimeter) should first be evaluated for parasites, especially hookworm and tapeworm, and for *Ascaris*, schistosomiasis, *Strongyloides* (roundworm), filarial worms, trichinal infestation, and *Toxocara* species. Patients also should be assessed for overactive T-cell activation, usually representing allergic reactions to drugs, foods, or exposures.

If these are not readily apparent, a large number of unusual systemic diseases characterized by T-cell immune activation must be considered ([Table 216.2](#)). If no such causes are found, the clinician should evaluate for the possibility that the patient has a clonal T-cell lymphoproliferative disorder in which the abnormally expanded clone autonomously secretes IL-5 or IL-3 and therefore should pursue T-cell gene rearrangement studies of peripheral blood mononuclear cells. Chronic myeloid leukemia should also be considered if neutrophilia is present as well.

Acute eosinophilia
 Allergic reactions: drugs, food exposures
 Parasites
 Arthropod infestations (esp. scabies)
 Protozoan infections: Pneumocystis, Plasmodium, Entamoeba histolytica, Toxoplasma
Chronic eosinophilia
 Addison's disease
 Vasculitis: Wegener's granulomatosis, Churg-Strauss disease, Löffler's endocarditis, polyarteritis nodosa, Goodpasture's syndrome
 Sarcoidosis
 Postinfectious eosinophilia (esp. poststreptococcal infections)
 Eosinophilic gastroenteritis
 Inflammatory skin diseases: eczema, dermatitis herpetiformis, ichthyosis, pityriasis
 Chronic myelogenous leukemia
 Pernicious anemia
 Polycythemia vera
 Hodgkin's disease
 Carcinomas, lymphomas
 T-cell chronic lymphocytic leukemia
 Idiopathic hypereosinophilic syndrome

TABLE 216.2. COMMON CAUSES OF EOSINOPHILIA

If no specific diagnosis can be made to direct treatment, the patient is left with the diagnosis of idiopathic hypereosinophilic syndrome, at which point anti-eosinophilic treatment is initiated to prevent vasculitic and mesenchymal toxicities.

BASOPHILIA

Basophilia is rare and should prompt the clinician to consider many of the conditions that trigger eosinophilia. However, persistent basophilia (more than 100 cells per cubic millimeter) is a common sign of myeloproliferative diseases such as chronic myelogenous leukemia, or polycythemia vera and myelodysplasia (preleukemia). Patients with undiagnosed basophilia should undergo bone marrow aspiration for morphologic and karyotyping studies.

MONOCYTOSIS

Monocytes serve as the initiators of the immune response through antigen presentation, through secretion of activating cytokines such as IL-1a and tumor necrosis factor a, and as effectors of ingestion of invading organisms. Monocytosis (more than 1,000 cells per cubic millimeter) is most often the sign of an acute bacterial, viral, protozoal, or rickettsial infection. Monocytosis in the absence of significant neutrophilia occurs especially in cases of tuberculosis, syphilis, brucellosis, and

typhoid fever, and these diagnoses should be considered and evaluated. Chronic inflammatory conditions can stimulate sustained monocytosis.

Unexplained persistent monocytosis should raise the suspicion of occult leukemia, especially acute monocytic leukemia, and should be evaluated by bone marrow aspiration.

LYMPHOCYTOSIS

Most circulating lymphocytes are T cells, and their numbers increase as the normal response to any viral infection. The most common cause of lymphocytosis is an acute viral illness. In many cases, the numerous lymphocytes appear large and vacuolated, a sign of their activation against viral antigens on infected target cells, such as the Epstein–Barr virus–infected B lymphocytes of infectious mononucleosis.

Persistent lymphocytosis is unusual as a sign of infectious disease. Much more commonly, lymphocytosis is a sign of a clonal lymphoproliferative disease. If persistent lymphocytosis (more than 6,000 cells per cubic millimeter) is detected, chronic lymphocytic leukemia should be considered first in the differential diagnosis. The clinician should reinterview the patient, with particular attention to eliciting complaints of fevers, weight loss, and night sweats, and reexamine the patient, concentrating on the lymph nodes, liver, and spleen. The peripheral blood smear should be examined for the presence of many broken “smudge” cells, a sign of B-cell chronic lymphocytic leukemia, or large lymphocytes with fine granules, a sign of T-cell chronic lymphocytic leukemia. In cases of persistent, significant lymphocytosis, peripheral blood should be evaluated by flow cytometry for patterns of lymphocyte cell surface proteins diagnostic of T-cell or B-cell chronic lymphocytic leukemia.

PRESENTATION

Thrombocytosis is defined as a sustained elevation in platelet count. As will be discussed below, a variety of mechanisms may result in this condition, and presentation largely depends on the cause of the platelet count increase. In the vast majority of cases, thrombocytosis is asymptomatic and therefore comes to the attention of a physician only when a routine blood count reveals its presence. The likely reason for this will be discussed below. In those patients who do have symptoms directly referable to their elevated platelet count, the most common presenting complaints are related to occlusive phenomena of the microcirculation of the central nervous system and/or the peripheral vasculature. Headache, dizziness, or episodes consistent with transient ischemic attacks are common, as are paresthesias and acrocyanosis of the digits. A particularly dramatic presenting complaint is a syndrome known as erythromelalgia. It is characterized by erythema, burning, and intense pain of the fingers and toes, and it is often dramatically improved by a single dose of aspirin. Thrombosis of larger arteries or veins is less common but may be found in approximately 2% to 20% of patients at the time of diagnosis. Although it is not unusual for a patient to have thrombotic and bleeding complaints simultaneously, bleeding in the absence of thrombosis is several times less common. When an isolated hemorrhagic diathesis is present, it typically manifests itself in the form of epistaxis, hematuria, or gastrointestinal bleeding.

PATHOPHYSIOLOGIC FACTORS

Since platelets are derived from megakaryocytes it seems self-evident that a basic understanding of megakaryocyte developmental biology and thrombopoiesis would aid in the understanding of the pathogenesis of quantitative platelet production disorders. This subject is reviewed briefly below.

Megakaryocytes, like all hematopoietic cells, are ultimately derived from an undifferentiated pluripotent hematopoietic stem cell (Fig. 217.1). By mechanisms still unknown, a stem cell gives rise to a daughter cell that is committed to development within the megakaryocyte lineage. Subsequent development is characterized by progenitor cell proliferation, followed by terminal maturation of non-dividing cells. The proliferative step is necessary to produce the requisite numbers of megakaryocytes needed for daily platelet production. Terminal maturation is concerned with carrying out the steps needed for actual thrombopoiesis. These focus on cytoplasmic maturation, as well as on increasing cellular DNA content by a process known as endoreduplication in which multiple rounds of DNA synthesis occur in the absence of cell division. Endoreduplication is a development characteristic that is unique to megakaryocytes.

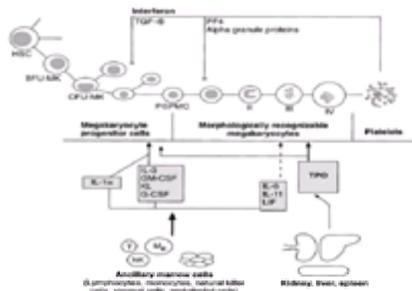

FIGURE 217.1. Human megakaryocytes are derived from a pluripotent hematopoietic stem cell. Human megakaryocyte progenitor cells, the burst-forming unit and colony-forming unit megakaryocyte, give rise to platelet glycoprotein–bearing mononuclear cells, which are the immediate progenitors of mature, platelet-producing megakaryocytes. Megakaryocytes evolve through four morphologically recognizable stages that are characterized on the basis of their nuclear morphology and nuclear/cytoplasmic ratio. When maturation is complete, the megakaryocytes give rise to platelets. Positive and negative regulators of this process are depicted in the figure.

Thrombopoiesis is also poorly understood. Platelets are formed within the megakaryocyte cytoplasm and may then be shed by a variety of mechanisms. For example, they may be released like seeds from a pod into vascular sinuses in the bone marrow. Alternatively, megakaryocytes may extend long pseudopods into the vascular sinusoids and then fracture into platelets as a result of flow-induced shear stress. It has also been postulated that entire cells migrate into the vascular sinusoids where they then travel to the lung. Cell fracturing and platelet release take place as the cells traverse the pulmonary vasculature.

The gene that encodes the major protein regulator of megakaryocyte development, thrombopoietin (*TPO*), has recently been cloned. It is perhaps not surprising that the human gene maps to the long arm of chromosome 3 (3q26–27) since inversions, insertions, and translocations involving the long arm of chromosome 3 have been associated with megakaryocyte hyperplasia and thrombocytosis. The *TPO* gene encodes a 322-amino-acid protein. The biological activity of the protein appears to reside in the amino terminus, which, interestingly, has significant homology to erythropoietin, the principal regulator of red cell production.

Although *TPO* appears to play a major role in regulating megakaryocyte and platelet production, other cytokines, including interleukins 3, 6, and 11, stem cell factor, and fetal liver kinase-2 (*flk-2*) ligand also influence this process.

HISTORY AND PHYSICAL EXAMINATION

Thrombocytosis may result from an intrinsic proliferative abnormality of megakaryocyte progenitor cells or an abnormal stimulus that drives otherwise normal megakaryocyte progenitor cells to proliferate. The former mechanism leads to primary, or essential, thrombocytosis (ET), whereas the latter leads to a secondary, or reactive, thrombocytosis (RT). Either circumstance leads to an increase in megakaryocyte mass and a rise in platelet count. The primary task for the physician evaluating a patient with thrombocytosis is to determine which mechanism is operative because the course, prognosis, and treatment of each form varies considerably (Table 217.1).

Diagnostic Features	Reactive Thrombocytosis	Essential Thrombocytosis
History		
Recent inflammatory disorder or infection	+	-
Neoplasms/malignancy	+	-
Acute blood loss or trauma	+	-
Splenectomy	+	-
Drug-induced thrombocytosis	+	-
Thrombotic/thrombotic phenomena	-	+
Physical Examination		
Fever, tachypnea	+	-
Splenomegaly	+	-
Hepatomegaly	+	-
Laboratory Evaluation		
Platelet count > 400,000/μL	+	+
Increased MPV, CD-reactive proteins, fibrinogen, interleukin-6 level	+	-
Morphologic abnormalities on blood or bone marrow smear	-	+
Abnormal marrow smear, normal or elevated serum ferritin, MCV normal	-	+
Increased marrow reticulin or marrow fibrosis	-	+
Abnormal cytogenetics	-	+
Increased bleeding time	-	+
Abnormal platelet aggregation on response to aspirin	-	+
Spontaneous megakaryocyte or erythroid colony formation	-	+

+, consistently (+); -, feature not observed; +/-, feature observed inconsistently or rarely; MPV, mean platelet volume.

TABLE 217.1. FEATURES HELPFUL IN DIFFERENTIATING ESSENTIAL FROM REACTIVE THROMBOCYTOSIS

A detailed history can be useful in attempting to differentiate ET from RT. RT is commonly observed in a diverse array of clinical conditions that have an accompanying inflammatory component. Acute and chronic tissue infections, rheumatoid arthritis, inflammatory bowel disease, malignancies, and injury or surgically related trauma may be accompanied by thrombocytosis. Recent splenectomy is particularly likely to produce thrombocytosis. The spleen serves as an important storage site for platelets, and counts are transiently elevated after the spleen is removed, although mild elevations can persist in about one third of these patients. Iron-deficiency anemia is commonly associated with RT and should be suspected in young female patients with a history of heavy menstrual bleeding. A history compatible with any of the above mentioned conditions should initially suggest a diagnosis of RT. Nevertheless, 20% to 30% of patients with ET may also have constitutional symptoms, including fever, weight loss, and night sweats. As bleeding or thrombotic complications are exceptionally rare in patients with RT, any such history should immediately suggest that the elevated platelet count is caused by ET. The results of previous blood tests are helpful in documenting duration and trend of the thrombocytosis and should be sought.

Although the physical examination is rarely definitive, it may at times be helpful in determining the cause of thrombocytosis. Neurologic findings and erythromelalgia would certainly suggest a diagnosis of ET. On the other hand, pale skin and conjunctiva, suggestive of recent blood loss or anemia, would be consistent with RT. Enlarged lymph nodes, spleen, or mass lesions are suggestive of an underlying malignancy as the cause of the elevated platelet count, as are the joint deformities common to rheumatoid arthritis. Nevertheless, the liver and spleen are enlarged in about 20% to 40% of ET patients, respectively. Accordingly, the physical examination may be very ambiguous.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

As neither the history nor the physical examination is conclusive, the diagnosis of ET or RT often depends on the results of laboratory testing. Since ET typically becomes a diagnosis of exclusion, the goal of testing is to exclude abnormalities known to be associated with RT, other myeloproliferative disorders associated with elevated platelet counts, in particular polycythemia vera and chronic myelogenous leukemia. From this perspective, evaluation of the peripheral blood smear and a bone marrow aspirate or biopsy can be helpful.

White blood cell counts may be elevated in both RT and ET and are not discriminatory unless morphologic abnormalities, such as immature or dysplastic myeloid precursors, are noted. The presence of such forms are suggestive of a myeloproliferative disorder or myelodysplastic syndrome. Anemia in the absence of other hematologic abnormalities suggests an RT. Platelet morphology is helpful only if megathrombocytes or large, bizarre-looking cells are present. Such abnormalities are associated with myeloproliferative disorder. Platelet counts per se are of little use in differentiating primary from reactive thrombocytosis. The pervasive notion that counts greater than $1,000 \times 10^9$ per liter signify the presence of ET is incorrect. Personal observation and published reports document that RT patients may have counts that exceed $2,000 \times 10^9$ per liter. Unfortunately, duration of platelet count elevation may not discriminate between RT and ET because many of the conditions associated with RT tend to be chronic.

In ET and RT patients, the bone marrow may be hypercellular, with an increase in the megakaryocyte-to-erythrocyte ratio. As was true in the peripheral blood, absence of morphologic abnormalities does not reliably discriminate between ET and RT. However, if such abnormalities are demonstrable, it becomes unlikely that the condition is reactive. Much attention is typically paid to cells of the megakaryocyte lineage. Hematopathologists look for dysplastic megakaryocytes, which are characterized by unusually large or small sizes and by abnormally lobulated nuclei. Small, hypolobulated megakaryocytes are thought to be typical of chronic myelogenous leukemia. Megakaryocyte clusters or aggregates are often associated with ET, but they are not specific because such formations may be found in as many as 25% of RT patients. Marrow reticulin is not increased in RT, and there is no fibrosis. In ET, marrow reticulin ranges from normal to slightly increased in essential thrombocytosis to grossly fibrotic in myelofibrosis with myeloid metaplasia.

It is difficult to diagnose ET in the absence of stainable marrow iron because polycythemia vera characteristically has absent marrow iron and RT is associated with iron deficiency. Nevertheless, absent marrow iron may result from artifact. Helpful clues to discern such artifact would be normal or increased serum ferritin and normal red blood cell mean corpuscular volume. In addition, recent studies suggest that a hematocrit greater than 60 is always due to polycythemia vera and never ET.

Marrow cytogenetics are not often diagnostic because they are normal in RT and in more than 95% of cases of ET. Despite this, cytogenetic testing may be worthwhile because it occasionally detects an abnormality consistent with a myelodysplastic syndrome (5q-) or the Philadelphia chromosome t(9:22) of chronic myelogenous leukemia.

Platelet function tests are commonly employed to differentiate ET from RT. Results of these tests, which typically include a bleeding time and aggregation in response to various agonists, are normal in patients with RT. For ET patients, prolonged bleeding time, spontaneous aggregation, and impaired aggregation, especially in response to epinephrine, have been widely reported. Unfortunately, spontaneous aggregation is an unreliable test, and some otherwise normal patients (15%) have impaired aggregation in response to epinephrine or other aggregating agents, thereby lessening the test's discriminatory power. The common use of aspirin, nonsteroidal anti-inflammatory drugs, and other agents that impair platelet function is also problematic because they obviously render platelet function tests uninterpretable. The physician should be certain that the patient has not used these drugs or over-the-counter preparations containing these medications before carrying out platelet function studies.

Several cytokines may augment megakaryocytopoiesis and thrombopoiesis. Of these, IL-6 has been shown to be particularly active in vitro. This cytokine has several other activities, the most important of which may be its B-cell-stimulatory activity. Interleukin-6 production is augmented in acute inflammatory responses and in a variety of chronic inflammatory states. Plasma levels of IL-6 have been reported to be elevated in patients with RT but not in those with ET. The C-reactive protein levels parallel IL-6 levels and therefore give similar, but less expensive, information. Plasma fibrinogen levels in excess of 500 mg per deciliter have been reported to be sensitive and reasonably specific for RT. Least expensive of all these options, and one that probably yields qualitatively similar information, is the erythrocyte sedimentation rate. It is a sensitive, although nonspecific, test for inflammatory states.

With the recent cloning of the *TPO* gene and its receptor, *c-mpl*, it has been natural to explore the relationship between expression and/or mutation of these genes and the development of thrombocytosis. A number of publications suggest that *TPO* levels are elevated in ET but not in RT. One investigation of familial ET suggested that there were no mutations present in the *c-mpl* receptor. It is of interest, however, that a splice donor mutation in the *TPO* gene resulting in higher levels of *TPO* has been reported in a kindred with hereditary ET. The practicality and reliability of these assays remain to be determined.

In many cases, none of the standard tests can differentiate RT from ET, and it may be useful to contact a laboratory that is capable of cloning hematopoietic progenitor cells. My colleagues and I reported several years ago that patients with ET have dramatically increased numbers of assayable megakaryocyte colony-forming units (CFUs-MK) compared with normal controls or patients with RT. The CFUs-MK from ET patients had significantly increased proliferative capacity and the ability to form colonies without an exogenous source of growth factors. This observation has been confirmed by several groups and may therefore be of use in diagnosing particularly difficult cases. However, colony assays are not standardized, and long-term follow-up studies correlating colony-forming ability with disease status have not been reported. These factors, combined with the limited availability of such testing, suggest that CFU-MK assays should not be considered part of the routine workup of these patients.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of an elevated platelet count has been suggested by the discussion in the preceding paragraphs. The major decision is whether the condition is secondary or primary. As discussed in previous sections, there are multiple secondary causes of an elevated platelet count, and treatment of the underlying cause normalizes the platelet count in virtually all cases; this is a major differential point. As was mentioned above, several primary marrow disorders may manifest with a prominent thrombocytotic component. These conditions include myeloproliferative disorders, myelodysplastic syndrome associated with the 5q- syndrome, and even some acute leukemias. The latter are associated with inversion of chromosome 3.

Although it has been estimated that as many as one-third of cases of thrombocytosis will ultimately be found to have an underlying myeloproliferative disorder, more

recent reports cast doubt on this figure. A recent study of 280 hospitalized patients found that even when the platelet count exceeded 1×10^9 per liter, approximately 80% had a nonhematologic condition as underlying cause of their elevated platelet count, and only 14% had a myeloproliferative disorder. Modern clonality studies using molecular analytical techniques suggest that this figure may be even lower.

STRATEGIES FOR OPTIMAL CARE

Management depends on whether the cause of the platelet count elevation is primary or secondary. Since bleeding or thrombotic complications directly attributable to the platelet count elevation are quite rare in patients with secondary thrombocytosis, intervention (other than identifying and treating the underlying cause, and advising patients who smoke to quit) is rarely indicated.

Patients with essential thrombocytosis have an excellent long-term prognosis. Although extended follow-up studies are few, the disease appears to be highly compatible with a normal life expectancy. ET rarely transforms into acute leukemia, and only about one-third of patients experience a major bleeding or thrombotic complication. Unfortunately, neither bleeding nor thrombosis can be predicted on the basis of platelet count elevation or platelet function abnormalities. Accordingly, it is not always clear as to who should be treated and when such treatment should be initiated. In a young, asymptomatic patient with no history of coronary or peripheral vascular disease, it is defensible to observe the patient only. In older individuals, in particular those with vascular disease, treatment is likely indicated. Recent studies suggest that thrombotic complications are uncommon in individuals with platelet counts below 600×10^9 per liter. Many hematologists therefore use this value as a goal when initiating treatment.

In the acute setting, such as significant bleeding or a major thrombotic event, platelet pheresis combined with myelosuppressive therapy, typically administration of hydroxyurea, rapidly lowers the platelet count. The usual dosage of hydroxyurea in this setting is 2 g per day or higher. The clinical goal again is to bring the platelet count below the level of 600×10^9 per liter.

For long-term control, hydroxyurea has been the drug of choice. Studies of a relatively large number of patients suggest that this drug may be particularly useful in patients who are at high risk of developing thrombotic complications. Hydroxyurea is inexpensive and generally well tolerated. When carefully monitored, its side effects usually are limited to gastrointestinal upset and dermatologic manifestations, especially hyperpigmentation. It is important to note, however, that this agent is not without risk. There are data to indicate that hydroxyurea is leukemogenic in myeloproliferative disorder patients. Having said this, however, the Polycythemia Vera Study Group's final report on ET indicates that leukemia only developed in patients who received hydroxyurea followed by another myelosuppressive agent, such as phosphorus 32, busulfan, or cyclophosphamide. In those treated with hydroxyurea only, there was no increased incidence of acute leukemia. Accordingly, the drug remains recommended. Usual doses are from 500 mg to 2 g per day, and the goal is to reduce the platelet count to less than 600×10^9 per liter without inducing leukopenia.

In addition to hydroxyurea, long-term control of platelet count can be maintained with anagrelide or interferon- α . Anagrelide, a quinazoline derivative, has been extremely effective in the management of thrombocytosis. The drug appears to affect thrombopoiesis at the level of the maturing megakaryocyte and to have no other significant effects on hematopoietic progenitor cells. When given in the usual doses of 1 to 4 mg per day, it is effective in more than 75% of patients. Its usual side effects include palpitations, headache, nausea, and fluid retention, which may be encountered in 20% to 30% of patients. This drug has recently received Food and Drug Administration approval, so that reports of its use in larger numbers of patients should become available before too long. Interferon- α is also effective. Typical doses are 3 to 5 $\times 10^6$ units per day for 3 to 7 days a week. The drug is injected subcutaneously, which is problematic for some patients. In addition, it is expensive and is often poorly tolerated because of its side effects, which include fatigue, musculoskeletal pain, headache, and other flulike symptoms.

Symptoms due to erythromelalgia are easily managed with aspirin (300 to 500 mg per day) or nonsteroidal anti-inflammatory drugs. However, many authorities recommend that these agents be avoided, except for the indication previously discussed, because their use is associated with increased hemorrhagic complications.

As was noted above, the management of asymptomatic patients is somewhat controversial. Several studies of individuals younger than 40 years suggest that it is appropriate to manage such patients expectantly and to initiate treatment only when a patient develops vasomotor symptoms or a major bleeding or thrombotic episode. The long-term prognosis for these patients is excellent, and this must be balanced with the known and unknown risks of long-term administration of drugs such as hydroxyurea and anagrelide. In older patients, especially those with a history of thrombotic disease, it is probably wise to keep the platelet count below 600×10^9 per liter.

Pregnant patients are also problematic. The incidence of fetal wastage, probably caused by placental infarction, is not known with certainty; however, in one series the incidence was reported to be 45% of the 34 pregnancies observed in 18 patients. In this series, the outcome of the pregnancy could not be predicted from the height of the platelet count, the history of complications or lack thereof, or the treatment administered. Not giving any treatment appeared to be an acceptable alternative. Other series report that aspirin administration has been associated with successful pregnancies, although aspirin may increase the mother's risk of serious bleeding at the time of delivery.

Hydroxyurea and busulfan have been administered to a small number of patients during the first trimester without incident, but other physicians have reported an increase in fetal malformations. In patients who require chemotherapeutic agents for control of their platelet count, the most conservative course would be to advise against pregnancy. Attempts to control platelet counts with interferon may be an alternative strategy in this selected subset of patients. The teratogenic risk of interferon in human patients is unknown, but it has been administered to rhesus monkeys at 20 to 500 times the therapeutic dose without apparent teratogenic effect. However, in rhesus monkeys interferon had abortifacient activity.

The management of surgical patients can be complicated and should involve consultation with a hematologist–oncologist. In general, drugs that interfere with platelet function should be avoided because patients receiving agents such as aspirin are more likely to have bleeding complications. Suppressing the platelet count to less than 600×10^9 per liter is probably also indicated, especially for patients older than 60 years or those with previous thrombotic complications.

PRESENTATION

Excessive bleeding complicates many medical and surgical illnesses. Patients requiring evaluation for a bleeding disorder usually present in a manner reflecting their underlying medical conditions, as well as the specific defect responsible for their hemorrhagic diathesis. For example, an apparently healthy woman with previously undiagnosed von Willebrand disease may present with a chief complaint of progressive fatigue, with hematologic evaluation revealing iron deficiency anemia. Further questioning may reveal a history of long-standing menorrhagia, with directed laboratory studies confirming the diagnosis of the coagulopathy. Such a presentation contrasts sharply with that of an elderly patient with no prior bleeding history who develops acute hemorrhage as a result of a vascular defect incurred during a surgical procedure.

Because of this wide array of clinical presentations, evaluation of the patient with excessive bleeding depends on a basic understanding of normal hemostatic mechanisms and the specific clinical symptoms resulting from their disruption. In this chapter, we review normal hemostatic pathways as well as the pathophysiology of some of the more common defects in this system that are associated with bleeding.

PATHOPHYSIOLOGIC FACTORS

Coagulation may be considered as two interdependent processes, referred to as primary and secondary hemostasis. Primary hemostasis is characterized by the formation of a platelet plug at the site of vascular trauma. This involves the adhesion of circulating platelets to subendothelial matrix components such as collagen, fibronectin, and von Willebrand factor, which are exposed after vessel damage. Platelet adhesion is mediated through specific cellular receptors such as the collagen receptor (platelet glycoprotein Ia/IIa) and the platelet glycoprotein Ib/IX/V complex, which binds von Willebrand factor incorporated into the subendothelial matrix. Adhesion to the damaged vessel wall induces platelet activation, a complex process that involves “outside-in” signaling responses transmitted by platelet integrin receptors. As a consequence, platelets undergo shape change, secrete the contents of their α and dense granules, and expose and activate fibrinogen receptors (platelet glycoprotein IIb/IIIa). Exposure of fibrinogen receptors facilitates the recruitment of additional platelets to the platelet plug by allowing the dimeric fibrinogen molecule to bridge receptors on adjacent platelets and induce platelet aggregation.

Platelet activation also results in rearrangement of membrane phospholipid, with increased expression of anionic phospholipid on the platelet surface and the release of anionic phospholipid-enriched platelet microparticles. Exposed anionic phospholipid provides a surface that supports the binding and activation of circulating coagulation factors, particularly those most important in the assembly of key coagulation complexes such as the “tenase” and prothrombinase complexes (see below). Thus, the surface of the activated platelet provides a fertile site for the generation of thrombin. In turn, thrombin promotes the direct activation of additional platelets through its binding and proteolytic activation of the platelet thrombin receptor.

Although primary hemostasis usually leads to the cessation of bleeding, the shear forces associated with flowing blood are sufficient to cause the eventual dissolution of the platelet plug. The role of secondary hemostasis, which involves the sequential activation of soluble coagulation factors, is to solidify the platelet plug through the formation of a stable, cross-linked fibrin clot. Secondary hemostasis has been conceptually subdivided into three major pathways: the intrinsic, extrinsic, and final common pathways (Fig. 218.1).

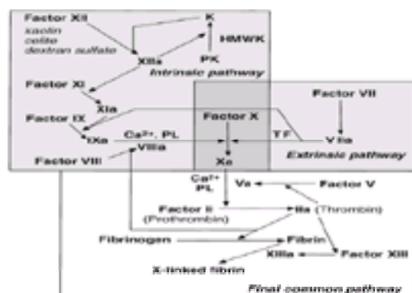

FIGURE 218.1. The coagulation cascade. The intrinsic (*lightly shaded*) and extrinsic (*more densely shaded*) pathways converge at the activation of factor X (*densely shaded*). The reactions of the final common pathway are enclosed in the box without shading. HMWK, high molecular weight kininogen; K, kallikrein; PK, prekallikrein. (Reproduced from Feldman MD, McCrae KR. Applications of the clinical coagulation laboratory in the perioperative period. In: Lake CL, Moore RA, eds. *Blood: hemostasis, transfusion, and alternatives in the perioperative period*. New York: Raven Press, 1995:155, with permission.)

Although the physiologic activators of the intrinsic pathway remain controversial, factor XII (FXII) may be activated (FXIIa) following contact with negatively charged substances (e.g., collagen) exposed as a result of vascular trauma. Activation of FXII to FXIIa leads to the activation of FXI (in a reaction catalyzed by high molecular weight kininogen) and prekallikrein (Fletcher factor). Newly activated FXI then activates FIX, and in the final reaction of the intrinsic pathway, FIXa activates FX through the formation of the tenase complex, which consists of FIXa, FX, calcium, phospholipid, and FVIII. This reaction constitutes a particularly important regulatory step in the coagulation cascade. However, the proximal steps in the intrinsic pathway are not essential for normal hemostasis, since individuals deficient in FXII, prekallikrein, or high molecular weight kininogen do not have a bleeding diathesis.

The extrinsic pathway is characterized by the direct activation of FX by a complex formed between FVIIa and tissue factor. This pathway is of central importance in initiation of the hemostatic response. Tissue factor, the only cell-associated, noncirculating coagulation factor, is produced by endothelial and other cells of the vascular wall. This factor is normally deposited in the subendothelial matrix but not expressed on the luminal aspect of the vessel wall under static conditions. After vessel damage, the exposure of tissue factor promotes the binding of FVIIa and the subsequent activation of FX. The activity of tissue factor is rapidly quenched through the action of a naturally occurring coagulation inhibitor, the tissue factor pathway inhibitor (TFPI). However, since the tissue factor/FVII complex also activates FIX, limited FXa generation may still occur through the assembly of the tenase complex.

The final common pathway represents convergence of the intrinsic and extrinsic pathways. In this pathway, FXa activates prothrombin to form thrombin, in a reaction involving the formation of the “prothrombinase” complex. This complex is analogous to the tenase complex, with FVa performing a catalytic role similar to that performed by FVIIIa in the latter. Newly generated thrombin cleaves fibrinogen to form fibrin monomers; these monomers self-associate to form mature fibrils, which are subsequently cross-linked by FXIIIa, leading to the formation of insoluble fibrin.

From the discussion above, it is evident that normal hemostasis involves numerous reactions, beginning with interactions of platelets with damaged vessel walls and proceeding through platelet activation and aggregation, the expression of platelet procoagulant activity, and the activation of soluble coagulation factors. Defects in any of these processes may lead to a bleeding diathesis.

Some of the more common congenital bleeding disorders are von Willebrand disease, hemophilia A, and hemophilia B. von Willebrand disease is inherited in an autosomal dominant manner, and results from either diminished production or the production of a functionally abnormal von Willebrand factor protein. Because von Willebrand factor plays a critical role in the adhesion of platelets to exposed subendothelium, particularly at sites of high-shear stress (such as the arterial circulation), its deficiency leads to impaired formation of the platelet plug and clinical manifestations similar to those caused by disorders of primary hemostasis. Conversely, impairment of the activity of the tenase complex in the hemophilias leads to defects of secondary hemostasis and clinical manifestations that are distinct from those attributable to platelet dysfunction (see below).

The majority of patients with bleeding do not have congenital or acquired coagulation defects. Bleeding in these individuals may result from a myriad of acquired conditions ranging from traumatic defects in the vascular wall, which may be of sufficient size that bleeding is not controlled by normal hemostatic mechanisms, to deficiencies in the levels of coagulation factors resulting from hepatic dysfunction.

HISTORY AND PHYSICAL EXAMINATION

BLEEDING HISTORY

The bleeding history must be carefully obtained, and the answers to only specific, directed questions designed to probe for truly abnormal bleeding events should be sought. Vague questions such as “Do you have heavy menstrual bleeding?” or “Do you bruise easily?” should be avoided since the responses to these queries are highly subjective. Similarly, the number of pads used in the course of a typical menstrual period may depend as much on the personal habits of the patient as on the amount of bleeding. Instead, questions such as “How many days do your menstrual periods last?” or “Do you frequently notice bruises larger than a quarter in areas where you do not remember receiving any trauma?” should be substituted.

