Strategies to curb or eliminate tobacco and alcohol use by these patients are crucial. Accumulating evidence suggests that certain vitamin A analogues, called retinoids, may be able to interrupt or reverse premalignant changes. A randomized, placebo-controlled trial suggested that treatment with 13-*cis*-retinoic acid (50 mg per square meter daily) decreased the rate of second primaries, although overall survival was not improved. A confirmatory trial is in progress. Until these results become available, the use of chemopreventive agents remains investigational in the adjuvant setting.

CHAPTER 226: CANCER OF UNKNOWN PRIMARY ORIGIN

JOHN D. HAINSWORTH AND F. ANTHONY GRECO

[Poorly Differentiated Neoplasms](#)
[Adenocarcinoma of Unknown Primary Site](#)
[Squamous Cell Carcinoma of Unknown Primary Site](#)
[Poorly Differentiated Carcinoma of Unknown Primary Site](#)

Metastatic cancer with no obvious primary site accounts for about 5% of all cancers. Until recently, affected patients attracted little attention, because prognosis was believed to be uniformly poor, regardless of treatment. Effective therapy is now available for many types of advanced cancer, and it is not surprising that some carcinomas of unknown primary site are sensitive to chemotherapeutic agents. The clinician must approach each patient with two objectives: to identify treatable neoplasms using clinical and pathologic criteria and to avoid superfluous diagnostic procedures and inappropriate treatment.

The typical patient has symptoms at a metastatic site, but the history, physical examination, chest radiograph, and laboratory studies fail to identify the primary site. Light microscopic study of the biopsy sample usually reveals adenocarcinoma, squamous cell carcinoma, or poorly differentiated carcinoma. Occasionally, the less specific diagnosis of poorly differentiated neoplasm is made; this means the pathologist cannot differentiate carcinoma from lymphoma, sarcoma, and melanoma. These four groups identified by light microscopy differ with respect to clinical characteristics, recommended diagnostic evaluation, treatment, and prognosis.

POORLY DIFFERENTIATED NEOPLASMS

The diagnosis of poorly differentiated neoplasm can describe several neoplasms, many of which are responsive to systemic therapy. Further pathologic evaluation is always necessary and usually results in a more precise diagnosis, often with specific therapeutic implications. The most common cause of a nonspecific pathologic diagnosis is a small, inadequate biopsy. Fine-needle aspiration biopsy is often the initial diagnostic procedure in patients with suspected cancer; however, this biopsy technique is usually inadequate in the evaluation of poorly differentiated neoplasms, because histologic characteristics are poorly preserved and adequate material is not available for special studies. Often, a definitive diagnosis can be made by obtaining a larger biopsy. Close communication between the surgeon and pathologist is important if repeat biopsy is performed.

In some patients, light microscopic examination alone fails to provide a diagnosis more specific than poorly differentiated neoplasm or poorly differentiated carcinoma, even with a large, adequately preserved biopsy specimen. Further evaluation with immunoperoxidase staining is indicated. Immunoperoxidase stains are not specific and should not be used alone to make a diagnosis, but they are frequently useful in conjunction with the light microscopy and clinical features. Staining for leukocyte common antigen provides strong evidence for the diagnosis of lymphoma; other diagnoses that can be suggested by immunoperoxidase staining include melanoma, neuroendocrine carcinoma, and sarcoma. Some neoplasms can only be called carcinomas, and inconclusive results are obtained for about 30% of neoplasms.

Electron microscopy can provide important information in the differential diagnosis of poorly differentiated neoplasms. Because this diagnostic technique is less widely available than immunoperoxidase staining and requires special tissue preparation, electron microscopy is usually reserved for the examination of tumors for which immunoperoxidase staining provides inconclusive results. The detection of specific ultrastructural features makes electron microscopy more specific than immunoperoxidase staining in the diagnosis of neuroendocrine carcinoma (i.e., in identifying neurosecretory granules) and melanoma (i.e., in identifying premelanosomes).

Two specific chromosomal changes associated with solid tumors have been identified and occasionally aid in the diagnosis of neoplasms. A large percentage of germ cell tumors have an isochromosome of the short arm of chromosome 12 (i12p). Peripheral neuroepithelioma and Ewing's tumor share a chromosomal translocation (11:22). Chromosomal analysis should be considered for young men with poorly differentiated mediastinal or retroperitoneal tumors and no specific diagnosis after other pathologic studies.

ADENOCARCINOMA OF UNKNOWN PRIMARY SITE

CLINICAL FEATURES AND NATURAL HISTORY

About 70% of all carcinomas of unknown primary site are adenocarcinomas. Although many patients are elderly and have multiple sites of metastases, the clinical features of this patient group are variable. Common metastatic sites include liver, bones, and lungs.

The clinical course is usually dominated by symptoms related to the sites of metastases. The primary site becomes evident during life in only 15% of patients. Autopsy series performed before the routine use of CT scanning detected primary sites in almost 70% of patients, often in the pancreas, lung, or other gastrointestinal sites. Improved diagnostic methods currently available undoubtedly result in the detection of many of these primary sites at initial evaluation, so the results from previous autopsy series are probably misleading. Adenocarcinomas of the breast and prostate, which are common in the general population, are rarely found in these patients.

PATHOLOGY

The diagnosis of adenocarcinoma is based on the formation of glandular structures and is usually made easily by light microscopy. The morphologic characteristics of the biopsy usually are not specific for the site of origin. Specialized pathologic evaluation rarely is useful. Immunoperoxidase stains for prostate-specific antigen (PSA) or estrogen receptors should be considered when a patient has clinical findings suggesting prostate or breast cancer, respectively.

The diagnosis of poorly differentiated adenocarcinoma should be viewed with caution, because patients may differ in tumor biology and responsiveness to systemic therapy. This diagnosis is often made when only minimal glandular formation is seen by light microscopy or sometimes is based on a positive mucin stain alone in a tumor that would otherwise be called poorly differentiated carcinoma. Additional pathologic study with immunoperoxidase stains or electron microscopy should be considered. Evaluation and treatment should be the same as for patients with poorly differentiated carcinomas.

DIAGNOSTIC EVALUATION

A summary of the recommended evaluation is outlined in [Table 226.1](#). CT scans of the abdomen can identify the primary site in 20% to 35% of patients and should probably be included. Additional evaluation should address findings identified by the history, physical examination, or routine laboratory studies; radiologic or endoscopic evaluation of asymptomatic areas is rarely useful.

Histology	Clinical Evaluation	Special Pathologic Studies	Subsequent Diagnostic Studies	Prognosis
Adenocarcinoma	CT scan of abdomen New primary-specific antigen Additional pathologic studies to exclude distant neoplasms, lymphoproliferative disease, and laboratory studies	New primary-specific antigen Immunoperoxidase stains Immunoperoxidase stains for progesterone receptor	Metastatic workup Metastatic workup Metastatic workup Metastatic workup	Poor for curative intent; 5- to 8-yr survival Better for metastatic relapse
Poorly differentiated carcinoma	CT scan of abdomen Serum tumor markers Additional pathologic studies to exclude distant neoplasms, lymphoproliferative disease, and laboratory studies	Immunoperoxidase staining Receptor studies	Neuroendocrine staining Neuroendocrine tumor marker as indicated Immunoperoxidase, light studies	Variable; some include with distant-based chemotherapy
Squamous cell carcinoma	Direct laryngoscopy with examination of nasopharynx Additional pathologic studies to exclude distant neoplasms, lymphoproliferative disease, and laboratory studies		Metastatic workup Metastatic workup	50-60% Long-term survival with radical surgery or radiation therapy

*In addition to a history, physical examination, blood and urine chemistry, and a chest radiograph, CT, computed tomography.

TABLE 226.1. EVALUATION OF CANCERS OF UNKNOWN PRIMARY SITES

TREATMENT AND PROGNOSIS

Optimal therapy depends on the recognition of certain treatable patient subgroups. Women who have adenocarcinoma involving axillary lymph nodes should be considered as possibly having breast cancer. About 50% of these women have primary tumors found at mastectomy, even when physical examination and mammographic results are normal. Estrogen receptors in the tumor strongly suggest breast cancer. Women who have no evidence of other metastatic sites should be treated by following guidelines for stage II breast cancer and are frequently cured with therapy. Initial treatment should include either a mastectomy or an axillary node dissection plus radiation therapy to the breast. Systemic therapy should be based on estrogen receptor status and the number of nodes involved. Women with metastatic sites in addition to axillary lymph nodes may have metastatic breast cancer; hormonal therapy or chemotherapy often provides palliation.

Some women who have peritoneal involvement with adenocarcinoma can be treated effectively using the guidelines established for ovarian cancer. The histology in these women often suggests ovarian cancer, even when the ovaries are pathologically uninvolved or in cases of previous bilateral oophorectomy. Therapy should include laparotomy with maximal surgical cytoreduction, followed by combination chemotherapy effective against ovarian carcinoma (e.g., paclitaxel plus platinum). Median survival in this group of patients is 18 to 24 months, with 10% to 15% achieving long-term, disease-free survival.

Male patients with blastic bone metastases, elevated serum PSA levels, or tumor staining with PSA should be suspected of having adenocarcinoma of the prostate and should receive a trial of hormonal therapy as used in advanced prostate cancer.

Occasional patients have only a single detectable metastasis after complete evaluation. These single lesions can occur in a wide variety of sites, including bone, lymph nodes, lung, adrenal gland, and brain. Definitive local treatment is recommended, either with surgical resection or radiation therapy, depending on the site of involvement. Such treatment affords substantial palliation, and many patients have significant intervals before further metastases appear.

Most patients with adenocarcinoma of unknown primary site do not fit into any of these clinical subsets. If such patients have good performance status, a trial of empiric chemotherapy should be considered. A recently developed regimen containing paclitaxel, carboplatin, and etoposide produced a 47% response rate and a 13-month median survival in these patients; 20% of patients lived more than 3 years. For patients who are debilitated, symptomatic care remains the most appropriate management.

SQUAMOUS CELL CARCINOMA OF UNKNOWN PRIMARY SITE

Squamous cell carcinoma of unknown primary site is unusual. Because effective treatment is available for some patients, appropriate evaluation is important.

The most common metastatic site is in the cervical lymph nodes. Most patients are middle-aged or elderly and have a history of tobacco use. Patients with involvement in upper or mid-cervical lymph nodes should be suspected of having a primary lesion in the head and neck region. These patients need a thorough examination of the oropharynx, nasopharynx, hypopharynx, larynx, and upper esophagus by direct laryngoscopy, with biopsy of any suspicious areas. Patients with tumor involving the lower cervical or supraclavicular lymph nodes are more likely to have lung cancer and should be evaluated with bronchoscopy if the head and neck examination and chest radiograph are unrevealing.

In patients with no identified primary site, treatment should follow guidelines for regionally metastatic head and neck cancer. Similar treatment results have been obtained with radical neck dissection, high-dose radiation therapy, or a combination. However, approximately 40% of patients treated with radical neck dissection alone eventually develop an obvious primary site in the head and neck region; for this reason, radiation therapy is usually included as part of initial therapy. In patients with high or midcervical adenopathy, 3-year survival rates range from 35% to 60%; patients with smaller adenopathy have a better prognosis. The chance of long-term survival is relatively poor for patients with lower cervical or supraclavicular adenopathy, probably because most have lung cancer. A minority (less than 15%) achieve long-term survival after local treatment to the cervical area, as described previously.

Patients with squamous cell carcinoma involving the inguinal lymph nodes usually have identifiable primary lesions in the genital or anorectal area. Women should undergo careful examination of the vulva, vagina, and cervix, with biopsy of any suspicious areas. Uncircumcised men should have careful inspection of the penis. The anorectal area should also be examined digitally and by anoscope in both sexes, with biopsy of suspicious areas. Therapy for carcinomas of the vulva, vagina, cervix, and anus can be curative in some patients even after spread to regional lymph nodes. When no primary site is identified, long-term survival has been reported after inguinal node dissection.

Patients with metastatic squamous cell carcinoma in other visceral sites almost always have lung cancer. If clinical features suggest the possibility of lung cancer, CT scans of the chest and bronchoscopy are appropriate. As described for patients with adenocarcinoma, the clinician should be suspicious of the diagnosis of poorly differentiated squamous cell carcinoma, particularly if other clinical features are unusual for lung cancer (e.g., young patient, nonsmoker, unusual metastatic site). Additional pathologic evaluation and a trial of therapy as described for patients with poorly differentiated carcinoma should be considered.

POORLY DIFFERENTIATED CARCINOMA OF UNKNOWN PRIMARY SITE

About 20% of carcinomas of unknown primary site have a poorly differentiated histologic pattern. Until recently, patients with this diagnosis were not considered separately from the larger group with adenocarcinoma of unknown primary site. However, a minority of these patients has tumors that are highly sensitive to platinum-based chemotherapy; therefore, a trial of systemic therapy is recommended in all of these patients.

PATHOLOGY

Additional pathologic study is indicated with immunoperoxidase staining and electron microscopy, as described for patients with poorly differentiated neoplasms. These studies can suggest unsuspected diagnoses in up to 25% of these patients, including some malignancies, such as lymphoma, germ cell tumor, and neuroendocrine tumors, for which specific therapy is available.

DIAGNOSTIC EVALUATION

The initial evaluation should be similar to that described for patients with adenocarcinoma of unknown primary site ([Table 226.1](#)). CT scanning of the chest and abdomen should be performed because these tumors frequently involve the mediastinum and retroperitoneum. Measurement of the serum tumor markers, human chorionic gonadotropin and α -fetoprotein, is essential, because markedly elevated levels suggest the diagnosis of a germ cell tumor.

TREATMENT

When specialized pathologic studies result in a specific diagnosis (e.g., lymphoma, melanoma), patients should be treated appropriately. Young men who have clinical features of extragonadal germ cell tumor (location in mediastinum or retroperitoneum; elevated human chorionic gonadotropin or α -fetoprotein) should be treated using the guidelines for poor prognosis germ cell tumors, even if the diagnosis of germ cell tumor cannot be confirmed pathologically.

Another subset of patients with poorly differentiated carcinoma have high-grade neuroendocrine tumors identified by immunoperoxidase staining or electron microscopy or both. Although the nature of these tumors is unclear, the response rate to platinum-based chemotherapy is approximately 75%, and a minority of patients (10% to 15%) have long-term survival. Paclitaxel-containing regimens may further improve treatment results and are under active investigation.

Most patients with poorly differentiated carcinoma of unknown primary site do not have a more specific diagnosis made after complete pathologic evaluation. An empiric trial of platinum/etoposide-based chemotherapy should be given to all patients in this group except those who are very debilitated. Those who will benefit from chemotherapy can be identified after a brief trial (3 to 6 weeks). Clinical features predicting chemotherapy responsiveness include location of tumor in the mediastinum, retroperitoneum, or lymph nodes (instead of other visceral sites); tumor limited to one or two metastatic sites; no previous cigarette use; and younger

age.

CHAPTER 227: ACUTE LEUKEMIAS

PETER H. WIERNIK

[Incidence and Epidemiology](#)
[Etiology](#)
[Pathogenesis and Pathophysiology](#)
[Clinical Findings](#)
[Laboratory Findings](#)
[Optimal Management](#)

Acute leukemias result from the uncontrolled proliferation of a malignant clone of hematopoietic cells. The abnormal clone has survival advantages over normal progenitor cells and becomes dominant. Dominance is achieved because the malignant clone responds poorly or not at all to regulatory factors that control normal hematopoietic cell growth. The abnormal clone does not differentiate and mature normally and may suppress the growth and differentiation of normal hematopoietic cells. The result is an expanding clone of functionless cells together with a progressive decrease in the number of normal blood cells. Anemia, thrombocytopenia, and granulocytopenia, rather than abnormal cell production, cause most of the serious problems that beset the patient.

Acute lymphocytic leukemia (ALL) is characterized by the presence of an abnormal clone of cells with morphologic, biochemical, and immunologic characteristics of lymphoid cells. The term *acute myeloid leukemia* (AML) is used for all other types of acute leukemia. Subgroups of AML are defined by morphologic and other characteristics of the abnormal cells that predominate in the blood and marrow, and terms such as erythroleukemia or acute myelocytic, promyelocytic, monocytic, myelomonocytic, and megakaryocytic leukemia more precisely characterize AML in a given patient.

INCIDENCE AND EPIDEMIOLOGY

About 10,000 new cases of acute leukemia are diagnosed in the United States each year, and the rates have remained constant during the past 25 years. Of all neoplastic diseases, acute leukemia is associated with the least variation in incidence worldwide. Acute leukemias are more common in male adults and children than female adults and children, and in the United States, they are more common in whites than blacks. Acute leukemia is especially more common in elderly whites than in elderly blacks and is more common in Jews than in non-Jews. The unifying factor may be socioeconomic rather than genetics, because acute leukemia is more common in higher socioeconomic groups. There is an increased incidence of acute leukemia among patients with diseases associated with chromosomal nondisjunction, such as Down's syndrome, or increased chromosomal fragility, such as Bloom's syndrome and Fanconi's anemia. Although spatial, time, and familial clusters of acute leukemia are occasionally observed, no incontrovertible evidence exists that human acute leukemia is a transmissible disease.

Only about 25% of patients with ALL are older than 15 years. The incidence of the disease is roughly equal in all decades of adult life, and the median age of patients with the adult disease is about 42 years. Most adults respond well to initial therapy, but unlike children with ALL, most ultimately die of the disease. Although the initial treatment results for adult ALL may be better than those for adult AML, the long-term results are not and may actually be worse.

The average patient with AML is older than 55 years at diagnosis. Most AML patients are adults, and the incidence of AML increases steadily in successive decades of life. Most patients ultimately die of leukemia, but an increasing percentage—perhaps 30% to 40% or more—is apparently cured with current therapy. The likelihood of cure is greater for younger patients.

ETIOLOGY

The cause of human acute leukemia is obscure, but certain facts are known. Ionizing radiation is leukemogenic in humans, and radiation dose is directly correlated with the incidence of AML. Chemicals, including certain drugs that may cause bone marrow hypoplasia, are also associated with an appreciable incidence of AML. Most notable among such agents are benzene, chloramphenicol, and phenylbutazone.

Some cancer chemotherapeutic agents, especially alkylating agents and topoisomerase II inhibitors, are associated with an increased incidence of AML in surviving cancer patients. The incidence of secondary AML in such patients may be as high as 2% to 3% and is highest in patients who were treated with alkylating agents and radiation therapy, especially when such treatments were given sequentially for recurrent cancer. In some diseases, such as multiple myeloma, the incidence of secondary AML is higher in patients treated continuously with alkylating agents than in those treated with the same total dose of drug using an intermittent high-dose schedule. However, patients with chronic lymphocytic leukemia may receive alkylating agents for many years without an increased incidence of acute leukemia. The implication of this observation is that interaction of alkylating agents with another unknown (possibly genetic) factor may be leukemogenic, but either factor alone may not be. Alternatively, the agent responsible for the underlying neoplasm may also be important in the cause of what is recognized as secondary leukemia, and secondary leukemia may be a late manifestation of the primary disease experienced by some long-term survivors.

Certain viruses are known to be leukemogenic in rodents, birds, cats, and other species, and a specific RNA tumor virus (i.e., human T-cell lymphotropic virus type I [HTLV-I]) is the causative agent of the adult T-cell leukemia-lymphoma syndrome, a rare form of leukemia endemic in certain areas of Japan and the Caribbean and seen in immigrants from those areas in the United States as well.

Oncogenes are genes found in normal human cells that are homologues of viral genes that are leukemogenic or carcinogenic in certain animals. They may provide a link between putative leukemogenic agents such as ionizing radiation and chemicals. Oncogenes may play a role in the regulation of normal cellular growth and differentiation. Oncogenes can be activated by a chromosomal translocation that physically separates a given gene from the promoter–enhancer region that normally controls it. By this mechanism, an oncogene is moved to a location on another chromosome, where it comes under the influence of a promoter–enhancer region normally associated with a transcriptionally active gene, and the second gene is removed to another location by the same event. Such translocations may be of great significance in human leukemogenesis. In such cases, increased oncogene product results from increased transcriptional activity, and the total amount of oncogene DNA remains normal. This situation has been demonstrated in Burkitt's lymphoma-leukemia in which it is associated with increased *MYC* gene transcriptional activity and product.

PATHOGENESIS AND PATHOPHYSIOLOGY

The leukemic cell has a relatively normal generation time of 15 to 16 hours and a low growth rate of about 5%. Normal blood cell precursors undergo a series of sequential developmental events that ultimately yield a differentiated, specialized cell that circulates and eventually dies. The capacity for cell division is lost in the process of differentiation. Leukemic cells do not have the capacity to differentiate completely. Although most leukemic cells are in the G₀ phase of the cell cycle at any one time, they retain the capacity for cell division and may be induced to divide by a variety of events at random. The result is an expanding mass of immature immortal cells. Leukemic cells are randomly introduced into the blood from the bone marrow. They may divide in the blood or infiltrate an organ such as the spleen, liver, or lymph nodes, in which they may also divide and then reenter the blood.