The characteristics of bleeding in individual patients provide insight into the nature of the bleeding disorder. Defects in primary hemostasis are usually characterized by superficial bleeding involving the skin or mucous membranes, particularly those of the gastrointestinal or female genital tracts. Bleeding most often occurs immediately after trauma and usually does not recur after it is stopped. In contrast, bleeding that results from defects in secondary hemostasis, such as hemophilia, usually involves deeper tissues and may result in intramuscular hematomas, hemarthroses, or retroperitoneal hemorrhages. Bleeding events such as these may be delayed by a variable period after initial trauma, reflecting the inability of the platelet plug to be appropriately stabilized through activation of the coagulation cascade and the generation of cross-linked fibrin.

In all cases, it is essential to inquire about whether the patient has undergone previous surgical procedures (including dental extractions) and, if so, whether they were complicated by excessive hemorrhage. Subjective reports concerning a history of surgical bleeding may be misleading, and the physician should determine whether such episodes required a return to the operating room or blood transfusion through the direct review of the patient's records. Another critical aspect of the history is whether any immediate or first-degree family members have experienced excessive bleeding. In many cases, the patient's recollection of such events is vague, and in such circumstances direct questioning of the family member should be pursued. If a family history of bleeding exists, careful documentation may allow the pattern of inheritance to be established, providing information that will be useful in determining the nature of the bleeding disorder.

PHYSICAL EXAMINATION

A thorough physical examination is mandatory during the evaluation of a patient for a potential bleeding diathesis. Specific attention should be devoted to examination of the skin for petechiae (pinpoint hemorrhagic lesions occurring primarily in dependent areas, which are characteristic of quantitative or qualitative platelet dysfunction). Although nonpalpable purpura may also reflect quantitative or qualitative platelet abnormalities, other causes of such lesions, such as senile purpura, scurvy, corticosteroid excess, cholesterol or fat emboli, systemic infections, and dysproteinemias and defects in secondary hemostasis, should be considered. The finding of lax, velvety skin in a patient with a history of bleeding suggests Ehlers–Danlos syndrome, a disorder of collagen synthesis leading to weakened vessel walls. The mucous membranes, particularly the oropharynx, should also be closely inspected because this is another site where petechiae are frequently observed. Examination of these areas may also reveal lesions such as the arteriovenous malformations of Osler–Weber–Rendu disease (hereditary hemorrhagic telangiectasia), which occur throughout the gastrointestinal tract and may cause chronic gastrointestinal blood loss. The latter has recently been shown to result from mutations in the gene for endoglin, or *ALK1*.

The physical examination is of particular importance when evaluating the hospitalized patient with acute hemorrhage. In many cases, such patients are too ill to provide a reliable bleeding history, and the relevant history may not have been obtained at the time of admission. In this situation, the physical examination should focus on determining whether the bleeding is localized to a single site or is diffuse, since these two scenarios suggest different underlying causes. For example, postoperative bleeding from a single chest tube after coronary artery bypass grafting is likely to indicate the presence of an inadequately ligated vessel, a lesion that may require surgical reexploration. In contrast, hematuria, epistaxis, and oozing from venipuncture or intravenous catheter sites may reflect an acquired or previously unrecognized inherited bleeding disorder requiring systemic therapy.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

Perhaps more than in any other situation in medicine, the diagnosis and treatment of bleeding disorders depends on the prompt and appropriate performance and interpretation of laboratory tests. These may be divided into tests of platelet function and tests of the coagulation system.

TESTS OF THE COAGULATION SYSTEM

Tests to determine the integrity of the coagulation system include, among others, the prothrombin time (PT), activated partial thromboplastin time (aPTT), thrombin time (TT), mixing studies (inhibitor screen), and specialized studies such as those used to evaluate the levels and function of specific coagulation factors. The two tests most commonly performed to evaluate the integrity of intrinsic and extrinsic coagulation pathways, respectively, are the aPTT and the PT. The techniques used to perform the PT and aPTT are outlined in [Fig. 218.2](#). The PT measures the time required for plasma to clot after the addition of calcium and tissue thromboplastin. Tissue thromboplastin is an aqueous extract, generally prepared from rabbit brain, which is rich in anionic phospholipid and tissue factor. When added to plasma in the presence of calcium, thromboplastin preferentially supports the activation of coagulation through the reactions of the extrinsic pathway. For this reason, an isolated prolongation of the PT is most often caused by deficiencies of FVII. However, because this test is more sensitive than the aPTT to deficiencies of final common pathway factors, prolongation of the PT may also result from mild to moderate deficiencies of FX, prothrombin, or fibrinogen.

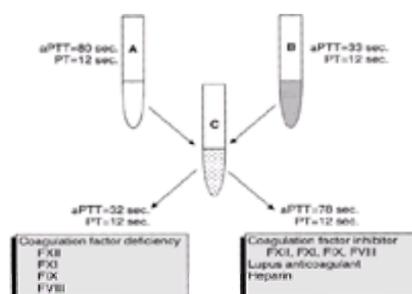

FIGURE 218.2. The inhibitor screen. In this example, the activated partial thromboplastin time (aPTT) of sample A is prolonged at 80 seconds (normal range, 30 to 36 seconds). Sample B represents normal plasma, and sample C represents a 1:1 mixture of A and B. A normal aPTT of sample C would demonstrate that the prolonged aPTT of sample A resulted from a coagulation factor deficiency (box on left). If the aPTT of sample C remained abnormal, it would be assumed that sample A contains a coagulation factor inhibitor (box on right).

In the 1980s, it was realized that the use of different commercial thromboplastin preparations among clinical coagulation laboratories often led to discrepant PT values in individual patients tested at different locations. To address this problem, the World Health Organization developed a reference thromboplastin reagent, against which all manufacturers of such reagents were required to standardize their products. Hence, all commercial thromboplastins now are assigned a specific ISI (International Standardized Index) number. These values are used to translate a specific PT value to an INR (international normalized ratio), which is defined as:

$$\text{INR} = (\text{patient PT}/\text{control PT})^{\text{ISI}}$$

Common clinical settings associated with a prolonged PT (INR) include vitamin K deficiency, which causes functional deficiencies of the vitamin K–dependent coagulation factors (prothrombin, FVII, FIX, and FX), and disseminated intravascular coagulation, which leads to consumption of fibrinogen. In addition, the anticoagulant warfarin (Coumadin) induces functional vitamin K deficiency by preventing regeneration of oxidized vitamin K. Therapeutic INR values for patients on warfarin range from 2.0 to 4.0, depending on the indication for anticoagulation.

In contrast to the PT, the aPTT measures the time required for plasma to clot after the addition of calcium, phospholipid, and an FXII activator (kaolin), which induces coagulation through the intrinsic pathway. The aPTT is prolonged in situations characterized by deficiency of any of the proteins involved in this pathway (FXII, FXI, FIX, FVIII, prekallikrein, or high molecular weight kininogen). Hence, the aPTT is prolonged in hemophilia A and B. The aPTT may also be prolonged by deficiencies of final common pathway factors (although in this situation a prolonged PT would be expected as well) and by standard preparations of unfractionated heparin that stimulate the inhibitory activity of antithrombin III toward thrombin and other coagulation proteases. In contrast, low molecular weight heparin preparations have more potent inhibitory activity toward FXa and do not cause significant prolongation of the PTT. Hence, these agents must be monitored (if monitoring is deemed necessary), through measurement of plasma anti-FXa activity. Common causes of an abnormal PT and/or aPTT are listed in [Table 218.1](#). The clinician should be aware, however, that the most common cause of a prolonged PTT is a lupus anticoagulant, which is paradoxically associated with an increased risk of thrombosis.

immune-mediated in this setting, should be evaluated by obtaining a platelet count and examining the peripheral blood film. Thrombocytopenia in the presence of reduced numbers of normal-appearing to slightly large platelets is most consistent with a diagnosis of immune thrombocytopenic purpura. However, because individuals with specific subtypes of von Willebrand disease may also be thrombocytopenic, an aPTT should also be assessed in this situation, with any observed prolongation pursued by a directed evaluation for von Willebrand disease. In contrast, if this individual was found to have reduced numbers of large, abnormal-appearing platelets, an inherited disorder of platelet function, such as the Bernard–Soulier syndrome or a platelet storage pool disease (see [Chapter 239](#)), must be considered.

FIGURE 218.3. Hypothetical evaluation of a young woman with menorrhagia and epistaxis. aPTT, activated partial thromboplastin time; FVIII, factor VIII; vWD, von Willebrand disease.

If the initial evaluation of this individual revealed a normal platelet count with normal-appearing platelets, von Willebrand disease would be the most likely diagnosis. Such a patient should be fully evaluated for this disorder, regardless of the aPTT, by obtaining a bleeding time (or PFA-100 analysis), assays for FVIII activity and antigen, von Willebrand factor antigen, and ristocetin cofactor activity. A platelet activation defect should also be considered in this setting, particularly if the aPTT is normal. Evaluation for such a disorder includes a bleeding time (or PFA-100 analysis) followed by specific platelet aggregation studies and/or measurement of platelet cyclic nucleotide content.

An entirely different differential diagnosis must be generated for the patient with excessive postoperative bleeding. The most common cause of postoperative bleeding is a vessel that was not adequately ligated during surgery. Bleeding of this nature is often localized and may present, for example, as hemorrhage from a single surgical drain. In contrast, postoperative bleeding from systemic causes, such as a dilutional coagulopathy (transfusion of multiple units of packed red blood cells without replacement of plasma and platelets) or unrecognized sepsis leading to disseminated intravascular coagulation, is usually associated with diffuse bleeding. A systemic cause of bleeding should thus be suspected in the presence of symptoms such as excessive oozing after venipuncture or around vascular access sites, mucous membrane or gastrointestinal bleeding, or hematuria.

An inherited bleeding disorder such as von Willebrand disease, mild hemophilia, or a platelet function disorder occasionally presents for the first time after surgery or major trauma. However, the initial discovery of such a condition in this setting is rare, particularly if a bleeding history is obtained before elective surgical procedures have been done.

STRATEGIES FOR OPTIMAL CARE

MANAGEMENT

Appropriate management of the bleeding patient requires identification and understanding of the underlying cause of hemorrhage. Comprehension of the pathophysiologic basis of congenital and acquired hemorrhagic syndromes is particularly important for employing the expanding repertoire of hemostatic agents in a cost-effective manner. Selection of appropriate therapy depends on the nature of the immediate bleeding event and the underlying bleeding diathesis. A full discussion of the therapy of inherited or acquired bleeding disorders is beyond the scope of this chapter, but several guidelines should be considered prior to initiating procoagulant therapy ([Table 218.2](#)).

1. Accurately discern the cause of bleeding using clinical and laboratory data.
2. Define the goals of therapy prior to its administration.
3. Employ the product that is optimal for treatment of the specific patient.
4. Use the minimum of product required to achieve adequate hemostasis.
5. Monitor the efficacy of therapy closely.

TABLE 218.2. GUIDELINES FOR USE OF PROCOAGULANT THERAPY IN THE BLEEDING PATIENT

First, the cause of the bleeding must be discerned as accurately as possible. The patient's history alone is rarely sufficiently reliable to allow for the design of a specific plan of therapy. The author has personally observed several instances when inaccurate information from either medical personnel or the patient led to that individual inappropriately receiving plasma-based therapy for a bleeding disorder that he or she did not have. A laboratory-documented diagnosis must be obtained prior to institution of coagulant therapy in all but the most urgent circumstances. Furthermore, the specific set of events that triggered the bleeding episode in question must be understood in the context of the patient's underlying diagnosis.

Second, the goals of therapy should be accurately defined. For example, infusion of plasma into a patient with advanced hepatic disease in order to transiently decrease the hemorrhagic risk of liver biopsy may be justified, although achieving a complete and sustained correction of the coagulopathy in such a patient would be unlikely.

Third, the product most appropriate for the optimal management of bleeding should always be employed. For example, severe hypofibrinogenemia in the setting of disseminated intravascular coagulation should be treated with cryoprecipitate because the limiting concentrations of fibrinogen in plasma preclude the use of fresh-frozen plasma as effective therapy.

Fourth, only the minimum amount of blood product that is required to induce adequate hemostasis should be used. Achieving supraphysiologic levels of coagulation factors in plasma does not increase the efficacy of therapy and in some conditions may predispose to thrombosis.

Fifth, all therapy should be closely monitored by appropriately timed coagulation studies to ensure that pertinent and cost-effective therapy is delivered.

COMPLICATIONS AND PITFALLS

The clinical coagulation laboratory plays a central role in the management of patients with bleeding disorders. The ability to obtain reliable coagulation studies promptly is essential in appropriately diagnosing causes of excessive bleeding and monitoring therapeutic interventions. Because of the vast array of disorders associated with bleeding, the laboratory must be capable of performing many specialized tests, which may not be automated and therefore depend on the technical expertise of laboratory personnel. These tests must be performed with a short turnaround time, since they may affect the management of a critically ill patient.

An example of the complexity of diagnosing a common bleeding disorder is provided by consideration of von Willebrand disease. A panel of laboratory studies is usually required to diagnose this disorder and may need to be repeated on several occasions, since the plasma levels of von Willebrand factor fluctuate over time. Furthermore, individuals with type O blood normally have significantly lower levels of von Willebrand factor than those of patients with other blood types, requiring the establishment of separate normal ranges. Hence, to offer a service capable of diagnosing von Willebrand disease accurately, a laboratory must be able to perform several sophisticated assays with a high degree of reproducibility. A competent clinical coagulation laboratory should also maintain an accurate and facile system for prompt retrieval of the results of prior coagulation studies.

In attempts to reduce health care costs, the staffs of many clinical laboratories have been reduced, and in some cases technicians have been asked to perform assays with which they have little training and experience. Although this may not be inappropriate for certain automated assays, technicians who perform specialized coagulation analyses must have a thorough understanding and extensive familiarity with the technical aspects of these studies. Thus, although common automated studies such as the aPTT and PT may be performed during non-peak hours in a consolidated general clinical or "stat" laboratory, complex and/or nonroutine coagulation studies should be performed only by highly trained and experienced personnel (who should be available to perform such studies as patient needs dictate).

Indications for HOSPITALIZATION

The mode of presentation of the patient with excessive bleeding is highly variable. The evaluation of patients who present for investigation of a chronic bleeding diathesis can be performed in the outpatient setting. Similarly, patients with milder forms of von Willebrand disease or platelet function disorders who present with non-life-threatening bleeding events such as epistaxis usually can be managed without hospital admission. The use of agents such as intranasally administered arginine vasopressin [desmopressin acetate (DDAVP)], which has efficacy equal to that of intravenous DDAVP in the therapy of mild hemophilia and von Willebrand disease, has facilitated the outpatient management of such individuals.

Uncontrolled, spontaneous bleeding of any type is an absolute criterion for hospital admission and occurs most commonly in patients with known bleeding diatheses, such as hemophilia. Despite the efficacy of prophylactic home therapy in such individuals, therapy of active and significant bleeding in patients with hemophilia should be administered and monitored in the hospital, with the length of stay depending on the nature of the bleeding episode. Similar considerations must be applied to patients with bleeding diatheses who require minor surgical procedures, for which normal individuals are generally not hospitalized. In such cases, hospitalization ensures that hemostatic therapy is delivered on an appropriate schedule designed to minimize the risk of intraoperative and postoperative hemorrhage. However, most patients with mild or moderately severe bleeding disorders can usually undergo minor dental procedures in the outpatient setting, since bleeding related to such procedures can usually be well controlled by the direct application of highly effective local hemostatic agents to the bleeding site.

Indications for REFERRAL

The diagnosis and management of bleeding disorders is a complex issue that requires the expertise of appropriately trained physicians. Any patient suspected of having a congenital or acquired bleeding disorder should be evaluated by a hematologist prior to surgical intervention. Similarly, the management of patients with acute hemorrhage, including those with postoperative bleeding, warrants hematologic consultation. However, appropriate management of surgical patients, or patients with hemorrhage in specialized settings such as the puerperium, requires close collaboration between the hematologist and the appropriate specialist.

COST-EFFECTIVENESS

Significant changes in the practice of medicine have occurred in the United States in the past decade. These primarily reflect the financial stresses faced by hospitals and physicians in response to diminished reimbursement for inpatient and outpatient care. Since severe hemorrhage attributable to coagulopathy is an uncommon event, there has been a tendency on the part of many hospitals to divert scarce resources to programs with a greater potential for revenue generation. Though this may be a fiscally sound approach, the quality of patient care will ultimately suffer in the absence of a carefully conceived institutional strategy to the management of patients with congenital and acquired coagulopathies.

Despite these concerns, a significant proportion of the studies performed in most clinical coagulation laboratories are indeed unnecessary, resulting in poor utilization of technician time and avoidable expenditures. One example of this practice is the continued utilization of the bleeding time, an extremely labor-intensive assay, in patients without a clear history of bleeding (and thus with a low pretest probability). A particular example of this practice is the routine measurement of preoperative bleeding times. The bleeding time has no predictive value in this setting; in fact, the predictive value of a carefully obtained bleeding history is superior not only to that of the bleeding time but also to that of routine coagulation assays. Detection of a clinically insignificant abnormality in a screening coagulation assay (particularly the bleeding time) in a patient without a bleeding diathesis forces the performance of additional and costly studies to exclude an underlying hemorrhagic disorder.

Education of physicians with regard to the ordering of screening coagulation assays does not seem to be an effective means of altering their test ordering behavior. Only through education coupled with restrictions on the ordering of specific assays can the volume of such studies be reduced. One approach to this dilemma may be the use of a questionnaire developed by physicians with expertise in coagulation, in collaboration with surgical staff, which would be completed by patients scheduled for elective surgical procedures at the time of preadmission testing. A predetermined threshold of positive responses would prompt further evaluation of selected patients by a hematologist, potentially leading to substantial savings.

CHAPTER 219: APPROACH TO THE PATIENT WITH THROMBOSIS

JOEL S. BENNETT

[Presentation](#)
[Pathophysiologic Factors](#)
[History and Physical Examination](#)
[Laboratory Studies and Diagnostic Tests](#)
[Strategies For Optimal Care](#)

PRESENTATION

Thrombosis is among the most common problems encountered by physicians and is the leading cause of death in the United States. Thrombosis can be segregated into arterial and venous disease based on differences in clinical presentation and pathophysiology.

Arterial thrombosis is principally a manifestation of arteriosclerosis, and patients present with coronary ischemia and with cerebrovascular and peripheral vascular disease. The substrate for an arterial thrombosis is usually an arteriosclerotic lesion, and thrombosis may be the first indication of such a lesion.

Venous thrombosis occurs most often in the veins of the lower extremities, where it presents as thrombophlebitis, a syndrome of pain and swelling in the lower leg. A diagnosis of venous thrombosis in the lower extremities may be difficult to make on clinical grounds alone. As many as 70% of patients with pulmonary emboli have asymptomatic venous thrombi in their legs, and 50% of patients for whom the diagnosis of thrombophlebitis is considered are found to have an alternate diagnosis.

PATHOPHYSIOLOGIC FACTORS

Arterial thrombi are composed primarily of aggregated platelets (white thrombi) and form when the endothelial lining of an artery is breached, allowing platelets in the circulating blood to interact with subendothelial connective tissue. Thrombi form on the surfaces of arteriosclerotic plaques when their surfaces are denuded of endothelial cells or when a plaque is physically disrupted, exposing platelets to highly thrombogenic material in the plaque interior. A detailed description of the formation of platelet thrombi is presented in [Chapter 240](#).

Venous thrombi are composed primarily of fibrin and trapped red cells (red thrombi). Fibrin is produced by a series of biochemical reactions that culminate in the activation of coagulation factor X, the cleavage of prothrombin by activated factor X (FXa) to liberate thrombin, and the cleavage of fibrinogen by thrombin to yield fibrin monomer. Sensitive assays have shown that small amounts of FXa and thrombin are continuously being generated in normal individuals but that the activity of these enzymes is sufficiently controlled by proteins such as antithrombin III and the complex of protein C with protein S to prevent the formation of thrombi. As discussed in [Chapter 240](#), venous thrombi can form in regions of venous stasis when conditions such as immobilization, malignancy, pregnancy, oral contraceptive use, nephrotic syndrome, or the presence of anticardiolipin antibodies shift the coagulation–anticoagulation balance toward the generation of procoagulant activity. This shift is further enhanced when the control of FXa and thrombin activity is impaired by hereditary deficiencies of antithrombin III and proteins C and S or inherited resistance to the anticoagulant effect of protein C.

HISTORY AND PHYSICAL EXAMINATION

Because arterial thrombi obstruct the flow of oxygenated blood, they result in tissue ischemia and manifest most often as acute myocardial infarction and stroke. When arterial thrombosis complicates a myeloproliferative disorder such as polycythemia vera, essential thrombocythemia, or heparin-associated thrombocytopenia, it is likely to occur in arteries involved by arteriosclerosis. The hyaline thrombi characteristic of thrombotic thrombocytopenic purpura obstruct normal arterioles, producing waxing and waning symptoms of tissue ischemia that often involve the central nervous system.

Venous thrombosis occurs most often as thrombophlebitis in the lower extremities, as superficial thrombophlebitis usually involving varicosities, or as potentially more serious deep venous thrombosis. Deep venous thrombosis in the leg can be complicated by pulmonary embolism. Thrombi that result in clinically significant pulmonary embolism are almost invariably located in the proximal veins of the legs, but many begin as calf vein thrombi that extend into the proximal veins in the thigh.

The symptoms of venous thrombosis result from obstruction of venous outflow and from accompanying local inflammation. Classically, leg vein thrombosis presents as a triad of calf pain, edema, and pain on dorsiflexion of the foot (Homans's sign). However, this presentation is observed in less than one-third of patients, and more often, symptomatic leg vein thrombosis presents as calf discomfort or tenderness or as unexplained leg edema. Moreover, when leg vein thrombosis is considered on clinical grounds alone, it can be confirmed by objective testing in fewer than 50% of cases. Conditions confused with deep venous thrombosis in the legs include muscle strains and tears, swelling of a paralyzed leg, lymphatic obstruction, Baker's cyst, cellulitis, internal derangements of the knee, and the postphlebotic syndrome. Of particular concern, asymptomatic deep venous thrombosis has been found in 70% of patients with confirmed pulmonary embolism. Conversely, asymptomatic pulmonary embolism has been detected in 50% of patients with proximal deep venous thrombosis.

Venous thrombi usually arise in the large venous sinuses in the calf, in the pockets of valves in the deep veins in the calves, and at sites of vascular damage. Although small calf vein thrombi usually resolve completely, complete lysis of larger thrombi is uncommon. Instead, these thrombi may organize and recanalize. The resulting venous obstruction and venous valve destruction can result in a postphlebotic syndrome of chronic calf pain associated with brawny edema, hyperpigmentation, induration, and ulceration of the lower leg.

Clinically significant thrombosis can involve the axillary, mesenteric, hepatic, renal, and cerebral veins, but these forms of thrombosis are considerably less common than thrombi of the calf venous sinuses. Hepatic vein thrombosis (Budd–Chiari syndrome) is a feature of the myeloproliferative disorders and paroxysmal nocturnal hemoglobinuria. Acute and chronic forms of renal vein thrombosis occur in the nephrotic syndrome, especially when the nephrotic syndrome is secondary to membranous glomerulonephritis. Mesenteric and cerebral venous thromboses have been reported in patients with the inherited causes of thrombosis discussed in [Chapter 240](#), myeloproliferative disorders, paroxysmal nocturnal hemoglobinuria, or the antiphospholipid antibody syndrome, and after estrogen administration.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

Evaluation of patients with thrombosis should be tailored to their clinical situations. Because most cases of arterial thrombosis result from arteriosclerosis and not from abnormalities of platelet function or blood coagulation, studies should focus on the extent of the arteriosclerosis and on factors that may contribute to its progression. However, when arterial thrombosis occurs in the absence of significant arteriosclerosis, the possibility of hemostatic abnormalities must be considered.

Venous thrombosis is a common occurrence, especially in immobilized medical and surgical patients. However, because tests to detect a specific cause of the thrombosis are expensive and unlikely to change the management of a patient after the first episode of thrombosis, such testing should be restricted to patients with recurrent thrombosis, unless the patient has a family history that strongly suggests a hereditary disorder. Moreover, measurement of the proteins associated with familial thrombosis (antithrombin III, protein C, and protein S) may not be reliable after an acute thrombotic episode. It is preferable to wait several weeks before obtaining these studies. Meaningful measurements of protein C and protein S, both of which are vitamin K–dependent proteins, cannot be performed when patients are receiving the oral anticoagulant warfarin. Consequently, measurement of the levels of these proteins should be delayed until warfarin has been discontinued for several weeks.

Venous thrombosis associated with malignancy occurs more frequently in patients with advanced disease. The biochemical basis for the procoagulant effect of tumors is not always apparent and may be different for different types of tumors. For example, some tumors express tissue factor, others produce activators of factor X, and still others produce fibrinolytic inhibitors. The continuous elaboration of procoagulant activity by tumors can produce chronic disseminated intravascular coagulation (DIC). Although acute DIC generally produces thrombocytopenia, prolongation of the prothrombin and partial thromboplastin times, depletion of fibrinogen, and increased concentrations of fibrin-split products, tumor-associated chronic DIC may manifest as only recurrent thromboembolism and persistent elevation of fibrin-split

products.

Venous thrombosis can be a presenting symptom of malignancy, particularly when patients have mucin-producing carcinomas (Trousseau's syndrome). Venous thrombosis in an otherwise healthy patient raises concern about the possibility of an occult malignancy. When this issue was studied prospectively, malignancy was found in 3% to 10% of patients presenting with venous thrombosis and was discovered in 7% to 11% of patients in the ensuing 6 to 24 months. Malignancy was found most often in patients without an obvious cause for venous thrombosis, in patients with recurrent idiopathic thrombosis, and in patients older than 60 years. However, it was not apparent from these studies that an extensive workup to detect occult malignancy in these patients resulted in improved survival. A reasonable approach to the evaluation of patients with venous thrombosis and in whom malignancy is a possibility is to supplement routine studies with multiple fecal samples for occult blood loss, prostate-specific antigen measurements in men, and mammography in women.

A diagnosis of deep venous thrombosis in the lower extremities is difficult on clinical grounds alone and should be supplemented by objective tests. Objective testing to rule out the presence of thrombosis is cost-effective because the costs of hospitalization substantially exceed the costs of testing. The standard for venous thrombosis is *venography*, against which all other tests for the detection of venous thrombosis are compared. Venography detects thrombi in the deep veins of the calf and in the popliteal, femoral, and iliac veins. However, venography is an invasive study that is not suitable for serial studies. It is associated with a 2% to 3% incidence of chemical phlebitis.

Several noninvasive studies can detect venous thrombi with variable degrees of success. *Impedance plethysmography* (IPG) measures changes in electrical impedance in the calf after deflation of a pressure cuff around the thigh and detects impairment in venous outflow from the leg. IPG can detect venous thrombi in the thigh, but it is insensitive to isolated calf vein thrombi. Although initial reports indicated that IPG was highly sensitive and specific for proximal thrombi, later studies suggest that IPG is far less sensitive than previously thought and that it may fail to detect occlusive and nonocclusive proximal thrombi. Consequently, IPG cannot be recommended as a noninvasive test to rule out the presence of venous thrombi in symptomatic or asymptomatic patients.

Real-time B-mode ultrasonography uses very high frequency sound waves to produce two-dimensional images. It is purported to be 97% sensitive and 97% specific for detecting proximal deep venous thrombosis in symptomatic patients. The most sensitive finding is failure of a vein to collapse under gentle pressure (compression ultrasonography). B-mode ultrasonography can be supplemented by Doppler flow detection (duplex scanning), but the contribution of the latter to the diagnostic accuracy of the test is not clear. Like IPG, ultrasonography is not sensitive to calf vein thrombosis, and its sensitivity drops considerably in asymptomatic patients.

An increased concentration of the D-dimer fragment of fibrin in plasma has been used as an indication of the presence of venous thrombosis. A D-dimer results from the degradation of cross-linked fibrin by plasmin and serves as a marker for the activation of coagulation. Although an increased concentration of D-dimer in plasma correlates highly with venous thrombosis (sensitivity of 97%), its sensitivity is low (specificity of 35%). Absence of an increased D-dimer concentration cannot rule out venous thrombosis.

Because of cost and availability, the roles of *computed tomography* and *magnetic resonance venography* in the routine management of venous thrombosis are likely to be limited.

For a patient with symptoms suggesting venous thrombosis, most recent studies suggest it is safe to withhold anticoagulant therapy in the face of normal serial real-time B-mode ultrasonographic examinations, and an abnormal test result is an indication for treatment ([Fig. 219.1](#)). There is no satisfactory objective test to screen asymptomatic patients for venous thrombosis.

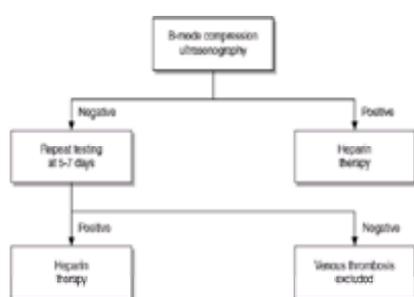

FIGURE 219.1. Algorithm for the diagnosis and treatment of suspected deep venous thrombosis of the lower extremity using B-mode compression ultrasonography. If this noninvasive test is unavailable, venography should be performed to rule out venous thrombosis. Venography should also be performed to resolve ambiguous studies

STRATEGIES FOR OPTIMAL CARE

MANAGEMENT

The pharmacology of agents employed in the medical management of arterial and venous thrombosis is discussed in [Chapter 240](#).

Except for specific circumstances, such as early acute myocardial infarction or selected cases of peripheral arterial thrombosis for which thrombolytic therapy is effective, the goal for the medical management of arterial thrombosis is prevention of recurrence. Drugs that inhibit platelet function such as aspirin and ticlopidine help to prevent thrombosis in patients with arteriosclerotic vascular disease. Aspirin, a drug that prevents platelet prostaglandin synthesis, decreases the risk of myocardial infarction and death in patients with unstable angina; reduces the risk of recurrent cardiovascular complications in patients with myocardial infarction, transient cerebral ischemia, and stroke; and decreases the risk of cardiovascular events in healthy patients or patients with chronic stable angina. Ticlopidine, an alternative to aspirin that primarily inhibits adenosine diphosphate–induced platelet aggregation, reduces the risk of nonfatal and fatal thrombotic strokes in patients with transient attacks of cerebral ischemia or completed thrombotic stroke, and is as effective as aspirin in preventing myocardial infarction in patients with unstable angina or intermittent claudication in patients with peripheral vascular diseases.

Heparin, administered in small subcutaneous doses, is frequently used to prevent venous thrombosis in immobilized medical and surgical patients and in patients congenitally predisposed to thrombosis at times of increased risk. The basis for low-dose heparin therapy is the ability of the drug to inhibit excess FXa that could shift the normal hemostatic balance toward thrombosis. Prophylactic heparin is given at a dose of 5,000 units every 12 hours, and it usually has no effect on the activated partial thromboplastin time (aPTT). When given in this way to surgical patients, the incidence of venous thrombosis and fatal pulmonary emboli is decreased by 60% to 70%. However, low-dose heparin has been less effective as prophylaxis after orthopedic surgery or trauma in which the stimulus for thrombosis may be greater. In these patients, subcutaneous heparin adjusted to maintain a top normal aPTT, low molecular weight heparin, or moderate-dose warfarin therapy has been more efficacious therapy. Although a patient given low-dose heparin is free from the risk of serious bleeding, because of the potential for minor bleeding, it should not be used in patients undergoing cerebral, spinal, or ophthalmologic surgery. Despite the lower dosage, prophylactic heparin remains a cause of heparin-associated thrombocytopenia.

Heparin at a dose sufficient to prolong the aPTT to 1.5 to 2.5 times the mean of the control aPTT is the treatment of choice for active venous thrombosis. Achieving this dose within the first 24 hours of treatment minimizes treatment failure and recurrent thrombosis. There is essentially no difference in the efficacy and incidence of complications for heparin given by continuous intravenous infusion or by intermittent subcutaneous injection, although the latter requires a larger heparin dosage to reach the therapeutic range within 24 hours. Generally, an initial bolus of 5,000 units followed by more than 30,000 units within 24 hours is required to achieve and maintain the therapeutic range when heparin is given intravenously, and more than 33,000 units within 24 hours is required when it is given subcutaneously. Given in this way, the incidence of bleeding is 2% to 7%.

Low molecular weight heparin (see [Chapter 240](#)) preferentially catalyzes the inhibition of FXa over thrombin and has potential advantages of greater bioavailability at

low dosage and longer duration of action than standard heparin. Given at a fixed dosage subcutaneously once or twice daily and without laboratory monitoring, low molecular weight heparin has been found to be at least as effective and safe as standard heparin in prophylaxis against thrombosis and in the treatment of thrombi. These results suggest that low molecular weight heparin may be useful for the outpatient management of venous thrombosis, bypassing the considerable costs of hospitalization. However, issues of efficacy, neutralization of low molecular weight heparin by protamine, safety in pregnancy, and incidence of osteoporosis and thrombocytopenia must be resolved.

Following initial treatment with heparin, patients are treated with oral anticoagulants (warfarin, see [Chapter 240](#)) to prevent the recurrence of thromboembolism. Current practice is to treat with heparin for at least 5 days, starting warfarin on day 1. Warfarin dosage is adjusted using the prothrombin time and the INR (International Normalized Ratio) calculated from it. An INR of 2.0 to 3.0 is recommended to prevent recurrent venous thrombosis. Treatment with warfarin is overlapped with heparin for at least 2 days to ensure that patients are adequately anticoagulated when the heparin is stopped and to prevent the rare occurrence of warfarin-induced skin necrosis. The duration of warfarin therapy depends on the inciting cause of the venous thrombosis. In patients with reversible risk factors for venous thrombosis such as recent surgery, 6 weeks of therapy may be sufficient. However, in patients with idiopathic thrombosis, the risk for recurrence may be as high as 18% at 2 years, 25% at 5 years, and 30% at 8 years. Accordingly, more prolonged treatment with warfarin is necessary. Although the optimal duration remains to be established, a trial of treatment for 3 months versus more prolonged treatment revealed a recurrence rate of 27.4% per patient year in the group treated for 3 months compared to 1.3% per patient year in patients treated for an average of 12 months, suggesting that treatment for 3 months is inadequate.

When there are contraindications to the use of anticoagulant drugs such as active bleeding or if thrombosis recurs despite adequate anticoagulation, interventions to prevent pulmonary embolization by interrupting the inferior vena cava should be considered. The most popular device is the Greenfield filter, which is associated with a caval patency rate of 95% and an overall incidence of recurrent pulmonary embolization of less than 5%. Migration of the filter and perforation of the caval wall have been rare occurrences. Other types of filters have been devised, but as yet there is no clinical evidence that they are superior to the Greenfield filter. Nevertheless, a long-term follow-up of high-risk patients with filters revealed that their initial benefit was counterbalanced by a significant increase in deep vein thrombosis and no change in mortality.

Indications for HOSPITALIZATION

Treatment of established thrombotic disease requires hospitalization for the administration of medication and monitoring of drug dosage. Patients with suspected deep venous thrombosis of the lower extremity can be safely followed as outpatients if serial B-mode ultrasonographic examinations remain negative. A caveat to this practice is that it was previously thought safe to follow outpatients with negative IPG studies, although we now know that this is not the case. Further clinical experience will determine if serial B-mode ultrasonographic examination is as specific and sensitive as currently thought. Whether replacement of standard heparin with low molecular weight preparations will permit outpatient treatment of established thrombosis is a question that cannot be answered until clinical trials have been carried out.

DEFINITIONS

Several different types of malignancies are found in the human breast, each defined by a specific histologic appearance. The term *breast cancer* usually refers to adenocarcinoma. This is the most common malignant neoplasm of mammary tissue and, with lung cancer, one of the two most common cancers of women in the developed world. The rare primary malignancies of the breast include cystosarcoma phyllodes, various sarcomas, and lymphomas. Cancers from other primary sites, such as the skin (i.e., melanoma), lung, ovary, cervix, prostate, and bladder, may sometimes metastasize to the breast, and metastases of breast cancer to the contralateral breast are not uncommon.

Breast cancer is occasionally diagnosed in men, at a rate that is approximately 1% of its incidence in women. Female breast cancer is one of the oldest diseases in the medical literature, having been described in ancient Egyptian texts. It has also been one of the most studied of human cancers and remains a major focus of much contemporary science. Although significant progress has been made in the understanding, diagnosis, and clinical management of breast cancer, universal cure has not yet been attained. Although most individuals diagnosed with breast cancer in high-incidence areas such as North America and Europe will now be cured, it is one of the most common causes of cancer fatality among women in these same areas.

Normal breast anatomy consists of specialized epithelial breast tissue, the outer layer of skin, subcutaneous adipose and connective tissues, nerves, blood and lymph vessels, and other supportive stroma. The specialized breast tissue itself largely consists of numerous ducts, arranged in intertwined treelike (fractal) structures rooted at the nipple and connecting terminally to secretory lobules. The nipple is surrounded by a cutaneous hyperpigmented areola. Because the development of breast tissue is influenced positively by female hormones, including progesterone as well as estrogen, the male breast is anatomically complete but grossly hypoplastic compared with that of postpubertal women.

Most breast adenocarcinomas are thought to arise from the ductal epithelial cells close to or at the juncture of a duct and a lobule. These cancers may be *in situ* or *infiltrating* (also called *invasive*). The *in situ* carcinomas are further classified as *lobular carcinoma in situ (LCIS)* or *ductal carcinoma in situ (DCIS)*. DCIS is also called *intraductal carcinoma*, a term often and erroneously confused with *infiltrating ductal carcinoma*. DCIS and LCIS do not invade the parenchyma or stroma of the breast and have a very low potential for generating metastases. Invasive breast adenocarcinomas, which do infiltrate into surrounding normal tissues, also fall into ductal and lobular types, with the ductal types predominating. About 15% of breast cancers have “special” histopathologic patterns, including mucinous, papillary, medullary, tubular, and adenoid cystic types.

The ability of cancer cells to grow into normal breast parenchyma and stroma is called *invasion*. This property is correlated with the ability of these cells to grow in sites other than the breast itself, including noncontiguous sites—a process called *metastasis*. Cancer cells gain access to foreign tissues through the flow of blood and lymph. The most common site of metastasis is the axillary lymph nodes. The number of lymph nodes containing breast cancer cells is a good indicator of that primary cancer's propensity for metastasizing to more distant anatomical sites such as bone, lung, liver, and brain.

Breast cancer is staged by assessing tumor (T) size, nodal (N) involvement, and presence or absence of distant metastasis (M). The TNM classification for breast cancer developed by the Union International Contra le Cancrum and the American Joint Committee on Cancer Staging (AJCC) is shown in [Table 220.1](#). Proper staging is achieved by pathologic examination of the breast tissue and the axillary lymph nodes, physical examination, chest radiograph, and assay of serum markers such as liver transaminases and the various alkaline phosphatases. Physical examination is not a reliable way of assessing axillary nodal involvement because nodes can be involved without being palpable and not all palpable nodes are positive histologically for cancer. Recently, a technique for assessing axillary involvement called *sentinel lymph node mapping* has been developed and popularized. This technique was pioneered in the treatment of melanoma. It introduces a radioactive tracer or a dye or both into the breast at the time of tumor resection and dissects the one to several nodes that first take up the substance. If these sentinel nodes are free of cancer, the overwhelming likelihood is that the rest of the axilla will be free as well. This saves the patient unnecessary axillary surgery and allows the pathologist to concentrate (using immunohistochemistry and molecular techniques in addition to routine histology) on the few nodes removed.

T Tumor Size	
T ₀	In situ
T ₁	≤2 cm
T ₂	2–5 cm
T ₃	>5 cm
T ₄	Extension to chest wall or skin
N Nodal Involvement	
N ₀	None
N ₁	Movable, ipsilateral axillary
N ₂	Fixed, ipsilateral axillary
N ₃	Extensive ipsilateral
M Metastases	
M ₁	(Includes supraclavicular nodes)

TABLE 220.1. TNM CLASSIFICATION FOR BREAST CANCER

Most patients in North America and Europe present with disease in stages I and II. Stage I cancers, small and without axillary lymph node involvement, have the best prognoses. A greater risk of eventual systemic recurrence is associated with stage II cancers. These can be of any size up to 5 cm in diameter with axillary lymph nodes that are movable but histologically positive. Stage II also includes cancers without axillary lymph node involvement if the tumors are larger than 2 cm in diameter. In practice, many clinicians classify breast cancers as “node-negative” or “node-positive,” crossing TNM categories; a node-negative case could be in stage I, II, or even IIIA.

Nodal involvement is quantified by the number of involved nodes, with the denominator (total number of nodes examined) serving to indicate that an adequate dissection has been performed. Nodes are also described by their level; level I nodes are lateral to the pectoralis minor muscle, level III nodes are medial, and level II nodes are between levels I and III. The level of nodal involvement is important only because it correlates with the number of involved nodes. Skip metastases (e.g., level II being positive when level I is negative) do occur rarely and may indicate sampling error in the examination of the level I nodes.

Hence, the wider use of sentinel lymph node mapping may make these cases even more unusual.

Locally advanced breast cancers (mostly stage III) are either larger than 5 cm in diameter, invade into the skin or chest wall, or are associated with fixed, histologically positive axillary nodes. Their prognosis is worse than those in the earlier stages, but the outcome is still largely a function of the number of involved axillary lymph nodes. Stage III is a common presentation in economically underdeveloped parts of the world, largely because of the failure of early diagnosis rather than rapidly growing disease.

Stage IV tumors demonstrate evidence of metastatic spread to regions outside the breast and axilla, including, since reclassification in 1988, supraclavicular lymph nodes.

The TNM staging system evolved primarily to aid surgical decisions. This is because most stage I cancers, many stage II cancers, and some stage III cancers can be cured with local therapy alone. Patients with more advanced stage III cancers and with stage IV disease are not curable by surgery alone, although an operative procedure to achieve local control may be indicated. Medical oncologists use classic TNM staging but they also commonly categorize patients by the number of involved axillary lymph nodes. This has guided and continues to facilitate decisions regarding systemic adjuvant drug therapy, although modern chemotherapies are becoming effective enough that we may soon reach a point where all patients will receive the same treatment regardless of axillary status.

Toward the end of the nineteenth century, William Halsted promulgated the idea that breast cancer spreads in an orderly fashion from the breast to the axillary lymph nodes and then to distant sites if the cells are not arrested in the axillary “filter.” This concept supported the use of aggressive local surgery to remove all of the cancerous cells before they could spread, as well as the evolution of more extensive operations, culminating in Jerome Urban's extended radical mastectomy, which resected parts of the chest wall. A more modern idea, associated with the work of Bernard Fisher and colleagues, is that cancer cells have anatomical access to the entire body even when the primary tumor is very small. These cancer cells may grow in sites other than the breast because of the fertility of these fields rather than mere mechanical access. Applying this concept, axillary nodal involvement is only a sign of the potential for systemic disease. An emerging composite hypothesis, associated with the writings of Samuel Hellman, is that both anatomical and biochemical factors are important. Axillary nodes are often involved because they are fertile fields biochemically and because they are accessible by virtue of the pattern of lymph flow. The fact that sentinel lymph node mapping works supports this latter view. By the composite hypothesis, local control is insufficient to ensure cure but is necessary for optimal management. Recent data showing that radiotherapy to the chest wall after complete mastectomy increases long-term cure rates are consistent with this idea.

INCIDENCE AND EPIDEMIOLOGIC FACTORS

Breast cancer and lung cancer are the most common malignancies in women in the economically developed world. In 2000, an estimated 182,800 women will be diagnosed with breast cancer in the United States, and 40,800 women will die of this disease. One of the strongest risk factors for the development of breast cancer in women is advancing age. Between 1994 and 1996, the probability of an American woman presenting with infiltrating breast cancer was 0.43% before the age of 40, 4.06% from 40 to 59 years of age, and 6.88% from 60 to 79 years, giving an overall risk of 12.56%. Women with a personal history of breast cancer develop contralateral disease at a rate of a little over 1% per year. This risk, however, is not equally spread among the members of this population; women with specific hereditary predispositions, or those who received prior radiation exposure (such as in treatment of Hodgkin's disease), clearly carry higher risks.

Breast cancer is becoming more common, although it remains unclear as to whether this is due to the increasing age of the population, the efficiency of mammographic diagnosis, or a true change in the character of the disease. Europe, Canada, the United States, Australia, and the developed parts of South America have higher rates than most Asian countries. Germ line differences in predisposition alone cannot account for these observations, and environmental and lifestyle factors—including diet—are under intense scrutiny. Although there is no convincing evidence that dietary fat (or total calories, which is inextricably linked to fat content) is etiologic within a country, societies composed of individuals who consume less fat, fewer calories, and more vegetables also have less breast cancer. Because the range of fat intake between countries in these studies is greater than that between subjects in the studies within one culture, the fat–breast cancer link has not yet been disproved. Daily alcohol consumption of one drink or more per day is associated with an increased risk of breast cancer, especially among younger women. The relationship is not linear, however, and rises more quickly with more alcohol consumed.

ETIOLOGIC FACTORS

The etiology of breast cancer is clearly multifactorial ([Table 220.2](#)). Family history is a major component of the overall risk profile. A woman's family history of breast cancer in a first-degree relative (mother or sister) increases her risk by up to threefold. This risk is highest in association with a family history of bilateral disease or of premenopausal cancer. Nevertheless, it is estimated that only 10% of breast cancers are related to a hereditary predisposition. Henry Lynch and others have long described a familial association between breast and ovarian cancers, and links with colon, salivary gland, skin (melanoma), and, especially, prostate cancers are also under study. Although some of these familial patterns may be associated with factors other than hereditary predisposition, genetic epidemiology is revolutionizing our view of the cause of breast cancer.

Family history
Germ line mutations
Hormonal exposure
Age at menarche
Age at menopause
Age at first full-term pregnancy
Exogenous estrogen
Oral contraceptives
Estrogen replacement
Radiation exposure
Hyperproliferative benign breast lesions
Prior breast cancer
Diet
Alcohol intake

TABLE 220.2. POTENTIAL ETIOLOGIC FACTORS FOR BREAST CANCER

Germ line deleterious mutations of the gene *BRCA1*, identified on chromosome 17, and the gene *BRCA2*, mapped to chromosome 13, are associated with a higher risk of breast and ovarian cancer. Although these genes have characteristics similar to those of tumor suppressor genes, and their function is not completely clear, there is growing evidence that they may be involved in the cell's response to DNA damage. Following Knudson's multistep paradigm, inactivating germ line mutations coupled with the random loss of the other allele may be catastrophic to the individual. Mutations of these genes are more common in those with a family history of early-onset breast cancer and ovarian cancer. *BRCA1* and *BRCA2* mutations account for a significant proportion of hereditary breast cancers, perhaps as high as 90%, but there is evidence that other as yet unidentified genes also contribute to this syndrome. Rarer breast cancer–related familial syndromes, thought to be inherited in an autosomal dominant pattern, include Cowden's disease (multiple hamartomas), Muir's syndrome (skin and gastrointestinal tumors), and Li–Fraumeni or SBLA syndrome (soft tissue and bone sarcomas, brain tumors, leukemia, adrenocortical carcinoma, and others). Li–Fraumeni syndrome is associated in many cases with germ line *p53* mutations.

Men who are heterozygous in *BRCA1* do not carry an increased risk of developing breast cancer. Men who are heterozygous in *BRCA2* have a higher risk than normal men but a lower risk than women with these lesions. Hence, estrogen plays a role in the expression of familial breast cancer. Similarly, for sporadic cases, about 90% of the total cases, estrogen seems to be implicated in etiology. The disease is rare in women with congenital absence of ovarian function. Men who are homozygous normal in *BRCA1* and *BRCA2* seldom develop breast cancer unless they are hyperestrogenemic by virtue of Klinefelter's syndrome, liver disease, massive obesity, or exogenous hormone use. In women, the early onset of menarche (12 years) and a greater number of ovulatory cycles are associated with increased risk. Nulliparous women or those with their first pregnancy after age 35 have a higher incidence of breast cancer. An early full-term pregnancy may be partially protective. Intense physical activity on the positive side and malnutrition on the negative side can delay menarche or decrease the number of ovulatory cycles; both situations also diminish risk, as does natural menopause before age 45 or a bilateral oophorectomy before age 50. Moderate levels of physical activity, particularly in childhood, are also somewhat protective. There is some evidence that the beneficial effect may be mediated by factors other than the suppression of

ovarian function.

All ductal hyperproliferations of breast tissue seem to increase the risk of carcinogenesis, although not all carry the same degree of negative impact. Atypical ductal hyperplasia, for example, is associated with increased subsequent risk, especially if coupled with a positive family history. Benign lesions not involving hyperproliferation, such as cysts, most fibroadenomas, or mastitis, are not predisposing. It is likely, therefore, that the hyperproliferative lesions carry some genetic changes that are necessary but not sufficient for full neoplastic transformation. Consistent with this view is the fact that exposure to ionizing radiation, by radiotherapy or secondary to radiation accidents, increases the risk of breast cancer, particularly if the event occurs before 20 years of age. Links to chemical exposure from pesticides or industrial contamination, some of which is known to be mutagenic, have been suggested by some studies, and more work is needed in this area.

Considering the importance of estrogen in breast cancer etiology, it would seem reasonable that exposure to exogenous estrogens in the form of birth control pills or postmenopausal replacement would be deleterious. Evidence is accumulating that both treatments are associated with slightly increased risk, especially after prolonged use, although it is possible that the breast cancers that arise secondary to estrogen use tend to be positive for estrogen receptors and may carry a better prognosis for this reason. Recommendations in regard to the use of exogenous estrogens are controversial largely because the beneficial effects of such treatment may outweigh the increased risk of breast cancer in certain individuals. At present, the physician and patient must weigh the risks and benefits carefully and make individual, independent decisions regarding use of these treatments. As newer estrogens (such as raloxifene for the prevention of osteoporosis) come into wider use, the controversies may diminish because these agents may actually reduce the risk of breast cancer. Currently, these topics are under intense scrutiny.

PATHOPHYSIOLOGIC FACTORS AND PATHOGENESIS

Ductal carcinoma in situ comprises a heterogeneous group of lesions that are usually regarded as a unilateral, very early, preinvasive form of true breast cancer. Future, further subclassifications of this entity will probably be based on molecular analysis. One type is characterized by comedo necrosis, high mitotic rate, and pleomorphic nuclei. This form of DCIS often overexpresses the ligandless receptor protein tyrosine kinase HER2 (also designated as *neu* and *c-erbB2*). It more commonly transforms or progresses into microinvasive or frank invasive cancer than the noncomedo types: solid, papillary, or cribriform types. DCIS is commonly multifocal or even diffuse throughout the breast, and it often appears as microcalcifications on mammograms.

Lobular carcinoma in situ is often thought of as a marker of carcinogenic potential rather than a true cancer. It is characterized by a proliferation of small, uniform cells and often is multifocal. A patient with a biopsy showing LCIS carries a risk of developing invasive cancers of ductal or lobular types of 1% to 2% per year. Both breasts are at equal risk. LCIS lesions rarely form microcalcifications and are usually invisible by mammography.

Among the invasive cancers the most common histologic type, accounting for approximately 75% of tumors, is infiltrating ductal carcinoma (not to be confused with intraductal carcinoma, which is DCIS). Infiltrating ductal cancers tend to grow as discrete masses, sometimes with microcalcifications, and more commonly as solitary rather than multiple lesions. Good nuclear grade (i.e., graded from 1 to 3, with grade 3 the least differentiated) is associated with a better prognosis. Histologic grading is inverse, with grade 1 indicative of a well-differentiated tumor with better prognosis. The absence of cancer cells in lymphatic channels or blood vessels is also relatively favorable.

Infiltrating lobular carcinoma constitutes approximately 10% of breast cancers. They usually grow as spreading sheets with indistinct edges. Because they tend not to calcify and not to form distinct masses, they are more difficult to diagnose by palpation or mammogram. Some reports associate lobular invasive cancer with bilaterality and multicentricity, but this observation is not universal. Infiltrating lobular carcinomas generally have the same prognosis as infiltrating ductal carcinomas of the same size and number of involved axillary lymph nodes. However, infiltrating lobular carcinomas have a greater tendency to metastasize to the meninges and serosal surfaces, such as the peritoneum.

The less common, special types of invasive breast cancer—mucinous (invasive colloid), papillary, medullary, tubular, and adenoid cystic—seem to have particularly good prognoses if they are small and do not involve the axillary lymph nodes. However, if they are large or node-positive, they may be very aggressive, especially if the medullary type.

Paget's disease of the nipple occurs in 1% to 2% of patients with breast cancer. The usual presentation is an eczematoid change of the nipple, such as scaling or a bloody discharge. This lesion is associated with a cancer involving the breast ductal parenchyma under the nipple. The prognosis for Paget's disease depends on its histologic type and other features of the underlying cancer. Intraductal Paget's disease is quite curable with complete excision, which usually means mastectomy.

Inflammatory breast cancer is an especially aggressive form of invasive disease, accounting for fewer than 5% of breast cancers in North America. It is seen more frequently in women in other parts of the world, especially in North Africa. Typical findings include diffuse swelling of the breast, erythema and warmth of the skin, breast pain, and peau d'orange type of edema of the skin. Because these changes bear a superficial resemblance to bacterial infection, it may be misdiagnosed as mastitis. The essential feature of this presentation, discoverable only on histopathologic examination, is dermal lymphatic invasion. However, the disease may be diagnosed on clinical grounds even if dermal lymphatic invasion is not found on biopsy as the result of a sampling error.

PROGNOSTIC FACTORS

The major factors reported to predict the prognosis of breast cancer are listed in [Table 220.3](#). Of these, only a few are sufficiently well characterized to be useful for clinical guidance. The number of positive axillary lymph nodes is the most reliable prognostic factor. Survival rates decrease, and relapse rates increase as the number of involved lymph nodes rises.

Established
Number of positive axillary lymph nodes
Tumor size
Histologic tumor type
Histologic features, including grade
Estrogen and progesterone receptor status
Patient's age
S-phase fraction
Invasiveness
Ploidy
Proliferative indexes
Thymidine labeling index
Topoisomerase II
Histones
Ki-67
Cyclins
Growth factors
Transforming growth factors
Epidermal growth factor receptor
Insulin-like growth factors
Genes (e.g., *ras*, *src*, *myc*, *int2*, *brca1*, *brca2*, *nm23*)
Cathepsin D
Angiogenesis factors
Anastomosis in tumor and stroma
Laminin receptor
Heat shock proteins

TABLE 220.3. FACTORS EVALUATED IN BREAST CANCER TO AID IN PROGNOSTICATION

A less favorable outcome is usually associated with larger tumors, more poorly differentiated lesions, and absence of receptors for estrogen and progesterone in the cancer cells. The hormone receptor status can be determined by the older dextran-coated charcoal biochemical assay, which requires fresh-frozen and abundant tissue, or by the newer method of immunohistochemistry. This can be performed on lesions of any size or on archival (paraffin-embedded) specimens, and is subject to fewer false-negative results because of handling errors. The biochemical assay, however, provides a quantitative result, which has prognostic importance. Hence, there is value in both techniques.

Several studies indicate that development of breast cancer at a young age (less than 35 years) is associated with a higher risk of relapse, although this effect may not be independent of other prognostic factors such as tumor size, hormone receptor status, and nodal positivity. Many of the other prognostic factors, while profoundly interesting, remain experimental. Much of the data are preliminary, many of the assays are not standardized, some of the reports are contradictory, and reliable corroboration is often lacking. DNA ploidy measures the amount of DNA in cells, with diploidy being normal and aneuploidy abnormal. Aneuploidy, which usually means too much DNA per cell, tends to correlate with differentiation. The S-phase fraction, measured by flow cytometry or by thymidine labeling index, estimates the percentage of cells preparing for mitosis. This also correlates positively with differentiation and with tumor size, and is felt by many investigators to be a reliable and

independent prognostic factor. However, variations in the technical aspects of this assay can make comparisons between studies difficult.

There has recently been a surge of interest in growth factors and their receptors, such as the epidermal growth factor receptor (EGFR) and HER2, and in mitosis regulators such as p53, which may play an important role in carcinogenesis and in the clinical course of the disease. Tumors that overexpress HER2 and involve axillary lymph nodes tend to behave more aggressively, as do HER2-positive metastatic lesions. It remains controversial as to whether HER2 status is prognostic in node-negative disease. However, recent data indicate that tumors that overexpress HER2 may be more sensitive to doxorubicin-based chemotherapy regimens and perhaps paclitaxel as well. Therefore, some of the factors studied for their prognostic value may be as or more useful in terms of their ability to predict response to certain types of therapy. The classic example of this phenomenon is the estrogen receptor, which was developed to predict response to hormonal therapy but has some prognostic value as well.

CLINICAL FINDINGS

PREOPERATIVE EVALUATION

As in all fields of medicine, good practice demands a thorough history and physical examination. The history should ascertain potential risk factors as discussed previously and disclose symptoms associated with local or systemic disease. These include changes in the breast or axilla: erythema, edema, masses, dimpling of the skin, nipple discharge, or pain. A complete review of systems should focus on possible metastatic indicators such as bone pain or respiratory difficulties.

The physical examination should be complete while focusing on the breast, axilla, and supraclavicular areas. These sites are evaluated for the presence of erythema, edema, dimpling, masses, skin nodules, ulceration, and skin discoloration. Abnormalities in the breast are better described by using a clock distribution than by specifying the quadrant. Although clinical assessment of axillary node palpability is important, it is notoriously inaccurate regarding actual histologic involvement. The supraclavicular nodal examination is crucial because the presence of nodal involvement is an indication of metastatic disease, dramatically altering the patient's prognosis and treatment. Evaluation of this area may be facilitated by asking the patient to shrug her or his shoulders forward.

POSTOPERATIVE EVALUATION

Guidelines for the follow-up of patients after primary therapy remain somewhat controversial. The American Society of Clinical Oncology surveillance recommendations include a history and physical examination every 3 to 6 months for 3 years, then every 6 to 12 months for 2 years, and then annually. Symptomatic patients should undergo further evaluation promptly in all cases, and all abnormal laboratory findings, discussed subsequently, should be thoroughly investigated.

SCREENING

The only screening technique available is mammography. There is considerable controversy regarding the timing of this study. The American Cancer Society and most professional groups recommend that women 50 years of age and older undergo yearly mammograms, with mammograms every 1 to 2 years starting at age 40 for those younger than 50. The value of breast self-examination has been questioned, but it has no significant deleterious effects except possibly for causing increased patient anxiety, which should be correctable by patient education. Women should be encouraged to perform monthly self-examinations, and they should have an annual professional manual breast examination. These examinations should be in addition to routine screening for gynecologic and gastrointestinal tumors.

LABORATORY AND RADIOGRAPHIC FINDINGS

PREOPERATIVE EVALUATION

A mammogram is useful in evaluating the remainder of the abnormal breast and the contralateral breast for masses or calcifications before definitive surgery. A negative mammogram does not rule out malignancy. A persistent mass must be biopsied regardless of the mammogram findings.

Evaluation of a palpable breast mass and abnormal mammograms are further discussed in [Chapter 205](#). Bone scans and liver scans are not routinely performed preoperatively in asymptomatic patients with normal laboratory values because the probability of detecting occult metastases in these women is less than 2%. Chest radiographs are obtained routinely, primarily because they are required for surgical anesthesia.

A complete blood count and chemistry profile are routinely obtained before surgery. Persistent elevation of bone or hepatic enzymes, specifically alkaline phosphatase or aspartate transaminase, warrant further evaluation with scans to rule out metastatic disease. However, these laboratory tests are nonspecific and frequently reflect a benign problem. There is no definite role for preoperative assessment of tumor-associated antigens such as carcinoembryonic antigen (CEA) or serum glycoprotein CA 15-3.

POSTOPERATIVE EVALUATION

A yearly mammogram is obligatory. Due to lack of evidence to suggest clinical benefit, the American Society of Clinical Oncology does not recommend routine bone scans, chest x-rays, or liver imaging. Many medical oncologists obtain complete blood counts, liver transaminase levels, and alkaline phosphatase levels on a routine basis, although available data do not support this practice. The value of other serum markers, such as CEA and CA 15-3, is also controversial. An isolated abnormal value is not necessarily an indication of recurrent disease, but a persistent or rising level is worrisome. The CEA level may be increased because of smoking or other benign or malignant disease of the liver, lung, gastrointestinal tract, ovary, or breast. Almost half of patients with documented metastatic breast cancer have increased CEA values, and the CA 15-3 level is elevated in as many as 80% of these patients. The CA 15-3 test is thought to have greater sensitivity than the CEA level, but an abnormal result may also be attributed to benign and malignant conditions similar to those associated with an elevated CEA level, except for smoking. There is, however, no doubt that assessment of the trend of CEA and CA 15-3 levels may be useful in following the clinical course of disease after metastases have been documented.

OPTIMAL MANAGEMENT

Because clinical breast cancer is conspicuously heterogeneous, the best guidelines are general, with excellent care often requiring marked variances from specified pathways. This is especially so because psychosocial factors often dominate the clinical setting in a disease as emotionally stressful as breast cancer. Nevertheless, certain principles have been established by clinical experience and by prospective, randomized clinical trials, and these form a basis for decision making and the evaluation of therapeutic practices.

The therapy of primary breast cancer is aimed at local control and the prevention of the appearance of systemic recurrence (metastatic spread). Local therapeutic modalities include surgery and radiation therapy. Established systemic therapies are chemotherapy and hormonal therapy. An immunotherapeutic approach is also emerging as a potentially effective treatment.

The first step in planning good treatment is to verify the histology of the tumor. In situ and infiltrating tumors are managed differently, and for both types of breast cancer, the histologic features may affect the prognosis and therapeutic decisions. For invasive lesions, knowledge of the status of receptors for estrogen (and progesterone, if available) is also key.

DUCTAL CARCINOMA IN SITU

Ductal carcinoma in situ can present as a mass, but it is more commonly found by biopsy of abnormal calcifications seen on a mammogram. The diagnosis of DCIS has increased during the past several decades, probably because of the increased use of mammographic screening. The optimal management of this condition is not yet established. In former years, the standard therapy was a mastectomy, which is so effective that there is a paucity of information on the natural history of this disease. Axillary dissection is usually not recommended for DCIS unless microinvasion is present. However, some surgeons are now offering sentinel lymph node mapping at the time of surgery for DCIS.

Local excision of a DCIS lesion leaves the rest of the breast at risk for recurrence. This risk is influenced by the extent of the DCIS (diameter of involved breast

tissue), the presence of comedo necrosis, and the status of the margins of resection. Half of recurrences in the breast are infiltrating cancers, rather than DCIS. The National Surgical Adjuvant Breast and Bowel Project (NSABP) reported that radiation therapy to the remaining breast after local excision reduces the local recurrence rate by 50%, with more efficacy in preventing invasive recurrences than recurrent DCIS. Therefore, most patients receive radiation therapy after undergoing local excision. However, there may be some who do not require radiation therapy. The identification of patients at an extremely low risk of relapse remains an active area of research, with several ongoing trials.

Even with the best therapy for DCIS, recurrences do occur and postsurgical follow-up is necessary. In addition, very long-term research will be needed to determine if the local failure rate of breast-conserving surgery plus irradiation for DCIS is acceptable. The likelihood of systemic metastases occurring from true DCIS is extremely small, and there has been no clear role for systemic adjuvant drug therapy. However, recent preliminary results from the NSABP indicate that tamoxifen can decrease the risk of invasive breast cancer in patients treated with lumpectomy and radiation. Further follow-up is necessary to determine an effect on overall survival. Therefore, tamoxifen may be appropriate therapy in patients with DCIS and may be useful to decrease the incidence of contralateral intraductal and invasive disease, as discussed below.