The marrow precursor of normal circulating blood cells is a pluripotent, self-generating stem cell that forms progenitor cells irreversibly committed to a certain hematopoietic cell lineage. It is unclear whether these cells become committed to restricted differentiation pathways by an intrinsically determined mechanism or by the influence of microenvironmental factors. The commitment of their progeny to mature along one of the various hematopoietic lineages depends on the expression of receptors for certain factors that regulate cell proliferation, maturation, and mortality.

Starting at band 5q22-35 and extending to the terminus of human chromosome 5, the genes for granulocyte-macrophage colony-stimulating factor (GM-CSF), multi-CSF, β_2 -adrenergic receptor, platelet-derived growth factor receptor, endothelial cell growth factor, macrophage colony-stimulating factor (CSF1) and its receptor (encoded by the *CSF1R* gene, formerly designated *FMS*), interleukin-3, -4, and -5 are sequentially located. Deletions often involve this region of the long arm of chromosome 5 in AML, which may result in homozygosity for the *CSF1R* locus, truncation of the GM-CSF gene (*CSF2*), or deletion of the gene for *CSF1*. Whether loss or mutation of any of these genes important for normal hematopoiesis is a crucial event in leukemogenesis is still unclear.

The genes encoding the α and δ chains of the human T-cell receptor have been localized to the long arm of chromosome 14, near the breakpoint for t(11;14), a

pattern found in 25% of children with T-cell ALL. Those loci may participate in oncogene activation in some T-cell neoplasms.

Adult T-cell leukemia-lymphoma syndrome associated with HTLV-I may rely on a different mechanism. The viral genome encodes a protein that stimulates viral replication and mediates cellular transformation. This protein may activate cellular genes capable of immortalizing and transforming T cells. It is unknown whether such transformation is limited to the spectrum of T-cell diseases associated with the HTLV group or whether it has greater significance.

CLINICAL FINDINGS

ACUTE LYMPHOCYTIC LEUKEMIA

Adults with ALL usually present with subacute onset of nonspecific signs and symptoms, such as fatigue, lethargy, malaise, anorexia, pallor, and occasionally weight loss. Symptoms of anemia may be dominant. Evidence of thrombocytopenia, such as petechiae, easy bruising, prolonged or heavy menstruation, or other bleeding may cause the patient to seek medical attention. Young adults may have bone pain or arthralgias as evidence of an expanding bone marrow mass. Most patients have palpable lymphadenopathy, especially cervical, and the spleen is palpable in 50% of patients, but the liver is infrequently palpable. An abdominal radiograph may reveal kidneys enlarged by leukemic infiltration.

Signs of increased intracranial pressure or cranial nerve dysfunction secondary to leukemic infiltration of the central nervous system (CNS) may be evident at diagnosis, although such findings are more common in childhood ALL. The long cranial nerves (VI and VII) are the most frequently infiltrated with leukemic cells. Funduscopic evidence of increased intracranial pressure or leukemic infiltration of the retina appearing as Roth-like spots, both of which may be silent clinically, may be found.

About 15% of patients present with fever due to infection, which may be occult. Classic signs may be absent on the chest radiograph of a patient with pneumonia, and fluctuance and inflammation may be minimal at the site of a soft-tissue infection because of severe granulocytopenia.

The diagnosis of ALL can be made by examining the peripheral blood in most cases. In about 15% of adult patients, peripheral blood studies reveal serious abnormalities but no characteristic lymphoblasts necessary for the diagnosis. Bone marrow examination establishes the diagnosis. Bone marrow examination is necessary in all patients to assess marrow cellularity, the status of normal blood cell production, cytogenetic abnormalities, immunophenotype, and histochemical reactions to classify the leukemia properly and to obtain important prognostic information.

Anemia, granulocytopenia, and thrombocytopenia are almost always present at the time of diagnosis of ALL. Anemia is usually moderate, and granulocytopenia is often severe but rarely absolute. The platelet count is usually less than 100,000 per microliter and frequently less than 40,000 per microliter. Patients rarely sustain serious hemorrhage if the platelet count is more than 20,000 per microliter or maintained above that level with transfusion. The white blood cell (WBC) count is normal or elevated in more than 90% of patients and reduced in the rest. The WBC count usually is between 10,000 and 30,000 cells per microliter at diagnosis, but extreme hyperleukocytosis (more than 100,000 cells per microliter) occasionally occurs. The peripheral blood smear is consistent with the blood counts. For 85% of patients, examination of the blood smear reveals characteristic lymphoblasts, usually in large numbers. They usually have small nucleoli and agranular cytoplasm. Unlike typical lymphoblasts of childhood ALL, these cells have more than a scant rim of cytoplasm, and morphologic variation from cell to cell is much greater in adults.

The bone marrow biopsy specimen is almost always hypercellular. Lymphoblasts predominate, and normal hematopoietic elements are reduced in number. The normal marrow fat spaces are partially or completely obliterated by the leukemic infiltrate.

It is especially important to examine the cerebrospinal fluid (CSF) in patients with ALL, but only after successful platelet transfusion if the patient is thrombocytopenic. This procedure is done to determine whether CNS leukemia is present, which may occur without signs or symptoms. Meningeal leukemic infiltration is usually associated with CSF pleocytosis, which is readily detected by examining the fluid with methods that concentrate cells on a glass slide or millipore filter. The diagnosis of CNS leukemia is important because most antileukemic agents are denied access to the leukemic cells by the blood-brain barrier.

Two mechanisms have been suggested for meningeal infiltration. One is that leukemic cells are deposited in the pia-arachnoid by petechial hemorrhage. This is supported by the inverse relation between the incidence of meningeal leukemia and the blood platelet count. Another postulation after study of an experimental mouse model suggests that an expanding skull bone marrow mass causes leukemic infiltration of the dura and eventual infiltration of the adventitia of vessels that traverse the potential space between the dura and the pia-arachnoid. Recently, differentiation of human neural stem cells into early hematopoietic cells has been demonstrated. This fact and the fact that tissues lining the third ventricle in certain lower species function as a hematopoietic organ suggest that CNS leukemia may arise in situ under some circumstances.

Lumbar puncture in a patient with meningeal leukemia reveals a normal or elevated opening pressure. The CSF is usually clear and colorless and has a normal glucose concentration, but the protein concentration is usually elevated. The cell count by routine methods is normal or high. When normal, leukemic cells are demonstrable in more than 50% of patients with meningeal leukemia by cell-concentrating techniques. When cranial nerves alone are infiltrated with leukemic cells, the CSF is devoid of leukemic cells. However, the CSF protein concentration is almost always elevated, and the b2-microglobulin concentration may be elevated, as in overt meningeal leukemia. Determination of the latter may provide a sensitive and relatively specific indicator of meningeal leukemia in the absence of other suggestive CSF findings.

Independent factors in ALL patients that negatively influence the likelihood of a complete response to therapy are advanced age and mature B-cell immunophenotype. Factors that shorten response duration and survival are a hyperleukocytosis at diagnosis, a complex abnormal karyotype, and CNS leukemia at diagnosis or shortly thereafter.

ACUTE MYELOID LEUKEMIA

Adults with AML usually present with a vague history of chronic, progressive lethargy. However, as many as one third may present acutely ill with significant infection, usually of the respiratory tract, with or without septicemia. The patients usually have petechiae. More serious bleeding such as ecchymoses or orificial hemorrhage secondary to a combination of clotting factor deficiency and fibrinogenolysis may be evident in some patients, especially those with the *acute promyelocytic (APL) subtype of AML*.

Lymphadenopathy is unusual, splenomegaly is found in less than 20% of patients with de novo AML, and hepatomegaly is even less common. Gingival hypertrophy from leukemic infiltration occurs in about 50% of patients with the acute myelomonocytic or monocytic variants. Patients with these subtypes are more likely to have extramedullary leukemic infiltrations of all sorts and are the AML patients most likely to present with or subsequently develop meningeal leukemia, retinal infiltrates, and leukemia cutis.

Granulocytic sarcomas are tumors of leukemic cells that may be palpable, especially around the ribs or orbits, to which they are usually firmly attached. They have rarely been observed in organs such as the dura, ovary, and small intestine. Granulocytic sarcomas may appear before other diagnostic evidence of AML, soon after diagnosis, or as the first evidence of relapse. When biopsied, the lesions often have a dull green color, which fades rapidly on exposure to air because of the high peroxidase content of the leukemic cells. In some studies, granulocytic sarcomas, especially paraspinal tumors, were more common in patients with the t(8;21) cytogenetic translocation.

WBC count is normal, elevated, or depressed with equal frequencies at diagnosis of AML. Leukopenia is somewhat more common in AML than in ALL patients, and among the AML subtypes, it is most common in acute promyelocytic leukemia (APL), a subtype that accounts for approximately 10% of AML patients. Roughly 5% of patients with AML present with a WBC count of more than 100,000 cells per microliter. The rare patient who presents with extreme hyperleukocytosis (>200,000 cells per microliter) has a substantial risk of dying of sudden intracerebral hemorrhage. Unlike mature cells, myeloid blast cells have great intrinsic viscosity, and in such numbers, they cause sludging at the low-pressure venous side of the capillary bed. As the cell mass enlarges, the capillary may rupture. If this happens in the brain, sudden death may occur.

Blast cells are initially absent from the peripheral blood in about 15% of patients with AML. Such patients require bone marrow examination to make the correct diagnosis. Granulocytopenia is essentially universal in patients with AML, and 50% of patients have a serious risk of infection because of severe granulocytopenia of 500 cells per microliter or less. The platelet count is usually lower than in ALL, and platelet counts of less than 20,000 per microliter are common. Electronic platelet

counts may be falsely elevated in acute monocytic leukemia, because cytoplasmic fragments the size of platelets are frequently broken off of monoblasts and may be counted as platelets. Phase-contrast microscopy is necessary to estimate the true platelet count in these patients. The hematocrit is almost always low in AML, but severe anemia is uncommon.

The bone marrow is usually markedly hypercellular but may be hypocellular in secondary AML that developed after treatment for another neoplastic disease. It may also be hypocellular in elderly patients, especially those with an antecedent preleukemic phase. At least 50% to 75% of the marrow nucleated elements are leukemic cells in the typical patient with AML. Megakaryocytes are reduced in number, as are red blood cell precursors in most patients. However, some patients with acute myelomonocytic leukemia have a relative increase in red cell precursors involved in ineffective erythropoiesis. There is little evidence of maturation in marrow granulocytes in most patients. In addition to a routine morphologic examination, the special studies required by patients with ALL are also required for those with AML.

Patients with end-stage acute leukemia may rarely manifest special problems caused by leukemic infiltration of various organs. Heart conduction defects and pericarditis have been reported, and an acute asthma-like syndrome resulting from pulmonary capillary plugging by leukemic cells occasionally occurs.

Patients with secondary acute leukemia, which is almost always myeloid, may be difficult to diagnose accurately. Such patients are often severely pancytopenic and may have only an occasional blast cell in the peripheral blood smear. The marrow may be hypocellular and relatively devoid of frank blast cells. The predominant marrow cell may be a dysmyelopoietic promyelocyte or myelocyte with megaloblastoid features. An increased number of sideroblasts, including ringed sideroblasts, may be observed in the marrow. It may be difficult to differentiate secondary leukemia from refractory anemia with excess blasts or from other myelodysplastic or myeloproliferative disorders. Cytogenetic studies may be helpful in such cases.

Other hematologic disorders may mimic acute leukemia. Severe folate deficiency may be misdiagnosed as acute leukemia. Such patients are severely pancytopenic and have an extremely hypocellular bone marrow with many bizarre blastlike cells. The patient almost always gives a history of more than one cause of folate deficiency, such as alcoholism and pregnancy. Red cell folate levels are usually extremely low, if measurable at all, which is never the case in uncomplicated acute leukemia. Idiopathic or drug-induced aplastic anemia may superficially mimic acute leukemia, because pancytopenia can be a feature of both. Adults with aplastic anemia rarely have organomegaly or blasts in the marrow or blood. Acute leukemia may be preceded by aplastic anemia, however, and increasing marrow cellularity with a predominance of immature forms may be a harbinger of that transition rather than marrow recovery.

Patients with disseminated tuberculosis may present with a leukemoid reaction characterized by infiltration of the blood and marrow with cells indistinguishable from those of AML. Patients with blasts containing Auer rods have been reported whose hematologic disorder resolved with antituberculous therapy alone.

LABORATORY FINDINGS

Morphology, histochemical reactions, cytogenetics, enzymology, and cell surface antigen identification are the principal laboratory tools used to differentiate ALL from AML and to identify clinically important subtypes of both.

Serum lactate dehydrogenase levels are usually elevated in patients with ALL because of intramedullary destruction of lymphoid cells. The serum uric acid concentration is often elevated in ALL and AML patients, and renal tubular urate deposition may cause renal failure, especially in those with ALL. The serum and urinary lysozyme (muramidase) concentration is usually markedly elevated in acute myelomonocytic or monocytic leukemia. Excretion of lysozyme may cause renal tubular damage, resulting in hypokalemia. Patients with APL may have decreased plasma fibrinogen concentrations and increased serum fibrin degradation products. In such cases, factor-dependent coagulation tests give abnormal results.

Leukemic cell morphology is usually examined with Wright's stain or a similar stain of a peripheral blood and bone marrow aspirate smear. The blast cells of AML are generally larger and have more cytoplasm than those of ALL. Also, greater variation in the size and shape of blasts and of their nuclei and nucleoli is seen in AML than in ALL, but adults with ALL usually have more cell-to-cell variation in morphology than do children. Most patients with AML have some cytoplasmic granularity in most blast cells, but ALL blast cells are agranular. Cytoplasmic granules (lysosomes) in about 10% of patients with AML may appear as large, elongated, pink or red structures (Auer rods), especially in patients with t(8;21). Occasionally, cytoplasmic granules may be too small to be observed by light microscopy, even with specific histochemical stains, but they are detectable by electron microscopy or by a monoclonal antibody to myeloperoxidase. Lymphoblasts have negative reactions to histochemical stains that identify the granules of myeloid cells but frequently have a strong reaction to periodic acid–Schiff (PAS) reagent. The blasts of some patients with AML may also be PAS-positive because of fine, punctate cytoplasmic staining rather than the chunky cytoplasmic positivity of ALL.

The study of leukemic cell surface antigens with monoclonal antibodies results in more precise definition of the lineage from which a given leukemic cell population is derived. Many antibodies are available, and those with reactivity against the same antigen are given a common cluster of differentiation (CD) designation. More than 160 clusters have been created, based on antibody specificity determined at several international workshops.

Most patients with ALL have terminal transferase (TdT) activity in the blast cell nucleus, which may be detected immunologically. Usually, 90% or more of blasts are TdT⁺. In adult ALL patients, B-lineage leukemias are more common than those of T lineage. Among B-lineage ALL patients, the CALLA⁺, CD10⁺ early pre-B subtype is the most common one. Philadelphia chromosome–positive ALL is characterized by CD10 and CD34 expression. TdT⁺ blast cells are found in 5% to 50% of patients with AML. Often, no other lymphoid antigens are found in such cases. T-cell antigens, especially CD7, are more commonly expressed on leukemic myeloblasts than are B-cell antigens. Myeloid antigens can be detected on the surface of leukemic lymphoblasts in 50% to 80% of cases. However, intracytoplasmic antigens, such as intracytoplasmic CD3, intracytoplasmic CD22, and myeloperoxidase may be considered lineage-specific for T-ALL, B-ALL and myeloid leukemia, respectively, in such cases.

Cytogenetic studies yield important information about classification and prognosis in acute leukemia. Aneuploidy resulting from the addition or deletion of specific chromosomes, or part of them, affects prognosis positively (e.g., trisomy 21 in patients without Down's syndrome) or negatively (e.g., -5, -7), depending on the chromosome involved. Balanced translocations usually involving two chromosomes are often associated with significant disease characteristics. Specific karyotypic abnormalities are identified in 80% or more of acute leukemia patients, more frequently in AML than in ALL. ALL chromosomes frequently appear fuzzy, with indistinct delineation of bands, and they are usually shorter than those of AML. This makes the observation of subtle translocations difficult in ALL. Cytogenetic analyses are best performed on bone marrow cells, because mitoses are more frequently found in them than in blood blasts. Specimens for immunophenotyping and cytogenetic analysis must be collected in heparin, acid citrate dextrose, or EDTA (ethylenediaminetetraacetic acid).

Cytogenetic information is not usually available when initial treatment decisions are made because of limitations of current technology. Such information is used primarily to define prognosis rather than to dictate initial therapy. However, cytogenetic information may be helpful in formulating postremission therapy for patients with AML. Some new molecular techniques can provide results rapidly and may be useful in diagnosis and treatment planning in some cases. For instance, the PML-RAR α fusion transcript, pathognomonic of APL, can be detected by such techniques within 24 hours. Therefore, patients suspected of having APL can be identified by the detection of that transcript long before the classic t(15;17) is revealed by standard cytogenetic studies. This is important, because relatively specific therapy has been developed for APL, as discussed in a subsequent section.

SUBTYPES OF ACUTE LYMPHOCYTIC LEUKEMIA

The French–American–British (FAB) morphologic classification system is used to define subtypes of acute leukemia. Three subtypes of ALL have been designated: L1, L2, and L3. Features of these subtypes are detailed in [Table 227.1](#). At least 80% of children with ALL have the L1 subtype, and the L2 subtype is at least twice as common as L1 in adults. The rare L3 subtype, identical with the cells of Burkitt's lymphoma, occurs equally as frequently in ALL patients of all ages and accounts for less than 2% to 3% of all ALL.

FAB Type	Morphology	Histochemistry	Cytogenetics
L1	Small blasts with scant cytoplasm, little variation, round nuclei with single, small nucleoli	NS, PDC, acid phosphatase (lysozyme) F-actin AL	t(1;19) t(12;22) Tq(1) Tq(1)
L2	Larger cells with more abundant cytoplasm, variation from cell to cell, irregularly shaped nuclei, often with multiple nucleoli	Same as L1	t(12;22) Tq(1)
L3	Large cells with basophilic cytoplasm that may be vacuolated, fine chromatin in a round nucleus, multiple nucleoli, often basophilic	NS, PDC, vacuole usually of red cytoplasm	t(14)

ALL, acute lymphocytic leukemia; NS, periodic acid-Schiff reaction; PDC, peroxidase; AL, acid phosphatase; Tq, terminal transferase.

TABLE 227.1. FAB CLASSIFICATION OF ACUTE LYMPHOCYTIC LEUKEMIA

The L1 and L2 subtypes in children other than infants are usually CD10⁺ and other early B antigen-positive, as well as TdT⁺. In infants, there is a preponderance of undifferentiated ALL or pre-pre-B (CD10⁻, TdT⁺) ALL. In adults, CD10⁺, or early pre-B ALL is the major immunophenotypic subtype. A minority of children and adults with L1 or L2 morphology have pre-B ALL, which has intracytoplasmic μ heavy immunoglobulin chains and is CD10⁺. A small number of patients have immature (TdT⁺, early T antigen⁺) or mature T-lineage ALL (TdT⁻). The L3 subtype almost always consists of relatively mature B cells (CD10^{+/} and TdT⁻) with surface immunoglobulins, usually IgM. Except for mature B-ALL, there appears to be little prognostic significance of B-lineage ALL subtypes. T-lineage ALL seems to have a better prognosis than B-lineage ALL in some studies. ALL surface immunologic features are detailed in [Table 227.2](#).

Immunologic Type ^a	TdT	CD10	HLA-DR	Other
Undifferentiated ALL	-	-	-	None
Pre-pre-B ALL	-	-	-	Cytoplasmic CD22, CD19
Early pre-B ALL	-	+	+	None
Pre-B ALL	-	+	+	Cytoplasmic μ , CD20
B-cell ALL	-	+	+	Surface immunoglobulins
Prothymocyte ALL	-	-	+	Cytoplasmic CD3, CD7
Early thymocyte ALL	+	-	-	CD2, CD5
Common thymocyte ALL	+	-	-	CD1, CD4, CD8
Mature thymocyte ALL	+	-	-	CD4 or CD8, membrane CD3
T-cell ALL	-	-	-	Surface T-cell receptor proteins

ALL, acute lymphocytic leukemia; TdT, terminal deoxynucleotidyl transferase.
^a These immunologic types of ALL are independent of FAB morphologic types, except for B-cell ALL, which is almost always FAB type L3. In adults, ALL is most commonly FAB type L2 and immunologically more often positive for CD10 than negative. Ph-dromosome-positive adult ALL is always CD10 positive.