LOBULAR CARCINOMA IN SITU

Because lobular carcinoma in situ is usually not palpable and is invisible by mammography, the diagnosis of LCIS is commonly incidental to a breast biopsy performed for another reason. Because LCIS is an indicator of a propensity for developing invasive cancers and because both breasts are at equal risk, treatment options include observation alone or bilateral simple prophylactic mastectomies. There is no role for radiation therapy. Ipsilateral mastectomy with a contralateral biopsy has been performed in the past, but it is not advised because a negative contralateral biopsy does not rule out the risk of subsequent cancer occurring in the contralateral breast. Prophylactic mastectomy surely decreases the risk of the patient later presenting with invasive cancer. However, the magnitude of benefit is not certain because no mastectomy is absolutely complete, and patients have had recurrences in residual breast tissue in the chest wall or axilla after this procedure. Hence, current standard practice includes careful observation, with a growing movement toward the use of chemoprevention. Until recently there was also no clear-cut role for systemic drug therapy in the treatment of LCIS. However, recent data from the NSABP Breast Cancer Prevention Trial P-1 demonstrate an approximately 50% reduction in the risk of infiltrating breast cancer in patients with a history of LCIS after the administration of tamoxifen.

INFILTRATING TUMORS

Local Therapy Local treatment of breast cancer involves surgery and radiation therapy. In the late nineteenth century, Halsted popularized the radical mastectomy (RM). This operation resected the breast, all axillary lymph nodes, a significant amount of skin, and the pectoralis major and minor muscles. Motivated by the prevailing biologic hypotheses of his time, Urban's *extended radical mastectomy* added dissection of the internal mammary lymph nodes to Halsted's operation.

Largely because of public demand, to circumvent the disfigurement caused by these operations, the modified radical mastectomy (MRM) was investigated, starting in the 1940s. This operation removes the breast tissue, overlying skin, and axillary lymph nodes without resection of the muscle of the chest wall. Randomized studies have demonstrated no significant difference in disease-free or overall survival after RM or MRM, thereby establishing the less mutilating procedure as the standard. These results raised questions about the validity of the biologic concepts that motivated the more extreme resection.

Based on some of the newer concepts mentioned above, and in response to patients' concerns, Bernard Fisher in the United States, Umberto Veronesi in Milan, and subsequently others led investigations of even less mutilating surgery. These studies have established that breast-conserving surgery (BCS)—quadrantectomy or lumpectomy—plus axillary dissection plus radiation therapy to the remaining breast was as curative as MRM. Axillary dissection, when performed, should include the lymph nodes lateral to and underneath the pectoralis minor muscle. Fisher's group, the NSABP, demonstrated that the risk of local relapse exceeds 40% without radiation therapy. With radiation and good surgery (margins free of cancer), the national average for local control is in excess of 90%. However, BCS is not appropriate for all patients. Potential contraindications include multicentric tumors, large cancer-to-breast ratio, history of previous irradiation of the breast (for breast cancer or for treatment of lymphoma or other cancers), scattered malignant calcifications throughout the breast, very young age, extensive DCIS involving the lumpectomy margins, or anatomical factors that may predispose to a poor cosmetic result. It has long been felt that a history of connective tissue disease would contraindicate breast irradiation, for fear of a poor cosmetic result, but recent experience has raised doubts about this point.

When mastectomy is indicated, some surgeons are now performing a procedure called skin-sparing mastectomy. This leaves much of the skin overlying the breast intact, which facilitates reconstruction using the patient's own tissues.

It is also notable that sentinel lymph node mapping is now standard in many hospitals, being used instead of routine axillary dissection, especially in conjunction with BCS. However, major questions regarding this procedure are still unanswered, prompting much ongoing research by the American College of Surgeons and other groups.

When systemic adjuvant chemotherapy is used, radiation therapy is usually administered after chemotherapy. While this is still a point of some controversy, most radiation is being delivered in this sequence. Radiation therapy to the chest wall may also be administered after MRM in patients with large tumors or in those with a large number of positive nodes. In these cases the risk of local recurrence is high. In addition, several recent studies have demonstrated decreased mortality in premenopausal patients treated with radiation therapy after MRM. These results have generated much discussion. In general, based on these data, radiation therapy should be considered following MRM for most patients with four or more positive axillary nodes. Some patients with fewer positive nodes may also be considered candidates, largely because of factors that increase the likelihood of local recurrence, although specific treatment guidelines are in evolution.

Toxic effects from surgery and radiation therapy include self-limited pain, rare and usually treatable infection, disfigurement, and lymphedema. The availability of breast reconstruction using tissue expanders and saline-filled implants or using myocutaneous flaps should be discussed with the patient before local therapy. Lymphedema is a persistent problem that afflicts about 10% of patients undergoing axillary dissection. One of the advantages of sentinel lymph node mapping is that it may decrease the risk of the development of this complication. If the sentinel node is positive, then a complete axillary dissection is performed. If the sentinel node is negative, further axillary surgery is not performed because there is a low chance of there being positive axillary lymph nodes. While this procedure is now widely used, it clearly requires considerable expertise to be successful, and its ultimate reliability is still being studied.

Systemic Therapy

The drug treatment of breast cancer involves the use of several different types of therapy. For many decades the mainstays of treatment were chemotherapy and hormonal therapy, but these were recently joined by antibody therapy following approval of the drug trastuzumab. Drugs are used in three settings. The first setting is as an adjunct to the local therapies described previously. The intention is to damage micrometastatic cells that are likely to be present but are not yet apparent on physical examination or by laboratory tests. The second setting is in the treatment of overt metastatic disease. A third setting is primary therapy for locally advanced breast cancer, used to render the local disease amenable to surgical and radiotherapeutic approaches. A variant on this third setting, which remains investigational, is to shrink resectable breast cancer to make BCS feasible in cases that otherwise would require mastectomy. For all of these uses, detailed knowledge of the drugs, their indications, toxicities, and interactions is essential (see [Chapter 254](#)). Chemotherapeutic drugs, designed to attack mitosis or biochemical precursors to mitosis, are notable for their toxicity as well as their efficacy. Many normal tissues—gastrointestinal mucosa, hematopoietic cells, hair follicles—do have high mitotic rates and are therefore susceptible to chemotherapeutic damage. Granulocytopenia used to be a common life-threatening emergency caused by the use of chemotherapy drugs, but it can now be ameliorated in most cases by the use of recombinant granulocyte colony-stimulating factor (G-CSF).

Hormonal therapies are rooted in the incidental observation made in the nineteenth century that oophorectomy was beneficial to women with metastatic breast cancer. This is based on the fact that many breast cancer cells need estrogen to grow and to remain viable. The biochemical correlate of this need is the presence of hormone receptors. Since progesterone receptor is induced by activated estrogen receptor, estrogen receptor negativity plus progesterone receptor positivity in the same tumor means that the estrogen receptor negativity must be a false result. Hormone therapies work by the disruption of growth factor loops mediated by estrogen. Because they are so targeted, they are generally associated with less acute toxicity than chemotherapy.

Chemotherapy Agents

Most of the chemotherapy drugs used as postoperative adjuvant therapy were first employed in the treatment of metastatic disease. The most common chemotherapies used in breast cancer are listed in [Table 220.4](#) according to their presumed primary mechanism of action. Almost all of these agents can be administered in an outpatient setting. Cyclophosphamide (C), methotrexate (M), 5-fluorouracil (F), doxorubicin [Adriamycin] (A), and the taxanes, paclitaxel and

docetaxel, are the most commonly used drugs, often in various combinations ([Table 220.5](#)).

Hormonal Therapy
 Tamoxifen
 Anastrozole, letrozole
 Exemestrol acetate
Chemotherapy
Alkylating agents
 Cyclophosphamide (C)^a
 Ifosfamide
 Thiopeta (T)
Antimetabolites
 Methotrexate (MT)
 5-Fluorouracil (5-FU)
 Capecitabine
Antitumor antibiotics
 Doxorubicin (D)
 Epirubicin
 Mitomycin C (Mito-C)
 Mitoxantrone
Virba alkaloids
 Vinorelbine
 Vincristine
 Vinorelbine
 Vinorelbine
Taxanes
 Docetaxel
 Paclitaxel
Others
 Gemtuzumab

^a Commonly used abbreviations are given in parentheses.

TABLE 220.4. COMMONLY USED DRUGS IN THE TREATMENT OF BREAST CANCER

CMF (cyclophosphamide, methotrexate, 5-fluorouracil)
 CAF (cyclophosphamide, doxorubicin, 5-fluorouracil)
 CMFVP (cyclophosphamide, methotrexate, 5-fluorouracil, vincristine, prednisone)
 AC (doxorubicin, cyclophosphamide)
 VAT (vinorelbine, doxorubicin, thiotepa)
 VATH (vinorelbine, doxorubicin, thiotepa, halotestin)
 Mitomycin C + vinorelbine
 Doxorubicin followed by CMF
 AC followed by paclitaxel

TABLE 220.5. COMMONLY USED DRUG COMBINATIONS

One of the most frequently prescribed adjuvant regimens has been CMF (cyclophosphamide, methotrexate, 5-fluorouracil), which is usually administered for a total of 6 months. Doxorubicin is used alone or in combination with other drugs (e.g., AC, CAF). The adjuvant AC regimen is four cycles of intravenous drugs every 3 weeks and hence is of shorter duration than CMF. An overview analysis has suggested that doxorubicin (and similar drugs, called anthracyclines) in combination is slightly more active than CMF, but this benefit may be restricted to certain subsets of patients, a topic of intense current study.

A toxicity common to CMF, taxanes, and the doxorubicin-based regimens is myelosuppression (anemia, leukopenia, and thrombocytopenia). These hematologic values are transiently reduced, with their nadir occurring 1 to 2 weeks after the administration of chemotherapy. Platelet transfusions are rarely required, erythrocyte transfusions are somewhat more common, and antibiotics are only occasionally needed to treat neutropenic fevers. The use of G-CSF is mentioned above. Nausea and vomiting from CMF or the doxorubicin regimens are usually well controlled by the use of the antiemetics granisetron and ondansetron. Mucositis, diarrhea, and severe weight gain are unusual toxicities. The CMF and CAF regimens are associated with a slightly increased incidence of thromboembolic events, which are somewhat more likely when prednisone or tamoxifen is added. Alopecia requiring the wearing of a wig occurs in almost all patients treated with doxorubicin or a taxane, but CMF causes this in only a minority of patients.

Irreversible amenorrhea is induced by the drugs in approximately half of premenopausal patients. It is much more common in older premenopausal patients than in younger patients (up to their mid-thirties). Several studies have suggested that adjuvant AC causes less amenorrhea than CMF, but this lack of amenorrhea is not associated with an inferior response to therapy. The mortality rate from standard adjuvant chemotherapy in expert hands is much less than 1%. Life-threatening complications from chemotherapy are more common in the setting of metastatic disease, probably because of multiple organ impairment from the disease itself. Secondary leukemia is a theoretical concern with the use of adjuvant chemotherapy, but more than 20 years of experience with the CMF regimen has uncovered no higher rate than the expected background incidence. In contrast, the AC combination seems to be associated with a small but real incidence of drug-induced leukemia, and cytogenetic changes have been reported more commonly in patients who received very high doses of chemotherapy with autologous stem cell infusions as hematologic support. There is still no evidence that adjuvant chemotherapy increases the risk of any type of secondary cancer other than leukemia.

Hormonal Therapy

Among their many biologic effects, estrogens are known to stimulate production of growth factors such as transforming growth factor α , which can increase breast tumor proliferation in an autocrine (acting on the cell itself) and paracrine (acting on adjacent cells) manner. The hormonal manipulation of breast cancer involves the inhibition of estrogen's actions by lowering estrogen levels or interfering with the actions of estrogen on the cellular level.

Ovarian Ablation

The classic hormonal therapy for premenopausal breast cancer is ovarian ablation. This is achieved by surgical oophorectomy, by irradiation (which is slow and often incomplete), or by the administration of a gonadotropin-releasing hormone agonist. Adrenalectomy and hypophysectomy are rarely performed today because of their morbidity and their lack of therapeutic advantage over other hormonal therapies. The luteinizing hormone-releasing hormone analogues leuprolide or goserelin provide reversible medical castration by reducing the levels of follicle-stimulating hormone and luteinizing hormone. Ovarian ablation produces postmenopausal symptoms such as hot flashes, vaginitis, and sexual dysfunction.

Antiestrogens

The most commonly used drug for the hormonal therapy of breast cancer is tamoxifen, which is commonly classified as an *antiestrogen*, although this is an incomplete description of the drug's actions. The exact mechanisms by which tamoxifen exerts its antitumor effect remain unclear, but it is clearly not just by interference with estrogenic cell stimulation. In cultured cells, the binding of tamoxifen to estrogen receptors causes a cytostatic rather than a cytotoxic effect, with cells piling up in the cell cycle phase (G1) just before DNA synthesis. Estrogen receptors are required for tamoxifen to work. Because cells that seem progesterone receptor-positive but estrogen receptor-negative are really falsely negative for the estrogen receptor, tamoxifen will usually work in these cases as well. Yet the clinical response rates are highest when the tumors express both estrogen and progesterone receptors. Tamoxifen is administered orally at a dose of 20 mg per day. Higher dose levels are not more effective but are more toxic. The most common toxicities are hot flashes, irregular menses, vaginal discharge, depressed mood, and, rarely, thromboembolic events. In general, however, the drug is extremely well tolerated.

Ocular changes and thrombocytopenia do occur but are uncommon. Postmenopausal patients who have received tamoxifen in the adjuvant setting have a slightly higher rate of presenting with uterine cancer, including rare excess fatalities. Screening methods including serial endometrial biopsies and pelvic ultrasound examinations for the early detection of uterine abnormalities in this setting are under investigation, but so far no screening program has proven useful. Meanwhile, women receiving tamoxifen should have a clinical pelvic examination at least yearly. In terms of ancillary positive benefits, tamoxifen's estrogenic effects produce a decrease in cholesterol levels and an improvement in bone mineral density.

Antiestrogens, such as tamoxifen, that have an estrogenic effect on some cells but an antiestrogenic effect on others are now commonly classified as selective estrogen receptor modulators (SERMs), a term first used to describe the antiosteoporosis drug raloxifene. Like tamoxifen, raloxifene seems to decrease the incidence of new breast cancers, at least in postmenopausal women being treated for osteopenia. Unlike tamoxifen, raloxifene does not seem to stimulate growth of the uterine

lining. A prospective randomized comparison of tamoxifen and raloxifene as cancer prevention agents is currently under way. The search for better hormonal agents that have an antitumor effect on breast cancer cells and endometrial cells, an estrogenic effect on bone cells and serum lipids, and fewer toxicities is ongoing.

Progestational Agents

Medroxyprogesterone acetate and megestrol acetate are the most frequently used progestational agents in the treatment of advanced breast cancer. They are seldom used in the adjuvant setting. Possible mechanisms of action include a direct cytotoxic effect and indirect effects on the hormonal axis and on tumor growth factors. Megestrol acetate is usually preferred because of its lower rate of toxicity, but it does cause weight gain, fluid retention, and, sometimes, mild hyperglycemia. The standard dosage of megestrol acetate is 160 mg daily. Although higher dosages have been used to treat cachexia, they offer no additional anticancer benefit. Megestrol acetate in lower dosages (20 to 40 mg per day) is often used to treat hot flashes in postmenopausal women.

Aromatase Inhibitors

In postmenopausal women, aromatase in adipose and liver cells catalyzes the rate-limiting step by which adrenal androstenedione is converted to estrone, the major estrogen. Aminoglutethimide and related drugs inhibit this reaction, but they also impair adrenal biosynthesis. Several newer aromatase inhibitors, with proven superior activity/toxicity ratios, are now available, and others are in development. Examples are anastrozole and letrozole. These are usually used as second-line therapies for recurrent breast cancers that are no longer responsive to tamoxifen. A role in the adjuvant setting is under investigation.

Estrogens and Androgens

Pharmacologic doses of estrogens themselves can produce clinical responses in breast cancer, although the actual mechanism is uncertain. Diethylstilbestrol is the prototypic drug, but it is almost never now used because of a significant incidence of troubling toxicities such as nausea, vaginal bleeding, fluid retention, and thromboembolic events. Androgens such as fluoxymesterone have been used to treat breast cancer, although these drugs produce unpleasant virilization.

Adjuvant Therapies

The goal of adjuvant drug therapy is to prevent the growth of microscopic metastatic cells that may have disseminated from the primary tumor. Most patients with primary breast cancer have no clinical evidence of metastatic disease at the time of initial presentation. However, many patients eventually demonstrate metastatic disease. The probability of systemic recurrence varies largely as a function of tumor histopathology and the number of involved axillary lymph nodes. A patient with a small (less than 1 cm in diameter) infiltrating ductal or lobular carcinoma and no involvement of the axillary lymph nodes has an almost 90% chance of being recurrence-free at 20 years. In contrast, a patient with 10 or more involved axillary lymph nodes has less than a 15% chance of being disease-free at 10 years. Adjuvant drug therapy has been proven to improve these odds. It is of theoretical as well as practical interest to recognize that patients with the worst prognoses are the ones who benefit most from adjuvant drug therapy.

Most adjuvant drug therapy is initiated several weeks after the completion of primary breast surgery. A prospective randomized trial by the International Breast Cancer Study Group found that patients receiving at least 6 months of adjuvant chemotherapy fared equally well if they started the treatment immediately after surgery or about 5 weeks later. In the treatment of inoperable stage III disease, chemotherapy drugs are commonly applied before definitive local treatment, an approach termed *primary* or *neoadjuvant chemotherapy*. In the treatment of stage II and operable stage III disease this approach has proven capable of rendering large primaries suitable for BCS. A prospective randomized trial in this setting has been completed by the NSABP and has concluded that preoperative and postoperative AC produce equivalent benefits in such patients in terms of disease-free and overall survival. Long-term results in terms of local control rates are awaited.

Historically, adjuvant chemotherapy was first investigated in the late 1960s and early 1970s in patients with positive axillary lymph nodes. It was thought to be more ethically justifiable to apply potentially toxic treatments to patients with relatively poor prognoses. As the efficacy of adjuvant chemotherapy became clearer, patients without involved nodes were studied, confirming the positive impressions regarding benefits gained from the node-positive trials. Adjuvant hormonal therapy, largely with tamoxifen, has also been studied in node-negative and node-positive patients.

Adjuvant Chemotherapy

The impetus for the widespread study of adjuvant chemotherapy throughout the world were two classical controlled trials. One was the study of L-phenylalanine mustard by the NSABP and the other was the study of the CMF combination by the National Cancer Institute in Milan, led by Gianni Bonadonna and supported by the U.S. National Cancer Institute. Both trials, which treated node-positive patients only, demonstrated real clinical benefit and created a level of excitement that has been the motivation behind hundreds of trials to this day. Topics that have been studied over the years include various combinations of drugs, various dose levels and schedules, and various durations of treatment.

Until recently, 6 months of CMF was the most widely used regimen in general practice. Both the four-cycle AC combination and 6 months of CAF have also proven popular. However, doxorubicin is associated with a real but low incidence of cardiac damage and of drug-induced leukemia. These toxicities have not been seen with CMF. Until recently, there was a lack of data to support the superiority of a doxorubicin-based regimen over CMF for most patients. However, a recent overview (meta-analysis) of all randomized trials has identified a small additional benefit from anthracycline-containing combinations such as AC and CAF. A prospective randomized trial by the Cancer and Leukemia Group B (CALGB) has found that reductions in dose of doxorubicin below 40 mg per square meter are associated with worse outcome. The most dramatic beneficial effects of doxorubicin were seen in patients whose tumors overexpressed HER2 and who received doxorubicin at 60 mg per square meter. Hence, reductions in doses of standard adjuvant chemotherapy regimens or significant delays in treatment courses are not justified by the available evidence.

The concept of *dose intensity*, which is the amount of drug administered per unit of time, was formulated by William Hryniuk and colleagues. Based on retrospective analyses, these researchers proposed that the more dose-intensive regimens would result in improved outcome. Dose intensity is properly subdivided into *dose escalation* (increasing the dose level) and *dose density* (decreasing the time between administrations). In this regard, the NCI-Milan group conducted a now classic study of patients with four or more involved lymph nodes. They found that a regimen of doxorubicin for four 3-week cycles followed by CMF for eight 3-week cycles provided significantly decreased relapse and death rates, in comparison with an equally well-tolerated regimen giving the same drugs in an alternating pattern. The doxorubicin followed by CMF is more dose-dense than CMF alternating with doxorubicin because in the superior regimen the same amount of doxorubicin is given over a much shorter interval. However, dose escalation above standard dose levels was not employed in this regimen. The question of whether escalation of dose levels over the standard levels is beneficial or not remains open. As an ultimate application of dose escalation, a short course of chemotherapy can be given at such a high dose level that the reinfusion of autologous hematopoietic stem cells and/or granulocyte colony-stimulating factor (G-CSF) is necessary to accomplish adequate hematopoietic recovery. Based on promising pilot studies, the concept that clinical results of treating high-risk primary breast cancer can be improved by giving such treatment is undergoing extensive evaluation in prospective randomized trials. Preliminary results in several studies in the United States and Europe have indicated no benefit of high-dose chemotherapy and stem cell support over conventional therapy. However, these studies have been either of insufficient size or too short follow-up duration, so that definitive conclusions await longer follow-up. One South African trial was positive and awaits confirmation. Pending the results of these trials, adjuvant high-dose chemotherapy, popularly called autologous bone marrow (or stem cell) transplantations, remains investigational.

A recent study by CALGB has demonstrated that AC followed by paclitaxel was more effective than AC alone in women with node-positive breast cancer. This trial was based on the same concept of sequential dose-dense therapy as the study of doxorubicin and CMF from Milan. Ongoing trials will determine the optimal sequencing, dose, and schedule of administration of these agents, whether docetaxel has any advantages over paclitaxel in this setting, and if trastuzumab (see below) can safely augment the activity of the taxane.

Adjuvant chemotherapy has found its place in the treatment of node-negative and node-positive disease. In 1990, more than three-fourths of all newly diagnosed breast cancers were in stage I or II. Almost two-thirds of these women had node-negative disease. About one-fourth of the patients with node-negative disease would eventually have recurrences in the form of systemic metastases within 10 years of diagnosis if they were treated with local therapy alone. By 1988, studies from several U.S. and European cooperative groups had demonstrated that recurrence rates could be decreased by adjuvant chemotherapy in these patients, as had been previously shown for those with node-positive disease. However, some of these patients are at a sufficiently low risk of developing recurrent disease that the advantages of adjuvant chemotherapy do not outweigh the disadvantages of acute toxicity. Hormonal therapy may also offer these patients significant benefit, as it may for those with node-positive disease. Guidelines for offering adjuvant drug therapy follow the discussion of adjuvant hormonal therapy.

Adjuvant Hormonal Therapy

The hormonal therapies in common use in the adjuvant setting are tamoxifen and ovarian ablation. Ovarian ablation, applicable only in premenopausal patients, is the oldest of adjuvant therapies. Indeed, a trial of this treatment was initiated in 1948 by the Christie Hospital in England. Tamoxifen, with its low toxicity rate and ease of administration, is the most studied drug, with trials beginning in the 1970s. Premenopausal and postmenopausal patients have participated in tamoxifen trials. Major benefits are associated with the use of 5 years of tamoxifen in premenopausal and postmenopausal patients with estrogen receptor–positive cancers. Its use in other patients has been a subject of several worldwide meta-analyses.

There had been concern about the possible deleterious effects of the hyperestrogenemia that can accompany the use of tamoxifen in young premenopausal patients. However, this has not been shown to have significant clinical impact. The optimal duration of adjuvant tamoxifen use has yet to be determined with certainty, although most oncologists prescribe 5 years of the drug based on data summarized below. Longer durations are under study. In cultured cells, tamoxifen, by causing a cell cycle arrest before DNA synthesis, interferes with the cytotoxicity of some chemotherapy drugs, but it synergizes with others. There is no clinical evidence of any adverse interaction of tamoxifen with chemotherapy, but the optimal timing of chemotherapy and hormone therapy remains a subject of ongoing clinical trials. Because chemotherapy and tamoxifen can increase the incidence of thrombotic complications, their sequential use (chemotherapy followed by 5 years of tamoxifen) is advised by many. There is also significant ongoing research regarding ovarian ablation in premenopausal patients, as either an alternative to chemotherapy or an adjunct to chemotherapy and/or tamoxifen.

WORLDWIDE TRIALS

A meta-analysis by the Early Breast Cancer Trialists' Collaborative Group, published in 1992, retrospectively analyzed data on 75,000 women who participated in randomized trials before 1985. This approach provides a means by which to use large numbers of patients to find benefits that may escape notice in smaller, individual clinical trials. A major innovation was that the benefit to patients was expressed as the percent reduction in the annual odds of recurrence or death. The results, modified by the further analyses of Gelber and colleagues, are summarized in [Table 220.6](#). This analysis indicates that female patients of all ages benefit from tamoxifen and chemotherapy; however, the benefit of chemotherapy is greater in those who are less than 50 years old, whereas tamoxifen has a greater impact in those who are older than 50. Tamoxifen, as expected, is particularly active against cancers rich in estrogen receptors. Ovarian ablation in those younger than 50 years resulted in an approximately 25% reduction in the annual risk of relapse and death. Tamoxifen was also found to decrease the risk of contralateral breast cancer.

Age	Type of Therapy	Recurrence*	Death*
<50	TAM vs. no drug	27 ± 07	5TS
	CMF vs. no drug	37 ± 05	27 ± 06
	CMF + TAM vs. CMF	NS	NS
	CMF + TAM vs. TAM	5TS	5TS
≥50	TAM vs. no drug	30 ± 2	19 ± 03
	CMF vs. no drug	22 ± 04	14 ± 05
	CMF + TAM vs. CMF	28 ± 03	20 ± 05
	CMF + TAM vs. TAM	26 ± 05	NS

* Percent reduction (1/1 - SD) in the annual odds.
 5TS, sample too small for firm conclusions; NS, not significant.
 TAM, tamoxifen; CMF, cyclophosphamide, methotrexate, 5-fluorouracil.
 (Data from Early Breast Cancer Trialists' Collaborative Group. Systemic treatment of early breast cancer by hormonal, cytotoxic, or immune therapy. *Lancet* 1992;339:1; and Gelber RD, Goldhirsch A, Coates AS for the International Breast Cancer Study Group. Adjuvant therapy for breast cancer: understanding the overview. *J Clin Oncol* 1993;11:580-585.)

TABLE 220.6. BENEFIT OF ADJUVANT THERAPY IN BREAST CANCER

To use this overview to help make individual clinical decisions, the meaning of "percent reduction in the rates of recurrence or death" must be clarified. A patient at high risk of such events, such as a woman with numerous involved axillary lymph nodes, would benefit considerably from a therapy that gives even a moderate reduction in the rates. However, a patient at very low risk of recurrence and hence death, such as a woman with a cancer smaller than 1 cm in diameter and without axillary nodal involvement, might not benefit appreciably, even from a therapy with a relatively strong impact on these rates.

An update of the overview analysis in 1998 reevaluated the role of tamoxifen in early breast cancer. The use of tamoxifen (in estrogen receptor–positive or estrogen receptor–unknown tumors) for 5 years resulted in a greater effect on recurrence and mortality than its use for approximately 2 years. The impact on survival continued to increase for at least 10 years. The benefit in estrogen receptor–negative tumors was minimal. However, tamoxifen decreased the risk of contralateral breast cancer by nearly 50% after 5 years of use, regardless of the estrogen receptor status.

On the basis of data from large, prospective, randomized individual trials and the overview analysis, several sets of guidelines have emerged for the use of adjuvant drug therapy. One respected proposal, based on a consensus conference held in St. Gallen, Switzerland, in 1998, is paraphrased in [Table 220.7](#). For node-positive disease, chemotherapy is clearly indicated for premenopausal and most postmenopausal patients, whereas tamoxifen is indicated for all patients with estrogen or progesterone receptor–positive tumors. Most patients who are at high risk of recurrence will benefit from both types of therapy. For node-negative disease, the same guidelines generally apply. Some patients at very low risk would receive inconsequential benefit from adjuvant therapy in terms of prevention of recurrent disease, but these same patients might benefit considerably from adjuvant tamoxifen in terms of prevention of contralateral disease. This latter point is particularly relevant to patients with very tiny cancers and with special histologic subtypes, as discussed previously. One subtle point to be kept in mind, however, is that the Southwest Oncology Group has presented preliminary data suggesting that young patients with estrogen receptor–negative tumors are actually harmed, in terms of disease recurrence, by the use of tamoxifen. Hence, even chemopreventive use of tamoxifen may be inadvisable in this subgroup. Confirmatory analyses using other data sets are under way.

Axillary Node–Negative Disease
 Premenopausal and postmenopausal women
 No therapy
 Chemotherapy (CMF, AC, AC followed by paclitaxel) ± tamoxifen
 Tamoxifen alone
Axillary Node–Positive Disease
 Premenopausal women
 Chemotherapy (CMF, AC, AC followed by paclitaxel) ± tamoxifen
 Chemotherapy (CMF, AC, AC followed by paclitaxel) ± ovarian ablation
 Ovarian ablation ± tamoxifen
 Postmenopausal women
 Chemotherapy (CMF, AC, AC followed by paclitaxel) ± tamoxifen
 Tamoxifen alone

* Treatment decisions are based on evaluation of prognostic factors, the patient's overall medical condition, and consideration of the potential risk and benefits. Patients should also be offered investigational protocols if available. Ovarian ablation remains investigational.
 Note that the regimens in parentheses are in common use but are not completely routine.
 CMF, cyclophosphamide, methotrexate, 5-fluorouracil; AC, doxorubicin, cyclophosphamide.
 (Data from Goldhirsch A, Gelber RD, et al. Meeting highlights: international consensus panel on the treatment of primary breast cancer. *ANCJ* 1998;90:1601-1608.)

TABLE 220.7. TREATMENT OPTIONS FOR ADJUVANT THERAPY OF BREAST CANCER^a

The major type of chemotherapy represented by the overview analysis and subsequent analyses is 6 months of CMF or an equally effective variant. However, some of the newer chemotherapy regimens, such as the doxorubicin- and taxane-based regimens, may offer more benefit, at least in patients at high risk of recurrence. Many ongoing trials are investigating innovative regimens that vary the dose or schedule, use combinations of chemotherapy and hormonal therapies (including ovarian ablation), and apply immunotherapeutic agents such as monoclonal antibodies against HER2 and vaccines. This field is evolving rapidly and is already sufficiently complex that treatment decisions must be made by consultation with experienced specialists. As in all areas of internal medicine, patient-directed goals and lifestyle concerns are also essential in the decision making process. They are especially relevant when the benefits of relatively toxic treatments are slight.

LOCALLY ADVANCED DISEASE

In most parts of the world, locally advanced breast cancer is not an uncommon stage at presentation. However, in the United States and Europe, only 5% to 20% of patients present at this stage of disease. This range reflects socioeconomic and geographic differences. Before chemotherapy, decades of experience with aggressive surgery and high-dose radiation therapy alone were profoundly disappointing. Most patients are now treated with preoperative chemotherapy, followed by modified radical mastectomy, additional chemotherapy, and radiation therapy. Tamoxifen is also used thereafter when appropriate.

METASTATIC DISEASE

Because stage IV breast cancer is not curable with conventional therapy, the primary goal of treatment is palliation of symptoms. Prognosis varies widely. Patients with most of their disease in soft tissues fare better than those who have primarily bone involvement; those with visceral metastases fare worse; and those with brain metastases have the worst prognosis. Patients with a large number of sites involved do more poorly than those with one site, and estrogen receptor–positive cancers tend to have more indolent growth rates and respond much better to both hormonal therapy and chemotherapy. Involvement of certain sites may create complications that are best managed by surgery and, in particular, radiotherapy, in addition to systemic drug treatment.

SITES OF RECURRENT DISEASE

When breast cancer recurs in metastatic sites, it is inapparent by signs or symptoms in about one-half of cases. The most common sites of initial presentation of stage IV disease are the skin and soft tissues of the chest wall, axilla, or supraclavicular areas (regional recurrence) and bone. Osseous recurrences are usually painful and are frequently associated with elevated alkaline phosphatase levels. Less common locations for the first sites of metastatic disease are the lung, liver, and, most uncommonly, the central nervous system. Most patients with initial stage IV disease have one or at most two different organ systems involved. As the disease progresses, involvement of multiple sites usually becomes evident. At autopsy, metastatic cancer is usually more widespread than could be suspected from clinical examination. Metastases at autopsy have been found in nearly every organ of the body, including heart, kidneys, ovaries, thyroid gland, and gastrointestinal tract.

HORMONAL THERAPY FOR METASTATIC DISEASE

About one-third of unselected patients benefit from the initial administration of a wide spectrum of hormonal treatments, listed in [Table 220.8](#). The median duration of response is 1 to 2 years. Patients whose tumors have strongly positive estrogen or progesterone receptors experience a higher response rate, and those with truly receptor-negative cancers rarely benefit. Ovarian ablation is only effective in premenopausal patients, and aromatase inhibition is only effective in those who do not have ovarian estrogen secretion. Otherwise, the choice of initial hormonal therapy is based primarily on considerations of feasibility and tolerance. Tamoxifen, one of the least toxic drugs, is commonly the first therapy offered to postmenopausal patients. It can also be effective in premenopausal patients but is more active in the absence of ovarian function. The response to tamoxifen in this group of patients predicts good response to subsequent ovarian ablation. The best candidates for hormonal therapy as the first treatment of metastatic disease are those with slow-growing cancers as manifest by a long interval between initial presentation in the breast and the first appearance of stage IV disease. Because falsely negative estrogen receptor determinations can occur, hormonal therapy may be attempted in patients with indolent tumors even if the biochemistry of the specimens would seem to predict a poor response rate. Because responses to hormonal therapy tend to be slow, an observation period of as long as 16 weeks may be necessary to see substantial tumor regression.

Premenopausal and postmenopausal women
Tamoxifen
Progestins
Androgens
Adrenalectomy
Premenopausal women
Oophorectomy
LHRH analogues
Postmenopausal women
Aromatase inhibitors
Estrogens

LHRH, luteinizing hormone-releasing hormone.

TABLE 220.8. HORMONAL THERAPY OPTIONS FOR METASTATIC BREAST CANCER

If a patient's tumor shrinks in response to hormonal therapy but later regrows, the cancer may respond again if a second hormonal therapy is tried. Third-line responses are also seen, but the odds of response decrease with each new episode, the durations of response become shorter, and eventually most breast cancers become refractory to hormonal manipulation. Some patients who demonstrate progression of the disease on tamoxifen may show tumor shrinkage after withdrawal of the drug for at least 6 weeks. Although best described for diethylstilbestrol (almost never used) and tamoxifen, all hormonal therapies may cause bone pain or the appearance of transiently rapid growth of soft tissue involvement within the first month of administration (a phenomenon called *flare*). This is a good prognostic sign because it often portends a good subsequent response. However, considerable skill must be exercised to differentiate flare from frank tumor progression.

CHEMOTHERAPY FOR METASTATIC DISEASE

For patients with hormone-refractory stage IV disease, de novo or after initial response, chemotherapy is the best option. It may also be used instead of hormonal therapy if the patient's degree of visceral involvement or the rapidity of tumor growth does not permit a sufficiently long observation time to monitor a hormonal treatment.

Chemotherapy is not curative at standard doses. The patient's quality of life is a very important consideration in the choice of regimen and time to initiate treatment. Doxorubicin, paclitaxel, and docetaxel are the most effective single agents for the treatment of metastatic disease. Doxorubicin combinations are more active than CMF, although at the price of greater toxicity. A standard taxane combination has not yet been established. Some studies indicate a higher than expected incidence of cardiac toxicity with the combination of paclitaxel and doxorubicin. In the past, combination chemotherapy produced longer durations of response than single agents; however, high response rates have been observed with the use of single-agent taxanes. Newer drugs with real activity in breast cancer have recently expanded the therapeutic options and are now often used after the failure of the primary drugs listed above. These newer drugs include capecitabine, vinorelbine, and gemcitabine.

The median duration of response and survival rates are given in [Table 220.9](#). Chemotherapy is often useful in controlling the symptoms of cancer, but it may make an asymptomatic patient ill with toxic effects. The optimal duration of chemotherapy is unclear. There is little evidence to suggest that prolonged courses beyond the time needed to achieve stable tumor volume regression are beneficial. One plan that has been widely used is to treat the patient with a regimen to the point of maximal tumor response and then administer one additional cycle of chemotherapy, followed by observation. Chemotherapy should be reinstated at the time of documentation of progressive disease. As with hormonal therapy, when chemotherapy fails, other regimens may be used to good effect, but the chance of response decreases with each episode.

First-line regimens

CMF
CAF, AC, doxorubicin alone
Paclitaxel, docetaxel

Response data after first-line regimens

Time to first response (median): 4–8 wk
Response duration (median): 5–13 mo
Survival of responders (median): 15–33 mo

A, doxorubicin; C, cyclophosphamide; F, 5-fluorouracil; M, methotrexate.
(Response data from Harris, Morrow M, Bonadonna G. Cancer of the breast. In: DeVita VT Jr, Hellman S, Rosenberg SA, eds. Cancer: principles and practice of oncology, fourth ed. Philadelphia: JB Lippincott, 1993.)

TABLE 220.9. CHEMOTHERAPY FOR METASTATIC BREAST CANCER

The administration of high-dose chemotherapy with bone marrow or peripheral stem cell support plus G-CSF has been used widely in the United States in the treatment of metastatic breast cancer, usually in patients whose cancers are responding to conventionally dosed treatments. This usage was motivated by the results of uncontrolled, single-institution pilot studies, which have demonstrated that approximately 20% of patients remain free of disease for at least 5 years after such treatment. High-dose chemotherapy is toxic, both acutely and chronically, and is associated with a small but reproducible mortality rate. Some oncologists have claimed that the long-term disease-free percentages seen may be the consequence of the careful selection of patients for inclusion in these programs rather than the therapy itself. Others are convinced that these results indicate that such treatment is effective, if only for properly chosen patients. Such controversy can only be settled by prospective, randomized clinical trials, several of which are in progress.

IMMUNOTHERAPY FOR METASTATIC DISEASE

One of the most exciting developments in the past few years has been the discovery of the monoclonal antibody trastuzumab. This agent binds with the extracellular domain of the transmembrane glycoprotein HER2. Several trials have demonstrated modest clinical benefit when trastuzumab was used alone in patients with HER2-overexpressing disease who had ceased to benefit from chemotherapy. Of greater interest, a randomized trial found the drug to be most effective when used in conjunction with chemotherapy (AC or paclitaxel) in patients with HER2-overexpressing disease who had received no chemotherapy for metastatic disease. Significant cardiac toxicity has been observed with the combination of trastuzumab and doxorubicin. Hence, the combination of trastuzumab and paclitaxel has now become standard in the treatment of HER2-overexpressing metastatic breast cancer. Numerous trials are ongoing to evaluate the optimal use of this antibody with a variety of chemotherapeutic agents. In addition, the evaluation of other antibodies and vaccines remains a particularly active area of investigation. Several large national trials are testing the activity of trastuzumab plus paclitaxel in the adjuvant setting.

SPECIAL THERAPEUTIC SITUATIONS

MALE BREAST CANCER

Because of the small size of the normal male breast, physical examination should disclose primary tumors of relatively small size. Nevertheless, many male patients have presented with advanced local disease because of their lack of knowledge regarding the possibility of developing breast cancer. The prognosis for a man with breast cancer seems to be equivalent to that of a postmenopausal woman with breast cancer of the same TNM stage. Modified radical mastectomy is the acceptable local treatment. The systemic therapy in the adjuvant setting or for stage IV disease should follow recommendations for postmenopausal female breast cancer.

PREGNANCY

Breast cancer is reported to complicate approximately 1 in 4,000 pregnancies. Although most patients present with a breast mass, delays in diagnosis are common because of the density of the breast in these patients. Although pregnant patients experience the same prognoses stage for stage as their nonpregnant counterparts, they tend to present at more advanced stages or, within the stage II category, with more involved axillary lymph nodes. This may be because of delay in diagnosis, but a growth-stimulatory role of the high levels of female hormones and growth factors associated with pregnancy cannot be excluded. Breast biopsies can be performed safely during pregnancy and should be followed, if a diagnosis of invasive malignancy is confirmed, by mastectomy in most cases. Breast conservation in the first two trimesters is ordinarily contraindicated because the obligatory breast radiation therapy is precluded by its potential for harming the fetus. BCS can be performed in the last trimester, with chemotherapy and especially radiation therapy delayed until delivery. If indicated, chemotherapy can be administered after the first trimester, but antimetabolites, being teratogenic, are best avoided. For this reason, many oncologists prescribe the combination of doxorubicin and cyclophosphamide as adjuvant chemotherapy. Tamoxifen should not be given during pregnancy.

Considerable controversy exists regarding the safety of a subsequent pregnancy in a woman with a personal history of breast cancer. There are no conclusive data to indicate that prognosis is worsened by this event, but some researchers advise caution because the available information is scanty. Following the model established for Hodgkin's disease, patients are often counseled to avoid pregnancy for at least 2 years after the therapy of primary breast cancer. This is to allow for the recovery of normal organs from the toxicity of drug therapy and to eliminate the possibility of rapid recurrence of aggressive disease. Metastatic spread in pregnant women tends to follow the same anatomical distribution as in other patients. Metastases to the placenta are rare, and fetal metastases have not been reported.

BONE METASTASES

Pain is commonly associated with osseous metastases, and pain relief is a good indication of the anticancer efficacy of drugs or irradiation. For impending or frank pathologic fractures, especially of the weight-bearing bones of the spine, pelvis, and lower extremities, surgical stabilization is often necessary (see [Chapter 210](#)). Vertebral fractures unresponsive to radiation therapy, especially when the integrity of the neural canal is threatened, may sometimes be amenable to surgical approaches even though this is technically challenging. A back brace and physical therapy can be useful. Bisphosphonates, in particular pamidronate, have routinely been used for treatment of hypercalcemia. However, several studies have shown a decrease in bone pain and skeletal complications with monthly doses of pamidronate. The role of bisphosphonates in the adjuvant setting remains investigational.

LUNG METASTASES

Malignant pleural effusions, usually exudates, are often associated with dyspnea, pain, and cough. Thoracentesis may provide temporary relief of symptoms, but pleurodesis with a sclerosing agent (e.g., tetracycline, talc, bleomycin) is preferable for longer term control. Lymphangitic involvement of the lung commonly presents suddenly and, if unresponsive to systemic therapy, progresses rapidly. It is characterized by dyspnea and cough, appears as diffuse reticulonodular infiltrates on radiographs and especially on computed tomography (CT) scans, and often causes hypoxemia. Infectious and other nonmalignant causes must be ruled out. Biopsy by means of bronchoscopy or thoracoscopy is often helpful, but lymphangitic disease can be a diagnosis of exclusion. Chemotherapy rather than hormonal therapy is the treatment of choice. The use of corticosteroids and inhaled oxygen may temporarily decrease symptoms.

LIVER METASTASES

Liver metastases are primarily treated with systemic chemotherapy. There is usually no role for radiotherapy in this setting. Attempts at increasing response rates or reducing systemic toxicity by infusing chemotherapy directly into the hepatic circulation have so far been disappointing. Surgical resection of hepatic lesions after an initial chemotherapy response and in the absence of other sites of metastases has been used in special cases, but it is not recommended for routine management.

CENTRAL NERVOUS SYSTEM METASTASES

Epidural compression of the spinal cord or the cauda equina may result in permanent neurologic damage if these are not treated promptly. Pain is the most common presenting symptom, followed by sensory and motor deficits with loss of sphincter control. Lesions may be located by a thorough neurologic examination plus spinal

imaging, particularly the use of magnetic resonance imaging (MRI). Treatment usually involves corticosteroids to decrease localized edema plus radiation therapy. Decompressive surgery is sometimes appropriate.

Brain metastases commonly manifest with headaches or neurologic symptoms. The diagnosis can be confirmed with CT or MRI. Corticosteroids are used to decrease edema, and anticonvulsants are prescribed to control seizure activity. Radiation therapy is recommended for the treatment of multiple metastases, but it is associated with considerable toxicity, including hair loss and loss of cognitive function. Surgery, alone or followed by radiation therapy, has been used for solitary lesions. There is increasing experience with the use of radiosurgery (i.e., the use of very carefully designed, highly specifically localized radiation fields) in the management of brain involvement with a few dominant masses. This can be used in conjunction with whole-brain radiotherapy.

Leptomeningeal involvement (carcinomatous meningitis) is best diagnosed by lumbar puncture, although radiographic imaging may also be helpful. Patients may present with a variety of symptoms, including headache, alteration of mental status, nausea, and neurologic deficits. Radiation therapy, corticosteroids, and chemotherapy by the intrathecal or intraventricular route provide the mainstays of therapy.

HYPERCALCEMIA

Hypercalcemia is a common complication of very advanced stage IV breast cancer, and it generally denotes bone involvement, which usually is already apparent. In the treatment of less advanced metastatic disease, the serum calcium level may rise acutely in response to hormonal therapy, especially associated with the flare reaction. In these cases, the hypercalcemia is transient, often preceding a good therapeutic response. Hypercalcemia causes mental status changes, nausea, vomiting, and constipation. Acute therapy consists of intravenous hydration and bisphosphonates (e.g., pamidronate). The longer term management of hypercalcemia depends on the control of the metastatic process with anticancer drugs.

LOCAL RECURRENCE

Patients who have disease recurring on the chest wall after mastectomy have a very high rate of systemic relapse. Treatment options in the absence of other sites of stage IV disease have included local resection and radiation therapy, which can be considered standard management. A variety of other treatments have been used—including standard-dose chemotherapy, high-dose chemotherapy, and hormonal therapy—but no clear advantages of such approaches are apparent. Patients who have recurrent disease in the breast after breast conservation are usually treated with mastectomy. The role of systemic therapy in this situation is not yet established, but adjuvant chemotherapy or hormone therapy is often applied. Patients with local recurrences are often ideal candidates for investigational therapies such as vaccines.

PREVENTION

Interest in preventing breast cancer, a goal of obvious intrinsic merit, has been heightened by several observations hinting at potentially profitable lines of investigation. The association between breast cancer incidence and various states of altered estrogen levels has led to some trials seeking to simulate early pregnancy. Other trials seek to deny breast tissue estrogenic stimulation while maintaining beneficial estrogenic effects on end organs such as bone and blood vessels. The largest of these is the P-1 trial of the NSABP, discussed below. Other large, randomized, controlled trials of tamoxifen are under way in Europe. These trials were explicitly motivated by the observation of decreased contralateral primary disease in patients taking tamoxifen as adjuvant therapy.

Recent data from a randomized trial by the NSABP clearly demonstrate a 49% decrease in the risk of invasive breast cancer and a 50% reduction in the risk of noninvasive disease with tamoxifen versus placebo. The impact was exclusively on the appearance of estrogen receptor–positive cases, with no differences noted between tamoxifen and placebo in estrogen receptor–negative disease. Eligibility criteria included age 60 years or more, or age 35–59 years with a high risk of developing breast cancer based on a mathematical epidemiologic model or because of a personal history of LCIS. A small increased risk of early-stage endometrial cancer and thrombotic events was found in the patients receiving tamoxifen. This may not be a problem if only women at considerable risk of breast cancer take the drug, but it could be a problem if tamoxifen is prescribed for women at borderline or average risk. Two European trials were not able to confirm the results of the NSABP trial although these studies differed from the U.S. trial due to allowance of hormone replacement therapy, smaller numbers of patients, and patient noncompliance. Therefore, the findings of the large NSABP trial are important. They have led to the approval of tamoxifen by the U.S. Food and Drug Administration as a preventive agent for breast cancer in women who fit the above eligibility criteria. It is important to note that the potential benefits and toxicities for any given patient need to be evaluated on an individual basis.

As described above, in a large, prospective randomized trial with the primary end point of determining its effects on bone mineral density, the SERM raloxifene was shown to decrease breast cancer incidence in postmenopausal women with osteopenia by about 75%. This has led to the P-2 trial of the NSABP in which volunteer postmenopausal women with increased risk, or women aged 60 or greater, are randomly allocated to receive tamoxifen or raloxifene. Effects on the endometrium as well as the breast will be ascertained. Since many postmenopausal women with osteopenia and osteoporosis are now taking raloxifene, an incidental but considerable lowering of breast cancer incidence may be noted.

Attention is being paid to possible environmental causes of high breast cancer risk, in addition to the personal behaviors associated with diet, exercise, and childbearing. Except for unnecessary radiation exposure, which should clearly be avoided, these studies are too preliminary to lead to specific recommendations. Nevertheless, efforts to limit exposure to potentially carcinogenic chemicals such as pesticides and industrial pollutants are commendable on a variety of health grounds. Exercise and a healthy diet are standard medical prescriptions.

As genetic analysis of breast cancer susceptibility becomes part of our available options, many questions will be posed for the individual, for the implicated family, and for society as a whole. We do not know the roles of lifestyle changes, exogenous hormone ingestion, more intense surveillance, or prophylactic resection of the breasts or ovaries on cancer incidence and mortality in carriers of mutant *BRCA1* or other such altered genes. Allele-specific penetrance in terms of incidence and virulence is also unknown. The lack of a specific *BRCA1* or *BRCA2* mutation does not imply that there is no increased risk of cancer because other genes may be mutated. Nevertheless, many women want to know the best estimate of their risk, and formal genetic counseling must become a common part of standard oncologic practice. The availability of hereditary predisposition testing raises ethical and legal issues, including the so far theoretical potential for employment and insurance discrimination, that must be addressed. Despite these problems, a growing knowledge of the genetic basis for breast cancer, both hereditary and acquired, offers real hope for a fundamental improvement in our ability to control and even eradicate this common disease.

CHAPTER 221: GYNECOLOGIC MALIGNANCIES

MARK A. MORGAN

[Cervical Cancer](#)
[Uterine Cancer](#)
[Ovarian Cancer](#)
[Gestational Trophoblastic Disease](#)

CERVICAL CANCER

DEFINITION

Invasive squamous cell carcinoma is the most common malignancy of the uterine cervix. Histologic subtypes include both large cell keratinizing and nonkeratinizing cancer as well as poorly differentiated and small cell cancer with neuroendocrine features. The latter two have a worse prognosis. Adenocarcinoma accounts for 10% to 20% of invasive cervical cancers. The clear cell variant is associated with diethylstilbestrol exposure in utero but may occur in the absence of such exposure.

INCIDENCE AND EPIDEMIOLOGIC FACTORS

The incidence of cervical cancer has been decreasing since the introduction of the Pap smear in 1941. There are about 12,800 new cases of invasive disease diagnosed each year and 4,800 deaths in the United States. The disease is more common in low socioeconomic groups and in third world countries (e.g., Latin America). In the United States, the mortality for African American women is twice that for caucasians, primarily due to more advanced disease at diagnosis. There is a bimodal age distribution, with peaks at 35 to 39 years and 60 to 64 years.

Risk factors for cervical cancer are strongly related to sexual activity and include early age of first intercourse, intercourse with multiple partners, and intercourse with a "high-risk" male (multiple partners, penile condyloma). Women who use barrier contraception have a decreased risk. Oral contraceptives have been possibly linked to increased incidence of dysplasia and invasive cancer, as well as to adenocarcinoma of the cervix. Cigarette smoking is also associated with an increased risk.

ETIOLOGIC FACTORS

The epidemiologic profile of cervical cancer is that of a sexually transmitted disease, so that studies on the etiology have focused on infectious agents, in particular herpes simplex virus type 2 (HSV-2) and human papilloma virus (HPV). HPV DNA has been found in a high percentage of cervical dysplasias and invasive cancers, and genetic integration of the viral genome into the cervical cell has been demonstrated. HPV proteins have also been found to bind to and inhibit the protein product of both the retinoblastoma and P53 tumor suppressor genes. HSV-2 and other cervical infections are now thought to be cofactors with HPV in the development of cervical neoplasia.

PATHOGENESIS/PATHOPHYSIOLOGIC FACTORS

Invasive cervical cancer is felt to progress in an orderly fashion from dysplasia to carcinoma in situ over a period of 10 to 20 years. This long lead time is partially responsible for the effectiveness of Pap smear screening. Also, there appears to be an early or "microinvasive" stage wherein the risk of nodal metastasis is negligible. Once invasion occurs, there is progression to regional lymphatics and occasionally hematogenous spread. Pelvic lymph nodes are usually involved prior to para-aortic nodes. Patients who are immunosuppressed have a higher incidence of lower genital tract HPV infection and neoplasia, and patients with AIDS have been found to experience more rapid progression of disease.

CLINICAL FINDINGS

Preinvasive and early invasive cervical cancer is asymptomatic and is usually detected by Pap smear screening or colposcopy. As the cancer spreads more deeply to the cervical stroma, abnormal vaginal bleeding can occur, particularly postcoital bleeding. Progression of disease is often associated with a malodorous discharge, a gross cervical tumor, weight loss, and local pain.

Cervical cancer is the only gynecologic malignancy staged clinically by the International Federation of Obstetrics and Gynecology (FIGO). Allowable studies are listed in [Table 221.1](#). More sophisticated studies, such as computed tomography and magnetic resonance imaging, or surgical findings are not allowed for staging purposes but may be used for treatment planning.

Examination under anesthesia
Intravenous urogram
Barium enema
Chest x-ray
Skeletal x-ray
Cystoscopy
Proctoscopy

TABLE 221.1. CLINICAL STAGING PROCEDURES FOR CERVICAL CANCER

LABORATORY FINDINGS

Patients with cervical cancer are often anemic, and the serum creatinine may be elevated in the presence of ureteral obstruction. Serologic markers such as the cancer antigen (CA-125) and the squamous cell carcinoma antigen have been found to be elevated in some patients with cervical cancer but in general are not useful in screening or follow-up.

OPTIMAL MANAGEMENT

Microinvasive cervical cancer can only be diagnosed by cone biopsy. In very early lesions, if the margins are negative, conization itself may be adequate treatment. In the United States, if the depth of invasion is less than 3 mm and there is no lymphovascular invasion evident in the cervical stroma, simple hysterectomy is the most common treatment.

Disease limited to the cervix with deeper invasion (stage IB) or to the upper vagina (stage IIA) may be treated with radical hysterectomy and regional lymph node dissection, or radiation therapy. The ovaries may be preserved with radical hysterectomy, but they cease to function after radiation therapy. The 5-year survival for stage I disease is about 85% with either treatment modality. Patients found to have positive lymph nodes, deep stromal invasion, or positive margins at radical hysterectomy should be offered postoperative radiotherapy. Recent evidence also suggests that the addition of cisplatin and 5-fluorouracil chemotherapy to radiotherapy may prolong survival. In selected cases, patients who present with bulky (more than 4 cm) tumors confined to the cervix may also be considered for

treatment with preoperative radiation and chemotherapy followed by simple hysterectomy. When cancer invades the lower vagina, parametrium, or surrounding organs (stages IIB to IVA), radiation therapy combined with chemotherapy, either cisplatin alone or cisplatin plus 5-fluorouracil, is indicated. Pretreatment evaluation of the para-aortic lymph nodes by lymphangiography, computed tomography, or extra-peritoneal lymph node dissection may be performed to determine whether patients require extended-field radiation. Cisplatin and ifosfamide are the two most active chemotherapeutic agents for distant disease, although paclitaxel has recently also demonstrated activity in squamous and nonsquamous cervical cancer.

A central recurrence of cervical cancer after radiation therapy is potentially curable with exenterative surgery. This usually involves removal of the bladder, rectum, and vagina. Newer techniques of urinary diversion, vaginal reconstruction, and surgical critical care have made this a more acceptable procedure in terms of morbidity and mortality.

Current clinical trials are evaluating the role of new chemotherapeutic agents and combinations of agents in advanced disease. Neoadjuvant chemotherapy is also being tested to reduce tumor size in bulky disease confined to the cervix prior to radical hysterectomy. In addition, viral vaccines, using-HPV related antigens, are being actively investigated in disease treatment and prevention.

UTERINE CANCER

Cancer of the uterus usually refers to adenocarcinoma of the endometrium, although the term includes uterine sarcomas and, rarely, squamous cell cancers. Sarcomas account for only about 3% of uterine malignancies and are distinguished from benign mesenchymal growths by their high mitotic count and nuclear atypia. Mixed mesodermal tumors combine admixtures of malignant epithelial and stromal elements and account for about 40% of uterine sarcomas.

INCIDENCE AND EPIDEMIOLOGIC FACTORS

In 1999 there were an estimated 37,400 new cases of uterine cancer and 6,400 deaths in the United States. This makes uterine cancer the most common gynecologic malignancy. It is more common in caucasian women and occurs primarily in postmenopausal women.

Risk factors are related to prolonged unopposed exposure to estrogen, such as occurs with obesity, anovulation, estrogen therapy without progesterone, and estrogen-secreting tumors. Smoking and oral contraceptives decrease the risk. Recently, tamoxifen, probably because of its weak estrogen effect, has been associated with an increased risk of endometrial cancer. Endometrial cancer also may be seen as part of the Lynch II familial cancer syndrome in association with breast, colon, or ovarian cancer.

ETIOLOGIC FACTORS

Whether endometrial cancer progresses from endometrial hyperplasia has been debated for years. It appears that both can develop in response to unopposed estrogen; however, the likelihood of progression of hyperplasia to cancer is very low in the absence of cytologic atypia.

PATHOGENESIS/PATHOPHYSIOLOGIC FACTORS

Approximately 85% of endometrial cancers are stage I or II (limited to the uterus and cervix). Endometrial adenocarcinoma invades the myometrium and may spread by lymphatics, blood vessels, or local extension to other organs. It may also spread into the peritoneal cavity through the fallopian tubes. Pelvic lymph nodes are almost always involved when more distant para-aortic nodes are found to contain disease. Depth of invasion into the myometrium and histologic grade of the tumor are directly related to the probability of lymph node involvement and prognosis. The Gynecologic Oncology Group (GOG) has evaluated this in a large surgical staging study ([Table 221.2](#)). Patients with estrogen and/or progesterone receptors have a better prognosis than those without receptors. The papillary serous histologic type is notorious for early spread, especially to the upper abdomen (similar to the spread pattern of epithelial ovarian cancer).

Depth of Myometrial Invasion	Histologic Grade			Total
	G1	G2	G3	
Endometrium	0 (0)	3 (3)	0 (0)	1 (1)
Inner third	3 (1)	5 (4)	9 (4)	5 (3)
Middle third	0 (5)	9 (0)	4 (0)	6 (1)
Outer third	11 (6)	19 (14)	34 (23)	25 (7)
Total	3 (2)	9 (5)	18 (11)	

TABLE 221.2. PELVIC AND PARA-AORTIC NODAL INVOLVEMENT IN STAGE I ENDOMETRIAL CANCER BASED ON DEPTH OF MYOMETRIAL INVASION AND HISTOLOGIC GRADE (%)

CLINICAL FINDINGS

Postmenopausal bleeding is by far the most common symptom associated with endometrial cancer. However, abnormal uterine bleeding in premenopausal women with a history of anovulation may be a sign of endometrial cancer. Diagnosis may be made by an office endometrial biopsy, but if this is not diagnostic, then a dilation and curettage should be performed. Hysteroscopy is sometimes helpful as well. Currently, there is no ideal screening test for asymptomatic women.

The complete staging of endometrial cancer requires surgery to remove the uterus and ovaries, to sample retroperitoneal lymph nodes, and to obtain peritoneal cytologic specimens. Computed tomography and magnetic resonance imaging are not routinely recommended in the preoperative evaluation.

LABORATORY FINDINGS

There are no tumor markers specifically associated with endometrial cancer, although CA-125 may be elevated in patients with recurrent or metastatic disease, especially in the abdomen. Estrogen and progesterone receptors status may be useful in guiding future therapy. High levels of hormone receptors are more common in well-differentiated lesions.

OPTIMAL MANAGEMENT

Total abdominal hysterectomy and bilateral salpingo-oophorectomy should be performed whenever possible. Washings are obtained for pelvic and peritoneal cytologic study and the abdominal cavity is explored. Although complete staging requires sampling of pelvic and para-aortic lymph nodes, these procedures are often omitted when the tumor is confined to the endometrium, or the grade is low (G1) and invasion is superficial. These prognostic factors may be assessed during surgery by frozen section of the resected uterus. Vaginal hysterectomy, with laparoscopic evaluation of the abdomen and lymph nodes, is currently being studied. Radical hysterectomy is sometimes used when there is extension to the cervix (stage II). Some centers use preoperative radiotherapy in patients with stage II disease or high-grade (G3) disease. If disease has spread beyond the pelvis, hysterectomy may still be useful to palliate bleeding. The role of debulking surgery in advanced disease is uncertain, although it is probably beneficial if all gross disease can be removed.

Patients with positive pelvic lymph nodes are usually treated with postoperative external-beam pelvic radiation. Patients with high-risk factors in the uterus (e.g., deep invasion and histologic grade 2 or 3) and negative lymph nodes may benefit from radiation therapy, at least in terms of recurrence, but a survival benefit is not clear at this time. Some patients with positive para-aortic lymph nodes may be salvaged with extended field radiotherapy. The role of vaginal radiotherapy, alone or in

combination with external-beam therapy, is controversial. Intraperitoneal phosphorus 32 or whole-abdominal radiotherapy has been advocated for patients with positive peritoneal cytology, although the significance of this finding and proper treatment for these patients is still being debated.

Patients with advanced or recurrent disease with well-differentiated tumors and high levels of progesterone receptors are much more likely to respond to progestin therapy, with response rates of 80% or higher being reported. Unfortunately, these patients tend to have more poorly differentiated lesions. This probably accounts for the response rate of only 18% reported in the GOG study of the use of progestins in endometrial cancer. In addition, the effect of progestins does not appear to be dose-related above a certain threshold. Responses to tamoxifen (an antiestrogen) have been reported, and the role of tamoxifen combined with sequential progestin is currently being explored.

Doxorubicin is the most active chemotherapeutic agent in endometrial cancer, with a response rate of about 40%. The addition of cisplatin to doxorubicin improves response rates, but an improvement in survival has not been demonstrated. Recently, paclitaxel has been found to be active against endometrial cancer and is being tested in combination with doxorubicin.

The mainstay of therapy for uterine sarcomas is total abdominal hysterectomy and bilateral salpingo-oophorectomy. Surgical excision of stage I tumors is the only known curative therapy. Adjuvant chemotherapy with doxorubicin has not proven beneficial. Radiation therapy appears to decrease pelvic recurrence after hysterectomy but does not improve survival. Doxorubicin is the most active single agent in advanced leiomyosarcoma, and cisplatin, paclitaxel, and ifosfamide have the highest response rates (30% to 40%) in mixed mesodermal tumors.

OVARIAN CANCER

DEFINITION

Epithelial cancers of the ovary, which account for about 90% of ovarian malignancies, derive from the coelomic epithelium of the ovarian surface. Approximately 75% of epithelial ovarian cancers are of the serous type, with mucinous, endometrioid, clear cell, Brenner, and undifferentiated lesions making up the rest. In addition, tumors of low malignant potential (borderline tumors) can occur, especially in young women. These tend to behave in a relatively benign fashion, although they can metastasize and be fatal.

INCIDENCE AND EPIDEMIOLOGIC FACTORS

There are about 25,200 new cases per year in the United States with 14,500 deaths, making ovarian cancer the most common cause of death from gynecologic malignancy. The incidence increases with age, and there is a lifetime risk of 1% to 2% in the United States.

The incidence of ovarian cancer decreases with increasing parity. It is unclear as to whether infertility by itself contributes to the risk, but there is some suggestion that ovulation-inducing drugs may increase a woman's risk. Oral contraceptives and tubal sterilization have consistently been associated with a decreased risk, although there appears to be no significant effect from postmenopausal hormone use. Perineal talc use has also been associated with increased risk, possibly due to contamination with asbestos. Dietary intake of fat is related to increased risk, but the effects of coffee, alcohol, and tobacco are unclear. Patients with ovarian cancer appear to be at a greater risk for breast cancer and vice versa.