TABLE 227.2. IMMUNOLOGIC CHARACTERISTICS OF ACUTE LYMPHOCYTIC LEUKEMIA

The Philadelphia chromosome is found in approximately 15% of adult patients with ALL. These patients usually have L1 or L2 morphology and CD10⁺, CD34⁺, and TdT⁺ blasts. This finding raises the question whether de novo ALL or lymphoid blast crisis of chronic myelocytic leukemia is the correct diagnosis. Molecular studies can be helpful, because the breakpoints that result in t(9;22), recognized cytogenetically as the Philadelphia chromosome, are usually but not always different in the two leukemias. Translocations between chromosome 8 and 2, 14, or 22 are common in B-cell ALL and involve genes encoding immunoglobulin heavy chains (chromosome 14) and light chains (chromosomes 2 and 22). Translocations involving chromosome 14 also occur in T-cell ALL at a chromosomal breakpoint different from that found in B-lymphoid malignancies and involve the T-cell receptor α - or δ -chain locus.

SUBTYPES OF ACUTE MYELOID LEUKEMIA

The FAB system describes nine subtypes of AML, characteristics of which are given in [Table 227.3](#). FAB types M1, M2, and M4 each account for approximately 20% of adult AML patients. Subtypes M2, M3, and M4 generally have the best prognoses for complete remission, remission duration, and survival. FAB subtypes M5A and M6 have variable prognoses, and patients with the rare M0 and M7 subtypes have a dismal prognosis. The leukemic cells in subtypes M0, M1, and M2 express early myeloid antigens on the surface and are positive for a major histocompatibility complex class II antigen, HLA-DR (HLA-DR⁺), and often for the hematopoietic precursor antigen CD34. FAB subtype M3 expresses most of the myeloid antigens expressed by subtypes M0 through M2, but it is HLA-DR⁻ and CD34⁻. FAB subtypes M4 and M5 express antigens specific for monocytoid cells. Myeloid antigens found in M0 through M3 may also be found in M4. M6 expresses glycophorin A, blood group H antigen, or both. Antibodies to specific megakaryocytic antigens allow identification of subtype M7, which cannot be identified by morphology alone.

TABLE 227.3. FAB CLASSIFICATION OF ACUTE MYELOID LEUKEMIA

Cytogenetic abnormalities correlate with FAB subtype, immunophenotype, or both. For instance, t(15;17) is pathognomonic of APL, or FAB M3. The translocation t(8;21), which occurs primarily in FAB subtype M2, and inversion (inv)16, which occurs primarily in FAB subtype M4E, confer a good prognosis. Patients with secondary acute leukemia often have a loss of all or part of chromosome 5, chromosome 7, or both, or they have a translocation involving 11q23. In other cases, very complex cytogenetic abnormalities involving many chromosomes may be found. All these cytogenetic abnormalities confer a poor prognosis for response to therapy and response duration in secondary acute leukemia.

OPTIMAL MANAGEMENT

ACUTE LYMPHOCYTIC LEUKEMIA

Therapy for acute leukemia should be offered only in a facility with adequate supportive care resources and conducted only by an experienced team of physicians, nurses, and other health care professionals. The difference between success and failure often is experience and adequacy of supportive care rather than leukemic cell drug resistance.

Before instituting chemotherapy, active infection must be brought under control with intravenous antibiotics, and hyperuricemia must be resolved with hydration and administration of allopurinol. The latter should be given at least 24 hours before starting chemotherapy, even if the serum uric acid level is normal and continued until

the blood WBC count is in the low-normal range. Other presenting medical problems should be addressed and resolved, if possible, before antileukemic therapy is given.

Standard induction therapy regimens for adult ALL include drugs such as vincristine, prednisone, daunorubicin, and L-asparaginase. Vincristine (2 mg) is given intravenously weekly, and oral prednisone (60 mg per square meter per day) is given for 4 weeks. Daunorubicin (45 mg per square meter per day) is given intravenously daily for the first 3 days of treatment, and L-asparaginase (6000 U per square meter per day) is given intramuscularly daily on days 17 to 28 of this 4-week program. A complete response rate of at least 75% can be expected in unselected adults with ALL so treated, and good-risk patients, such as those younger than 50 years who do not have the Philadelphia chromosome or a B-cell ALL phenotype have an 85% or greater complete response rate.

Daunorubicin is myelosuppressive, and treatment with it results in profound marrow hypoplasia and severe pancytopenia for 2 to 3 weeks or longer. During that time, the patient has a significant risk of infection and hemorrhage. Empiric broad-spectrum antibiotic therapy is required for fever with granulocytopenia (less than 500 granulocytes per liter) in at least 75% of treatment courses, and prophylactic platelet transfusion is almost always required for severe thrombocytopenia (less than 20,000 platelets per liter). Daunorubicin is relatively contraindicated in patients with underlying heart disease because it is cardiotoxic. Cardiotoxicity is manifested clinically in only about 1% of patients with normal pretreatment cardiac function who receive a cumulative total dose of 450 mg per square meter or less of daunorubicin. Nevertheless, the drug can be dangerous in patients with an impaired cardiac ejection fraction, especially if cardiomyopathy is the underlying cause. In such patients and certain others, moderately large doses of intravenous methotrexate may be substituted for daunorubicin in the regimen described previously, without significant change in overall results.

After the patient has achieved complete remission and recovered from induction therapy, some form of intensive postremission therapy is necessary to maximize the duration of response. If no such therapy is given, relapse occurs in at least 95% of patients within months. Usually, drugs not used during induction therapy are used here, with or without allogeneic or autologous bone marrow transplantation. There is no consensus on the best therapy for ALL, but randomized, prospective trials are addressing this question. The purpose of this phase of treatment is to kill subclinical leukemia, which, if not eradicated, will almost certainly lead to recurrent and relatively resistant disease. If chemotherapy alone is used during this phase it is usually delivered repetitively over many months and is often followed by less intensive therapy given for years. Intensive chemotherapy followed by bone marrow transplantation is fraught with greater toxicity, but the treatment requires less time than chemotherapy alone.

Complete responders to treatment for ALL have a 25% to 40% chance of developing CNS leukemia during remission. This complication is more common in patients who present with leukocytosis, have L3 morphology, or T-cell ALL. Incidence of CNS leukemia is also inversely related to age at diagnosis. Prophylactic CNS leukemia therapy greatly reduces its incidence. The standard approach is to give cranial irradiation and multiple intrathecal methotrexate (12 mg per dose) injections as soon as complete hematologic remission is documented. This reduces the incidence of CNS leukemia to 5% or less among patients who remain in long-term complete remission. Cytarabine is sometimes substituted for methotrexate for intrathecal therapy, but there is a greater chance of adhesive arachnoiditis (perhaps 1%) with it.

The median duration of complete remission in adult ALL treated as outlined is approximately 1 to 2 years. Approximately 30% to 40% of patients are 5-year disease-free survivors, and most appear to be cured. Long-term results are best in patients younger than 40 years. Although late relapses do occur, they are infrequent, and most relapses occur within 3 years of obtaining complete remissions.

Patients who relapse generally achieve a second complete remission, especially if the relapse occurs more than 1 year after complete remission was diagnosed initially. Virtually no relapsed patient is subsequently cured, except for some younger patients who have successfully undergone allogeneic marrow transplantation for early relapse or while in second complete remission. About 25% to 40% of such patients have second remissions substantially longer than the first, which is uncommon when second remission is achieved without transplantation.

Relapse may first occur in the CNS and may be manifested by signs and symptoms of increased intracranial pressure. Lumbar puncture typically discloses increased opening pressure, CSF pleocytosis, increased CSF protein concentration, and normal glucose concentration. Examination of a concentrated CSF specimen shows blast cells, which in most cases are TdT⁺. Intrathecal methotrexate given every 3 days usually results in complete resolution of this complication after treatment for 1 to 2 weeks. The treatment must be given monthly thereafter to maintain a leukemia-free CSF for as long as possible. An intraventricular reservoir (Ommaya) placed under the scalp may be used to avoid repeated lumbar puncture. If CNS relapse has occurred within 1 year of the initial diagnosis of ALL, bone marrow relapse is likely. Isolated late CNS relapse may occur, however, and not influence the patient's chance for cure.

ADULT ACUTE MYELOID LEUKEMIA

Remission induction therapy for adult AML usually consists of only two drugs, cytarabine and daunorubicin or idarubicin. Idarubicin, an analogue of daunorubicin, was found in three prospective, randomized studies to be a more effective remission induction agent in treating adult AML. Idarubicin is given as an intravenous bolus injection of 12 mg per square meter per day for 3 consecutive days. Cytarabine is given as a continuous intravenous infusion for 7 days at the rate of 100 mg per square meter per day. Both drugs are started on the same day. The treatment leads to severe bone marrow hypoplasia and pancytopenia, from which the patient does not recover for 3 to 4 weeks after treatment. There is considerable risk of infection and hemorrhage after treatment, and almost all patients require prophylactic platelet transfusions periodically, and at least 90% of patients require empiric broad-spectrum antibiotic therapy for fever while they are granulocytopenic.

Complete remission is achieved in 70% or more of adults with this regimen, and about 90% of patients who completely respond do so after only one treatment course. Some complete responders require an additional treatment course, as evidenced by only partial improvement in the marrow after the first treatment. It is imperative in those patients to document that complete remission has not been achieved with two bone marrow examinations performed with an intervening interval of several days or more before embarking on a second course of therapy. The platelet count usually rises steadily once normal marrow regeneration has begun and may reach 100,000 per microliter or more before granulocytes reappear in the blood. It is tempting to deliver a second course of induction therapy to a patient whose platelet count has risen to that level or higher when the granulocyte count remains low. In such cases, a bone marrow examination usually demonstrates a cellular marrow without a significant number of leukemic cells. Time alone usually demonstrates that no further treatment is necessary. Occasionally, these patients may more quickly achieve normal blood and marrow parameters with the administration of folate or with the withdrawal of other myelosuppressive drugs such as amphotericin B and allopurinol.

Some patients, especially some with APL, achieve complete remission after treatment without enduring major marrow hypoplasia. Leukemic cell differentiation and maturation may have been induced by chemotherapy in such cases. The facility with which APL cells can be induced to mature and differentiate in vitro when exposed to a multitude of agents led to the discovery that all-*trans* retinoic acid (ATRA) induces remission of APL by induction of maturation and differentiation rather than by cytotoxicity. Most patients respond completely to ATRA with less toxicity than expected from standard chemotherapy. ATRA rapidly corrects the coagulopathy associated with APL, and, in some studies, more patients survive induction therapy with ATRA than with standard chemotherapy. ATRA therapy is not entirely safe, however. The WBC count must be kept low during its initial administration to avoid a potentially fatal pulmonary syndrome that may occur secondary to engorgement of pulmonary capillaries and alveoli with maturing granulocytes. This is most commonly done by administering chemotherapy immediately after ATRA has resolved the coagulopathy.

Complete remissions induced with ATRA alone are frequently short for reasons that are not entirely understood but may be related to the fact that the agent induces its own catabolism through a mechanism involving cytochrome P450. There is little evidence that cytarabine has significant activity against APL but abundant evidence that anthracyclines do. Some investigators have recommended immediate therapy with idarubicin alone after ATRA. Complete response rates approaching 90% have been reported with this approach, and remissions have been of substantial duration for most patients so treated.

Because only a few AML patients develop CNS leukemia while in remission, prophylactic therapy is not usually given. CNS leukemia may rarely be present at diagnosis, especially in patients with the M4E subtype. Most such patients have no CNS signs or symptoms. It is probably not necessary to perform a lumbar puncture to discover CNS leukemia in asymptomatic AML patients with no signs of increased intracranial pressure because therapeutic levels of cytarabine will be achieved in the CSF with doses parenterally administered during induction therapy.

Intensive postremission therapy prolongs the complete remission duration in AML. The four options usually considered are high-dose cytarabine (3 g per square meter given as an intravenous bolus injection every 12 hours every other day for 12 doses), allogeneic bone marrow transplantation, autologous bone marrow transplantation, and prolonged maintenance therapy. It is unclear which method is more effective in yielding cures, but each can cure 30% to 40% of selected complete responders. Various factors must be considered when choosing a postremission therapy. Allogeneic bone marrow transplantation is available to only a few

patients with AML, because an HLA-compatible and related donor is required for optimal results. There are age limitations to both types of marrow transplantation because of the significant toxicity associated with each. Age greater than 45 years usually is a contraindication to high-dose cytarabine therapy because of toxicity, and some evidence exist that this therapy may be effective only in patients with favorable karyotypes such as inv(16) and t(8;21).

Only long-term, relatively tolerable maintenance therapy may be available to most AML patients in complete remission who are older than 50 years. A successful maintenance regimen consists of the administration of cytarabine (100 mg per square meter) given intravenously every 12 hours together with oral 6-thioguanine given on the same schedule and at the same dose. The regimen is given every 3 months for 5 to 10 days, until significant marrow hypoplasia is achieved. Cycles are repeated for 2 to 3 years. This regimen has been well tolerated and has been given safely to patients up to 75 years of age, with results that are comparable to the more intensive treatments described previously.

The median duration of complete remission in adults with AML is 12 to 24 months in most studies in which some form of intensive postremission therapy is given. About 30% to 50% of complete responders survive disease-free for at least 5 years after discontinuing all therapy. Late relapses occur but, as in ALL, they are rare. Results with all methods of induction and postremission therapy are best in young patients. Elderly patients are particularly vulnerable to serious toxic effects from treatment, but less intensive treatment of the elderly reduces their opportunity for successful outcomes without reducing the overall toxicity. The safety of standard treatment for the elderly may be enhanced by administering a hematopoietic growth factor, such as GM-CSF, after marrow hypoplasia has been achieved with induction therapy and until the granulocyte count has recovered.

Most AML patients who experience relapse after complete remission of at least 1 year's duration achieve a second complete remission, often with the same drugs that were initially successful. Most second remissions are shorter than first remissions, except when allogeneic bone marrow transplantation is performed early in second remission, in which case 15% to 20% of patients appear to be long-term disease-free survivors. Some evidence exists that maintenance chemotherapy prolongs the second remission and that biologicals such as interleukin-2 may be useful in this setting.

CHAPTER 228: CHRONIC LEUKEMIAS

GEORGE P. CANELLOS

[Chronic Lymphocytic Leukemia](#)
[Chronic Myelocytic Leukemia](#)
[Hairy Cell Leukemia](#)

The chronic leukemias are a group of heterogeneous proliferative disorders derived from lymphoid or myeloid precursor cells that retain some capacity for differentiation to recognizable mature elements. The natural history of the chronic leukemias tends to be longer than untreated acute leukemia, but successful therapy of the latter has narrowed the differences. Depending on the aggressiveness of the chronic leukemia, the natural history may be abbreviated.

The symptoms and signs of the chronic leukemias result from the continuous proliferation and eventual replacement of the normal hemopoietic components of the bone marrow. Although intensive therapy is required to survive the acute leukemias, most chronic leukemias are still treated palliatively with less intense treatments. Perhaps because of the availability of malignant cells for study, the molecular biology and pathogenesis of the chronic leukemias have become much better understood during the past 5 years.

CHRONIC LYMPHOCYTIC LEUKEMIA

CLINICAL FEATURES

The chronic lymphocytic leukemias (CLLs) represent a group of disorders in which the malignant cell is a recognizable mature lymphocyte of varied structure. The subtypes can be divided according to immunophenotypic origin. Most patients have a disease of cells originating in the bone (B) marrow. B-cell CLL is primarily a disease of Western (European) populations. CLL with thymic (T) markers is more common in Japan but can occur in Western countries, where it is usually associated with a generally worse prognosis. The immunophenotype of B-cell and T-cell CLL tends to favor a more differentiated pattern, which is readily defined by appropriate antibodies. Immunofluorescence for cell surface immunoglobulins is usually less intense than normal. The immunophenotype of the CLL lymphocyte includes the presence of CD5, a mature T-cell marker in addition to the usual pan-B-cell markers, CD19 and CD20. Flow cytometry also reveals a clonal preponderance of immunoglobulin light chain. CLL also has CD23 present in 70% of cases and is associated with a more favorable prognosis.

CLL occurs at the median age of 60 years at diagnosis and is equally distributed among men and women. The diagnosis tends to be made earlier because of the use of automated blood counts. The clinical features and extent of involvement determine the prognostic state of the CLL. About 50% of the patients present with *lymphadenopathy* in addition to a lymphocytosis that is usually greater than 15,000 per microliter. Splenomegaly may also be observed at presentation.

Patients may give a history of infections and even exaggerated responses to insect bites. Anemia and thrombocytopenia are usually late features unless an early autoimmune hemolytic anemia or thrombocytopenia has supervened. About 10% of patients have a small monoclonal M spike on serum electrophoresis, but in most cases absolute hypogammaglobulinemia occurs, worsening with progression of the CLL. Fever and painful lymphadenopathy are not features of the disease and usually suggest infection. In the absence of peripheral lymphocytosis, a variant low-grade lymphoma (small lymphocytic) has the same histologic picture on lymph node biopsy.

The bone marrow is usually diffusely replaced by small mature lymphocytes, but a nodular involvement may occur and be a more favorable sign. The peripheral blood usually reveals a monotonous lymphocytosis, but some patients may show an admixture of large transformed lymphoid cells (prolymphocytes). Hyperuricemia occurs only in patients with marked lymphocytosis and organomegaly. The median survival of patients can be prolonged to more than 10 to 15 years if only lymphocytosis and minimal lymphadenopathy are present at diagnosis; anemia and thrombocytopenia reduce the median survival to 2 to 4 years.

Cytogenetic abnormalities in B-cell CLL occur in 55% to 65% patients, with trisomy 12 being the most common anomaly. Abnormalities in the long arm of chromosome 13 or 14 also occur. The prognosis is usually more favorable with no cytogenetic abnormalities present.

The clinical course of CLL is determined by the initial presenting stage, but in time, it may accelerate, exhibiting an increased peripheral prolymphocyte count, anemia or thrombocytopenia, progressive lymphadenopathy, and marked splenomegaly. Prolymphocytes are usually recognized with prominent nucleoli that are absent from mature or CLL lymphocytes. In a few patients, the course of CLL may be complicated by abdominal tumors (e.g., gastric, small bowel, retroperitoneal), which has a histologic picture of large cell lymphoma (Richter's syndrome) with constitutional symptoms, fever, weight loss, and rapid deterioration. Associated autoimmune phenomena, such as hemolytic anemia, thrombocytopenia, and pure red blood cell aplasia can occur at any time in the natural history of the disease but usually do not influence the prognosis.

T-cell CLL is usually a more aggressive lymphoproliferative disorder than B-cell CLL, with anemia, thrombocytopenia, splenomegaly, and lymphadenopathy. A relatively unique feature of T-cell CLL is skin infiltration. The T-cell leukemia tends to respond less well to therapy than does the B-cell variety. The malignant cell may have a more convoluted nucleus and manifest the helper (CD4) T-cell immunophenotype. Suppressor (CD8) T-cell CLL is rare and usually presents as marked anemia or neutropenia out of proportion to the extent of marrow and organ involvement. The latter may also be defined as large granular cell leukemia. Death is usually related to infection because of granulocytopenia and hypogammaglobulinemia.

THERAPY

CLL usually has an indolent course with a natural history measurable in years and usually predicted by initial presenting features. Asymptomatic lymphocytosis with minimal lymphadenopathy with no anemia or thrombocytopenia does not require therapy. As a general rule, therapy is palliative and may not influence the overall survival.

In time, progressive lymphadenopathy and hepatosplenomegaly with or without anemia or thrombocytopenia require therapy. The reduction of the leukemic burden is achieved with oral alkylating agents such as chlorambucil (0.1 mg per kilogram) on a daily oral basis or intermittent monthly courses (0.8 mg per kilogram). Other oral alkylating agents, such as cyclophosphamide or melphalan, are also effective. Prednisone adds to the lymphocytolytic effect and can be added for short courses as a daily oral medication. Chronic prednisone therapy can produce other steroid-related problems and is best reserved for cases with anemia, thrombocytopenia, or autoimmune complications such as autoimmune hemolytic anemia. Patients refractory to alkylating agents may respond to parenteral fludarabine. Fludarabine is also an effective initial therapy but is more immunosuppressive because of its marked T-lymphocytotoxic effect and is associated with a relatively high rate of infection. In randomized comparisons of fludarabine with chlorambucil or combination chemotherapy, the former demonstrated a significantly higher overall and complete response rate but, as yet, no survival advantage.