A hereditary component has been suggested by well-described, familial cancer syndromes such as site-specific ovarian cancer, breast/ovarian cancer, and the Lynch II cancer family syndrome. Despite these well-publicized syndromes, familial ovarian cancer probably occurs in only 5% to 10% of patients. Nevertheless, a woman with one first-degree relative with ovarian cancer has about a threefold increased risk, and two first-degree relatives with the disease may confer up to a 50% chance of developing ovarian cancer. Mutations in the *BRCA1* or *BRCA2* gene play a role in many cases of familial ovarian cancer.

ETIOLOGIC FACTORS

Epidemiologic evidence suggests that women at highest risk for ovarian cancer have a reproductive history consistent with repetitive ovulation. This has led to the "incessant ovulation" theory whereby repetitive epithelial injury and regeneration leads to more frequent mutations and subsequent neoplasia. Elevated pituitary gonadotropins have also been postulated as an etiologic factor because of the association with infertility and "fertility drugs." Finally, carcinogens such as talc, radiation, or environmental toxins have been implicated.

PATHOGENESIS/PATHOPHYSIOLOGIC FACTORS

Epithelial cancers of the ovary probably grow within the substance of the ovary, in most cases before dissemination. Occasionally, however, they may arise on the surface of the ovary and spread intraperitoneally early in the disease process before recognizable ovarian enlargement has developed. It is possible that in some cases an ovarian-like cancer may develop simultaneously in areas of metaplasia in several sites in the peritoneal cavity.

Approximately 75% of ovarian cancers will have metastasized at the time of diagnosis. Spread from a primary ovarian cancer is predominantly by exfoliation into the peritoneal cavity, although lymphatic dissemination is common. Clockwise circulation of peritoneal fluid often spreads ovarian cancer to paracolic and subdiaphragmatic surfaces, especially on the right side. Pleural or parenchymal liver involvement tends to occur late in the course of disease.

CLINICAL FINDINGS

Early ovarian cancer rarely causes symptoms and is usually found fortuitously on pelvic examination or ultrasonography. As the disease progresses and spreads, pelvic pain and bowel dysfunction occur, and patients are frequently evaluated for gastrointestinal disease with inconclusive results. As ascites develop, the patient may complain of abdominal bloating. This is often attributed to weight gain following menopause.

A solid mass or nodularity in the cul-de-sac may be felt on pelvic exam. In advanced disease, an abdominal fluid wave may be detected or physical exam may detect a pleural effusion. Survival is highly correlated with stage. More than 80% of patients with stage I or II disease survive for 5 years, whereas fewer than 20% of stage III and IV patients survive for that long a time.

There is no proven effective screening method for ovarian cancer, although transvaginal ultrasound combined with serum tumor antigens and Doppler flow studies of ovarian circulation are currently being evaluated. Although these methods are unproven in the general population, transvaginal ultrasound and serum CA-125 studies are reasonable approaches at this time in high-risk women, such as those with a strong family history of ovarian cancer.

LABORATORY FINDINGS

Elevation of the serum CA-125 level, a glycoprotein detected by the ovarian cancer monoclonal antibody (OC-125), is the most consistent laboratory abnormality in patients with epithelial ovarian cancer. Although only about 50% of patients with stage I disease have elevations, more than 90% of patients with stage III and IV disease will have elevated levels. Unfortunately, many other conditions, both benign and malignant, have been associated with increased levels, thereby limiting its usefulness as a screening test ([Table 221.3](#)). The most accepted use for CA-125 measurement is to follow the clinical course of the disease once diagnosed and to follow patients in clinical remission. Carcinoembryonic antigen (CEA), CA 19-9, lipid-associated sialic acid, and other antigens are sometimes elevated in patients with ovarian cancer, but their current role in management or screening is unclear. Although an elevated CA-125 is a reliable predictor of persistent disease, a normal CA-125 (less than 35 units per milliliter) cannot rule out the presence of disease in patients who otherwise appear to be in clinical remission.

Gynecologic	Nongynecologic

TABLE 221.3. NON-OVARIAN CANCER CAUSES OF ELEVATED CANCER ANTIGEN 125

OPTIMAL MANAGEMENT

Since ovarian cancer is a surgically staged disease, exploration of the abdomen and pelvis should be performed as initial management in almost every case. Although ultrasonography, magnetic resonance imaging, and computed tomography are often used in the evaluation of an adnexal mass, they are not accurate enough to reliably distinguish a benign from malignant tumor or to estimate the extent of intra-abdominal disease.

Surgical management of an apparent early stage should involve a vertical midline incision that extends above the umbilicus. Washings of the pelvis and upper abdominal surfaces should be obtained for cytologic purposes. The primary tumor (ovary) should be removed intact if possible, and in most cases a total abdominal hysterectomy and bilateral salpingo-oophorectomy should be performed. In select cases of young women desiring to bear children, a unilateral adnexectomy may be performed if there is no other evidence of disease spread. A meticulous exploration of the abdomen should be performed, including evaluation of the subdiaphragmatic surfaces, along with random biopsies. At least an infracolic omentectomy should be performed. Para-aortic and pelvic nodes should be sampled on the side of the tumor. The role of laparoscopic treatment and staging of early ovarian cancer is currently being evaluated at several centers.

Patients with stage I low-grade tumors are adequately treated with surgery alone, as this is curative in over 90% of patients. Patients with higher grade cancers and positive peritoneal cytology are at higher risk for recurrence (20% to 40%) and are usually treated with adjuvant therapy. Early studies reported that intraperitoneal phosphorus 32 or melphalan were equivalent as adjuvant treatment; however, results from an Italian trial suggest that cisplatin is superior to phosphorus 32 or no therapy in prolonging disease-free survival in patients with stage I high-risk disease. The role of combination chemotherapy in early disease is being studied.

Advanced ovarian cancer currently requires an aggressive surgical approach to remove as much disease as possible since many clinical studies have documented the importance of the extent of residual disease as a prognostic factor. Optimal surgery has generally been defined as removal of all tumor nodules larger than 1 or 2 cm. Surgical cytoreduction or “debulking” usually involves a total abdominal hysterectomy with bilateral salpingo-oophorectomy, total omentectomy, retroperitoneal lymph node dissection, and, in select cases, bowel resection or splenectomy. A retroperitoneal approach is often used in the presence of massive pelvic tumor. Based on the results of a European trial, for patients who cannot be successfully debulked during initial surgery, a second attempt may be considered following several courses of chemotherapy. Patients who are debulked to residual tumor nodules less than 1 cm are good candidates for intraperitoneal chemotherapy.

The role of second-look laparotomy in ovarian cancer is controversial. Most evidence fails to suggest a survival benefit. However, second-look surgery is useful to define responses in patients without measurable disease, may provide some benefit by allowing secondary cytoreduction, and can define a group of patients suitable for aggressive second-line treatment protocols such as intraperitoneal chemotherapy or high-dose chemotherapy with autologous bone marrow or stem cell support. Surgery for resection of recurrent disease after primary chemotherapy may be beneficial if the time to recurrence is prolonged (6 to 12 months).

Currently, combination chemotherapy with platinum-based therapy is the standard treatment in patients with advanced ovarian cancer. A trial reported in 1996 by GOG has demonstrated superior response rates and survival with cisplatin and paclitaxel versus cisplatin and cyclophosphamide in patients with suboptimal disease. Carboplatin and paclitaxel seems to be as effective as cisplatin and paclitaxel, and can be given over a shorter duration as an outpatient. Although high response rates have been demonstrated with high-dose chemotherapy and stem cell support, a clear benefit in either primary or secondary treatment has yet to be demonstrated. This approach should be limited to carefully designed clinical trials at present. Promising new agents such as topotecan, liposomal doxorubicin, and gemcitabine have activity in the second-line setting and may eventually be incorporated into front-line therapy.

GESTATIONAL TROPHOBLASTIC DISEASE

Gestational trophoblastic disease encompasses a spectrum of disease from localized hydatidiform mole to metastatic choriocarcinoma. Although persistent and metastatic trophoblastic disease usually follows a molar pregnancy, it may occur after any kind of gestation, even a term pregnancy. Molar pregnancy occurs in about 1 in 1,500 to 1 in 2,000 gestations per year in the United States and malignant disease occurs in approximately 15% to 20% of these. Trophoblastic disease is almost always associated with the production of human chorionic gonadotropin, which serves as a sensitive tumor marker. Women with molar pregnancies are at increased risk for trophoblastic disease with subsequent pregnancies.

Molar pregnancy is successfully treated by evacuation of the uterus in over 80% of cases. In the remainder, persistent elevation of the human chorionic gonadotropin should provoke a search for metastatic disease. Lung metastases are most common, but disease may also be found in the vagina, liver, gastrointestinal tract, or central nervous system. In the absence of metastatic disease, hysterectomy may be offered as part of the primary treatment, although chemotherapy with methotrexate is curative in over 90% of cases. Patients with metastatic disease may be divided into high-, middle-, and low-risk (Table 221.4). Low-risk patients, even those with pulmonary metastasis, may be treated with single-agent methotrexate or actinomycin D with complete remission in close to 100% of patients. High- and middle-risk patients require multiagent chemotherapy. Using a combination of etoposide, methotrexate, actinomycin D, cyclophosphamide, and vincristine [Oncovin] (EMA-CO), a complete remission rate of 70% to 80% may be expected. Normal reproduction can be expected in most patients after treatment for persistent trophoblastic disease.

Prognostic Factor	Score			
	0	1	2	4
Age (yr)	<35	35-40	41-45	>45
Independent pregnancy interval*	Hydatidiform mole	Abortion	Term	
NCE (hcg)	<4	4-6	7-12	>12
hCG group (female = mole)	10 ⁷	10 ⁷ -10 ⁸	10 ⁸ -10 ⁹	>10 ⁹
Largest tumor, including uterine tumor	0 = 0	1 = 1	2 = 2	3 = 3
Site of metastases	Spleen, kidney	Orbits, liver	Brain	
Number of metastases identified	1-4	4-6	>6	
Prior chemotherapy		Single drug	2 or more drugs	

*The total score for a patient is obtained by adding the individual scores for each prognostic factor. Total score: 0-4, low risk; 5-7, middle risk; 8-10, high risk.
*Interval months between end of antecedent pregnancy and start of chemotherapy.
NCE, human chorionic gonadotropin; hCG, gestational.

CHAPTER 222: GERM CELL MALIGNANCIES IN MEN

STEPHEN D. WILLIAMS

[Definition](#)
[Incidence and Epidemiology](#)
[Etiologic Factors](#)
[Pathogenesis](#)
[Clinical Findings](#)
[Laboratory Findings](#)
[Optimal Management](#)

DEFINITION

Germ cell tumors are a heterogeneous group of diseases occurring in men and women. They are distinctly unusual tumors, but their importance is increased by the fact that they typically occur in young persons in the prime of life. These malignancies arise in germinal epithelium, typically the testis or ovary. In men and women, pathologically and biologically similar malignancies can also originate in extragonadal sites, typically but not invariably the retroperitoneum or mediastinum. Occasionally, the origin of a germ cell tumor may be obscure. Laboratory investigations are beginning to increase the understanding of the fundamental biology of these neoplasms.

The pathologic classification of male germ cell tumors is outlined in [Table 222.1](#). About 40% of germ cell tumors are pure seminomas. The remaining tumors may be a pure cell type, but they frequently are composed of more than one type. The major therapeutic implications of this classification is that seminomas are quite responsive to radiation therapy, but tumors other than seminomas are less so; surgery and chemotherapy are used in the treatment of nonseminomas.

Seminoma
Nonseminoma
 Embryonal carcinoma
 Teratoma
 Endodermal sinus tumor
 Choriocarcinoma
 Mixed tumors

TABLE 222.1. PATHOLOGIC CLASSIFICATION OF GERM CELL TUMORS

The treatment of testicular cancer has improved dramatically in the past 20 years. Most men who develop this disease can be successfully treated and cured, with a low incidence of late adverse effects of treatment. This therapeutic triumph has occurred because of close collaboration among physicians of many different disciplines, and it represents one of the great therapeutic successes of our time.

INCIDENCE AND EPIDEMIOLOGY

Testicular cancer is a relatively rare disease, with an annual incidence in the United States of approximately 5.5 per 100,000 males. For reasons that are not clear, the incidence of this disease has increased somewhat. There are fairly marked geographic and racial differences in the frequency of this tumor. In Scandinavian countries, particularly Denmark, it is much more common, and in Asian countries it is less common. The incidence is significantly lower among blacks.

Testicular cancer is a disease of young men. Most affected patients are in their twenties or thirties. Testicular cancer does occur in pediatric patients and older men, but it is much less common in these age groups. Patients with pure seminomas tend to be a bit older than those with tumors other than seminomas. The most common cell type in childhood is sometimes referred to as infantile embryonal carcinoma, which is essentially an endodermal sinus tumor. Pure endodermal sinus tumors in adults are rare.

Testicular cancer patients have a higher than expected incidence of congenital anomalies of the genitourinary tract. Testicular cancer patients also have a higher than expected incidence of dysplastic nevi and melanoma. Male relatives of these patients have a higher than expected incidence of testicular cancer, and about 1 of 100 testicular tumor patients develop a synchronous or metachronous tumor in the contralateral testis.

Extragonadal germ cell tumors are rare. They usually occur in young persons and share many common characteristics with their testicular counterparts, although there are some important differences. Extragonadal tumors, particularly mediastinal germ cell tumors, have a less favorable prognosis than testicular cancer. Mediastinal germ cell tumors are associated with Klinefelter's syndrome. Mediastinal tumors that contain elements of teratoma are associated with the synchronous or meta-chronous development of various hematologic malignancies, usually acute leukemia. The mechanism underlying this association is relevant to understanding the cause of these tumors.

ETIOLOGIC FACTORS

The cause of testicular germ cell tumors is unknown. It is much more likely to occur in individuals with a history of undescended testis. The involved testis and the contralateral testis are at increased risk. In patients with a history of unilateral cryptorchidism who develop testicular cancer, about 25% of the tumors occur in the opposite testis. It is likely that cryptorchidism and testicular cancer are related to some underlying disorder. There is presumptive evidence that early orchiopexy may lessen the risk of malignant degeneration. Absolute proof of this, however, is lacking. The relation between maternal diethylstilbestrol exposure and the subsequent development of testicular cancer is controversial.

Most patients with testicular cancer and extragonadal tumors have a characteristic cytogenetic abnormality located on chromosome 12. This finding can be helpful in classifying poorly differentiated neoplasms of obscure origin and will probably provide more information about the cause of these tumors.

PATHOGENESIS

Testicular cancer typically spreads in an orderly way to the retroperitoneal lymphatics and lung. Liver, bone, or brain involvement is sometimes found at diagnosis. Testicular cancer is a disease with a generally short natural history and early hematogenous dissemination; the diagnostic evaluation and initiation of therapy should be done in a timely fashion. Because of the pattern of spread, staging procedures should include a chest x-ray film and abdominal computed tomography (CT) scan. A chest CT scan should be done if the chest x-ray film is normal or equivocal. Serum markers and a lactate dehydrogenase (LDH) determination should be done. Other radiographic procedures should be done only as clinically indicated. With these standard procedures, most patients' disease is staged according to the staging system shown in [Table 222.2](#).

Stage I: Tumor confined to the testis

Stage II: Involvement of testis plus retroperitoneal nodes

Stage III: Supradiaphragmatic or visceral involvement

TABLE 222.2. STAGING OF TESTICULAR GERM CELL TUMORS

CLINICAL FINDINGS

A patient with testicular cancer ordinarily presents with a scrotal mass. The mass may be painless or it may be associated with discomfort. Occasionally, patients may have acute onset of severe pain and be misdiagnosed as having testicular torsion. Another common symptom is back pain related to retroperitoneal lymphadenopathy. This pain may be severe and typically is worsened with recumbency. Patients with very high serum levels of human chorionic gonadotropin (hCG) may have gynecomastia. Pulmonary symptoms, such as dyspnea, cough, or hemoptysis, occur occasionally, but it is unusual for patients to have advanced pulmonary disease at the time of diagnosis. Symptoms related to other potential areas of involvement (e.g., liver, bone, brain) are rare because of the uncommon involvement of these areas at diagnosis.

The symptoms of extragonadal tumors are variable. Patients with mediastinal tumors ordinarily have chest pain, dyspnea, or cough at the time of diagnosis. Patients with retroperitoneal tumors usually have back pain as a prominent symptom.

Most patients with testicular cancer have abnormal scrotal examination findings. The key finding is a mass that is not clearly separable from the testis. Occasionally, it may be difficult to differentiate a testicular mass from a hydrocele. An important maneuver is transillumination. A scrotal mass that does not transilluminate should be considered to be a testis tumor until proven otherwise. Other potential physical findings include an abdominal or supraclavicular mass and gynecomastia.

LABORATORY FINDINGS

An important finding in the diagnosis and therapy of testicular cancer is the laboratory determination of tumor markers. α -Fetoprotein (AFP) and b-hCG levels are elevated in many patients, and these determinations are useful in the follow-up of such patients. However, most patients with seminomas and early-stage nonseminomas have normal markers. If elevated, they are useful in the diagnosis of a scrotal mass, but normal markers do not imply that a scrotal mass found on physical examination is benign. Most patients with bulky stage II and stage III tumors have an elevation of one or both markers at the time of diagnosis. The rate of marker decline after chemotherapy or surgery provides important information. A rising hCG or AFP level during or after therapy indicates recurrence or progression. LDH is frequently elevated, but the relative lack of specificity of LDH elevation makes it less clinically useful.

Testicular ultrasonography is useful in defining the scrotal anatomy and differentiating testicular from epididymal lesions. A few patients present with signs or symptoms of metastatic tumor, and with careful evaluation using ultrasonography they are found to have primary sites within the gonads that were unsuspected clinically. Another use of ultrasonography is for patients with suspected extragonadal germ cell tumors. In such patients, it is important to exclude a testis primary tumor by careful examination and ultrasonography.

Other radiographic studies that should be done include a chest x-ray film and, if normal, a chest CT scan and an abdominal CT scan. Other radiographic studies are done only if indicated by clinical findings.

OPTIMAL MANAGEMENT

In the 1970s, the activity of a then-new chemotherapy agent, cisplatin, in patients with advanced testicular cancer was recognized. Several trials employing this agent in combination chemotherapy regimens were conducted. The most widely used regimen is cisplatin combined with etoposide and bleomycin (BEP regimen; [Table 222.3](#)). All three drugs are active as single agents and have different toxicities that allow them to be administered in full or nearly full doses in combination. Cisplatin and etoposide appear to be synergistic in vitro and in vivo. Most patients with metastatic tumors treated with a cisplatin-containing regimen survive their disease. The development of an effective chemotherapy regimen for advanced disease has had profound implications for the management of patients with early-stage tumors.

Three to four courses given at 3-week intervals:

Cisplatin: 20 mg/m² on days 1–5

Etoposide: 100 mg/m² on days 1–5

Bleomycin: 30 U/week

BEP, bleomycin, etoposide, cisplatin.

TABLE 222.3. BEP CHEMOTHERAPY REGIMEN FOR TESTICULAR CANCER

Patients with stage III or bulky stage II nonseminomas are treated initially with BEP after inguinal orchiectomy, which confirms diagnosis and initiates therapy. Patients can be grouped into those with limited metastatic disease and a resultant favorable prognosis (more than 90% cure) and those with high tumor volume and a lower likelihood of survival (50% to 60% cure). Patients in the former group are those with small-volume retroperitoneal or pulmonary metastases and those with elevated markers as the only evidence of disease. Patients with high-volume tumors have large-volume pulmonary metastases, bulky retroperitoneal tumors plus supradiaphragmatic tumors, or liver, bone, or brain metastases. The relevant issues in the former group are cost and toxicity reduction; in the latter group, the important issue is improved therapeutic efficacy. A recent international collaborative study has noted the adverse prognostic impact of nonpulmonary visceral metastases and marked elevations of hCG, AFP, or LDH.

For good-prognosis patients, clinical trials have shown that three courses of BEP are equivalent to four courses; that if three courses of chemotherapy are given, the omission of bleomycin worsens the results; and that if bleomycin is not given, patients should receive four courses of treatment. Trials have also shown that carboplatin plus etoposide is less effective than etoposide plus cisplatin.

In patients with high tumor volumes, the use of high-dose cisplatin did not improve results, and there is no regimen that is known to be better than conventional dose BEP given for four courses.

Modern antiemetics (ondansetron, granisetron, and dolasetron) and other supportive-care aspects have allowed this form of chemotherapy to be relatively well

tolerated. Although alopecia is universal, serious toxicities (e.g., cisplatin-induced renal damage, bleomycin-induced lung disease) are rare; however, continuous intravenous hydration must be given to avoid nephrotoxicity. About 25% of patients experience an episode of fever and neutropenia, which is rarely of major consequence when managed appropriately.

Treatment must be given on schedule in appropriate doses to be optimally effective. Chemotherapy courses should almost never be delayed. The cisplatin dose is not altered. The etoposide dose was ordinarily reduced 25% for previously irradiated patients and those with an intervening episode of neutropenic fever or severe thrombocytopenia. However, the availability of hematopoietic growth factors (granulocyte colony-stimulating factor and granulocyte-macrophage colony-stimulating factor) have altered this approach (see [Chapter 256](#)). The routine use of these agents is unnecessary, but patients who are very ill may benefit from one of these drugs. It probably is appropriate to add a growth factor rather than reduce the dose for patients with a prior episode of neutropenia and fever. Bleomycin is immediately discontinued if clinical or radiographic signs of pulmonary fibrosis are detected. Subtle clinical findings that warrant discontinuation of bleomycin include basilar rales or a lag or diminished expansion of a hemithorax.

The importance of surgery after chemotherapy for patients with a persistent mass is well recognized. As many as 25% to 40% of patients undergoing chemotherapy have a radiographically apparent mass at the conclusion of treatment; the most common location is the retroperitoneum. It is impossible to accurately predict the histology of these masses. It has become common practice to surgically remove the masses after suitable recovery from chemotherapy. About 45% of these masses contain only fibrosis and necrosis. Another 45% contain mature or immature teratomas. The mechanism by which this “benign” tumor persists after treatment for a malignancy is unclear; presumably, it survives the chemotherapeutic eradication of the malignant elements. The remaining 10% to 15% of masses have microscopic evidence of persistent carcinoma. This latter group of patients have a high risk of recurrence and receive two courses of postoperative chemotherapy of the same type as given initially. Patients who are complete responders and those who undergo complete resection of teratomas following chemotherapy have a risk of relapse of about 10% and receive no further treatment. Patients with incompletely resected teratomas are at some risk of progressive local growth and cancer recurrence, and such individuals benefit from meticulous surgical resection.

Patients with *testicular nonseminoma* without pulmonary metastases and no or less than bulky retroperitoneal tumor undergo retroperitoneal lymph node dissection (RPLND) as a part of their initial therapy. After RPLND, patients with tumor-negative nodes do not receive adjuvant treatment; only about 10% of these tumors recur. However, the risk of recurrence in patients with completely resected tumor-positive nodes is much higher (about 50%), and these patients in former times routinely received adjuvant chemotherapy. The development of effective systemic treatment mandated reassessment of this concept.

The alternative approach involves observation, with treatment deferred until relapse occurs. This allows about 50% of patients destined to be cured by surgery to avoid chemotherapy. With careful follow-up, those who relapse can be treated promptly with chemotherapy if they have limited metastatic disease.

The alternative approaches were compared in an international randomized trial. About 50% of the observed patients had recurrences of their disease, but virtually all were successfully treated, and survival did not differ from that of patients who received two courses of immediate adjuvant chemotherapy, which prevented relapse. If observation is chosen, patients must be seen monthly for the first year and every other month for the second year, with a chest radiograph and hCG and AFP determinations done at each visit. Patients with pathologic stage I disease should be followed in the same fashion because 10% have recurrences; however, most of these patients can be cured with chemotherapy if treated when the tumor volume is small.

The concept of routine RPLND for patients with clinical stage I nonseminoma tumors has been challenged. If these patients undergo routine RPLND, about 15% to 30% are found to have tumor-positive nodes. Following a line of reasoning similar to that for pathologic stage II tumors, it seems possible that these patients could be followed with regular determinations of marker levels, chest x-ray films, and abdominal CT scans and avoid RPLND, with further treatment given only at the time of relapse. Although no randomized trials have been done for this situation, there are several studies with reasonably long follow-up of patients who have been observed after orchiectomy. Results of such management are excellent and seem to rival the almost universal cure rate of such patients treated with RPLND. The issues regarding choice of initial therapy are complex. For patients willing to submit to careful follow-up, either surveillance or RPLND is appropriate, with the choice based on patient preference and physician expertise.

The advantages of retroperitoneal lymph node dissection include the following:

1. Precise pathologic staging and a more certain natural history are available.
2. If desired, brief adjuvant chemotherapy can be given to node-positive patients.
3. There is less reliance on patient and physician compliance during follow-up.
4. The risk of recurrence is limited to 2 years; 3- and 4-year recurrences are rare but have been seen in some observed patients.
5. Fewer tests are required; observed patients should have an abdominal CT scan every 2 months during the first year and less frequently in subsequent years.
6. The cure rate approaches 100%.
7. As some stage II patients are cured with surgery alone, fewer patients require chemotherapy.

The advantages of observation include the following:

1. Surgery can be avoided.
2. Less urologic expertise is required.

The potential effects of treatment on subsequent fertility must also be considered. In earlier times, RPLND invariably disrupted the autonomic system responsible for ejaculation and produced infertility. A newer surgical procedure—nerve-sparing RPLND—preserves ejaculatory function in most patients. The impact of RPLND on fertility may be less than that of observation because fewer patients need chemotherapy.

The diagnosis of *seminoma* requires that the tumor be pathologically composed of seminoma only and that the serum AFP level be normal. Seminomas are extremely sensitive to radiation. Most seminoma patients have tumors limited to the testis at the time of diagnosis. These patients generally receive radiotherapy to their retroperitoneal lymphatics; the required dosage is low. Almost all remain free of cancer. Most patients with clinical stage II seminoma are also treated with radiation therapy. Of those with limited stage II tumor (IIA, less than 5 cm), 80% to 90% remain free of cancer after therapy.

Large-volume stage II disease fortunately is a rare occurrence. Reasonable therapeutic alternatives are irradiation or initial chemotherapy. The latter therapy cures most patients, and about 60% remain tumor-free after irradiation. However, most failing patients are successfully treated with chemotherapy at the time of relapse. Chemotherapy is also the choice for the rare patients with supradiaphragmatic involvement at diagnosis.

Most patients with early-stage seminomas and nonseminomas survive their disease with modern management. Fully 80% of patients with metastatic tumors are cured with chemotherapy. Only a small group of patients with extensive visceral metastases is at significant risk of death. Overall, about 95% of patients with nonseminomas survive their disease, as do a similar or higher number of patients with seminomas. The natural history of testicular cancer is short, and virtually all patients, regardless of stage and treatment, who are continuously disease-free for 2 years after initiation of treatment remain cancer-free.

For surviving patients, the late effects of treatment are an important issue. Anecdotal reports suggested that cisplatin-based chemotherapy might be associated with an increased risk of cardiovascular disease. The likelihood of adverse events was investigated in patients who were entered into a study of the therapeutic alternatives and outcomes for early-stage tumors other than seminomas. This study registered and observed patients with pathologic stage I tumors; some patients ultimately relapsed and required chemotherapy. Patients with stage II tumors randomly received two courses of adjuvant chemotherapy or were observed. Relapsing patients received four courses of therapy. A prospectively defined patient population received no chemotherapy or received two or four courses of treatment. There were no differences in the groups in terms of the incidence of cardiovascular disease or hypertension. The only differences noted were the frequencies of distal extremity paresthesias or Raynaud's phenomenon, primarily due to cisplatin, which were more likely to occur in patients who received longer courses of chemotherapy.

Etoposide is associated with the late development of a distinctive type of leukemia. This event appears to be dose-related and is rare in germ cell tumor patients who receive less than a total dose of etoposide of 2,000 mg per square meter. This total dose is exceeded only in testicular cancer patients who fail to achieve durable complete remissions with initial therapy.

The impact of chemotherapy on fertility is less severe than originally thought, although it is likely that at least some patients have chemotherapy-induced oligospermia

or azoospermia. However, many men resume normal or nearly normal spermatogenesis, and a significant number have fathered children.

CHAPTER 223: PROSTATE CANCER

KENNETH J. PIENTA AND DAVID C. SMITH

[Definition](#)
[Incidence and Epidemiology](#)
[Etiologic Factors](#)
[Pathogenesis and Pathophysiologic Factors](#)
[Clinical Findings](#)
[Laboratory Findings](#)
[Optimal Management](#)

DEFINITION

Prostate cancer generally refers to adenocarcinoma of the prostate, which accounts for more than 98% of all prostate cancers. Seventy percent of these cancers occur in the peripheral zone, 20% in the transitional zone, and 10% in the central zone. Less common prostatic malignancies include neuroendocrine tumors, squamous tumors, sarcomas, and transitional cell carcinomas.

INCIDENCE AND EPIDEMIOLOGY

Prostate cancer is the most common cancer in men (excluding skin cancers) and the second leading cause of cancer-related deaths in men. In 1998, an estimated 184,500 new cases of prostate cancer were diagnosed, and 39,200 prostate cancer–related deaths occurred. Currently, the incidence rates for prostate cancer are 82 per 100,000 for men aged 50 to 54; 518 for men aged 60 to 64; and 1,326 for men aged 70 to 74. The age-adjusted death rate due to prostate cancer in 1995 was 17.3 per 100,000 population. In 1994, prostate cancer accounted for 6.2% of white male cancer deaths and 9.4% of African American male cancer deaths. Deaths attributed to prostate cancer have demonstrated a slight decrease of 1% to 2% per year over the last 2 years, which may in part reflect the increased use of prostate-specific antigen (PSA) as a screening tool starting in the early 1990s.

The prevalence of both histologic and clinical prostate cancer increases with age. The presence of histologic cancer increases so that by age 80 approximately 70% to 80% of men have evidence of this latent cancer at autopsy. Most studies suggest that the baseline prevalence of latent disease is similar around the world, but the rate of clinically evident cancer varies tremendously from country to country. Only about 10% of these histologic cancers appear to develop into clinically significant disease, and the factors that influence disease promotion remain undefined.

ETIOLOGIC FACTORS

After age 50, the incidence rates of prostate cancer increase nearly exponentially with age. Risk continues to increase with age and, unlike other cancers, does not demonstrate a peak at any age. If the incidence of prostate cancer is reviewed by region, it is highest in Scandinavia and lowest in Asia. However, the highest incidence of prostate cancer in the world is found in African American men, who have a 9.8% lifetime risk of developing clinically recognized prostate cancer. The genetic and/or cultural factors contributing to this increased risk remain undefined. Interestingly, Japanese immigrants to the United States demonstrate an incidence rate intermediate between men living in Japan and white men in North America, suggesting that environmental factors contribute to the risk of developing clinically significant prostate cancer.

A hereditary risk of developing prostate cancer has been demonstrated, and early analysis suggests that an autosomal dominant pattern of inheritance may be responsible for a small percentage of the prostate cancer seen in men younger than 55 years and for slightly less than 9% of prostate cancer patients overall. If a first-degree family member has the disease, a male relative has a relative risk of approximately 2, which rises with each additional affected family member.

Several studies have demonstrated that socioeconomic factors, prostatitis, occupational exposures, smoking, infectious agents, and level of sexual activity are not linked to prostate cancer risk. Prostate cancer is an androgen-sensitive disease, and it has been hypothesized that a higher level of circulating androgens over time may increase prostate cancer risk; however, a clear link between endogenous testosterone levels and prostate cancer development has not been demonstrated. The role of vasectomy in the development of prostate cancer has been controversial, with several studies suggesting that a link, if it exists, is very weak. Currently, vasectomy is not considered a risk factor for prostate cancer.

Dietary fat and high red meat consumption may increase prostate cancer risk. A native Asian diet low in red meat intake is also rich in soy products and vegetables, which may confer a chemopreventive effect. Recent studies suggest that the antioxidants vitamin E and selenium may also lower the risk of developing prostate cancer if taken on a regular basis. The effect of vitamin A, carotenes, and vitamin D on the development or prevention of prostate cancer is not clear.

PATHOGENESIS AND PATHOPHYSIOLOGIC FACTORS

The prostate gland is a walnut-shaped organ situated at the base of the bladder. Most tumors arise in the peripheral zone of the prostate and are potentially palpable by digital rectal examination (DRE). The transitional zone is the area of the prostate that classically enlarges with age (benign prostatic hyperplasia).

The most prominent grading system for prostate cancer was defined by Gleason and reflects aberrations in glandular architecture. Tumors are graded on a scale of 1 to 5, from the most to the least well differentiated ([Table 223.1](#)). Tumor specimens are assigned a Gleason score that represents the sum of the most common and second most common patterns of tumor (e.g., 4 + 3 = 7). The Gleason score (2 to 10) has predictive power for clinical outcome. Stage for stage, patients with higher Gleason scores have shorter survivals.

Old Gleason System	New Gleason System	Description
2-4	2-4	Well-differentiated cancer that looks a lot like normal prostate cells and is minimally aggressive
5-7	5-6	Moderately differentiated cancer that looks somewhat like normal cells and is moderately aggressive
—	7	Moderately to poorly differentiated cancer that slightly resembles normal cells and is aggressive
8-10	8-10	Poorly differentiated cancer that does not look anything like normal cells and is very aggressive

TABLE 223.1. THE UPDATED GLEASON GRADING SYSTEM

Another common histologic finding on needle biopsy is high- or low-grade prostatic intraepithelial neoplasia (PIN). Data suggest that high-grade PIN is a precursor lesion for prostate carcinoma. Subsequent biopsies detect cancer in 35% to 50% of patients with high-grade PIN.

The most commonly employed staging paradigms are the American (ABCD) and tumor–node–metastasis (TNM) systems ([Table 223.2](#)). The American system is less accurate than the TNM but is still commonly used. The TNM system is more representative of the manner in which the diagnosis is made as well as providing a more accurate pathologic staging system. Specifically, many tumors are diagnosed based on an elevated PSA, negative DRE, but positive biopsy. These are classified as

T1c tumors in the TNM system but cannot be classified by the American system.

ABCD	TNM	Description
—	Tx	Cancer cannot be staged at this time
—	T0	There is no evidence of a cancer
A	T1	Cancer not palpable on DRE
A1	T1a	Cancer found at TURP involving <5% of prostate tissue removed
A2	T1b	Cancer found at TURP involving >5% of prostate tissue removed
B	T2	Cancer not palpable on DRE but detected by biopsy of one or both prostate lobes because of an initial high PSA level
B1 or B2	T2c	Cancer classified either prostate and/or apex of the prostate but not beyond the prostatic capsule
B1	T2a	Cancer involves only one lobe of the prostate
B2	T2b	Cancer involves both lobes of the prostate
C1-C2	T3	Cancer goes through the prostatic capsule
C1	T3a	Cancer with unilateral or bilateral extracapsular extension
C2	T3b	Cancer with invasion of one or both seminal vesicles
C2	T4	Cancer with invasion of nearby structures other than the seminal vesicles, including bladder neck, external sphincter, rectum, muscles, and/or pelvic wall
—	Nx	Lymph nodes cannot be staged
—	N0	No cancer in regional (pelvic) lymph nodes
D1	N1	Cancer in regional (pelvic) lymph nodes
—	Mx	Metastases cannot be assessed
—	M0	No evidence of metastases
D2	M1	Cancer has metastasized
D2	M1a	Cancer has metastasized to a nonregional node or nodes
D2	M1b	Cancer has metastasized to bone
D2	M1c	Cancer has metastasized to viscera

DRE, digital rectal examination; TURP, transurethral prostate resection; PSA, prostate-specific antigen.

TABLE 223.2. THE NEW ABCD AND TNM CLINICAL STAGING SYSTEMS FOR LOCALIZED PROSTATE CANCER AND WHAT THEY REALLY MEAN

In men who are not treated, average survival is approximately 8 to 10 years for stage A and B disease, 3 to 6 years for stage C, and 2 to 3 years for stage D disease. Men with higher Gleason grade tumors have shorter survival in each stage group. The most common site for distant metastasis is bone, with more than 90% of patients with metastatic disease developing bony lesions. The spine is most commonly affected, and the metastases are generally osteoblastic in nature. Among patients with metastases who develop symptomatic hormone-refractory disease, the mean survival time is 6 to 9 months.

CLINICAL FINDINGS

Localized prostate cancer is an asymptomatic disease. Urinary symptoms, such as frequency, dysuria, or decreased force, can be seen with prostate cancer but are much more common findings with benign prostatic hyperplasia. Microscopic hematuria, gross hematuria, or blood in the ejaculate may be associated with prostate cancer but are more representative of a urinary tract infection, urinary tract stones, or a bladder or kidney tumor. Patients with metastatic disease may present with bone pain, weight loss, or fatigue. Currently, approximately 75% of patients are diagnosed with clinically localized disease, mainly due to the use of PSA as a screening tool.

Just as there are few symptoms of localized prostate cancer, there are few clinical signs. The most obvious sign for prostate cancer is an abnormal DRE finding. DRE alone is not a sufficiently sensitive or specific test for the detection of prostate cancer, and as many as 50% of patients diagnosed by a DRE have tumor beyond the prostate capsule. Localized bone pain or urinary retention may be evident in more advanced cases but is neither sensitive nor specific for prostate cancer.

LABORATORY FINDINGS

Serum PSA determination has had a profound effect on the diagnosis and management of prostate cancer. It has taken a central role in prostate cancer screening and this is more fully described in [Chapter 207](#). PSA is a 34-kd glycoprotein serine protease that is a member of the kallikrein family of proteins. Normal epithelium, infected normal tissue, benign prostatic hyperplasia, and prostate cancer all produce PSA with a normal value that has been established as less than 4.0 ng per milliliter. Unfortunately, a value less than 4.0 ng per milliliter does not guarantee the absence of cancer (20% to 35% of clinically detectable prostate tumors display a PSA of less than 4.0 ng per milliliter), nor does a value above 4.0 ng per milliliter confirm the presence of cancer. As the PSA value increases, the chance of being diagnosed with cancer increases. A PSA value of 4 to 10 ng per milliliter has approximately a 20% chance of being associated with prostate cancer, and a PSA level above 10 ng per milliliter increases this association to over 50%. The combination of DRE and serum PSA is more sensitive and specific for detecting prostate cancer than either of these methods alone. It remains to be determined if this higher detection rate can decrease the death rate of this disease, but early indications suggest that this is true.

Serum PSA measurements are an excellent method to monitor patients after radical prostatectomy or radiation therapy, and they often provide the earliest data about treatment failure. In the post-surgical period, serum PSA levels should be in the undetectable range; following radiation therapy, serum PSA levels should remain stable. Persistent elevation of PSA postoperatively denotes surgical failure, as does the reappearance of detectable PSA levels after surgery. The interpretation of serum PSA measurements in patients treated with radiation therapy patients is less clear, but a favorable response usually occurs in those whose nadir values fall below 4.0 ng per milliliter or into the undetectable range and remain there. A rise in PSA level on three consecutive measurements is considered evidence of disease progression in this setting.

The diagnosis of prostate cancer is almost always made by transrectal ultrasound–guided needle biopsy of the prostate using a standard sextant biopsy technique in which samples are taken from the base, midportion, and apex of the prostate on each side. Additional biopsies may be obtained, depending on the level of clinical suspicion of disease and the presence of palpable lesions or visualized disease on transrectal ultrasound.

The skeletal system is the primary site of metastatic disease and a bone scan is the most sensitive method to detect osseous metastases. Bone scans must be interpreted with caution, however, because (1) they are not specific and (2) they demonstrate bony disease secondary to arthritis or injury. Patients with a PSA below 10 ng per milliliter have an extremely low chance of demonstrating bone metastasis, and for such patients, a bone scan may be eliminated as part of the metastatic workup. Computed tomography is also not routinely indicated in patients with PSA below 10 ng per milliliter.

OPTIMAL MANAGEMENT

The optimal treatment of any prostate cancer must take into account the age and health of the patient, the nature of the tumor (stage and grade), and the intent of treatment (cure or palliation). Treatment decisions with the intent to cure must be based on the probability of enhancing the 10-year and 15-year survival of any given patient.

LOCALIZED DISEASE

Standard treatment options for patients with clinically localized disease include watchful waiting, radical prostatectomy, and external-beam radiotherapy. Active observation, with androgen ablation reserved for palliative use at the time of progressive disease, may be a reasonable option for patients with a low-grade tumor and/or less than a 10-year expected survival. This must be assessed on a patient by patient basis.

For patients with an expected survival greater than 10 years, radical retropubic prostatectomy is considered a standard of care for men younger than 70 years. This procedure includes removal of the prostate and seminal vesicles in conjunction with a limited pelvic lymph node dissection. The surgical mortality rate is less than 0.5% and hospitalization is generally less than 4 days with newer methods of postoperative care. The principal morbidities from this surgery are permanent urinary incontinence, occurring in less than 5% of patients, and impotence, which occurs in over 50% of patients, depending on age, weight, and sexual function before surgery. Many patients display some degree of stress urinary incontinence. Patients with localized disease have an overall 5-year, PSA-negative, disease-free survival rate of 95%.

External-beam radiation therapy is another standard form of therapy for localized prostate cancer and is the preferred form of treatment for clinical stage C or T3 disease. Patients over the age of 70 are also commonly referred for radiotherapy. Treatment is provided in a fractionated manner for a total of 6,000 to 7,800 cGy. During therapy, patients may experience transient, non-debilitating bowel or bladder irritation. Long-term complications include a 2% to 5% rate of painless rectal bleeding or diarrhea, less than 1% incidence of incontinence, and a 20% to 80% incidence of erectile dysfunction. Studies suggest that androgen ablation by luteinizing hormone–releasing hormone (LHRH) agonists given through the course of radiation therapy increases the time to clinical recurrence of the disease. A recent study suggests that androgen ablation should continue for 3 years after completion of radiation therapy.

Retrospective comparisons of external-beam radiation therapy and radical prostatectomy do not demonstrate any significant differences in survival at 10-year follow-up assessments and these modalities are considered to be equivalent modes of therapy for localized disease. Patients often benefit from a multidisciplinary clinic approach where they are offered joint consultation from the departments of urology and radiation oncology so that they can develop an appreciation of the risks and benefits of each procedure.

Recently, the implantation of radioactive seeds (interstitial radiation or brachytherapy) has gained popularity as an experimental treatment for localized prostate cancer. Seeds consist of radioactive iodine or palladium and are placed through a transperineal approach using ultrasonographic guidance. Cryosurgical ablation of prostate tissue via transperineal probes is another investigational technique being performed at a few centers. Both of these techniques should be considered investigational, and long-term results with these techniques are not yet available.

RECURRENCE FOLLOWING PRIMARY THERAPY

Prostate-specific antigen provides an early indicator of disease recurrence in patients following definitive primary therapy. Typically, these patients will have no evidence of metastatic disease on bone and CT scan, and recurrence is only documented by a rising PSA. Postprostatectomy patients should have an undetectable PSA, and any elevation is an indication of disease recurrence. The time to recurrence has been shown to be an important prognostic indicator, with those patients whose PSA never becomes undetectable or whose PSA begins to rise within a year of prostatectomy having a high likelihood of diffuse metastatic disease. In contrast, patients developing a rising PSA after a year may be manifesting local recurrence. Treatment in this situation is controversial, but some studies have suggested that a significant proportion of these patients may be cured by salvage radiotherapy. This is also the situation in which newer imaging modalities may prove useful. Unfortunately, currently available tests lack sufficient sensitivity and specificity to be useful.

Defining PSA recurrence following radiotherapy is more difficult. Patients receiving radiation do not have complete ablation of the gland; thus, persistence of some level of PSA is frequent. PSA failure after radiotherapy has been defined as three consecutive rising PSA values. This definition has faced wide criticism but is a reasonable approach if applied appropriately. Patients meeting this definition who were reasonable candidates for prostatectomy initially may be considered for salvage prostatectomy. This procedure is associated with a high probability of incontinence due to the cumulative effects of radiation and surgery.

Patients with a rising PSA who are not candidates for radiotherapy or salvage prostatectomy present a difficult management problem. Some will not develop significant evidence of disease progression for prolonged periods. Others will rapidly develop diffuse metastatic disease. Initiation of hormonal therapy in this setting is controversial in that individual patients may be committed to a prolonged period of therapy without evidence that early hormonal therapy is of benefit. Decisions in this setting are often based on individual patient preference since definitive data to guide therapy are lacking. These patients may be excellent candidates for clinical trials designed to test new approaches to the therapy of prostate cancer since they presumably have a minimal tumor burden. Trials conducted in this setting must have a low probability of toxicity since this population is generally otherwise healthy; trials must also have appropriately defined biologic end points since measurement of overall benefit is difficult.

METASTATIC DISEASE

Patients with positive lymph nodes but negative osseous disease are generally treated with some form of androgen ablation. The use of pelvic irradiation in these patients remains controversial but is often used in younger patients. The 5-year overall survival rate is 70% to 85%.

Patients with distant metastatic disease (osseous or bone disease) are classically treated with androgen deprivation, which results in tumor regression in at least 80% of patients. The typical duration of response is approximately 2 years. Androgen deprivation is accomplished either through surgical castration or through the administration of depot-injectable LHRH agonists such as leuprolide and goserelin. The principal side effects of androgen deprivation are diminished libido, erectile dysfunction, hot flashes, sweats, and weight gain. When severe, hot flashes may be controlled by megestrol acetate (10 to 40 mg daily), bellergal, or low doses of the newer generation of serotonin antagonist antidepressants. Upon initiation of treatment with an LHRH agonist, the pituitary releases an initial surge of follicle-stimulating hormone and luteinizing hormone, followed by cessation of excretion. In the first month of therapy this surge should be blocked by administration of an antiandrogen, such as flutamide, bicalutamide, or nilutamide.

Administration of LHRH agonists or orchiectomy will result in castrate levels of circulating androgens, but 5% to 10% of circulating androgens from adrenal and peripheral adipose sources remain. The continued use of antiandrogens after the first month has been termed "complete or total androgen blockade." It remains a controversial strategy, with mixed results from studies that have attempted to determine whether this approach results in improved survival.

Classically, chemotherapy has been unsuccessful in the treatment of hormone-refractory prostate cancer. Recent studies have begun to show some promise for chemotherapy in the setting of advanced metastatic prostate cancer. The regimen of mitoxantrone and prednisone has been demonstrated to improve quality of life in patients with hormone-refractory prostate cancer but not to improve survival. These studies led to the approval of mitoxantrone for the treatment of hormone-refractory prostate cancer by the Food and Drug Administration. Other promising chemotherapeutic approaches include estramustine-based regimens and other chemohormonal therapy combinations. Response rates as high as 60% have been reported for combinations of estramustine with either paclitaxel or docetaxel, and estramustine has also been combined with vinblastine, oral etoposide, and vinorelbine. Ketoconazole has been given in combination with doxorubicin, and more recently this combination was studied in an alternating schedule with estramustine and vinblastine with good results. Cyclophosphamide with prednisone has also been shown to have some activity in this disease. Each of these combinations must be given in a setting in which a full assessment of the individual patient's comorbidities has been performed. Although none of these combinations has yet proven to improve overall survival, the activity is promising and continued evaluation is under way.

CHAPTER 224: SARCOMAS OF SOFT TISSUE AND BONE

J. SYBIL BIERMANN AND LAURENCE H. BAKER

[Definition](#)
[Incidence and Epidemiology](#)
[Etiologic Factors](#)
[Pathologic Factors](#)
[Clinical Findings](#)
[Laboratory Findings](#)
[General Management Principles](#)

DEFINITION

Most cancers are epithelial and are called carcinomas. Common carcinomas include cancer of the lung, breast, prostate, and colon. Sarcomas usually arise in structures that derive from the mesoderm (i.e., bone, cartilage, fat, muscle, tendon, and fibrous tissue). Bone and soft-tissue sarcomas are among the least common malignancies. By convention, sarcomas also include malignant tumors that arise in peripheral nerves and are derived from neuroectoderm. Sarcomas may also arise in blood and lymphatic vessels. Sarcomas are malignant tumors that are locally aggressive and capable of invasive growth, recurrence, and distant metastasis. In the past two decades, there have been dramatic improvements in the management of osteogenic sarcomas, whereas progress in the management of soft-tissue sarcomas has lagged.

INCIDENCE AND EPIDEMIOLOGY

Only 1% of all cancers diagnosed in the United States this year will be sarcomas. In total, there will be approximately 8,000 new cases of which 2,000 will be bone sarcomas. Though uncommon, sarcomas occur in all age groups, even infants and newborns. Soft-tissue and bone sarcomas are second only to leukemias in incidence in the pediatric population. Evidence suggests there is an increase in the incidence of sarcomas, although most of this is related to HIV-associated Kaposi's sarcoma. The incidence and distribution of soft-tissue sarcomas seem to be similar in different regions of the world, and the incidence of osteosarcoma is also nearly identical from nation to nation. There are no known racial factors, with the exception that Ewing's sarcoma is rare in African Americans and Asians.

Sarcomas present in a wide variety of anatomical locations. Soft-tissue sarcomas occur most frequently in the extremities, chest wall, mediastinum, retroperitoneum, head and neck region, and within viscera (leiomyosarcoma of the uterus, gastrointestinal stromal sarcomas). Osteosarcomas have a predilection for the long-bone metaphyses and have been reported in nearly every bone. Occurring primarily in adolescents or young adults, osteosarcomas most often arise near the larger more active physes (distal femur, proximal tibia, proximal humerus), but may also arise in flat bones of the pelvis, skull, ribs, and scapula. The single most common site for sarcomas is the thigh, which is the region of the body with the most connective tissues.

Both soft-tissue and bone sarcomas are slightly more common in males. The gender and age incidences vary among the different histologic types. For example, embryonal rhabdomyosarcomas occur exclusively in the very young. Peak incidence for synovial sarcomas is in the third decade, and malignant fibrous histiocytoma is predominantly a tumor of older age with a peak incidence around 60 years.

ETIOLOGIC FACTORS

The pathogenesis of most soft-tissue or bone sarcomas remains unclear. Recognized causes include various environmental factors such as environmental carcinogens, radiation, and viruses, as well as inherited effects. Trauma is frequently implicated in sarcomas, but usually because trauma calls attention to a mass not previously recognized. The controversy on the role of pesticide exposure as a carcinogen continues. Evidence now exists for an increased incidence following exposure to phenoxacetic acids and the related chlorophenols. In recent years, there has been an increased concern over the long-term health risks associated with artificial breast implants. Thus far, all analyses have failed to show an increased risk for sarcoma after breast implantation.

There is a small but definite long-term risk for soft-tissue and bone sarcoma after therapeutic radiation. The mean latency period is 16 years; the median latency period is 10 years with a range of 4 to 31 years. The prognosis of these radiation-induced sarcomas is not worse than that of the sporadic sarcomas. Sarcomas have occurred following radiation to patients with Hodgkin's disease, breast cancer, and retinoblastoma. The most common postirradiation sarcoma is malignant fibrous histiocytoma; second is osteosarcoma, followed by fibrosarcoma.

Viruses play a role in the etiology of Kaposi's sarcoma. Virus particles have been found repeatedly in a variety of sarcomas, but no specific etiologic relationship has been identified. Immunologic deficiency may be the underlying mechanism in the development of angiosarcoma or lymphangiosarcoma that arises in an edematous extremity following modified radical mastectomy and external radiation (Stewart-Treves syndrome).

Several genetic diseases are associated with the development of sarcomas. Neurofibromatosis type I, an autosomal dominant disease, manifests early in life with large multiple café-au-lait spots, and later with the development of numerous neurofibromas. Malignant peripheral nerve sheath tumors will occasionally develop from malignant degeneration of a neurofibroma. This is the only example of a benign soft-tissue tumor becoming malignant.

The inherited bilateral form of retinoblastoma is frequently associated with the development of osteosarcoma, usually within the irradiated field, or with the development of a soft-tissue sarcoma well outside of any field of radiation. Further, the retinoblastoma gene (*Rb*) is frequently mutated in patients with sarcoma. Li-Fraumeni syndrome is a familial cancer syndrome in which there is a germ line mutation of the *p53* gene that results in familial rhabdomyosarcoma and other soft-tissue sarcomas or osteosarcomas, as well as early onset of bilateral breast cancer and several other neoplasms.

PATHOLOGIC FACTORS

Both bone and soft-tissue sarcomas are heterogeneous with regard to tumor grade, clonality, and morphologic subtypes. Most classifications are principally based on the line of differentiation of the tumor (i.e., the tissue being formed by the cancer rather than the tissue from which the cancer arose). Malignant fibrous histiocytoma and liposarcomas are the most common soft-tissue sarcomas in adults and together constitute about 40% of all sarcomas. Grading characteristics include the number of mitotic figures, the extent of tumor cell necrosis, and the degree of differentiation of the cancer. Some sarcomas including osteogenic sarcoma, Ewing's family of cancers, mesenchymal chondrosarcoma, and rhabdomyosarcoma are almost always high grade. Others, such as chondrosarcomas, liposarcomas, fibrosarcomas, and leiomyosarcomas, occur in low- and high-grade forms. High-grade lesions are potentially lethal and their clinical behavior is different from that of low-grade lesions. Once grade and tumor sizes are accounted for, the clinical behaviors of most types of soft-tissue sarcomas are similar.

Various chromosomal abnormalities have been detected in sarcomas. While the current classification of sarcomas continues to be based on morphologic resemblance between tumor cells and specific immunohistochemical staining patterns, the importance of cytogenetic criteria continually increases. [Table 224.1](#) characterizes cytogenetic abnormalities in sarcomas.

Tumor	Cytogenetic Abnormality	Frequency (%)
Clear cell sarcoma	t(12;22)(q13;q12)	>75
Dermatofibrosarcoma protuberans	Ring chromosome 17	>75
Ewing's sarcoma	t(11;22)(q24;q12)	95
Intra-abdominal desmoplastic small round cell tumor	t(11;22)(q13;q12)	>50
Primitive neuroectodermal tumor	t(11;22)(q24;q12)	95
Extraskeletal myxoid chondrosarcoma	t(9;22)(q11;q12)	50
Non-germinomatous germ cell tumor	Translocation at 12q13	>25
Leiomyosarcoma	Deletion of 5p	75
Liposarcoma		
Myxoid	t(12;16)(q13;q11)	75
Pleomorphic	Complex	90
Well-differentiated	Ring chromosome 12	80
Malignant fibrous histiocytoma		
High-grade	Complex	90
Myxoid	Ring chromosomes	>50
Malignant peripheral nerve sheath	Complex	90
Rhabdomyosarcoma		
Alveolar	t(2;13)(q35;q14)	80
Embryonal	t(2;13)(q11;q13)	80
Synovial sarcoma	t(X;18)(p11;q11)	95

TABLE 224.1. CHARACTERISTIC CYTOGENETIC ABNORMALITIES IN SARCOMAS

CLINICAL FINDINGS

SOFT-TISSUE SARCOMAS

The clinical management of soft-tissue sarcomas begins with suspicion based on the clinical presentation and the imaging studies. In patients with an extremity sarcoma, a painless mass is the most common presenting symptom, with pain present only in about 25% of cases. Often patients give a history of trauma to the area that can lead to delay in the ultimate diagnosis. Delay in diagnosis is still quite common, with the common differential diagnosis often being hematoma or muscle strain/sprain. In general, any soft-tissue mass in an adult that is symptomatic or enlarging, greater than 5 cm in diameter, or any new mass that persists for more than 6 weeks should be considered for biopsy. Patients with intra-abdominal or retroperitoneal sarcomas often experience nonspecific abdominal discomfort.

Most retroperitoneal sarcomas are either liposarcoma or leiomyosarcoma. These patients usually present with very large masses and lower back pain. Rarely, these retroperitoneal sarcomas produce an insulin-like protein and the patient may present with hypoglycemia. Gastrointestinal stromal sarcomas (GISTs) are an uncommon GI malignancy (compared to epithelial cancers) and can occur in the stomach, small intestine, or colon. In the past these cancers were called leiomyosarcomas because of morphologic similarity. These patients present with a GI bleed and, less often, with symptoms of an intra-abdominal mass. Patients with sarcomas of the uterus usually present with abnormal vaginal bleeding. Uterine sarcomas can arise from an admixture of mesodermal and endometrial adenocarcinomatous elements (mixed mesodermal tumors), or from myometrium (leiomyosarcomas) or endometrial stroma (endometrial stromal sarcoma). In older men the genitourinary tract can be a site of sarcoma, usually in the paratesticular region, prostate, or bladder. Leiomyosarcoma and liposarcoma are the most common types of sarcoma.

Metastasis of soft-tissue sarcomas is usually hematogenous; lymphatic metastasis is uncommon. In more than 70% of patients, the first site of metastasis is the lung. These pulmonary lesions are characteristically multiple, in the lung periphery, and round ([Fig. 224.1](#)). Gastrointestinal stromal sarcomas and occasionally retroperitoneal sarcomas will most often metastasize to the liver.

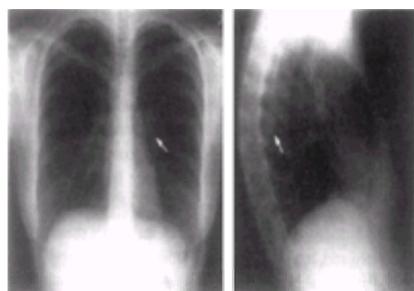

FIGURE 224.1. A small, round, peripheral metastasis in the lung fields characterizes metastatic sarcoma on this posteroanterior chest radiograph.

EWING'S FAMILY OF TUMORS

Ewing's family of tumors comprises bone and soft-tissue, small round cell neoplasms of neuroectodermal origin defined by the chromosomal aberration t(11;22)(q24;q12), and closely related variants. Tumors of the soft tissues are sometimes called extraskeletal Ewing's or primitive neuroectodermal tumors (PNETs). Molecular and cytogenetic analysis of Ewing's sarcoma and PNETs has resulted in the identification of genetic mutations that can distinguish these tumors from other small round cell tumors such as rhabdomyosarcoma or lymphomas. Typically, Ewing's sarcoma occurs in adolescents and young adults; it usually arises in the diaphyseal portion of the bone. The most common primary sites are the femur and pelvis, although any bone may be affected. On imaging the bone appears as mottled. Periosteal reaction is classic and is due to a periosteal reaction; it is referred to as "onion skin" by radiologists. Fever, weight loss, and fatigue sometimes are constitutional symptoms. Abnormal laboratory studies may include elevated lactate dehydrogenase and leukocytosis. The lungs, bones, and bone marrow are the most common sites of metastasis. Nearly one-quarter of these patients present with signs and/or symptoms of disseminated disease.

OSTEOGENIC SARCOMA

The most common primary malignant tumor of bone is osteogenic sarcoma. Classic osteosarcoma composes nearly 80% of osteogenic sarcomas; it is a high-grade, spindle cell tumor that by definition manufactures osteoid (immature bone). It is intramedullary in location. The most common site for this cancer is the distal femur or proximal tibia. Pain followed by swelling is an early symptom. Because the pain in the beginning is often intermittent, confusing it with "growing pains" is common. Osteogenic sarcomas spread hematogenously, and lung is the most common metastatic site. Sometimes patients present with evidence of metastasis at the time of diagnosis. Several other variants of osteosarcomas occurring in an older population include osteosarcomas secondary to Paget's disease or prior irradiation (bilateral retinoblastoma). The median age for all osteosarcoma patients is 20 years.

While most osteosarcomas are medullary, parosteal osteosarcoma is a low-grade variant occurring in a juxtacortical location, most often in the posterior distal femur. This variant tends to metastasize later than the classic form. Another juxtacortical variant is periosteal osteosarcoma, which most often involves the tibia and is intermediate in its behavior, falling somewhere between the parosteal and classic lesions.

The imaging of osteosarcomas includes plain films, which may show loss of trabeculation and new-tumor mineralization ([Fig. 224.2](#)). Computed tomography scan can show cortical disruption and extent of mineralization ([Fig. 224.3](#)). Magnetic resonance imaging (MRI) is the best multiplane imaging study because it shows intramedullary extent of the lesion as well as localization of any associated soft-tissue mass ([Fig. 224.4](#)). Alkaline phosphatase is frequently elevated in patients with osteosarcoma.

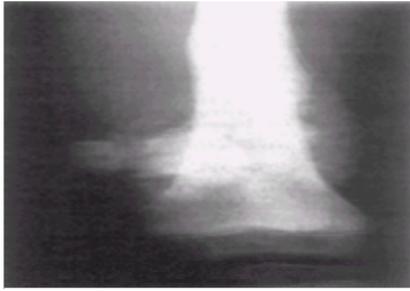

FIGURE 224.2. Anteroposterior view of a conventional osteoblastic osteosarcoma shows a poorly marginated sclerotic lesion with extensive soft-tissue mass and mineralization, as well as aggressive periosteal reaction.

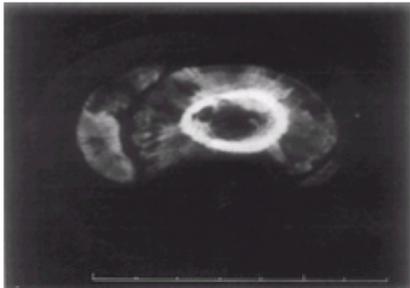

FIGURE 224.3. Computed tomographic scan of the femur with osteogenic sarcoma illustrates permeative destruction of the cortex and extensive extraosseous new-bone formation. Bones with osteosarcoma are often weakened despite their sclerotic appearance on plain films.

FIGURE 224.4. A T1-weighted coronal magnetic resonance image clearly defines the marrow extent of this tumor in the distal femoral diaphysis and metaphysis, extending into the epiphysis. The knee joint is uninvolved.

CHONDROSARCOMAS

Chondrosarcomas characteristically produce cartilage matrix devoid of osteoid from neoplastic tissue. These tumors are divided into primary lesions arising de novo from previously normal-appearing bone preformed from cartilage, and secondary tumors that arise or develop from preexisting benign cartilage lesions such as enchondromas or cartilaginous portions of osteochondromas. Malignant transformation has been reported in lesions of Ollier's disease (enchondromatosis). These sarcomas may occur at any age but usually begin 15 to 20 years after skeletal maturity. Whether the lesions are primary or secondary, the anatomical location and histologic grade are the important prognostic features. Primary chondrosarcomas constitute nearly two-thirds of all chondrosarcomas and can be high-grade lesions capable of distant metastasis as well as local invasiveness. Secondary tumors are usually low-grade with infrequent metastasis. Symptoms from chondrosarcoma are usually mild and depend on tumor size and location. Low-grade chondrosarcomas may become sizable without causing symptoms. Patients with pelvic lesions can present with severe pain and develop neurologic impairment, often because lesions arising in the pelvis are not recognized until late. Chondrosarcomas radiographically demonstrate cortical destruction and loss of medullary bone trabeculations with evidence of calcification. MRI will usually show the intramedullary extent as well as extraosseous extension of tumor.

LABORATORY FINDINGS

There are no specific marker studies of blood or urine to diagnose a sarcoma. Lactate dehydrogenase is sometimes elevated, especially in Ewing's family of sarcomas. Alkaline phosphatase is often elevated in patients with osteosarcoma. Unfortunately, sarcomas are often presumed to be benign lesions until biopsy or removal. Some genetic conditions can predispose the diagnosis of sarcoma. Patients with neurofibromatosis (*NF1* gene) have a 10% incidence of a neurofibroma becoming malignant (neurofibrosarcoma). Similarly, patients with Ollier's disease or Maffucci's syndrome (enchondromatosis with hemangioma) are predisposed to chondrosarcoma. The Li-Fraumeni syndrome is a rare hereditary disease characterized by the youthful occurrence of soft-tissue sarcomas, osteosarcomas, adrenocortical cancers, brain tumors, and bilateral breast cancer. The syndrome is inherited as an autosomal dominant trait with a high degree of penetrance. Within kindreds, the probability of an individual developing invasive cancer reaches 50% by age 30 and is 90% by age 70. Other predisposing conditions include prior exposure to radiation therapy and chronic lymphedema.