Other therapeutic approaches to CLL are usually dictated by the clinical circumstances. Hypersplenism may respond to low doses of fractionated radiation therapy, but hypersplenic cytopenias are more directly benefited by splenectomy. Autoimmune complications may require a variety of immunosuppressive agents, such as corticosteroids, cyclosporine, and azathioprine (Imuran).

An aggressive turn in the natural history, such as a lymphomatous transformation (Richter's syndrome) or prolymphocytic leukemia, requires parenteral combination chemotherapy such as that used for large cell lymphoma, including vincristine and doxorubicin, which are not used for the chronic lymphoproliferative disorders.

The median survival, varying according to presenting stage, is 3 years to more than 10 years. In select circumstances, younger patients with advanced CLL have received allogeneic bone marrow transplants with about 50% surviving in remission at 3 years. The role of autologous transplantation is under investigation and may be a consideration in younger patients.

CHRONIC MYELOCYTIC LEUKEMIA

Chronic myelocytic leukemia (CML) is one of the myeloproliferative disorders that results from a clonal proliferation of cells of bone marrow stem cell origin with a predominance of mature granulocytic precursors, although abnormalities of red blood cell and platelet production are also present. Studies to date indicate that CML is a disorder of the stem cell common to bone marrow cells and B lymphocytes. It is unclear, except through indirect evidence, that the T lymphocytes may be involved. Nonclonal reactive bone marrow–derived fibroblasts can result in myelofibrosis, especially with heavy deposition of reticulum. This is especially a feature of an advanced or accelerated phase.

Precursors of the cells previously mentioned, except fibroblasts, have the Philadelphia (Ph¹) chromosome. This represents a reciprocal translocation of chromosomal material between chromosomes 22 and 9, with translocation and activation of the protooncogene, *ABL*, from chromosome 9 at band 34 to chromosome 22 t(9;22)(q34;q11). This occurs in over 90% of patients with CML. The *ABL* gene is translocated close to a site of chromosomal breakage on chromosome 22, known as the breakpoint cluster region (*BCR*). The chimeric *ABL/BCR* gene codes for a new transcript of 8.2-kb mRNA, producing a unique oncoprotein of 210 kd, which has greater tyrosine–kinase activity than the normal *ABL*-encoded protein (145 kd). Translocation of *ABL* appears to be a critical abnormality. It is considered a crucial component but perhaps not the sole event in CML leukemogenesis. Ph¹ chromosome-positive acute lymphocytic leukemia (ALL) in adults, for example, is associated with a different structural *BCR/ABL* chimeric protein of 180 kd, reflecting a different breakpoint in *BCR*. The oncogenic mechanism of the *BCR/ABL* protein is suggested by its capacity for multiple protein–protein interactions linked to signal transduction pathways. New agents have been designed to inhibit the tyrosine kinase activity of *BCR/ABL*. Molecular probes for *BCR* rearrangement can increase the sensitivity for detection of leukemic cells. The Ph¹ and the *BCR/ABL* abnormality remain through the natural history of the disease. Additional new cytogenetic abnormalities may occur during evolution of the disease to a more aggressive phase, such as duplication of the Ph¹ chromosome, trisomy 8, and isochromosome 17.

PATHOLOGY AND CLINICAL CHARACTERISTICS

The basic hematologic abnormality of CML involves an excess production of mature-appearing granulocytes and intermediate mature cells, such as myelocytes and metamyelocytes. CML is usually diagnosed in midlife or later. Initially, patients are essentially asymptomatic, although complaints referable to a bulky spleen may be noted. The peripheral blood white blood cell (WBC) count is characteristically two to four times the upper limit of normal, and the WBC differential count discloses some immaturity of the granulocyte series, represented by myelocytes and metamyelocytes. The platelet count is usually normal or elevated, and anemia may not be present. Leukocyte alkaline phosphatase activity is low or absent in uncomplicated patients. Although the test is rarely done, it is normal or elevated in most other benign or myeloproliferative disorders such as polycythemia vera and agnogenic myeloid metaplasia.

The bone marrow is hypercellular—primarily because of an expanded, immature (but not blastic) granulocyte compartment—and the numbers of megakaryocytes and red cell precursors are often increased. This results in progressive granulocytic leukocytosis, with the appearance of bands, myelocytes, and metamyelocytes in the blood in increased numbers. Eosinophilia and basophilia may occur. Marrow or blood karyotypes demonstrate the Ph¹ chromosome in almost all patients, although it may not be present in every metaphase examined. In some patients with otherwise typical CML, no Ph¹ chromosome can be identified by cytogenetics, although the rearranged *BCR/ABL* gene can be detected with molecular biologic techniques. As the disease progresses, the accumulation of granulocytes is expanded in other reticuloendothelial sites such as spleen and the portal areas of the liver. Biochemical abnormalities, such as hyperuricemia and an elevated B₁₂-binding protein (derived from granulocytes) in CML are related to the extent of granulocytosis.

The initial prognosis can be correlated with the extent of leukocytosis, presence of blasts in the peripheral blood, extent of splenomegaly, and thrombocytosis. All these features are associated with a poor prognosis. Profound anemia and thrombocytopenia are almost unknown initially but can occur as the disease progresses, usually in 2 to 4 years after diagnosis. The latter stage, known as the accelerated phase, may be associated with marked basophilia, anemia, myelofibrosis, progressive splenomegaly, and the emergence of new cytogenetic abnormalities in addition to the Ph¹ chromosome.

In a median of 36 to 50 months (later for patients with disease diagnosed early), there is a transformation of the CML to a more blastic leukemia, referred to as *blastic phase* or *blast crisis*. This usually represents a terminal phase of the disease, with all of the features of the accelerated phase possible in addition to thrombocytopenia, anemia, and an increase in the number of blast cells in the marrow and blood to over 30%.

Rarely, myeloblastomas develop in lymph nodes, skin, bone, and other sites. The rapid rise in blast cell count to more than 100,000 per cubic millimeter can result in leukostasis in the cerebral and pulmonary vasculature.

The morphologic characteristics of the blastic phase can vary; 60% to 70% of patients retain the myeloblastic features, but a significant minority have lymphoid or mixed myeloid–lymphoid features in their blast cells. Megakaryocytic and erythroblastic transformation rarely occurs. The lymphoblasts of CML in lymphoid transformation are usually of pre–B-cell phenotype, consistent with the cell of common childhood ALL. Rarely, T-cell transformation with a mixed T-cell–myeloid phenotype has occurred. The median survival of the blastic phase is from 2 to 4 months.

DIFFERENTIAL DIAGNOSIS

Juvenile CML is a distinct disorder of children younger than 14 years of age. The accelerated course of this CML variant usually manifests with thrombocytopenia, monocytosis, and elevation of fetal hemoglobin. The Ph¹ chromosome is absent.

Ph¹-negative CML, erroneously described in older textbooks, probably does not exist. Patients whose illness has been categorized by this term usually had an elevated WBC count (secondary to an immature granulocytosis) in common with Ph¹-positive CML but were commonly anemic, thrombocytopenic, elderly, and ill when diagnosed, unlike most patients with Ph¹-positive CML. They may have an increased number of monocytic cells. The response to therapy and survival rates are inferior to Ph¹-positive CML. Careful evaluation of patients with apparent Ph¹-negative CML usually leads to a diagnosis of myelodysplastic syndrome or acute or chronic myelomonocytic leukemia ([Chapter 227](#) and [Chapter 229](#)).

Although bone marrow specimens from patients with polycythemia vera or primary thrombocytosis (essential thrombocythemia) may occasionally be confused with the marrow of patients with CML, numerous clinical and laboratory features of the three entities clearly segregate them ([Chapter 217](#) and [Chapter 231](#)).

Primary myelofibrosis with myeloid metaplasia may be confused clinically with CML, but the Ph¹ chromosome is absent and leukocyte alkaline phosphatase activity is normal or elevated. Myelofibrosis and extramedullary hematopoiesis may occur late in CML, but they rarely dominate the clinical picture. Initial massive splenomegaly, anemia, thrombocytopenia, and hepatomegaly occur more frequently in myelofibrosis than CML, and bone marrow in the former condition characteristically cannot be aspirated. A marrow core biopsy in patients with myelofibrosis usually discloses abundant, diffuse fibrosis and marked hypocellularity, rather than the hypercellularity characteristic of those with CML.

Leukemoid reactions to infection or neoplastic disease may suggest CML. Leukemoid reactions secondary to both underlying conditions are characterized by a mature granulocytosis without abnormalities or platelet or red cell production and without splenomegaly. Leukocyte alkaline phosphatase activity is often elevated and never low.

THERAPY

Treatment of those in the chronic phase of CML is directed toward control proliferation of the granulocyte mass. The principal chemotherapeutic agent is hydroxyurea given by mouth at 1 to 3 gm per day as initial therapy with reduction of dose when the WBC count approaches 50% of the initial value. The drug is short-acting so that continuous maintenance is needed. Excessive dosage can result in macrocytic anemia. The myelosuppressive effects are short-lived when the drug is stopped. There do not appear to be any long-term toxic effects to other organs. Allopurinol should be used initially but may be discontinued when the WBC count approaches the normal range.

Recombinant interferon- α is a very effective agent in the therapy of the chronic phase. A percentage of patients (about 20%) can be treated chronically to a relatively low granulocyte count and achieve a transient disappearance of the Ph¹ chromosome. Interferon requires frequent injections and has more side effects than oral chemotherapy. Some randomized trials from Europe suggested the superiority of interferon over hydroxyurea, but conversely two others showed no significant difference. These treatments are palliative and it is uncertain whether the blastic phase is delayed. The cytotoxic action requires continuous therapy but lacks the

myeloablative action of the cytotoxic drugs.

The achievement of cytogenetic remission may require prolonged therapy over 6 to 8 months at up to 5 million units per square meter per day. If the higher doses are tolerated, then 80% will achieve a hematologic remission, including a cytogenetic response. In a recent randomized trial comparing hydroxyurea with interferon, the latter showed a 16% complete or partial (less than 35%) cytogenetic response rate compared with 2% (only partial) with hydroxyurea. The overall survival was similar. Complete responders have a longer survival. The toxic effects of interferon include flu-like symptoms and long-term fatigue. The combination of interferon and cytotoxic agents, such as cytosine arabinoside, can increase the hematologic and cytogenetic remission rate, but the impact on survival is to be defined. Accelerated proliferation of granulocyte precursors in the accelerated or blastic phase may respond to increased doses of hydroxyurea or otherwise require more intensive antileukemic therapy. Lymphoid morphology and phenotype occur in about 20% of patients entering the blastic phase. In this circumstance, anti-ALL-type therapy may achieve a hematologic remission with persistence of the Ph¹ chromosome. The median survival remains less than 1 year but is better than the 1 to 2 months for cases of myeloblastic transformation.

Allogeneic bone marrow transplantation in the chronic phase of CML from a matched sibling donor can cure about 50% of patients. Younger patients have a better prognosis. Patients in relapse from allogeneic transplantation can be treated with peripheral WBCs from the original marrow donor and achieve a second immune cell-mediated remission, but not without the risk of graft-versus-host disease. Autologous bone marrow transplantation is transiently beneficial in the blastic phase and may alter the percentage of Ph¹-positive cells when done in the chronic phase. Splenectomy can palliate hypersplenic symptoms but does not affect the natural history of the disease. Recent data suggest that matched unrelated donor transplants are feasible with a 50% 5-year survival rate, with even better results with early transplantation of patients younger than 50 years.

HAIRY CELL LEUKEMIA

CLINICAL FEATURES

Hairy cell leukemia (HCL) is a rare form of a B-cell chronic lymphoproliferative disorder, whose malignant lymphoid cells have unique filamentous cytoplasmic projections and are nondividing. Unique cytochemical and immunologic characteristics of the abnormal lymphoid cells in HCL readily differentiate this disorder from CLL. They are of B-cell lineage according to surface markers and immunoglobulin gene rearrangement. Tartrate-resistant acid phosphatase is commonly found in HCL cells. Some surface antigens are uniquely expressed in HCL, and antibody studies may be diagnostic. The antigens that differentiate HCL from CLL include CD11c (myelomonocytic marker) and CD25 (interleukin-2 receptors).

The median age for presentation is in the sixth decade with a male predominance. Patients usually present with pancytopenia and impaired marrow function due to infiltration by leukemic cells. Splenomegaly is common. The course is indolent, with a tendency toward more profound marrow suppression and splenomegaly. On occasion, the cellular projections require electron microscopy for demonstration. Hairy cells are usually found readily in the blood, although in some patients they may be present in small numbers. The bone marrow is characteristically hypercellular, and aspiration is difficult or impossible.

THERAPY

The therapy for HCL has improved considerably over the last decade. Splenectomy was the only treatment for the associated cytopenias until the introduction of systemic agents, such as interferon- α and the purine analogues 2'-deoxycoformycin and 2-chlorodeoxyadenosine (2-CDA). The latter two agents can produce lasting complete remissions that were rarely achieved with interferon- α . 2-CDA has been used extensively. This agent is capable of inducing the long-lasting remission with a single course of parenteral treatment at 0.1 mg per kilogram by continuous infusion for 7 days. Patients refractory to interferon- α can also be successfully treated with the purine analogues. The major toxic effects of the purines are myelosuppression and lymphocytopenia. The overall response rate, however, is more than 90%, with almost 75% of patients achieving durable complete remissions. Relapse can be successfully retreated with the same drug.

CHAPTER 229: MYELODYSPLASTIC SYNDROME

FREDERICK R. APPELBAUM

[Incidence](#)
[Etiology](#)
[Pathogenesis and Pathophysiology](#)
[Clinical Findings](#)
[Laboratory Findings](#)
[Optimal Management](#)

The myelodysplastic syndrome (MDS) describes a group of clonal hematopoietic disorders characterized by impaired maturation of blood cells and the development of peripheral cytopenias. MDS is the result of neoplastic transformation of a cell at a level of differentiation close to that of the hematopoietic stem cell. Unlike acute leukemia, the transformed cell and its progeny retain the ability to differentiate, although not entirely normally, for a period of months to years. With time, the abnormal clone suppresses normal hematopoiesis and becomes increasingly abnormal, ultimately resulting in fatal pancytopenia or progression to an acute leukemia-like syndrome.

To aid in categorizing patients with MDS, the French–American–British (FAB) Morphology Cooperative Group recognizes five distinct forms of MDS based on marrow and peripheral blood morphology ([Table 229.1](#)): refractory anemia (RA), refractory anemia with ringed sideroblasts (RARS), refractory anemia with excess blasts (RAEB), refractory anemia with excess blasts in transition (RAEB-t), and chronic myelomonocytic leukemia (CMML). This classification system is used widely but includes a syndrome (CMML) thought by many to more appropriately be considered a myeloproliferative disorder and ignores the generally recognized syndromes of hypoplastic myelodysplasia and myelodysplasia with marrow fibrosis.

Classification	Peripheral		Ringed Sideroblasts	Neocytes ($\times 1000/\mu\text{L}$)
	Marrow Blasts (%)	Blood Blasts (%)	>1% of Bone Marrow	
Refractory anemia	<5	<1	-	-
Refractory anemia with ringed sideroblasts	<5	<1	+	-
Refractory anemia with excess blasts	5-20	<5	±	-
Refractory anemia with excess blasts in transition	20-30	≥5	±	±
Chronic myelomonocytic leukemia	<5	<5	±	+

TABLE 229.1. FAB CLASSIFICATION OF MYELODYSPLASTIC SYNDROMES

INCIDENCE

Earlier reports characterized MDS as being relatively rare, with an annual incidence of approximately 1 case per 100,000 persons. Later studies suggested a much higher incidence, particularly if mild forms of the disease are included. Although sometimes seen in young patients, the disorder is much more common in the elderly, with a median age of onset of over 60 years. Beyond the age of 70, the incidence of MDS is greater than 1 case per 1,000 persons, making it among the most common hematologic malignancies of the aged.

ETIOLOGY

The cause of the defect leading to MDS in most cases is unknown. Some cases of MDS are seen in children with DNA repair deficiency syndromes (e.g., Bloom's syndrome, Fanconi's anemia, ataxia-telangiectasia), Down's syndrome, and the Li–Fraumeni syndrome, and MDS occurs in siblings of patients with familial monosomy 7 syndrome. Secondary (therapy-related) MDS is increasingly recognized as a major complication of irradiation and chemotherapy. A number of cases of MDS involving chromosome 5 or 7 develop 3 to 5 years after patients have been exposed to alkylating agents. Other patients develop MDS involving chromosome locus 11q23 after exposure to the topoisomerase II inhibitors etoposide and teniposide.

PATHOGENESIS AND PATHOPHYSIOLOGY

The exact pathogenesis of MDS remains unclear, but studies of chromosomal morphology, glucose-6-phosphate dehydrogenase isoenzymes, and molecular markers suggest that the development of MDS is a multistep process involving the accumulation of genetic lesions. Early in the course of the disease, there appears to be a genetic event in an early hematopoietic progenitor, resulting in its expansion to a clonal population of hematopoietic stem cells, which, at least initially, maintains many normal characteristics. Evidence for early clonal hematopoiesis comes from studies of X-linked polymorphisms in patients with MDS with only very mildly disordered hematopoiesis that demonstrate that myeloid, erythroid, platelet, and, in some cases, lymphoid cells all arise from the same clone.

The reasons for expansion of the abnormal clone are not understood but appear to be related to independence from normal growth factor control, insensitivity to normal inhibitory factors, and active suppression of normal hematopoiesis. The abnormal clone appears to be genetically unstable, and successive genetic changes occur, accompanied by increasingly disordered hematopoiesis. Pancytopenia develops in the face of a hypercellular marrow as a result of defective maturation and premature intramedullary death of cells, presumably by means of an apoptosis pathway. With further genetic changes, hematopoiesis becomes increasingly malignant, ultimately resulting in a picture similar to acute leukemia.

The nature of the initial genetic event leading to MDS is unknown. Some studies have examined the role of protooncogenes and tumor suppressor genes. Mutations in the RAS protooncogene family, particularly NRAS, are found in 20% to 50% of cases and appear to be more common in more aggressive forms of MDS. Whether RAS mutations cause MDS or are a result of earlier genetic events is unknown. Similarly, mutations in the FMS protooncogene are found in some cases of MDS; as many as 20% of CMML patients demonstrate FMS mutations. Mutations in P53, although common in other malignancies, are seen in only a small percentage of MDS cases.

Single or complex cytogenetic abnormalities are found in 50% to 65% of patients with primary MDS and up to 90% of cases of secondary MDS. Whether some of these abnormalities represent the primary genetic event or are secondary to underlying genetic instability is unknown. The possibility that some cytogenetic abnormalities at least contribute to the development of disordered hematopoiesis is raised by observations that interstitial deletions of the long arms of chromosomes 5 and 7 are extremely common in MDS and that a large number of normal genes involved in hematopoietic growth and development map to these regions, especially to the 5q23–5q31 region, where the genes for interleukin-3 (IL-3), IL-4, IL-5, colony-stimulating factor 1 (CSF-1), and interferon regulatory factor-1 (IRF-1) are located.

CLINICAL FINDINGS

Clinical findings associated with MDS are almost solely the consequence of bone marrow failure. Fatigue, pallor, infection, and bruising or bleeding are the most common presenting complaints. Most MDS patients are anemic at diagnosis, and approximately 50% are granulocytopenic or thrombocytopenic as well. Splenomegaly is found in about 10% of cases. Occasional patients present with rheumatic or immunologic abnormalities, including cutaneous vasculitis or lupus-like syndromes.

LABORATORY FINDINGS

Laboratory findings in patients with MDS vary according to the category of disease. In RA, anemia is invariably accompanied by a low reticulocyte count. The numbers of peripheral blood granulocytes and platelets are normal or diminished slightly, and leukemic blasts are usually absent from the periphery and account for less than 5% of marrow cells. RARS has findings essentially identical with those of RA except that ringed sideroblasts make up 15% or more of marrow cells.

In patients with RAEB, thrombocytopenia and granulocytopenia are common; blasts make up 5% to 20% of marrow cells and account for up to 5% of the circulating white cells. RAEB-t has laboratory features similar to those of RAEB, but blasts are more common, accounting for up to 30% of marrow or peripheral blood leukocytes. If more than 30% of marrow or peripheral blood cells are blasts, the diagnosis of acute myeloid leukemia (AML) can be made. CMMoL has features similar to those of RAEB, with the addition of a circulating monocyte count of more than 1,000 per microliter.

Clonal chromosomal abnormalities are found in up to 65% of patients with primary MDS and 90% of patients with secondary MDS. Abnormalities of chromosome 5 or 7 are found in 25% of patients with primary MDS and 55% of those with secondary MDS. Other common abnormalities include trisomy 8 and interstitial deletions of the long arm of chromosomes 11, 13, 17, or 20. These abnormalities are also seen in some patients with AML and in that setting are associated with a poor prognosis. The cytogenetic abnormalities associated with a good prognosis in patients with AML, including t(8;21), t(15;17), and inv(16), are rarely seen in patients with MDS. Several myelodysplasia syndromes are associated with particular cytogenetic abnormalities. Patients with an interstitial deletion of the long arm of chromosome 5 (5q-) as the sole abnormality are frequently elderly women with macrocytic anemia and normal or elevated platelet counts. The bone marrow of such patients shows erythroid hyperplasia with hypolobulated megakaryocytes. This syndrome has a relatively benign course. t(5;12) (q33;p13) is specifically associated with the CMMoL subtype of MDS. As noted in the following text, cytogenetics is useful in determining prognosis in MDS.

OPTIMAL MANAGEMENT

The course of untreated MDS is highly variable; some patients survive for more than a decade, and others die within a year of presentation. An essential element in determining appropriate therapy is an assessment of the patient's prognosis. The FAB classification is of some prognostic use in that patients with RA and RARS have a better prognosis than patients with RAEB, RAEB-t, or CMMoL.

Several scoring systems provide greater prognostic precision. An International Prognostic Scoring System (IPSS) has recently been developed based on an analysis of 816 patients. The system rates the risk of a patient's disease according to three criteria: number and degree of cytopenias, bone marrow blast percentage, and cytogenetic findings. Risk scores for each of these three variables are defined, and by combining the scores, patients can be categorized as belonging to one of four prognostic categories: low-risk (median survival 5.7 years), intermediate-risk 1 (median survival 3.5 years), intermediate-risk 2 (median survival 1.2 years) or high-risk (0.4 years) (Table 229.2 and Fig. 229.1). Death of patients with MDS usually results from complications of pancytopenia or disease progression to AML. Infection and hemorrhage associated with low blood counts are the cause of 35% to 50% of all deaths in MDS. Patients with RAEB or RAEB-t have a 40% to 65% probability of disease progression to AML within 2 years, but the risk is much smaller for patients with RA or RARS.

Characteristic	Individual Score
Cytogenetics	
Good (normal, del 5q, del 20q, and -y)	0
Intermediate	0.5
Poor (3 or more abnormalities or abnormalities of 7)	1.0
Blasts (% in marrow)	
<5	0
5-10	0.5
11-20	2.0
21-30	2.0
Cytopenias (Hb < 10 g/dL, ANC < 1800/ mm³, platelets < 100,000/mm³)	
0-1	0
2-3	0.5
Risk Groups	Total Score
Low	0
Intermediate risk-1	0.5-1.0
Intermediate risk-2	1.5-2.0
High	>2.0

ANC, absolute neutrophil count; Hb, hemoglobin.
The IPSS assigns each patient a score for each of three characteristics: cytogenetics, marrow blast percent, and peripheral cytopenias. An overall risk group is determined by adding the three scores.

TABLE 229.2. INTERNATIONAL PROGNOSTIC SCORING SYSTEM (IPSS) FOR MYELODYSPLASTIC SYNDROME

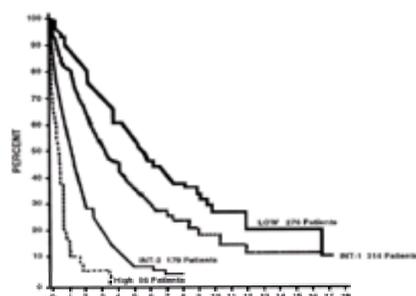

FIGURE 229.1. Survival according to IPSS risk classification. (From Greenberg P, et al. International scoring system for evaluating prognosis in myelodysplastic syndromes. *Blood* 1997;89:2079, with permission).

Because of the considerable variability in the aggressiveness of MDS, appropriate management also varies. Patients with RA or RARS with normal or near-normal granulocyte and platelet counts (low-risk according to the IPSS) may require no therapy or, at most, support with red blood cell transfusions. Patients with RAEB or RAEB-t (intermediate-risk 1, intermediate-risk 2, and high-risk by IPSS) have, on average, a predicted survival of 0.4 to 3.5 years, and more aggressive interventions should be considered.

The only form of therapy that can cure MDS is allogeneic marrow transplantation, which results in long-term disease-free survival of 40% to 60% of transplanted patients. Transplantation results are best in younger patients, those with human leukocyte antigen-matched siblings to serve as donors, and patients without excess blasts. Although many patients with MDS are not candidates for transplantation because of advanced age or lack of a donor, transplantation should be considered for any patient younger than 55 years with intermediate-risk 1 or higher-risk disease.

Although several therapeutic interventions have been explored in patients who are not transplantation candidates, the evidence that any of these approaches are superior to supportive care alone is scant. Although an occasional response to glucocorticoids has been reported, the likelihood of such a response is low and, because of the increased risk of infection with these agents, glucocorticoids are not recommended as routine therapy. A few responses to androgens have been reported, but in prospective, randomized trials, no benefit of androgen therapy was detected.

The demonstration that several compounds can induce myeloid differentiation in vitro led to testing similar agents in patients with MDS. Phase I and II trials suggested responses of 20% to 30% with one such agent, 13-*cis*-retinoic acid, but two prospective, randomized studies failed to detect any improvement in progression-free or overall survival rates.

The use of hematopoietic growth factors has been actively studied in MDS with the hope that these agents might reverse cytopenias by increasing production of normal cells or by inducing abnormal progenitors to differentiate more normally. The two most studied myeloid agents are granulocyte-macrophage colony-stimulating factor (GM-CSF) and granulocyte colony-stimulating factor (G-CSF). Use of either agent leads to an increase in granulocyte counts in approximately 75% of MDS

patients and appears to do so by increasing the production of normal and abnormal cells. Improvements in platelet or red cell production are uncommon with the use of GM-CSF or G-CSF, occurring in only 10% to 15% of patients. Two large, randomized studies of the use of myeloid growth factors in treating MDS have been reported. In both studies, increases in granulocytes occurred, accompanied by a decrease in infectious complications. However, neither study demonstrated a survival advantage or a delay in time to progression to AML. There is no consistent evidence of clinical benefit associated with the chronic administration of GM-CSF or G-CSF in MDS, but it is appropriate to consider the use of such agents in neutropenic patients with infection.

Erythropoietin has been studied in MDS patients with anemia. Although most MDS patients have high endogenous levels of erythropoietin, high doses of exogenous drug improved red cell production in 20% of patients, with more frequent responses seen in patients with lower pretreatment endogenous erythropoietin levels. Combinations of erythropoietin and G-CSF may increase the frequency of an erythroid response.

Chemotherapeutic approaches to MDS have ranged from low-dose single-agent therapy to high-dose multiagent treatments similar to those used in AML. Use of low-dose cytarabine (20 mg per square meter per day) has been extensively studied, with the hope that this treatment could induce differentiation of myeloid cells. A summary of numerous phase II reports and the results of one randomized study indicated that low-dose cytarabine produced responses in approximately 15% of patients but did not increase overall survival. Like low-dose cytarabine, low-dose 5-azacitidine can result in hematologic responses in some patients. A recently completed randomized trial suggests 5-azacitidine may prolong the interval to leukemic transformation or death by as much as 10 months and thus merits consideration in patients with intermediate-risk 2 or high-risk disease. The topoisomerase inhibitor, topotecan, has been studied as a single agent in MDS and found to result in short-lived but complete responses in approximately 30% of patients. Intensive combination chemotherapy, including higher-dose cytarabine and daunomycin, can produce complete responses in 30% to 60% of patients. However, few complete responses last longer than 12 months, and only rare patients are cured, results distinctly inferior to those seen in patients with de novo AML. Children with MDS appear to respond somewhat better to intensive chemotherapy than adults.

shoulders and with dystrophy of the nails and leukoplakia. Although both syndromes classically manifest in childhood, aplasia may begin in young adulthood. The diagnosis of these disorders is important, because the therapeutic options vary from those for acquired aplastic anemia.

LABORATORY FINDINGS

The laboratory findings in aplastic anemia include pancytopenia and a hypocellular bone marrow revealed by bone marrow biopsy. Aplastic anemia is classified as a normochromic, normocytic anemia, although some patients have macrocytosis. Residual leukocytes are morphologically normal, but the number and size of platelets are decreased. The reticulocyte count also is inappropriately decreased. The bone marrow reveals decreased hematopoiesis, and in its severe form, only a few lymphocytes, plasma cells, and mast cells may be evident. The bone marrow is replaced by fat, but without other apparent causes of pancytopenia. At examination, the different cell lines may be variably affected, and in some patients, a small amount of erythropoiesis may be evident. The iron-binding capacity is usually fully saturated, and an iron stain of the bone marrow reveals normal to increased iron stores.

Previously, the term *hypoplastic anemia* was differentiated from aplastic anemia and used to describe mild pancytopenia and hypocellularity of the marrow. Aplastic anemia is currently defined as mild or severe, based on the severity of the pancytopenia and the degree of cellularity of the bone marrow ([Table 230.2](#)). Patients with mild aplasia (not meeting the criteria in [Table 230.2](#)) may have a prolonged course or a complete spontaneous recovery. They may also degenerate into a severe aplastic anemia. Patients with severe aplastic anemia have only a 15% to 20% chance of spontaneous recovery and are likely to have a fulminate course with early death without successful treatment.

Peripheral Blood Values

All three of the following or two of three plus bone marrow criteria:

- Absolute neutrophil count of $<500/\text{mm}^3$
- Untransfused platelet count of $<20,000/\text{mm}^3$
- Reticulocyte count (corrected for hematocrit) of $<1\%$

Bone Marrow

Markedly hypocellular bone marrow ($<25\%$ normal cellularity)
Moderately hypocellular bone marrow (25% to 50% normal cellularity) with <30 hematopoietic cells

Progressive Decline in Blood Counts During the First 3 Months

TABLE 230.2. CHARACTERISTICS OF SEVERE APLASTIC ANEMIA

Laboratory evaluation should include studies that attempt to identify the possible cause of the aplasia, including tests for paroxysmal nocturnal hemoglobinuria, systemic lupus erythematosus, hepatitis, infectious mononucleosis, and pregnancy in females of childbearing age. Cytogenetic analysis should attempt to identify patients with hypocellular myelodysplastic syndrome and those patients with underlying chromosomal fragility states such as Fanconi's aplastic anemia. Flow cytometry enhances identification of an underlying paroxysmal nocturnal hemoglobinuria and abnormal lymphocyte subsets. The evaluation of a congenital disorder should include x-ray films of the hands, wrists, and kidneys. Unfortunately, no reliable tests exist to determine the presence of environmental toxins.

Further laboratory testing is needed for patient treatment. Complete erythrocyte typing should be established before transfusion. The patient's cytomegalovirus history should be determined serologically to provide appropriate transfusion products and to determine an appropriate hematopoietic stem cell transplant donor. Immediate human leukocyte antigen (HLA) typing of the patient and family should be undertaken to determine the availability of a potential sibling transplant donor. On rare occasions, a parent may be a suitable donor. Typing should include serologic typing for HLA-A, HLA-B, and HLA-DR. If a search for an unrelated donor is to be pursued, molecular typing for HLA-DR should also be performed.

OPTIMAL MANAGEMENT

Treatment for aplastic anemia involves general supportive management and specific treatment, both of which are determined by the clinical scenario and the severity of the aplastic anemia. Exposure to possible causal agents should be eliminated. Drugs that interfere with platelet function should be avoided. Women of childbearing age should have their menses suppressed, and in cases of menorrhagia, control of menses may require platelet transfusion and aggressive pharmacologic therapy. Because of the need for frequent blood drawing and infusions, an assessment of vascular access may suggest the placement of indwelling lines. Patients with low neutrophil counts should avoid exposure to potential infectious pathogens. Fever and potential infection should be managed promptly and aggressively. For the patient with mild aplastic anemia, no further treatment may be required except for anticipatory clinical and laboratory observation. About 20% of patients with severe aplasia may have spontaneous recoveries within 3 to 6 weeks ([Table 230.3](#)).

Initial Approach
Elimination of any potential causative agents
Assessment of severity of aplastic anemia
Rapid evaluation of potential therapeutic maneuvers
Careful and frequent serial medical and laboratory evaluation
Observation of mild aplasia
Supportive Care
Judicious transfusion support
Prevention of infection
Suppression of menses in females of childbearing age
Aggressive and prompt evaluation and treatment of fever and hemorrhage
Chelation therapy
Definitive Treatment
Hematopoietic stimulation
Androgens
Cytokines
Immunosuppression
Antithymocyte globulin
High-dose corticosteroids
Cyclosporine
Bone marrow transplantation
HLA-identical family member
Matched unrelated donor
HLA, human leukocyte antigen.

TABLE 230.3. TREATMENT OF APLASTIC ANEMIA

Transfusions should be administered judiciously. Erythrocyte transfusions should be based on both the hematocrit and the clinical features. Young patients often tolerate hematocrit values that are in the low teens, but older patients may become symptomatic at higher levels. Platelets should also be transfused on the basis of the count and the clinical evaluation. Active bleeding, particularly in the region of the head, should be treated promptly with platelet transfusions, especially if the count is less than 20,000 per cubic millimeter. Prophylactic platelets need not be administered until the platelet count is less than 5,000 to 10,000 cubic millimeter. Transfusions should be leukocyte depleted, and family-derived transfusions should be avoided if a family-derived stem cell transplant is being considered. The cytomegalovirus antibody–negative patient should receive blood products from cytomegalovirus antibody–negative donors. In the event of a suboptimal response, nonimmunologic causes should be evaluated. With alloimmunization, HLA-compatible transfusions should be attempted. Long-term transfusion-dependent patients may develop transfusional hemosiderosis, requiring iron chelation with desferrioxamine. Early transfusion therapy may influence the ultimate outcome of a subsequent hematopoietic stem cell transplantation.

Specific therapy for aplastic anemia includes marrow stimulation, immunosuppression, and hematopoietic stem cell transplantation. Although some patients with severe aplastic anemia respond to androgen therapy, studies have revealed no statistically significant response rate. However, patients with mild aplasia may often respond. Several cytokines have been tested in patients with severe aplastic anemia, and there is no evidence that patients have recovered with this therapy. However, some patients with neutropenia have a temporary response to the administration of granulocyte colony-stimulating factor or granulocyte-macrophage colony-stimulating factor, and these should be tried in cases of life-threatening infection and severe neutropenia. These agents do not affect erythroid or platelet production. Studies of other hematopoietic-stimulating cytokines singularly and in combination and concurrently being administered with immunosuppressive agents

are under investigation.

Immunosuppressive therapy improves the hematologic status of approximately 40% to 50% of patients with severe aplastic anemia, although only a small percentage of patients appears to have a complete response. This therapy consists of antithymocyte globulin, high-dose corticosteroids, high-dose cyclophosphamide, and cyclosporine. More favorable and complete responses have been achieved in patients receiving a combination of immunosuppressive agents. Responses may take as long as 12 weeks, and the patient often requires interim transfusion support. Long-term follow-up reveals that a significant number of patients may develop recurrences, a myelodysplastic syndrome or acute leukemia, or paroxysmal nocturnal hemoglobinuria. These complications are probably not the result of the therapy; they result from the long-term persistence of damaged hematopoietic stem cells. It is not clear whether these patients normalize their survival.

Because the most common pathophysiologic defect is functionally absent hematopoietic stem cells, the most logical treatment of severe aplasia is hematopoietic stem cell transplantation. The factors limiting broad application of marrow grafting are identification of an appropriate donor and transplant-related complications. If typing identifies an HLA-identical sibling donor, the primary therapy for younger patients with severe aplasia should be hematopoietic stem cell transplantation. For previously untransfused patients 18 years of age and younger, the long-term survival rate is 80%. Although the cure rate decreases to approximately 30% for older patients, hematopoietic stem cell transplantation should be considered as primary therapy for patients younger than 40 to 45 years of age. Because of the poorer results of transplantation in older patients, a trial of immunosuppression should be considered as initial treatment. The choice of primary treatment is extremely important, because an adequate trial of immunosuppression places the patient at risk of requiring transfusion support and developing a life-threatening infection, and transplantation complications may result in death.

Frequent complications of hematopoietic stem cell transplantation for aplastic anemia are graft failure, with either failure to achieve primary engraftment or subsequent graft rejection. In an HLA-identical donor and recipient, this immunologic rejection results from minor non-HLA transplantation antigen differences. Adequate immunosuppression must be achieved with the preparative regimen. Patients of any age with a normal identical twin should undergo hematopoietic stem cell transplantation. However, even in this circumstance, immunosuppressive preparation may be necessary in 50% of patients. HLA-identical sibling donors are identified for 35% to 40% of patients. Although donors matching at five of six HLA antigens can serve as marrow donors for patients with malignant disorders, the success rate in those with aplastic anemia is less favorable. Similarly, hematopoietic stem cell transplantation with matched unrelated donors has been less successful in aplastic anemia patients than in those with malignant disorders. Umbilical cord blood transplantations have been successful. Without a matched family donor, consideration should be given to immunosuppression as the initial therapy.

Patients with genetic aplastic anemia have different therapeutic options. These patients often have primary responses to androgen treatment, but immunosuppressive therapy is unlikely to be successful. Transplantation in this setting has its own preparative regimens and features. The long-term course of these patients is complicated by the development of a variety of malignancies.

PURE RED CELL APLASIA

Pure red cell aplasia (PRCA) is a selective bone marrow failure syndrome uniquely involving erythroid production. The disorder involves a normocytic normochromic anemia, usually with normal leukocyte and platelet production. The patient has a severe reticulocytopenia, with virtual absence of erythroid precursors in the bone marrow. This disorder may be genetic or acquired, and acquired forms may be primary or secondary.

INCIDENCE AND EPIDEMIOLOGY

Congenital red cell aplasia (Diamond–Blackfan syndrome) is a rare disorder with autosomal dominant and recessive patterns of inheritance. Ninety-five percent of patients with this syndrome present by 2 years of age; some may present as late as 6 years of age. Diamond–Blackfan anemia may be associated with a variety of skeletal anomalies. This disorder must be differentiated from transient erythrocytopenia of childhood.

PRCA is rare in adults, although transient red cell aplasia may be associated with a variety of infections, including B19 parvovirus, especially in the setting of stress erythropoiesis. PRCA of adults occurs equally in both sexes and most commonly in middle age.

PRCA may be a primary or secondary process. In adult PRCA, the major identifiable cause is thymoma, occurring in approximately 30% to 50% of patients. Approximately 5% of patients with thymoma develop PRCA. However, the disorder is also associated with a variety of lymphoproliferative disorders and autoimmune disorders such as systemic lupus erythematosus or rheumatoid arthritis. Approximately 5% of patients with chronic lymphocytic leukemia develop PRCA. Other associations include AIDS, viral hepatitis, nonhematologic solid tumors, and a variety of drugs, including *α*-methyl dopa, chloramphenicol, diphenylhydantoin, isoniazid, and phenylbutazone.

PATHOGENESIS AND PATHOPHYSIOLOGY

The major pathophysiologic mechanism in PRCA involves a cellular or antibody autoimmune process directed against erythropoietin, erythropoietin-responsive cells, or erythroblasts. The cellular processes may be inhibitory or cytotoxic. In cases of thymoma, erythroid-suppressive thymic cells migrate to the marrow. Drug-associated PRCA may result from direct toxic effects of the drugs or from drug-associated immune suppression.

CLINICAL FINDINGS

The major clinical symptom of PRCA is progressive fatigue resulting from the anemia. The major physical finding is pallor. The disorder is not associated with organomegaly or lymphadenopathy unless it is associated with underlying precipitating conditions.

LABORATORY FINDINGS

The major findings in patients with PRCA are a normochromic, normocytic anemia and a reticulocyte count less than 1% and often zero. The platelet and leukocyte counts are usually normal. The serum iron is elevated, with saturation of the iron-binding capacity. The bone marrow is usually normocellular, with normal numbers of myeloid cells and megakaryocytes but lacking erythroid precursor cells. Occasionally, a small increase in lymphocytes occurs. A CT scan of the chest may demonstrate a thymoma. Laboratory investigations should include a search for underlying disorders, including immune system abnormalities, hepatitis, B19 parvovirus, AIDS, and myasthenia gravis.

OPTIMAL MANAGEMENT

The major supportive therapy for these patients is erythrocyte transfusions to remedy the absence of red cell production. In patients with refractory PRCA, long-term transfusions inevitably lead to transfusion siderosis, with damage primarily to the heart, liver, and pancreas. Patients should be periodically evaluated for their iron status, and, when appropriate, they should be considered for early chelation therapy before the development of organ dysfunction.