GENERAL MANAGEMENT PRINCIPLES

The relative small number of cases of soft-tissue and bone sarcomas and their significant diversity in anatomical location, histologic appearance, and biologic behavior renders diagnostic and treatment decisions best served in a setting of multidisciplinary medicine with expertise in the management of these tumors. Team members should include an orthopedic oncologist, a pathologist, an interventional radiologist, a medical or pediatric oncologist, a radiation oncologist, and a physiatrist. Many patients consult a physician regarding a mass that is often painless or is intermittently painful.

Patients with intra-abdominal or retroperitoneal sarcomas often experience nonspecific abdominal discomfort and/or GI symptoms prior to diagnosis. Delays in diagnosis are common, with the most common incorrect diagnosis being hematoma or pulled muscle for an extremity or truncal lesion. Localized pain and swelling are the hallmark clinical features. Pain is often initially insidious and/or transient but becomes progressively more severe. Local soft-tissue swelling is often present.

Clinical management begins with suspicion based on the clinical presentation and the imaging studies. Locoregional staging should ideally be performed before the biopsy procedure. This implies that the T staging should be known prior to the procedure. MRI with and without contrast is the procedure of choice as it can determine tumor size, compartmental boundaries, neurovascular involvement, and presence of necrosis. Computed tomographic scanning may be indicated to evaluate possible cortical bone destruction and the presence or extent of mineralization.

After local tumor staging has been completed, the next step is to perform either a needle biopsy or an incisional biopsy. Biopsy should be done by an experienced surgeon because complications are common and might limit definitive limb-sparing surgery. Biopsy tracts must be oriented appropriately, usually in a vertical direction. This is necessary because the entire wound must be excised to obtain a clear margin in all directions. Transverse incisions, hematoma, or exposure of neurovascular structures may result in compromise of future surgical care and the loss of limb-sparing options. Limb salvage is the preferred surgical option for sarcomas of the extremities and can be accomplished in 95% of adult cases.

An important area in the clinical management of sarcomas is the follow-up strategy. Management of local recurrence is crucial since an increase in local failure leads to an increase in the rate of distant metastasis.

Surgical resection remains the cornerstone of primary treatment of sarcomas. Wide excision with limb preservation has supplanted amputation as the principal surgical method for eradication of local disease in patients with primary sarcomas of the limb and limb-girdle regardless of histologic type or tumor grade. Patient survival has not been compromised by this operative strategy. Development of soft-tissue and skeletal reconstruction techniques has expanded the capability of the limb reconstruction surgeon. Patients with metastatic disease to the lungs should be evaluated for surgical resection (metastasectomy). In one series, 72% of patients with isolated pulmonary metastases were rendered disease-free with surgery. The actuarial 3-year survival rate was 38%.

Radiation of extremity soft-tissue sarcomas is used as an adjuvant therapy after surgery. The routine use of radiation therapy in treatment of soft-tissue sarcomas is relatively recent. Only patients with small, superficial tumors are spared adjuvant radiation therapy.

In patients with an extremity sarcoma who relapse, the site of failure is usually pulmonary (70%) and locally (10%). The 5-year disease-free survival rate by tumor size for patients with intermediate-grade and high-grade sarcomas treated with surgery and radiation is shown in [Table 224.2](#). The treatment of retroperitoneal sarcomas and the role of radiation therapy remain a challenge. In no other location is the need for an adjunct modality after resection as high as in these patients.

Tumor Size	% Disease-Free
<2.5	94
2.6-4.9	77
5-10	62
10-15	51
15-20	42
>20	17

TABLE 224.2. FIVE-YEAR SURVIVAL BY TUMOR SIZE FOR INTERMEDIATE-GRADE AND HIGH-GRADE SARCOMAS TREATED WITH SURGERY AND REHABILITATION

The chemotherapeutic sensitivity of the soft-tissue sarcomas and osteogenic sarcomas is quite similar. The single most active drug in both disease categories is doxorubicin; the response rate is 26% in both tumor types. High-dose methotrexate therapy with folinic acid rescue appears to be more effective in patients with osteosarcoma (25% response) than the reported series of patients with soft-tissue sarcomas in which the response rate is 13%. Ifosfamide, like doxorubicin, has remarkably similar data in the two groups: 24% response in osteogenic sarcoma and 27% in soft-tissue sarcomas. Cyclophosphamide is also similar between the two groups (14% and 12%) and approximately half as effective as its analogue, ifosfamide. Cisplatin seems more effective in osteogenic sarcomas (18% versus 12%) than in soft-tissue sarcomas, and this is probably the reason for this drug to be included in adjuvant studies of osteogenic sarcomas, whereas adjuvant cisplatin therapy was only studied in patients with uterine sarcoma. The duration of response, frequency of complete remission, and overall survival all appear to be quite similar.

The data regarding the treatment of patients with disseminated soft-tissue sarcoma or osteogenic sarcomas with combination chemotherapy are again remarkably similar between the two groups. The combinations of doxorubicin and ifosfamide, or doxorubicin, ifosfamide, and dacarbazine, have reported response rates of 36% to 47%.

CHAPTER 225: EPITHELIAL MALIGNANCIES OF THE HEAD AND NECK

GEORGE J. BOSL AND DAVID G. PFISTER

[Epidemiology](#)
[Clinical Presentation and Differential Diagnosis](#)
[Clinical Evaluation and Staging](#)
[Optimal Management](#)

Malignancies of the epithelial surface of the upper aerodigestive tract, often referred to as *head and neck cancer*, represent approximately 3.5% of all new cases of cancer in the United States. Worldwide, over 500,000 cases are diagnosed annually. In this chapter, head and neck cancer collectively refers to the squamous cell carcinomas and undifferentiated carcinomas of mucosal origin, as well as the adenocarcinomas of major and minor salivary gland origin. Control of the primary site and cervical lymph node metastases (i.e., locoregional control) dictate patient management, because two-thirds of patients die of advanced locoregional disease without distant metastases. Proper initial treatment of the primary site and, when appropriate, the cervical lymph nodes is crucial.

EPIDEMIOLOGY

Squamous cell carcinoma or one of its variants is the histologic type of 90% to 95% of head and neck cancers. With the exception of tumors of the nasopharynx, paranasal sinuses, and salivary glands, squamous cell carcinoma is usually associated with tobacco or ethanol abuse. The increased use and popularity of smokeless tobacco among adolescents and young adults are especially troublesome in this regard. The median age at diagnosis is in the sixth decade, and men predominate. Patients often present with concomitant pulmonary, hepatic, and general physiologic impairment, and they are at risk for second primary tumors because of prior tobacco and alcohol exposures. Neglect of symptoms often leads to presentation with advanced locoregional disease and debilitation due to pain and malnutrition.

The cause of salivary gland cancers is largely unknown, although an increased incidence in salivary gland tumors has been reported after radiation exposure, similar to that of thyroid cancer. Most malignant salivary gland tumors are subtypes of adenocarcinoma rather than squamous cell carcinoma. Nasopharynx and salivary gland cancers occur in younger patients than do squamous cancers of the other head and neck sites. Nasopharynx cancers are associated with Epstein–Barr virus exposure and an Asian ethnic background. Various occupational exposures have been associated with the development of sinonasal tract cancers.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

Squamous cell carcinoma usually presents as an ulceration in the mucosal surface. Although infection may mimic the symptoms of malignancy, any persistent lesion should be considered possibly malignant. Because much of the mucosal surface is not visualized through the open mouth, symptoms often occur that are not pursued. Hoarseness, odynophagia, dysphagia, dentalgia (particularly upper teeth from maxillary sinus cancer), and otalgia may precede obvious disease by months. Posterior neck pain is often associated with involvement of the retropharyngeal lymph nodes or prevertebral fascia. Otalgia may imply an obstructed eustachian tube in the nasopharynx, and otitis media in an adult, especially when unilateral, is a common presenting scenario for nasopharynx cancer. Laryngeal and pharyngeal cancers can also cause pain that radiates into the ear, misleading the examiner. Base of skull extension may cause a skull vertex headache or palsies of cranial nerves IX, X, or XII. Diplopia is associated with intraorbital tumor or palsies of cranial nerves III, IV, or VI due to cavernous sinus invasion.

Trismus implies involvement of the pterygoid musculature. Maxillary antrum cancers may cause facial dysesthesias resulting from involvement of branches of the fifth cranial nerve. A persistent submucosal mass or mass in the parotid or submandibular region suggests a salivary gland tumor. Asymptomatic cervical lymphadenopathy can be the presenting complaint of a malignancy of upper aerodigestive tract origin. The patient's age and risk factors are important to consider. If the initial head and neck examination does not reveal a cause, a trial of antibiotic therapy for presumed infection is warranted for 7 to 10 days, with careful follow-up to ensure resolution. Persistent symptoms, ulceration, or adenopathy, especially in the older patient with a history of tobacco or alcohol use, must be pursued, generally by referral to an otorhinolaryngologist or head and neck surgeon.

CLINICAL EVALUATION AND STAGING

Precise knowledge of tumor extent dictates proper management and maximizes the likelihood of locoregional control. A thorough physical examination must be done by an experienced examiner, with careful attention to mucosal surfaces and the cervical lymph nodes. A digital examination of the accessible oral mucosa occasionally reveals lesions not otherwise visualized. Besides direct palpation of a mass, local bleeding precipitated by gentle palpation may indicate the location of a subtle primary lesion. Indirect mirror and rigid or flexible endoscopic examination facilitates evaluation of all head and neck mucosal surfaces. Direct examination under anesthesia is necessary for tumors that cannot be visualized through the open mouth. The routine use of “triple endoscopy” (laryngoscopy, esophagoscopy, and bronchoscopy) is controversial. It appears to be of greatest usefulness in two groups: patients with diffuse mucosal abnormalities suggesting a higher risk of synchronous cancers and patients with cervical adenopathy and no clear primary lesion.

CT is required to evaluate the base of the skull; the superior and inferior extent of the tumor; the parapharyngeal, retropharyngeal, and cervical lymph nodes; possible encroachment on the carotid artery; and direct brain extension. It is the principal imaging technique used to evaluate the locoregional tumor extent in these patients. MRI is superior to CT for evaluating intracranial tumor extent and is also helpful in evaluating submucosal disease spread with tongue cancers. Some centers use ultrasonography to facilitate assessment of the neck. Routine use of all these studies is costly and is, in most cases, not indicated. Positron emission tomography (PET) is being investigated, but the data are currently limited for these diseases. PET can be useful in identifying an occult primary lesion.

Systemic metastases are uncommonly present at diagnosis in patients with head and neck cancers (except those with nasopharynx or hypopharynx cancer) and generally occur when cervical lymph nodes are involved. The most common metastatic sites are the lungs and bones. A routine chest radiograph is required for each patient, as much to detect a secondary primary tumor in the lung as to find a distant metastasis. A routine biochemical screen is indicated, with follow-up imaging of the liver or a bone scan only when appropriate biochemical abnormalities are identified. A complete blood count may suggest vitamin B₁₂, folate, or other nutritional deficiencies.

As with all malignancies, histologic proof of cancer is necessary, preferably of the primary site. Patients with an enlarged, suspicious lymph node or nodes without a clear primary lesion present a special challenge. An excisional lymph node biopsy should not be the first diagnostic step, because alteration of lymphatic drainage may occur. Fine-needle aspiration is the procedure of choice. Random directed biopsies of the more common sites for occult primary lesions, such as the nasopharynx, oropharynx (tonsillar fossa, base of tongue, vallecula), and hypopharynx (piriform sinus) are generally done when no mucosal abnormality is seen on routine examination.

The process of determining the site and extent of a malignancy is called *staging*. Each primary site lesion is staged clinically in terms of the tumor (T) stage, the nodal involvement (N) stage, and the metastatic (M) stage ([Table 225.1](#)). Prognosis broadly follows the stage for each primary site, but the prognosis for a patient with a stage III glottic larynx cancer is different from the prognosis for a patient with a stage III oral tongue cancer. Accordingly, the prognosis depends on the overall stage and the primary site. Inspection of the T stages shows that staging of the primary site is complicated by the inability to measure accurately the size of most primary head and neck cancers, further complicating comparisons between primary sites. Although general rules with regard to staging the neck and the creation of overall stages apply to selected sites as highlighted in [Table 225.1](#), the outlined paradigm does not uniformly apply to all primary sites. For example, staging of salivary gland tumors follows a different overall staging scheme; nasopharynx cancers have different neck and overall staging criteria.

Site	Stage	Primary Tumor	Regional Lymph Nodes	Distant Sites
Oral Cavity	T1	≤ 2 cm	N0	M0
	T2	2-4 cm	N1	M0
	T3	> 4 cm	N2	M0
Nasopharynx	T1	≤ 2 cm	N0	M0
	T2	2-4 cm	N1	M0
	T3	> 4 cm	N2	M0
Hypopharynx	T1	≤ 2 cm	N0	M0
	T2	2-4 cm	N1	M0
	T3	> 4 cm	N2	M0
Larynx	T1	≤ 2 cm	N0	M0
	T2	2-4 cm	N1	M0
	T3	> 4 cm	N2	M0

TABLE 225.1. STAGING OF SQUAMOUS CELL CARCINOMAS OF THE HEAD AND NECK FOR SELECTED SITES

OPTIMAL MANAGEMENT

GENERAL PRINCIPLES

Control of the primary tumor and draining lymph nodes is the principal goal of all head and neck cancer treatment. Surgery, radiation therapy, and chemotherapy play roles in various circumstances. In many situations, a patient can be treated in more than one way with survival results that are equivalent. Accordingly, other factors such as anticipated functional or cosmetic outcome may influence choice of therapy.

Tumors begin as mucosal lesions, sometimes progressing from leukoplakia or erythroplasia. The whitish plaques of leukoplakia usually progress slowly and rarely develop invasive cancer. Erythroplasia is less common than leukoplakia but more likely to harbor in situ or invasive cancer, mandating more aggressive evaluation and intervention. Progression of the primary lesion occurs by superficial extension and deep infiltration. The depth of invasion (deeper than 2 mm) is associated with a greater potential for regional lymph node metastases. As a tumor grows, natural barriers such as fascial planes, cartilage, and bone are traversed. The diffuse mucosal abnormalities—field cancerization or condemned mucosa—often found are compatible with prior tobacco and alcohol exposure, multiple sites of premalignant change, and increased risks of synchronous and metachronous cancers. Indeed, even normal-appearing mucosa surrounding a tumor may harbor premalignant changes on genetic analysis.

The larger the primary tumor, the greater is the likelihood of regional lymphadenopathy. The lymph nodes at risk are determined by the primary site and are generally ipsilateral to the primary tumor. The nodes are often classified by *levels*. Level I is the submental triangle; levels II, III, and IV are the upper, middle, and lower thirds of the jugular lymph node chain; and level V is the posterior cervical triangle. The location of involved lymph nodes in patients without a clear primary site is often helpful in directing further evaluation. For example, a level I lymph node should prompt careful scrutiny of the oral cavity; an isolated level IV node should raise the possibility of a primary site below the clavicles.

SURGERY

Surgery for head and neck cancer is multidisciplinary. An adequate surgical resection requires margins free of tumor. This may result in considerable cosmetic or functional alterations for large tumors. Conservation procedures that preserve vital structures while completely removing the tumor exist, but they should not be confused with a conservative resection that violates surgical oncologic principles and incompletely excises a tumor. Because diffuse mucosal abnormalities are common, a negative margin by immunohistochemical criteria can be falsely reassuring. Other factors at the molecular biologic level (e.g., p53 mutations) are being investigated as a means to ensure a more complete resection.

Total laryngectomy or glossectomy is sometimes required. Mandibular mobilization may be necessary to expose large primary tumors, such as those of the tonsil and base of the tongue. Resection of bone (i.e., hard palate or mandible) may be required to resect all disease with adequate margins. A maxillofacial prosthodontist is often required to create obturators to close defects and restore speech and swallowing.

Radical neck dissection is required in patients with bulky or multiple affected nodes. The contents of the ipsilateral neck are frequently resected en bloc with the primary tumor. A classic radical neck dissection includes resection of the spinal accessory nerve, the internal jugular vein, and the sternocleidomastoid muscle. Various less morbid modified neck dissections are available for specific indications. The need for neck dissection in patients with a high likelihood of cervical metastases but without clinical incidence of disease is controversial. Postoperative irradiation provides equivalent control in these patients. However, a neck dissection that does not find involved nodes may prevent the need for radiation therapy, depending on how the primary site is managed.

Relative or absolute contraindications to surgery include nasopharynx cancer, fixed lymphadenopathy, base of skull extension, trismus, and fixation to the prevertebral fascia. In these circumstances, clear margins are rarely achieved. The plastic surgeon, prosthodontist, and others involved in the reconstruction and repair of the surgical defect should evaluate the patient preoperatively to facilitate treatment planning. Reconstructive procedures appropriate for repair of the surgical defect are optimally done at the time of the definitive ablative procedure.

RADIATION THERAPY

Radiation therapy alone may be administered by itself as definitive treatment for less advanced squamous cell head and neck cancers, or it may be delivered preoperatively or postoperatively. Although at least one large study showed that preoperative radiation therapy of 5,000 cGy did not increase the morbidity of surgery, most patients are treated postoperatively, because loco- regional control appears to be better with this approach.

The treatment volume and primary site dictate the radiation technique to be used. Total dose depends on the setting (definitive management or preoperative/postoperative) and fraction size. Treatment may require external-beam therapy and a temporary or permanent implant (*brachytherapy*). The treatment plan must be carefully designed to maximize effect and minimize treatment toxicity. Primary tumors treated with radiation alone generally require 6,500 to 7,000 cGy delivered over 6 ½ to 8 weeks in fractions of 180 to 200 cGy per day. Interstitial boosts with iridium Ir 192 by an afterloading technique (*temporary implant*) or iodine I 125 (*permanent implant*) may be required to boost the radiation dose in small volumes at high risk for recurrence. Altered fractionation (e.g., twice-daily radiation) is under study for treating large-volume tumors and appears to improve local tumor control. Conformal radiation therapy and intensity-modulated radiation therapy are being investigated as ways to optimally deliver treatment to the tumor while sparing more of the normal tissues and thus potentially facilitating dose escalation. Neutron-beam therapy has been suggested for certain salivary tumors, but it is not widely available.

Acute radiation injury impairs alimentation, and the maintenance of food intake is vital. A feeding tube or percutaneous gastrostomy may be required. Altered fractionation schemes or the concomitant use of chemotherapy with radiation can exacerbate acute toxicity. Evaluating ways to ameliorate or prevent local acute mucosal damage (e.g., chemoprotectants such as amifostine, growth factors, topical measures) are an important research priority. Long-term radiation injury includes xerostomia, accelerated caries formation, and weight loss. The results of a placebo-controlled randomized trial suggest that pilocarpine may help to ameliorate the salivary gland dysfunction and dry mouth associated with radiation therapy. Osteonecrosis is less common because of the advances in treatment planning and proper dental care. A dental consultation before radiation therapy is mandatory. Diseased teeth must be extracted, infected gingiva treated, and prophylactic fluoride treatment initiated.

CHEMOTHERAPY

By itself, chemotherapy cannot cure squamous cell head and neck cancers. The most active and commonly used single agents include cisplatin, carboplatin, methotrexate, bleomycin, 5-fluorouracil, paclitaxel, docetaxel, ifosfamide, and gemcitabine. Response rates depend on tumor bulk, degree of pretreatment, and drugs used. With cisplatin-based combination chemotherapy such as cisplatin plus continuous-infusion 5-fluorouracil, complete responses have been reported in 15% to 50% of previously untreated patients with stage III and IV disease and complete plus partial responses in 50% to 90%. Potential toxic effects such as nausea, vomiting, ototoxicity, nephrotoxicity, mucositis, and severe pancytopenia must be taken into account when considering chemotherapy in these sometimes debilitated

patients.

The use of combination chemotherapy in patients with stage III and IV squamous cell head and neck cancer has been widely studied in the hope of improving survival or decreasing the extent of required resection. Chemotherapy can be administered before surgery or radiation (by induction or neoadjuvant therapy), after this treatment (by adjuvant or maintenance therapy), concomitantly with radiation (typically for unresectable tumors), or with some combination of these approaches. Unfortunately, randomized trials have failed to demonstrate a survival advantage for the addition of neoadjuvant or adjuvant chemotherapy to planned surgery and radiation therapy in patients with locally advanced, resectable disease.

For example, one study allocated more than 460 patients with stage III and IV disease to three treatment arms. The survival distribution of patients receiving chemotherapy (i.e., one cycle of preoperative with or without 6 months of adjuvant chemotherapy) was equivalent to that of the standard surgery plus postoperative radiation therapy arm, although there was a decrease in distant metastases among patients receiving adjuvant chemotherapy. This and other similar studies have several methodologic limitations. Studies have frequently not been site-specific, combining patients with different prognostic and management issues. Most studies have focused on improved overall survival, which is difficult to prove for a disease with a relatively low proportion of distant metastases, high proportion of locoregional relapses, and competing causes of mortality (e.g., medical comorbidities, second primary cancers, and neoadjuvant or adjuvant therapy-related deaths). Other important outcomes, such as quality of speech and swallowing, often are poorly or not formally quantitated. Nonetheless, based on available data, the use of chemotherapy with planned surgery and radiation therapy in patients with resectable, advanced locoregional disease should be viewed as investigational.

Chemotherapy has evolved significantly in two settings in the last 10 years. The first setting is as part of a larynx-preservation strategy. In general, the response to radiation therapy parallels the response to chemotherapy. A major response to neoadjuvant chemotherapy at the primary site implies a high likelihood of further response with radiation therapy. Applying these concepts, pilot studies have shown that preservation of larynx function is feasible with neoadjuvant chemotherapy, followed by radiation therapy, with surgery reserved for nonresponse or relapse. These studies suggested that survival was similar to survival after standard total laryngectomy plus postoperative radiation therapy, and the larynx can be preserved in approximately two-thirds of these patients. Tumors of the larynx itself have been most extensively studied, but some oropharynx and hypopharynx tumors that require total laryngectomy as part of the planned initial therapy have also been evaluated. Major randomized trials by the Veterans Administration Laryngeal Cancer Study Group and the European Organization for Research and Treatment of Cancer (EORTC) evaluating this approach in patients with advanced larynx and hypopharynx cancers confirmed that larynx preservation can be achieved in a significant proportion of such patients. Survival was not compromised compared with standard management with surgery, including total laryngectomy, and postoperative radiation therapy. Preservation of function continues to be an important end point in studies of combining chemotherapy and radiation. The data for other primary sites are more preliminary.

The second promising area of chemotherapy with radiation therapy is the management of patients with unresectable disease. Evolving data from randomized trials and meta-analyses suggest that concomitant chemotherapy and irradiation is superior to irradiation alone in the management of these patient with most advanced disease. The optimal combination of chemotherapy and radiation therapy has yet to be defined. As noted earlier, novel radiation fractionation schedules are also being pursued in treating these patients with locally advanced disease. Two recent randomized trials report an improvement in disease control with the concomitant addition of cisplatin, 5-fluorouracil (\pm leucovorin) to an altered fractionation radiation program compared with the same radiation scheme alone. Toxicity, however, was greater with the addition of the systemic therapy.

SPECIFIC TUMOR MANAGEMENT

Oral Cavity

The oral cavity extends anteriorly from the vermilion border posteriorly to a plane joining the line of the circumvallate papillae of the tongue with the junction of the hard and soft palate. Primary sites within the oral cavity include the lip, hard palate, buccal mucosa, the alveolar ridges, the floor of the mouth, the oral tongue, and the retromolar trigone. Tumors are generally easy to visualize, but oral tongue and floor of mouth tumors have high local relapse rates because of unrecognized invasion of the root of the tongue and the tissues of the anterior neck. Cervical node metastases occur first in levels I or II.

Initial surgical resection or radiation therapy are probably equally effective for most stage I and II disease, but surgical excision is sometimes preferred to avoid the potential risk of osteoradionecrosis of the mandible and xerostomia. Surgery with postoperative radiation therapy is required for all resectable stage III and IV cancers. Systemic chemotherapy has no proven role in resectable oral cavity cancers.

Oropharynx

The oropharynx extends from the plane joining the circumvallate papillae and the junction between the hard and soft palate posteriorly to the posterior pharyngeal wall, superiorly to the superior border of the soft palate, and inferiorly to the level of the epiglottis. Primary tumor sites include the soft palate, pharyngeal wall, base of the tongue, and tonsil. Because of their location, the tumors tend to be larger at presentation than oral cavity tumors. The base of tongue tumors particularly may escape detection and be found only after months of symptoms.

Most early tonsil and soft palate tumors are treated with radiation therapy alone. More advanced tumors require surgery and postoperative radiation therapy. Prophylactic radiation therapy or radical neck dissection is needed for stage III or IV tumors, because the likelihood of microscopic disease is high. Based on nonrandomized data, interstitial radiation therapy by the afterloading technique with Ir 192 may reduce the likelihood of recurrence at the primary site from base of tongue tumors when it is added to standard external beam therapy. Cervical node metastases generally first involve levels II and III, and they may be bilateral for base of tongue tumors because of unrecognized spread across the midline. The management of stage III and IV tumors of the base of tongue occasionally requires total laryngectomy to prevent the sequelae of chronic severe aspiration. The role of chemotherapy in the advanced, resectable setting is in evolution, especially as part of an organ-preservation strategy. Preliminary data suggest that similar management principles can be successfully applied to this primary site in the organ-preservation setting.

Larynx

The larynx extends superiorly from the epiglottis and inferiorly to the level of the cricoid, where it meets the trachea. A tumor may be of supraglottic, glottic, or subglottic origin, depending on its relation to the true vocal cords. Larynx cancer is the most common of all head and neck cancers. Supraglottic and glottic tumors constitute about 99% of larynx cancers. Supraglottic tumors often have lymph node metastases, but glottic tumors only uncommonly metastasize.

Radiation therapy is equivalent to surgery for stage I and II tumors. Treatment with radiation therapy or surgery is individualized. Advanced laryngeal cancers typically require total laryngectomy, although function-preserving procedures such as supraglottic laryngotomy and hemilaryngectomy can be applied in selected patients, and rehabilitative options to facilitate speech such as a tracheoesophageal puncture (TEP) can be performed. Subglottic larynx cancers require special management because of their propensity to spread to paratracheal lymph nodes. Embryologically, the subglottis arises from the lung bud and meets the upper aerodigestive tract at the glottis, thus explaining the propensity to involve inferiorly draining lymphatics that is characteristic of these tumors. Because total laryngectomy is among the head and neck operations most feared by patients, the use of chemotherapy with radiation as part of an organ preservation approach has received considerable attention. Randomized and nonrandomized studies indicate that laryngectomy can be potentially avoided in patients with stage III and IV larynx cancer by the chemotherapy plus irradiation approach outlined previously, without compromising survival.

Hypopharynx

The hypopharynx extends superiorly from the level of the epiglottis and inferiorly to the level of the cricoid, where it meets the cervical esophagus. Primary tumor sites include the posterior pharyngeal wall, the postcricoid mucosa, and the piriform sinuses. Patients often present with long histories of odynophagia and level III or IV cervical lymph node metastases.

Aggressive surgery and radiation therapy are usually indicated, including total laryngectomy. Even early-stage lesions can have deceptively bulky disease, compromising the efficacy of radiation therapy as a single modality. As noted previously, results from a randomized trial suggest that chemotherapy plus radiation treatment with the intent of larynx preservation, similar to that studied in patients with advanced larynx cancer, can be applied to these patients as well.

Nasopharynx

The nasopharynx begins with the superior border of the soft palate and extends to the roof of the pharynx. The eustachian tubes enter the nasopharynx laterally. Tumors are often asymptomatic until nasal obstruction, unilateral or bilateral level II or V cervical node metastases, otitis media, or cranial nerve palsies occur. The incidence of distant metastases is especially high among patients with undifferentiated carcinomas—the type more common in Asia and the Mediterranean basin.

Historically, radiation therapy has been the cornerstone of standard management. Surgery to the primary site is rarely used, except in highly selected cases in the recurrent disease setting, because the resection of even small primary lesions poses substantial technical challenges and can be associated with significant morbidity. Until recently, chemotherapy's role was primarily limited to the palliative setting. However, a recently reported study favored concomitant chemotherapy-radiation in stage III and IV disease.

Paranasal Sinuses

Tumors of the paranasal sinuses are rare, and those of the maxillary sinus are the most common. Presenting symptoms are often obscure and nonspecific, mimicking the much more common inflammatory symptoms. Patients with maxillary sinus tumors often present with proptosis due to orbital invasion, facial swelling, or dysesthesia, upper gingivobuccal sulcus ulceration, or trismus. Primary tumors of the ethmoid are uncommon, and tumors of the frontal and sphenoid sinuses are rare.

The widest spectrum of pathologic entities in the head and neck arise in the sinuses or nasal cavity. Surgery and radiation therapy are standard, but recurrence rates for all paranasal sinus malignancies are high. Integrated chemotherapy radiation is increasingly used for patients with unresectable disease.

Recurrent and Metastatic Disease

Recurrent or metastatic disease usually occurs within 2 years of initial treatment. Once a patient is beyond surgical or radiotherapeutic management, there is no cure. With the best available therapies, the median survival of these patients is approximately 6 months. Palliation is the goal. The same combinations of chemotherapy used in the neoadjuvant setting have been applied to patients with recurrent and metastatic disease. Response rates are significantly lower for recurrent than for previously untreated epidermoid cancer, and durable complete responses are very uncommon. Response proportions are somewhat higher with combination chemotherapy compared with treatment with single agents, but toxicity is also increased, and randomized trials fail to document a significant survival advantage for combinations over weekly single-agent methotrexate or single-agent cisplatin. Referral for clinical trials of new agents should be considered.

Salivary Gland Cancer

Cancers of the major and minor salivary glands are rare, constituting less than 10% of all head and neck malignancies. Histologic types include mucoepidermoid carcinoma, solid adenocarcinoma, and adenoid cystic carcinoma. The most common salivary tumor is the benign mixed tumor. Facial nerve paralysis generally implies a malignant primary parotid tumor.

Radical surgery and postoperative radiation therapy are indicated in the management of anything but the smallest malignant tumor. Unlike cases of squamous cell head and neck cancer for which surgery and irradiation are typically interchangeable for early-stage disease, surgery is the preferred treatment for early-stage salivary gland tumors. There is no standard chemotherapy.

The most common minor salivary gland tumor is adenoid cystic carcinoma. These tumors have a long natural history and high incidence of local recurrence. Surgery and radiation therapy are standard management. Pulmonary metastases may develop years later and are generally slowly progressive. No treatment is the standard approach in patients with only pulmonary metastases, because the disease progresses so slowly. There is no standard chemotherapy, but doxorubicin, cisplatin, and 5-fluorouracil have some activity against this tumor.

Second Malignancies

Second primary tumors occur at a rate of 3% to 5% per year in patients with squamous cell carcinomas of the head and neck. These are related to the tobacco and ethanol abuse that led to the first tumor. The risk persists for years, even if the patient abstains from subsequent tobacco and alcohol use. The second malignancies are generally of the mouth and throat, lung, and esophagus. The site of the index primary tumor can predict the likely site of the second primary tumor. For example, patients with laryngeal cancer, a site at which tobacco is a key risk factor, often have lung cancer as their second primary tumor. If a patient is free of disease from the first tumor for at least 2 years, a new tumor is more likely to be a second primary cancer than a recurrence. A solitary lung nodule should always be considered a new primary tumor unless proven to the contrary. Patients with head and neck cancer, particularly those who continue alcohol and tobacco abuse, must be kept under close and competent observation for the rest of their lives, seeking second and subsequent primary cancers.