All possible offending drugs should be immediately eliminated; in such cases, resolution occurs within a few weeks. If thymoma is the underlying problem, thymectomy should be performed. In an inoperable situation, irradiation of the thymoma has also been effective. Thymectomy has not been effective in patients without thymomas. If an underlying malignancy is identified, therapy should be directed to this disorder. Persistent parvovirus infection often responds to intravenous *g*-globulin infusions.

Immunosuppressive therapy should be carefully attempted in the patient with persistent PRCA, usually beginning with corticosteroids. If a response is not achieved, other immunosuppressive therapies, such as cyclophosphamide, azathioprine, antithymocyte globulin, and cyclosporine or combinations of these therapies, have induced responses. After the patient achieves adequate reticulocyte production and a sustained hematocrit, attempts should be made to decrease or discontinue therapy. Approximately 80% of patients have spontaneous or therapy-induced responses, although relapses occur.

CHAPTER 231: MYELOPROLIFERATIVE DISORDERS: POLYCYTHEMIA VERA, THROMBOCYTHEMIA, AND MYELOFIBROSIS

EUGENE P. FRENKEL

[Polycythemia Vera](#)
[Primary Thrombocythemia](#)
[Myelofibrosis](#)

The term “myeloproliferative” encompasses a group of disorders linked by common clinical and laboratory features resulting from an autonomous clonal proliferation of a multipotential stem cell that produces a generalized expansion of all of the bone marrow elements. The clinical nomenclature delineates subtypes based on the predominant peripheral blood expression of the autonomous hyperplastic marrow response: polycythemia vera (PV) indicates a proliferation of red cells; chronic myelogenous leukemia, white cells; myelofibrosis, extramedullary hematopoiesis; and primary or essential thrombocythemia, platelets.

The generic term myeloproliferative disorder is clinically useful, although it denotes our lack of understanding of the mechanisms through which growth control is lost as well as the absence of absolute marrow histologic criteria. It is especially appropriately applied to some patients for whom the specific peripheral phenotypic expression of the panmyelosis has not yet become clear. The term also suggests that transition from one type to another may occur.

Neoplastic transformation of the pluripotential stem cell is a multistep process. Events confer a growth advantage for this clone over those normally regulated in the marrow, and subsequent events provide further selective proliferation and amplification of a cell lineage-specific population (e.g., red cells in polycythemia). Because the molecular biologic, cytogenetic, and signal mechanisms have been characterized for chronic myelogenous leukemia ([Chapter 228](#)), it is appropriate to separate it from the more generic group described in the subsequent sections.

POLYCYTHEMIA VERA

PV is an autonomous clonal proliferation of a multipotential stem cell that results in a generalized hyperplasia (panmyelosis) of the bone marrow, increased production of red blood cells (RBCs), and an absolute increase in the numbers of circulating RBCs. The term *vera* implies that the erythron expansion occurs without an identifiable mechanism, separating it from nonautonomous causes of RBC production. The diagnostic criteria for PV developed by the Polycythemia Study Group are delineated in [Table 231.1](#). The American criteria were affected by the belief that bone marrow examination was nonspecific. During recent years, a European consortium has reexamined these criteria and emphasized the bone marrow morphologic findings of megakaryocyte clustering and hyperploid nuclei. In addition, a classic finding in PV is spontaneous erythroid colony growth with no erythropoietin (EPO). Their diagnostic criteria are also shown in [Table 231.1](#).

A1	Increased red cell mass	B1	Thrombocytosis
A2	Hemoglobin > 16.5 g/dL	B2	Platelet count > 400 × 10 ⁹ /L
A3	Hemoglobin > 15 g/dL	B3	Platelets > 12 × 10 ⁹ /L and no fever or infection
A4	Hemoglobin > 12 g/dL	B4	Platelet functional abnormality (bleeding time > 100 or reed & scowling > 1000 s) or raised anastomosis, binding capacity < 1.208 ng/L
A5	Splenomegaly on palpation		

Diagnosis of PV is acceptable if the following combinations are present: A1 + A2 or A3 or A4 + A5 or any two from categories B

The Rotterdam Criteria of Polycythemia Vera Proposed by the Thrombocythemia Vera Study Group (TVSG)

A1	Increased red cell mass	B1	Thrombocytosis
A2	Hemoglobin > 16.5 g/dL	B2	Platelet count > 400 × 10 ⁹ /L
A3	Hemoglobin > 15 g/dL	B3	Platelets > 12 × 10 ⁹ /L and/or raised mean platelet volume
A4	Presence of any cause of secondary erythrocytosis	B4	Abnormal platelet reactivity > 100 in the absence of fever or infection
A5	Microangiopathy of bone marrow biopsy (increased cellularity, panmyelosis, enlarged megakaryocytes with hyperploid nuclei, fibrosis, etc.)	B5	Splenomegaly on palpation or imaging
A6	Spontaneous erythroid colony formation in absence of EPO (spontaneous EEC)		

A1 + A2 + A3 + A4 is consistent with early stage PV (Polycythemia erythrocytosis)
A1 + A2 + A3 + A5 is consistent with essential thrombocythemia
A1 + A2 + A3 + A6 is consistent with primary myeloproliferative disorder

SPC, erythrocytosis; EEC, erythropoietin-independent erythroid colonies
*Adapted from Berlin et al. Diagnostic and classification of the polycythemia vera, essential thrombocythemia, and polycythemia vera by the thrombocythemia vera study group. *Blood* 1993;81:1333

TABLE 231.1. CRITERIA FOR THE DIAGNOSIS OF POLYCYTHEMIA VERA PROPOSED BY THE POLYCYTHEMIA VERA STUDY GROUP (PVSG)^a

EPIDEMIOLOGY

The annual incidence of PV in the United States is about 5 cases per 1 million persons. It is diagnosed most often in persons between 50 and 70 years of age, although it occurs in all age groups. A slight male predominance (1.2: 1) exists, but a previously reported predilection for Jews of European extraction has not been confirmed. No other epidemiologic factors have been defined.

PATHOGENESIS

Neither the pathogenetic mechanisms nor the molecular biologic events in PV are known. The clonal origin of the acquired mutation of the multipotential hematopoietic stem cell has been firmly established by isoenzyme characterization, clonogenic assays, and cytogenetic analysis. Cytogenetic abnormalities found in 12% of patients at diagnosis include trisomy 8, trisomy 9, and deletion of the long arm of chromosome 20 [del(20)(q12)]. The trisomy 8 is common in PV patients around the world, but the geographic distribution of the other genetic changes is not uniform. The molecular correlates of these pathogenic changes are unknown. Chromosomal evolution occurs during the course of the disease; but, the chromosomal abnormalities do not correlate with the clinical course, nor do they predict survival or leukemic transformation.

Clonal panmyelosis is a hallmark of all the myeloproliferative disorders. In PV, the process is exhibited through an unknown perturbation of the multipotential stem cell that results in selective proliferation and amplification of RBCs. Studies of cellular mosaicism and erythroid colony growth have shown the existence of normal and neoplastic multipotential stem cells and progenitors in the marrow early in the disease. Subsequent amplification of the neoplastic clone results in decreased production from the normal clones, especially beyond the erythroid burst-forming stage. Their growth appears relatively independent of erythropoietin, and the receptor structure, binding, and internalization are normal. The thrombopoietin receptor (Mpl) is absent or markedly reduced in platelets and megakaryocytes in patients with PV. Because thrombopoietin inhibits apoptosis, its dysfunction may result in a defect in programmed cell death with resultant cellular accumulation providing a mechanism for expansion of the erythron.

CLINICAL FINDINGS

The early clinical findings in PV result from the expanded RBC mass; however, during the disease course, several clinical stages evolve and manifest different features.

The *preerythrocytic* or *inapparent phase* of PV is often unrecognized, and the signs and symptoms of this developmental stage are commonly insidious. During this phase, the circulating RBC mass has not yet increased, and only splenomegaly or pruritus after bathing may be noticed. Occasionally, mild thrombohemorrhagic symptoms or erythromelalgia (painful, burning erythematous palms and soles) occur. This phase lasts for a few months to 1 or 2 years. Portal vein thrombosis, particularly with isolated splenomegaly, is a significant clinical event. The diagnostic complex is normal hematocrit, a low serum EPO, and evidence of spontaneous erythroid colony growth with no EPO.

The classic picture of PV is seen in the *erythrocytic phase*, often first recognized because of an occlusive arterial or venous lesion, such as cerebral or myocardial infarction or ischemia, portal venous obstruction, or peripheral venous thrombosis. The expanded RBC mass produces symptoms of hyperviscosity, and the reduced cerebral blood flow can result in headaches, dizziness, and visual disturbances. Plethora and conjunctival or oral mucosal suffusion are common. Some patients present with hemorrhagic phenomena, usually affecting the mucosa or skin in the form of epistaxis, gastrointestinal or genitourinary bleeding, or ecchymosis. Bleeding

sufficient to result in normal or low RBC values may obscure the underlying condition and confuse the diagnosis. Gastrointestinal symptoms and peptic ulcer disease also occur with increased frequency in this patient population.

Splenomegaly is the most common physical finding, identified in almost 90% of these patients; hepatomegaly occurs in about 50%. Episodes of acute gout associated with overproduction of urate may occur in 5%, and gout is occasionally the presenting complaint. With therapy, the erythrocytic phase may last 5 to 20 years.

In time, significant thrombocytosis occurs, frequently accompanied by renewed thrombohemorrhagic signs and symptoms; this change identifies the *proliferative phase* of PV. Asymptomatic leukocytosis is usually a feature of this phase, and increasing splenomegaly is common. The proliferative phase usually lasts a few years.

Subsequent evolution into the *postpolycythemic myeloid metaplasia phase* is gradual and occurs in 20% of patients. The median time to conversion is about 10 years. Asthenia is the most common symptom. Weight loss and generalized wasting, with clinical features of myelofibrosis, develop during this phase. Progressive splenomegaly occurs with increasing anemia and hemorrhagic findings. Extramedullary hematopoiesis in lymphoid sites may produce pressure symptoms in the gastrointestinal, respiratory, or central nervous system. Most patients in this phase have a shortened survival, dying of clinical complications, or the disease evolves to acute leukemia within 3 years, conferring an equally poor prognosis.

A small subset of patients undergo transition to a leukemic phase, producing the typical picture of acute nonlymphocytic leukemia. Such progression is most common (25% to 50%) in those who develop myeloid metaplasia. As in most secondary leukemias, therapy rarely produces durable remissions, and the survival is short.

LABORATORY FINDINGS

PV is usually recognized by an increase in the RBC count, hemoglobin concentration, and hematocrit. Early in the disease, the RBCs are of normal size. Because mucosal bleeding is common, iron deficiency frequently ensues, and RBC microcytosis develops. A low RBC mean corpuscular volume (less than 80 fL) with normal RBC values on presentation of a patient with recent blood loss is suggestive of PV.

Thrombocytosis (platelet count greater than 450,000 per microliter) is often seen at the time of the patient's initial diagnosis. Platelet size heterogeneity is common, as evidenced by the increased mean platelet volume, asymmetric histograms, or examination of the peripheral smear. Megakaryocytic hyperplasia, increased platelet production rate, and shortened platelet survival are found. Platelet functional abnormalities are common, and these correlate with an increased thrombohemorrhagic phenomena.

Leukocytosis, primarily granulocytosis with increased numbers of basophils, is seen in almost 50% of patients at diagnosis. There is increased granulocyte production, an increase in leukocyte alkaline phosphatase activity, and the production of cobalamin-binding proteins, which results in increased serum B₁₂ levels.

An absolute increase in the measured RBC mass, corrected for age, sex, and body surface area, is required for the diagnosis of PV. Measurement of the RBC mass is performed with radiochromate-tagged RBCs. As a consequence of the increase in the RBC mass, the whole blood viscosity is elevated in patients, and the incidence of vascular occlusive events relates to this increase.

The bone marrow is diffusely hypercellular (almost 100%), with an increase in all hematopoietic elements (panmyelosis) and an increase in clustered enlarged megakaryocytes with hyperplod nuclei and usually absent iron stores. Marrow reticulin fibers increase during the course of the disease.

Some of the laboratory changes correlate with clinical manifestations of the disease. Increased numbers of basophils, producing histamine or histamine-like substances, probably explain the postbathing pruritus. Hyperuricemia and clinical gout result from the increased cell turnover. The "spurious hyperkalemia" resulting from potassium released from the increased numbers of qualitatively defective platelets is common and can confuse laboratory results.

Three other aspects of laboratory evaluation merit emphasis. First, although cytogenetic analysis has not identified any specific nonrandom change, trisomy 8, trisomy 9, or deletion of the long arm of chromosome 20 can be detected in about 12% of untreated cases. Second, serum erythropoietin levels are reduced. Third, the demonstration of erythropoietin-independent erythroid colonies in vitro is diagnostic.

As PV progresses to the later phases, other laboratory features become evident. Leukoerythroblastosis (abnormal-shaped and nucleated RBCs and immature white cells) occurs with progressive anemia and thrombocytopenia, and marrow fibrosis develops during the postpolycythemic myeloid metaplasia phase. Patients who enter the leukemic phase have laboratory and cytogenetic findings characteristic of a secondary type of acute leukemia.

DIAGNOSIS

The criteria for the diagnosis of PV are shown in [Table 231.1](#). Established by the Polycythemia Study Group in 1967, these criteria have provided consistent parameters for the evaluation of the disease course and of responses in therapeutic trials. The recent modifications of these criteria by the European investigators are also shown.

OPTIMAL MANAGEMENT

The survival of patients with PV changed remarkably with the advent of treatment. Median survival without therapy was 18 months, but the median survival is 8.9 years for patients treated with an alkylating agent, 11.8 years with radiophosphorus therapy, and 13.9 years with phlebotomy alone. Appropriate therapy results in survival times approaching those expected for age-matched controls.

The changing clinical features that characterize the evolving phases of PV require different therapeutic approaches. In the preerythrocytic phase, when pruritus is a common symptom, histamine H₂ antagonists (e.g., 300 mg of cimetidine administered three times daily) in combination with an H₁ blocker (e.g., 4 mg of cyproheptadine three times daily or 10 mg of astemizole daily) are effective. Recombinant interferon- α (rIFN- α) has been effective at pruritus control where other measures have failed.

The excellent median survival rate accomplished with phlebotomy therapy alone had established this as the treatment of choice during the erythrocytic phase. Unfortunately, thrombotic events are common during the first 2 to 3 years of phlebotomy therapy. Alternate approaches now commonly instituted include hydroxyurea and, more recently, rIFN- α . These latter are particularly important in patients with a history of thrombotic events or in the elderly (particularly if obese or diabetic) in whom there is an enhanced risk of thrombosis with phlebotomy. Phlebotomy is still an important part of the maintenance program. Initially, antiplatelet agents, such as aspirin, were considered hazardous; recent results have led to the addition of low-dose aspirin. Clearly, however, the risk of thrombosis is best controlled by maintaining the hematocrit under 45.

Hyperuricemia should be managed with daily allopurinol. The iron deficiency secondary to phlebotomy does not merit therapy, because iron replacement encourages further expansion of the RBC mass.

For younger patients with a high phlebotomy requirement (more than 6 units per year) or for anyone with significant proliferative features (e.g., thrombocytosis, splenomegaly), myelosuppressive therapy is indicated. Hydroxyurea, has been the drug of choice, although recent data have defined an emerging therapeutic role for rIFN- α . The typical dosage for hydroxyurea is 10 to 15 mg per kilogram per day, administered with the goal of maintaining the hematocrit below 50% and the platelet count below 650,000 per microliter. Dosage adjustments may be required—downward for the development of cytopenias or upward for inadequate control. Most patients achieve excellent control within 12 weeks of beginning therapy. Uncommonly, hydroxyurea has been associated with painful refractory leg ulcers requiring its cessation. In addition, it is now evident that hydroxyurea does not protect against the leukemic transformation prevalent in the era of radiophosphorus therapy nor does it delay emergence of myelofibrosis. It is associated with approximately a 10% leukemic conversion by the tenth year. For these reasons, rIFN- α (3 million U three times per week; increased to 6 million per dose at 3 months if suppression is inadequate) has been used. It has been successful at myelosuppression in controlling pruritus and reducing spleen size. Its long-term efficacy relative to transformation is uncertain.

For patients in whom persistent thrombocytosis is a major problem, anagrelide, an imidazoquinazolin compound, is effective in reducing platelet numbers by interference with megakaryocyte maturation. In clinical trials, it was effective at a daily dose of 0.5 to 3 mg and produced little toxicity; it appears to be nonmutagenic

and nonleukemogenic.

Therapy during postpolycythemic myeloid metaplasia is supportive. Erythropoietin has reduced the transfusion requirement. Symptomatic extramedullary tumors respond well to radiation therapy. Recurrent painful splenic infarctions or symptomatic congestive splenomegaly may require splenectomy. Allogeneic HLA-matched bone marrow or peripheral stem cell transplantation has been successful for patients under the age of 55. The transition to leukemia, as with the development of other secondary leukemias, is associated with a poor response to therapy.

Surgery is a special problem in PV. Untreated patients have significant operative morbidity and mortality, but these risks decline to normal when the elevated RBC values are reduced to normal and remain stable before surgery.

PRIMARY THROMBOCYTHEMIA

Primary thrombocythemia, often called *essential thrombocythemia*, is an autonomous clonal proliferation of a multipotential stem cell that results in marrow panhyperplasia, increased platelet production, and an increased number of circulating platelets. The diagnostic criteria are shown in [Table 231.2](#). By definition, all secondary causes of increased platelet numbers, such as infection, trauma, and splenectomy, are absent. The controversial issue focuses on the number of platelets that makes up the primary parameter. The Polycythemia Vera Study Group in the United States had used 650,000 per microliter and the European Thrombocythemia Vera Study Group has used 400,000 per microliter; the reasonable rationale of the latter has focused on counts that are above normal, where other mechanisms have been excluded. Because the clinical correlates of thrombohemorrhagic manifestations only weakly relate to the absolute platelet numbers, the approach of the European groups appear appropriate.

Platelet count greater than $450 \times 10^9/L$ (confirmed on more than one occasion)
Absence of an identifiable cause for the increased platelet counts
Absence of a myelodysplastic syndrome or other myeloproliferative state
Bone marrow with:
Megakaryocytic hyperplasia
Fibrosis less than 1/3 of marrow cross-section
Ancillary supportive criteria:
1. Splenomegaly
2. In vitro: spontaneous megakaryocyte colony formation

TABLE 231.2. DIAGNOSTIC CRITERIA FOR PRIMARY (ESSENTIAL) THROMBOCYTHEMIA

EPIDEMIOLOGY

Incidence data and epidemiologic characterization do not exist for primary thrombocythemia. Most reported clinical series have a predominance of women.

PATHOGENESIS

Neither the pathogenic mechanisms nor the molecular biologic events are known. The clonal origin of the stem cell has been established by isoenzyme (glucose-6-phosphate dehydrogenase) distribution in heterozygotes. Using X-chromosome inactivation analysis of women with the appropriate diagnostic parameters, it is now evident that many patients are polyclonal. No consistent cytogenetic abnormalities have been identified. The net mass of megakaryocytes is increased, and the increased platelet production does not respond to the usual regulatory mechanisms. The autonomous proliferation of megakaryocytes increases the megakaryocytic volume, the reverse of reactive thrombocytosis, in which megakaryocytic volume decreases with increased platelet numbers. Unlike PV, the thrombopoietin receptor expression is normal.

CLINICAL FINDINGS

A significant but unknown percentage of patients with primary thrombocythemia are asymptomatic and are identified by an increased platelet count during a routine blood study. Thrombohemorrhagic symptoms and findings are the classic manifestations. It appears that the polyclonal patients may have fewer thrombotic events than the monoclonal ones. Mucosal bleeding is most common, followed by arterial and venous vascular thromboses that produce the variety of symptoms and signs expected with a vascular occlusion. Headaches and neurologic findings due to microvascular occlusions and Budd–Chiari syndrome are particularly prominent clinical problems. The only physical finding directly related to primary thrombocythemia is splenomegaly, which is detected in 20% of patients. Erythromelalgia, a characteristic thrombotic complication that results in red, swollen, burning painful extremities, also occurs.

LABORATORY FINDINGS

The criteria for diagnosis are shown in [Table 231.2](#). The primary diagnostic laboratory finding is a persistent elevation of the platelet count in the absence of a definable reactive cause, such as blood loss, splenectomy, cancer, chronic infectious or inflammatory states, or drugs. Large, atypical platelets and a measurable platelet functional defect are common. Pseudohyperkalemia and an elevated uric acid level are detected. Bone marrow examination reveals classic panmyelosis and clusters of mature megakaryocytes.

OPTIMAL MANAGEMENT

Therapy is directed toward reduction of platelet numbers. Hydroxyurea (approximately 10 to 15 mg per kilogram per day) has commonly been used. It can produce painful leg ulcers requiring its discontinuation. More complex and unsettled is its role in the uncommon leukemic transformation. An alternative is rIFN- α , which is successful in approximately 70% of patients, but durable control off therapy is uncommon. Control usually requires 5 million units per day, and maintenance requires 1 to 2 million units per day, making this therapy expensive and subject to the symptoms associated with interferon therapy.

Anagrelide is an alternative therapy. It is highly effective in reducing platelet numbers in patients with primary thrombocythemia and in other myeloproliferative disorders; the average daily oral dose is 0.5 to 3.0 mg. In acute or severe evolving thrombotic or hemorrhagic events, thrombocytapheresis can be used for crisis intervention; rapid reduction in platelet numbers can be achieved, but the effects are transient.

Pregnancy in patients with primary thrombocythemia is associated with frequent obstetric complications and fetal loss. The risks of the usual platelet suppressive measures have led to the use of aspirin, which has been effective and has allowed term delivery. This experience, as well as its remarkable efficacy in erythromelalgia, has led to the more general use of low-dose aspirin in patients with primary thrombocythemia.

MYELOFIBROSIS

Myelofibrosis is characterized by bone marrow fibrosis and extramedullary but ineffective hematopoiesis, which involves all cell lineages; the clinical signs and symptoms are the result of this extramedullary activity. This is a clonal stem cell disorder, typical of all myeloproliferative lesions.

The use of a variety of names, such as agnogenic myeloid metaplasia, myelosclerosis, and myeloid metaplasia, emphasizes our limited knowledge of the biology of this syndrome. No epidemiologic data exist for myelofibrosis.

ETIOLOGY AND PATHOGENESIS

Because a variety of mechanisms of marrow injury produce marrow fibrosis, the syndrome is generally considered to be the result of a defined or idiopathic injury. Two events, although not coordinated, appear to define myelofibrosis. Hematopoietic stem cells that are found in increased numbers in the circulation settle, develop, and proliferate in nonmarrow sites. The proliferation is clonal and has a "trilineage" of red and white cells and platelets. Fibroblastic proliferation in the marrow, the result of injury or the product of abnormal megakaryocytopoiesis, is reactive (nonclonal). It results in a decreased marrow mass, a disordered sinusoidal pattern with premature release of cells of all lineages, and an increased release of hematopoietic stem cells.

The known causes of myelofibrosis are chemicals (especially benzene), radiation, infections (especially granulomatous disease), metastatic cancer, and immune complexes; nevertheless, most cases of myelofibrosis are idiopathic.

CLINICAL FINDINGS

All the clinical findings in patients with myelofibrosis are directly attributable to marrow fibrosis and extramedullary hematopoiesis. A presymptomatic phase may be indicated by splenomegaly or abnormal peripheral blood. Later, constitutional symptoms, such as fatigue, weakness, and fever, form the common presentation. These result from the anemia and ineffectual hematopoiesis. Focal pressure symptoms due to potentially massive sites of extramedullary hematopoiesis are the hallmark of myelofibrosis, especially secondary to splenomegaly. Later, the lymph nodes and liver become enlarged. In time, easy bruising and mucosal bleeding occur, often constituting a cosmetic more than clinical problem. Symptomatic gout occurs in 10% of patients. Late clinical complications include portal hypertension and Budd–Chiari syndrome, ascites, and endocardial fibrosis with right-sided heart failure.

LABORATORY FINDINGS

Peripheral blood findings of leukoerythroblastosis (anemia with anisocytosis, teardrop-shaped and nucleated RBCs, leukocytosis with a left shift of white cells and increased basophils, and large, atypical platelets) provide evidence of an altered sinusoidal marrow matrix and resultant premature release of cells. These findings of ineffective hematopoiesis are documented by increased levels of lactate dehydrogenase, uric acid, and uramidase. Bone marrow aspiration is usually ineffective, and a biopsy reveals increased reticulum fibers (and in time, increased collagen) enmeshing a panhyperplastic marrow with particular megakaryocytic entrapment. Examination of the spleen, liver, and nodes reveals trilineage hematopoiesis characteristic of extramedullary hematopoiesis. Bone x-ray films or MRI findings reveal osteosclerosis.

OPTIMAL MANAGEMENT

After specific causes for myelofibrosis have been eliminated, all therapy is directed toward the clinical symptoms and complications. The care is supportive. Erythropoietin has reduced the transfusion requirement, particularly when serum levels are lower than expected for the degree of anemia. Other cytokine support is being examined. Low-dose hydroxyurea (500 mg every day or every other day) has been associated with reduction in spleen size, decreased marrow fibrosis, and improved peripheral blood findings; responses are very slow, usually requiring 12 to 18 months. Splenectomy has been used with success for specific indications: severe abdominal symptoms, especially suggesting splenic infarctions; severe unresponsive hemolysis or thrombocytopenia; and portal hypertension with bleeding varices. Allogeneic human leukocyte antigen (HLA)-matched bone marrow or peripheral stem cell transplantation has been used with success in patients younger than age 55.

CHAPTER 232: HODGKIN'S DISEASE

SANDRA J. HORNING

[Incidence and Epidemiology](#)
[Etiology](#)
[Pathology](#)
[Clinical Findings](#)
[Laboratory Features](#)
[Optimal Management](#)

Hodgkin's disease is a B-cell lymphoid neoplasm originally described as a clinical entity in 1832 by Thomas Hodgkin and defined microscopically by pathologists Carl Sternberg and Dorothy Reed at the turn of the twentieth century. The diagnosis is based on the recognition of Reed–Sternberg (R-S) cells interspersed among a reactive mixed-cell population of lymphocytes, eosinophils, histiocytes, plasma cells, and neutrophils. Four histologic types (lymphocyte predominance, nodular sclerosis, mixed cellularity, and lymphocyte depletion) are distinguished on the basis of the morphology and immunohistochemistry. The anatomical extent of disease, associated symptoms and, to a lesser degree, the histologic subtype are the primary factors determining the presenting features, prognosis, and optimal therapy of Hodgkin's disease.

Although uncommon, Hodgkin's disease is significant because the systematic, multidisciplinary approach to diagnosis, staging, and treatment serves as a paradigm in oncology. As one of the most highly curable malignancies, therapy for Hodgkin's disease is approached with optimism; however, late effects of treatment continue to instruct and provide an impetus for new therapeutics.

INCIDENCE AND EPIDEMIOLOGY

The annual incidence of Hodgkin's disease, about 7,600 cases or 3.2 per 100,000, has been stable over the past decade in the United States. The incidence is higher in men than women and higher in whites than blacks. A bimodal age–incidence curve has been described in which rates rise through early life, peak in the third decade, decline until age 45, and thereafter rise steadily. The nodular sclerosis subtype is more common in young adults, whereas the mixed-cellularity subtype predominates in children and the elderly. In the young adult population, high socioeconomic status, high intelligence, small family size, single-family dwelling, and high educational attainment of patients and their immediate families all have been associated with increased risk of Hodgkin's disease.

The incidence of Hodgkin's disease varies by geographic patterns. In less developed countries, childhood and mixed-cellularity histology predominate. In developed countries, young adults with more favorable histologic subtypes are typical. These data have led to the hypothesis that one or more subtypes of Hodgkin's disease has an infectious cause. Several reports of clustering of Hodgkin's disease at the time of diagnosis suggested the possibility of infectious transmission but these studies have been sharply criticized. A large population study has demonstrated abnormally high titers of some anti-EBV (Epstein–Barr virus) antibodies antedating a diagnosis of Hodgkin's disease. The demonstration of EBV viral genomes in R-S cells supports a relation between EBV and Hodgkin's disease, and the epidemiologic features fit a polio model in which delayed age at infection leads to an increased risk of young adult disease. However, the association with EBV in tumor tissue is inconsistent with the model in that positive cases occur most often in children, especially in less developed countries and with mixed-cellularity histology.

ETIOLOGY

The fact that R-S cells account for only about 1% to 10% of the cellular composition in Hodgkin's tissues complicated their classification for more than 100 years. Recent studies involving isolation of single cells demonstrate that R-S cells are B cells with an excessive load of mutations within the variable region of the immunoglobulin heavy-chain gene, resulting in a loss of function. A second transforming event is postulated since these follicular center B cells fail to undergo apoptosis despite crippling mutations. EBV has been implicated as the transforming event based on multiple lines of evidence. With *in situ* hybridization methods, 18% to 50% of Hodgkin's cases are EBV-positive, and the viral genomes are present in a monoclonal population of cells. As already discussed, EBV in Hodgkin's tissues is associated with histology and demographic variables.

The histologic subtypes of Hodgkin's disease are defined by the relative amounts of collagen sclerosis, inflammatory cells, and the cytology of the malignant R-S cells. As observed on primary tissue and well-established cell lines, R-S cells secrete a variety of cytokines that may be responsible for the presence and activity of the nonmalignant cells surrounding them. These reactive cells, in turn, produce cytokines that can influence R-S cells in complex autocrine or paracrine interactions.

A genetic basis for increased susceptibility to Hodgkin's disease is supported by a marked risk in monozygous twins and increased risk among siblings and close relatives. It has been hypothesized that immunoregulatory genes within or near the major histocompatibility complex that may govern susceptibility to viral infections influence susceptibility to Hodgkin's disease. This theory is supported by data demonstrating specific human lymphocyte antigen (HLA) regions in the cause of Hodgkin's disease and increased HLA haplotype sharing among relatives in multiple-case families. Furthermore, Hodgkin's disease is associated with a variety of defects in cellular immunity, and successfully treated patients may continue to have suppressed responses to neoantigens for years.

PATHOLOGY

Nodular sclerosis accounts for 40% to 70% of all cases of Hodgkin's disease and is distinguished by distinctive fibrous bands that divide the lymphoid tissue into cellular nodules in addition to R-S cells and the appropriate cellular background. Mixed-cellularity histology is found in 30% to 50% of patients at diagnosis. Classic R-S cells are easily found amid a cellular background composed of lymphocytes, eosinophils, plasma cells, and histiocytes. Lymphocyte predominance (LP) is primarily composed of benign lymphocytes and relatively abundant multilobated “popcorn” cells.

LP Hodgkin's disease is uncommon, representing about 10% of cases. The pathologic diagnosis is based on the expression of surface markers as well as microscopic features. Classic Hodgkin's disease (nodular sclerosis and mixed cellularity) express the CD30 antigen, a marker of lymphocyte activation, and the CD15 antigen, which has been found on granulocytes, monocytes, activated T cells, and virus-infected cells. In contrast, the B-cell antigen CD20 is expressed by the multilobated cells of the LP subtype. Lymphocyte-depleted (LD) is a rare form of Hodgkin's disease in which two histologic variants have been described: a reticular type characterized by sheets of pleomorphic neoplastic cells and the diffuse fibrosis type, which has a prominent fibroblastic proliferation with few normal lymphocytes and sparse R-S cells. On retrospective review, many cases of LD Hodgkin's disease have been reclassified as non-Hodgkin's lymphoma.

CLINICAL FINDINGS

Constitutional symptoms, referred to as “B” symptoms, may accompany the diagnosis of Hodgkin's disease and influence prognosis. These include temperature higher than 38°C, drenching night sweats, and weight loss exceeding 10% of baseline body weight during the 6 months preceding diagnosis. Fevers, present in about one-third of patients, are usually low grade and irregular, although, rarely, a cyclic pattern of high fevers for 1 to 2 weeks is noted to alternate with afebrile periods of similar length. This classic Pel–Ebstein fever is virtually diagnostic of Hodgkin's disease. Internists should be alert to unexplained, generalized pruritus in young adults as symptomatic of Hodgkin's disease. Pain immediately after the ingestion of alcohol in involved lymph nodes is a curious complaint that is nearly pathognomonic for Hodgkin's disease. The cause of these symptoms, speculated to be related to cytokines, remains largely unexplained.

Detection of an unexplained mass or swelling in the superficial lymph nodes, especially the neck, is the most common presentation of patients with Hodgkin's disease. The lymph nodes are characteristically nontender and have a rubbery consistency. A diffuse, puffy swelling rather than a discrete mass may be apparent in the supraclavicular, infraclavicular, or anterior chest wall regions. Facial swelling and engorgement of the veins in the neck and upper chest may result from compression of the superior vena cava. Physical examination is relatively insensitive to the detection of intra-abdominal and pelvic adenopathy or organ enlargement, but examination should be oriented toward the liver, spleen, and iliac and inguinal nodal regions.

Clinical features are strongly correlated with histologic subtype in Hodgkin's disease patients. There is a 4:1 male predominance in LP Hodgkin's disease, and patients typically present with limited peripheral adenopathy. Involvement of the lower cervical, supraclavicular, and mediastinal lymph nodes in adolescents and young adults, particularly females, is characteristic of the nodular sclerosis subtype. Mixed-cellularity Hodgkin's disease is seen at both ends of the age spectrum, is

more commonly associated with advanced, symptomatic disease, and is the predominant subtype found in patients infected with HIV. The rare LD subtype is overrepresented in older patients, who may present with fever of unknown origin, jaundice, and hepatosplenomegaly without palpable adenopathy. This subtype is also associated with AIDS.

LABORATORY FEATURES

The laboratory features of Hodgkin's disease are nonspecific. A routine complete blood count may reveal granulocytosis, eosinophilia, lymphocytopenia, thrombocytosis, or anemia of chronic disease. Cytopenias may occur as a result of marrow involvement, hypersplenism, or an autoimmune mechanism. The degree of elevation of the erythrocyte sedimentation rate (ESR) has prognostic significance, correlating with advanced disease and constitutional symptoms. Serum alkaline phosphatase may be elevated in patients with Hodgkin's disease, nonspecifically in those with limited disease, or in association with involvement of liver, bone, or bone marrow in advanced disease. Hypercalcemia is unusual in Hodgkin's disease and appears to be secondary to synthesis of increased levels of 1,25-dihydroxyvitamin D by Hodgkin's tissues. Laboratory abnormalities may be prominent in rare presentations of Hodgkin's disease. These include abnormal liver function tests associated with marked enlargement of porta hepatis nodes and biliary obstruction or intrahepatic cholestasis. The nephrotic syndrome is a rare presentation of Hodgkin's disease.

OPTIMAL MANAGEMENT

Upon establishment of a histologic diagnosis of Hodgkin's disease by an expert pathologist, a diagnostic evaluation is undertaken. In addition to a complete history and physical examination, all patients should have computed tomographic (CT) scans of the chest, abdomen, and pelvis. Intrathoracic disease is present in two-thirds of patients at diagnosis and is particularly common in young women with nodular sclerosis. Chest CT scans may reveal hilar adenopathy, pulmonary parenchymal involvement, pleural effusions, pericardial effusions, and chest wall masses, especially with bulky mediastinal disease. CT of the abdomen and pelvis may detect celiac, portal, splenic hilar, retroperitoneal, and pelvic lymph nodes. Despite technologic advances, the correlation with histologic involvement of the spleen continues to be disappointing. Exploratory (staging) laparotomy has been phased out of routine staging owing to changes in treatment as described in the following text. Bone marrow biopsy is indicated in patients who are symptomatic or have extensive disease or cytopenias. Patients with bone pain should have bone scans and directed skeletal x-rays, which may demonstrate osteolytic, osteoblastic, or mixed lesions. Single positron-emission computed tomography (SPECT) gallium scanning may be useful in serial evaluation of extensive mediastinal disease before and after treatment.

The diagnostic evaluation of a person with Hodgkin's disease leads to the assignment of stage and directs the patient's therapy. The anatomical distribution of Hodgkin's disease in contiguous lymphatic structures is largely predictable and nonrandom. These patterns of association form the basis for the four-stage Ann Arbor classification, used to define the extent of Hodgkin's disease. Disease on one side of the diaphragm is considered stage I (one nodal site) or II (two or more sites), whereas stage III is disease confined to lymph nodes on both sides of the diaphragm. Extranodal disease, representing extracapsular extension of lymph node disease that can be treated with a curative dose of radiation therapy, is distinguished from disseminated, stage IV disease. Staging is further characterized by the presence (B) or absence (A) of constitutional symptoms. The correlation of this staging classification system with prognosis has been extensively verified, and, in a recent modification known as the *Cotswold classification*, additional prognostic information has been included.

In practice, as noted in [Figure 232.1](#), patients are determined to have favorable stage I–II disease (asymptomatic, nonbulky), intermediate stage I–II disease (symptomatic, or bulky or contiguous extranodal disease), or advanced stage III–IV disease. Extended-field radiation therapy was the treatment of choice for favorable stage I–II Hodgkin's disease for more than three decades. However, late complications occurring 15 to 25 years after radiation therapy have created interest in combined-modality approaches using less toxic or abbreviated chemotherapy programs with involved-field radiation therapy. The combined-modality approach obviates the need for staging laparotomy and extended-field irradiation. Cure rates higher than 90% are regularly reported with this approach, which may require no more than 2 to 4 months of combination chemotherapy followed by 30 to 36 Gy of involved-field irradiation. Several chemotherapy combinations have been investigated in this setting. The ABVD (doxorubicin, bleomycin, vinblastine, dacarbazine) combination is favored by many practitioners because of its relatively favorable toxicity profile.

FIGURE 232.1. Optimal management of Hodgkin's disease. (CT, chemotherapy; RT, radiation therapy.)

Combined-modality therapy is indicated for intermediate Hodgkin's disease presenting as a bulky mediastinal mass. Cure can be expected in 70% to 80% of such patients. Chemotherapy alone or chemotherapy plus involved-field radiation therapy are standard treatments for stage IIB Hodgkin's disease. ABVD chemotherapy is recommended based on a randomized clinical trial demonstrating the superiority of this combination compared with an alternate regimen, both delivered with radiation therapy, in intermediate Hodgkin's disease.

On the basis of a series of successive randomized trials, ABVD chemotherapy has emerged as the most effective and least toxic combination for advanced Hodgkin's disease. Treatment with six to ten cycles yields continuous disease-free survival in 65% to 70% of patients with stage III or IV disease 5 years after treatment. Although high rates of cure have been reported with consolidative radiation therapy given in low dose after chemotherapy, randomized trials have failed to establish definite benefit. Further improvement in these outcomes has been reported with newer chemotherapy programs, but assessment of these requires longer follow-up and confirmation in additional studies.

As demonstrated in [Figure 232.2](#), the prognosis for patients with any stage of Hodgkin's disease is excellent with current approaches. This is due to advances in staging, identification of prognostic features that direct therapy, and the application of curative radiation therapy and chemotherapy. Nonetheless, a number of challenges remain. Older age, high tumor burden, and preexisting immunodeficiency have been recognized repeatedly as adverse prognostic factors in Hodgkin's disease. In 1998, an international group described seven adverse prognostic factors for advanced Hodgkin's disease: age over 45 years, stage IV disease, male gender, white blood count higher than 15,000 per microliter, lymphocyte count less than 600 per microliter or less than 8%, albumin less than 4 g per deciliter, and hemoglobin less than 10.5 g per deciliter. Disease-free survival at 5 years was 74% for patients with 0 to 2 factors compared with 55% for patients with more than three factors.

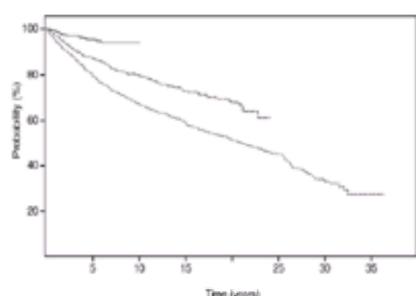

FIGURE 232.2. Overall survival in 2,789 patients with Hodgkin's disease treated at Stanford University from 1962 to 1999. Curves represent the eras 1962 to 1974 (dotted line), 1975 to 1988 (dot and dash), and 1989 to 1999 (solid). (Courtesy of SJ Horning, RT Hoppe, and SA Rosenberg, Stanford University.)

The prognosis for patients with Hodgkin's disease is significantly less favorable for those who fail primary chemotherapy alone or combined with radiation therapy. The initial duration of remission and sensitivity to chemotherapy has a significant effect on the ability of patients to respond to subsequent treatment and maintain their response. High-dose therapy and stem cell rescue constitute the current favored treatment for patients who fail primary induction or have a relapse. Approximately 50% of such patients are alive and disease-free at 5 years.

The high rates of cure anticipated with any presentation of Hodgkin's disease have led to more emphasis on treatment complications. Acute side effects are relatively easily managed, whereas late treatment effects including second malignancy and cardiopulmonary disease, constitute a major concern. Whereas the risk of acute leukemia and myelodysplasia was increased proportional to the cumulative dose of alkylating agents in early combination chemotherapy for Hodgkin's disease, this risk is significantly less after ABVD chemotherapy. Non-Hodgkin's lymphomas (NHLs) may occur either early or late after treatment for Hodgkin's disease. No clear relation to the type of primary treatment is known. These NHLs may be attributed to ongoing immunodeficiency or a common cell of origin.

Cancers of the lung, stomach, breast, bone, and soft tissue have been observed after treatment for Hodgkin's disease in a temporal pattern consistent with radiation-induced neoplasms. An increased risk of solid cancers has been identified by several groups; the overall actuarial risk in the Stanford series was about 18% at 5 years. However, the latency for developing second cancers is an important consideration, because many are not noted with follow-up of less than 10 years and the risk appears to continue to increase beyond that time. Age at exposure may also be important. Breast cancer risk is increased in women treated before age 30 and is markedly increased in children and adolescents. The solid tumor risk has been related to radiation therapy, with tumors occurring infield or at the edges of the radiation therapy field. However, recent data indicate an increased risk of lung cancer in Hodgkin's patients treated with chemotherapy alone.

An increased risk of death from coronary artery disease and acute myocardial infarction has been identified in adults and children treated with mediastinal radiation therapy. Other types of cardiac disease that occur after chest radiation therapy are valvular disease, constrictive pericarditis, and cardiomyopathy. Theoretically, the use of ABVD might be associated with an increased risk of cardiac disease (doxorubicin-related cardiomyopathy) or pulmonary toxicity (bleomycin-related pneumonitis). In practice, cardiopulmonary complications have been infrequent.

The ABVD combination is associated with temporary amenorrhea and azoospermia, with full recovery noted in most patients. In contrast, sterility may follow the use of alkylating agents in high-dose regimens, in which the risk is related to cumulative dose, age at exposure, and gender. No increase in birth defects or complications of pregnancy has been seen after treatment for Hodgkin's disease.

The internist should be particularly aware of the late complications of treatment, many of which are related to radiation therapy. Screening programs for breast cancer should be initiated within 10 years of treatment in young women, and heightened surveillance for second malignancy and cardiovascular disease is indicated for all patients treated with radiation therapy. Furthermore, about 30% of patients develop hypothyroidism after neck irradiation, and the thyroid-stimulating hormone level should be monitored. Hyperthyroidism, Graves' ophthalmopathy, or thyroid neoplasms occur with increased frequency after neck radiation therapy. Overwhelming sepsis is a rare event among patients who have been splenectomized or received splenic irradiation in treatment for Hodgkin's disease, particularly children. Periodic vaccination for encapsulated bacteria and early intervention with antibiotics for febrile episodes are indicated.

It is anticipated that more than 80% of newly diagnosed patients will be cured of Hodgkin's disease, and less than 10% will die directly from the disease. However, serious morbidities and increased risks of life-threatening second neoplasms and cardiac disease are of concern. Current therapies are focused on maintaining high cure rates and reducing complications.

[Management of Non-Hodgkin's Lymphoma](#)
[Conclusion](#)

The term “lymphoma” comprises two clinically and biologically distinct groups of neoplasms—Hodgkin's disease and non-Hodgkin's lymphoma (NHL). NHLs are a heterogeneous group of malignancies that begin as a clonal malignant expansion of B or T lymphocytes. The clinical presentation of these illnesses is variable. Patients may give a history of chronic asymptomatic lymphadenopathy, which may have been present for months to years, or may present acutely with rapidly progressive lymphadenopathy, constitutional symptoms, and organ failure secondary to extranodal involvement from lymphoma. The choice of therapy is based on the histologic subtype of lymphoma, the clinical stage of disease, and the presence or absence of prognostic factors known to affect outcome in this illness (e.g., patient age, performance status).

INCIDENCE AND EPIDEMIOLOGY

NHLs remain the fifth most common cause of cancer and cancer-related death in the United States. In general, the disease shows an age-dependent increase over time, although certain subtypes appear to be seen more frequently in certain age groups (for example, Burkitt's lymphoma and lymphoblastic lymphoma are seen more commonly in childhood). The incidence of NHL appears to be increasing for reasons that are largely unknown. The presence of HIV infection appears to be associated with an increased risk of developing NHL, and the increasing prevalence of HIV therefore likely accounts for some of the increase in incidence of the disease. However, the increasing prevalence of HIV is not solely responsible for the increase in NHL, as demonstrated by the observation that lymphomas in patients over the age of 60 are also on the increase, as are lymphomas not typically associated with HIV infection (e.g., indolent NHLs). Newer diagnostic studies such as immunophenotyping have led to the identification of certain subtypes of NHLs that may have been previously misclassified as Hodgkin's disease. The increasing use of solid organ and stem cell transplantation to treat various diseases may also be contributing to the increase in NHL as a result of the long-term effects of chronic immunosuppression.

Mortality rates from NHL appear to be higher for urban areas and for higher socioeconomic groups. Mortality and morbidity rates in the United States and Europe have risen gradually over the past several decades among older adults, although mortality rates among children and young people have fallen slightly. NHL occurs throughout the world at rates that range from a threefold to fourfold increase in recent years. The maximum rates are seen in Western developed countries.

ETIOLOGY

Factors that predispose to the development of NHL include congenital (e.g., ataxia-telangiectasia, Wiskott-Aldrich syndrome) or acquired (e.g., solid organ or stem cell transplantation, HIV infection) immunodeficiency states. Autoimmune diseases such as Hashimoto's thyroiditis (thyroid lymphomas) and Sjögren's syndrome (lacrima/salivary gland lymphomas) are thought to be associated with an increased risk of lymphomas as a result of chronic inflammatory stimulation of the affected glands. Infectious agents such as human T-lymphotrophic virus type 1 (HTLV-1), Epstein-Barr virus, and *Helicobacter pylori* have also been associated with an increased risk of NHL. HTLV-1 appears to be the causative agent in T-cell leukemia/lymphoma endemic to southern Japan and some parts of the Caribbean. Epstein-Barr virus has been associated with African Burkitt's lymphoma and with post-transplantation lymphoproliferative disorders. Gastric infection with *H. pylori* has been associated with the development of mucosal associated lymphoid tissue (MALT) lymphomas.

Observational studies have demonstrated an increased risk of NHL in association with a variety of occupational and environmental exposures. Exposure to agents such as organophosphates and phenoxyacetic acid herbicides (e.g., in farm workers) has been associated with an increased risk of NHL. In some studies, the risk appears to correlate with increasing levels of exposure, particularly for those who handled or mixed substances directly. Exposure to organic solvents or chemicals (e.g., benzene, creosote, paint thinner) and hair dyes has also been linked to an increased risk of NHL. Finally, an increased risk of developing NHL has been observed in association with exposure to high nitrate levels in drinking water and in diets with a high intake of meat and fat from animal sources. Most lymphomas diagnosed in the United States, however, have no readily identifiable cause.

PATHOGENESIS AND PATHOPHYSIOLOG

NHL results from the malignant transformation of normal lymphoid cells at various stages of differentiation. During normal development and differentiation, lymphocytes undergo genetic rearrangement of either immunoglobulin genes (B-cell development) or T-cell receptors (T-cell development). Specific chromosomal translocations involving these genes are seen in many NHLs. These translocations are useful markers for diagnosis and prognosis and in certain subtypes of lymphoma lend some understanding to the pathogenesis of the disease. For example, Burkitt's lymphoma uniformly involves translocation of the *MYC* oncogene on chromosome 8 into the immunoglobulin heavy-chain (chromosome 14) or light-chain (chromosomes 2 and 22) genes. The resulting chromosomal translocations t(8;14), t(2;8), or t(8;22) deregulate the *MYC* gene and result in the constitutive production of a DNA-binding protein that appears to control aspects of gene expression or DNA replication. Approximately 70% to 80% of follicular lymphomas are associated with the presence of the translocation t(14;18), which translocates the *bcl-2* gene on chromosome 18 into the immunoglobulin heavy-chain locus on chromosome 14. This dysregulation of *bcl-2*, normally a gene associated with cellular apoptotic control, may result in the formation of a malignant clone of cells that lose normal apoptotic control and achieve a functional form of immortality, resulting in the generation of a follicular lymphoma. Most mantle cell lymphomas bear the translocation t(11;14), which translocates the *PRAD 1* (*CCND 1*) gene into the immunoglobulin heavy-chain locus on chromosome 14. This results in the overexpression of cyclin D1, which appears to cause disturbances in the regulation of the cell cycle. Exactly how this leads to lymphogenesis is not yet understood, but cyclin-D1 is known to regulate in some way movement of cells through G1 to S phase.

Several scenarios have been postulated to explain how Epstein-Barr virus infection and the observed chromosomal translocation interact to result in malignant transformation into a clinically recognized Burkitt's lymphoma. All these theories incorporate viral infection, spontaneous or virally induced mutation, environmental factors, and host factors including immune dysfunction. In the post-transplantation setting, the spectrum of Epstein-Barr virus-induced lymphoproliferation ranges from a predominance of polyclonal disease to true monoclonal aggressive NHL.

CLASSIFICATION OF NON-HODGKIN'S LYMPHOMAS

Classification of NHL has undergone a temporal evolution based on morphologic and biologic understanding of the illness at particular points in time. The Rappaport system developed in the 1950s classified lymphomas on the basis of appearance (nodular versus diffuse) and differentiation (well-differentiated versus poorly differentiated). In the 1970s, it became apparent that NHLs were derived from B or T lymphocytes. This knowledge became reflected in the staging system of Luke and Collins, in which lymphomas were classified primarily according to their presumed normal lymphoid counterparts. Confusion arising from the use of multiple classification schemes led to the development of the Working Formulation, which was proposed in 1982 ([Table 233.1](#)). This classification scheme identified specific histologic subtypes of NHL based largely on the appearance of the disease within the lymph node (i.e., a follicular versus diffuse pattern), as well as on the principal size of lymphoma cells within the node (small cleaved cells versus large noncleaved cells versus mixed populations). Although imperfect and subject to some degree of diagnostic interobserver variability, this classification scheme was able to divide NHLs into three reasonably distinct groups based on biology and prognosis: low-grade lymphomas, intermediate lymphomas, and high-grade lymphomas. Treatment patterns were based largely on these three subgroups, recognizing that within each group the illnesses were still to some degree, distinct entities.

- Low Grade**
- A. Small lymphocytic lymphoma/chronic lymphocytic leukemia
 - B. Follicular, predominantly small cleaved-cell lymphoma
 - C. Follicular, mixed, small cleaved and large-cell lymphoma
- Intermediate Grade**
- D. Follicular, large-cell lymphoma
 - E. Diffuse, small, cleaved-cell lymphoma
 - F. Diffuse, mixed, small cleaved and large-cell lymphoma
 - G. Diffuse, large-cell lymphoma
- High Grade**
- H. Immunoblastic lymphoma
 - I. Lymphoblastic lymphoma
 - J. Small noncleaved-cell lymphoma
 - Burkitt's
 - Non-Burkitt's

TABLE 233.1. THE WORKING FORMULATION CLASSIFICATION OF NON-HODGKIN'S LYMPHOMAS

Over the past 10 years, evolving knowledge and techniques for studying and understanding the biology of NHL led to the recognition that newer entities were being discovered that did not have a place in the Working Formulation (e.g., mantle cell lymphoma). In 1994, an international group of hematopathologists proposed a new classification scheme for both Hodgkin's disease and NHLs using morphologic, immunologic, and genetic techniques to more readily identify a list of easily definable disease entities. The proposed name was the "Revised European-American Classification of Lymphoid Neoplasms" or the "REAL" classification. Although some of the disease entities from the Working Formulation were essentially preserved (e.g., chronic lymphocytic leukemia, Burkitt's lymphoma) many new ones recognized by the REAL classification became quickly recognized as being clinically or biologically distinct entities (e.g., mantle cell lymphoma, primary mediastinal B-cell lymphoma). A recent retrospective study by the NHL Classification Project confirmed the clinical importance of these new disease entities. A revision of this classification was recently revealed by the World Health Organization. A modified version of this classification is presented in [Table 233.2](#).

- Precursor cell lymphomas**
- B-lymphoblastic leukemia/lymphoma
 - T-lymphoblastic leukemia/lymphoma
- Mature cell lymphomas**
- B-cell lymphomas
 - Follicular lymphoma
 - B-cell chronic lymphocytic leukemia/prolymphocytic leukemia/small lymphocytic lymphoma
 - Marginal zone lymphomas
 - MALT (mucosa-associated lymphoid tissue) lymphoma
 - Nodal marginal zone B-cell lymphoma
 - Splenic marginal zone B-cell lymphoma
 - Mantle cell lymphoma
 - Diffuse large B-cell lymphoma
 - Mediastinal diffuse large B-cell lymphoma
 - Burkitt's lymphoma
 - T-cell lymphomas
 - Peripheral T-cell lymphoma, unspecified
 - Anaplastic large T/null cell lymphoma
 - Mycosis fungoides/Sézary syndrome
 - Adult T-cell leukemia/leukemia

TABLE 233.2. MODIFIED WORLD HEALTH ORGANIZATION (WHO) CLASSIFICATION OF NON-HODGKIN'S LYMPHOMAS

COMMON OR CHARACTERISTIC DISEASE ENTITIES

B-cell chronic lymphocytic leukemia and small lymphocytic lymphoma are clinical variations of the same biologic process. This disease most often occurs after the fifth decade and tends to be an indolent slowly progressive illness. Lymphadenopathy is commonly present, and patients may present with repeated infections or evidence of hypogammaglobulinemia. Pathologically, the illness is characterized by monomorphic small lymphocytes, usually involving the bone marrow, often with evidence of circulating lymphoma cells. By convention, patients with large numbers of circulating lymphocytes are considered to have chronic lymphocytic leukemia rather than small lymphocytic lymphoma. Larger cells, prolymphocytes may be present either at diagnosis, or as part of a process of transformation to a higher-grade illness. The malignant cells express B-cell antigens (e.g., CD19, CD20) and may generate a monoclonal gammopathy. The disease is incurable with standard treatment, and survival is not known to be improved by early or more aggressive therapy.

Follicular lymphomas account for approximately 30% to 40% of all NHLs. This group of lymphomas is common in older adults and often involves lymph nodes, bone marrow, and spleen at diagnosis. Occasionally, extranodal disease is seen, although certain extranodal sites (e.g., central nervous system [CNS]) are distinctly uncommon. Although the course is generally indolent, transformation to a higher-grade illness is seen at a rate of about 6% per year and is generally associated with a poorer prognosis. Histologic transformation is often associated with identification of another cytogenetic abnormality in addition to the original clone. In advanced stages, follicular lymphomas are incurable with standard therapy, although early-stage disease may be curable with radiation therapy in a percentage of patients.

Mantle cell lymphoma was not recognized within the Working Formulation. Pathologically, it most often consists of a diffuse lymphoma with small lymphocytes, although it can have a nodular histologic pattern also. Mantle cell lymphoma seems to incorporate the worst features of both indolent and aggressive lymphomas. Although often relatively slow growing, this lymphoma does not share the high degree of responsiveness so characteristic of other indolent lymphomas. The median survival of patients with mantle cell lymphoma is distinctly shorter than patients with other forms of indolent lymphoma (in particular, the diffuse subtype) and appears to be incurable with standard therapy.

Diffuse large B-cell lymphoma (representing diffuse large cell and immunoblastic lymphoma in the Working Formulation) is the most common NHL subtype and represents an aggressive intermediate-grade or high-grade form of lymphoma. Patients with diffuse large B-cell lymphoma most often present with disease in the lymph nodes and tend more often to have localized disease compared with those with indolent lymphomas. However, extranodal sites of disease (e.g., involvement of gastrointestinal tract, testes, thyroid, skin, breast, or central nervous system) are seen more frequently than in indolent lymphomas. Involvement of Waldeyer's ring is associated with approximately a 20% risk of simultaneous or subsequent involvement of the gastrointestinal tract in other sites. When patients present with involvement of Waldeyer's ring, a complete evaluation of the small and large bowel should be included in their initial evaluations. Bone marrow involvement is seen in only 10% of diffuse large B-cell lymphoma at diagnosis. Unlike indolent lymphomas, in which enlarging tumor masses tend to abut but not invade contiguous organs, diffuse aggressive lymphomas can result in compression or infiltration of organs, such as peripheral nerves, spinal cord, liver, great vessels, bronchi, and bone. These lymphomas are curable in a number of patients.

High-grade lymphomas such as lymphoblastic lymphoma occur most commonly in children or adolescents. Lymphoblastic lymphoma is histologically and clinically similar to acute lymphoblastic leukemia. The illness is more common in males, and approximately 50% of patients present with mediastinal lymphadenopathy. Although the disease may appear to be localized at the time of diagnosis, rapid dissemination usually occurs to the bone marrow, peripheral blood, and meninges. Although highly clinically aggressive, the disease is curable in a subset of patients (generally those without adverse prognostic features) with currently available therapy. Burkitt's lymphoma is another high-grade lymphoma originally described as an endemic disease in Africa. It is more common in men, and the endemic form usually presents with large extranodal tumors involving the maxilla, mandible, or other facial bones. In the non-African (nonendemic) form of Burkitt's lymphoma, patients most often present with disease in the abdomen and bowel, with subsequent bone marrow and CNS involvement as the disease progresses. Patients with endemic Burkitt's lymphoma have a median age at presentation of approximately 7 years, and the sporadic cases occur over a broader age range, up to the third decade, with a median age of 11 years. The initiation of therapy in high-grade lymphomas can lead to tumor lysis syndrome, and frequent monitoring of electrolytes, calcium, phosphate, and urate are important during the first few days of therapy, because rapid tumor lysis can lead to life-threatening complications, such as hyperkalemia and acute renal failure.

CLINICAL FINDINGS

Patients with NHL generally seek medical attention as a result of progressive lymphadenopathy. However, numerous other signs and symptoms may be seen as the presenting features of the illness. Patients may present with unexplained constitutional symptoms (so-called B symptoms, consisting of fever, drenching night sweats, and unexplained weight loss), fatigue, early satiety secondary to splenomegaly, abdominal pain from enlarging or infiltrating tumor masses, or chest pain or dyspnea

resulting from a large mediastinal mass. Some patients present with atypical or recurrent infections resulting from immune dysregulation or with anemia or thrombocytopenia secondary to bone marrow involvement or as a result of autoimmune phenomena.

To some extent, specific histologic entities may reflect the presenting clinical features. Patients with follicular lymphomas may give a history of waxing and waning lymphadenopathy over a prolonged period of time, occasionally years. Patients with follicular lymphomas also commonly present with bone marrow involvement, and cytopenias may therefore be seen in these patients. Patients with intermediate-grade lymphomas generally present with a shorter history of enlarging nodes or constitutional symptoms that have been progressive over weeks or months. Finally, patients with high-grade lymphomas often present with tumor masses that have been enlarging rapidly over a short period of days or weeks, evidence of marrow failure, and circulating lymphoma cells in the peripheral blood and often have evidence of CNS (most commonly meningeal) involvement.

LABORATORY EVALUATION

The suspicion of a diagnosis of lymphoma should lead the clinician to notify the pathologist such that a series of special additional studies can be performed on the biopsy (cytogenetics, cell surface marker determinations, immunohistochemistry stains, and molecular biologic studies) in addition to the routine histology. These additional studies can add valuable information to help differentiate in particular some of the new NHL entities.

After confirmation of the diagnosis, various staging procedures are performed to assist in the determination of prognosis and to guide therapy. To some degree, the histologic subtype of NHL and the condition of the patient direct the type and speed of staging procedures performed. For example, a patient with a high-grade lymphoma that is rapidly progressing requires prompt, limited staging procedures to permit timely initiation of therapy. Indolent lymphomas in asymptomatic patients can be staged at the convenience of the patient and physician.

The various tests that are useful for staging NHLs are listed in [Table 233.3](#). Baseline studies should include a complete history and physical examination; a complete blood count; liver chemistries; renal function studies; and lactate dehydrogenase (LDH), β_2 -microglobulin, and calcium determinations. Imaging studies should include CT scans of the chest, abdomen, and pelvis as well as a bone marrow aspirate and biopsy. Additional studies that may be appropriate in certain circumstances are cytologic examination of effusions; a bone scan (with plain films of abnormal or symptomatic areas) if bony symptoms are present, and MRI of the brain or spinal cord if central or peripheral CNS symptoms are present. The presence of gastrointestinal symptoms or of lymphoma in Waldeyer's ring should prompt complete investigations of the gastrointestinal tract. Patients with high-grade lymphomas and patients with CNS symptoms compatible with meningeal involvement by lymphoma should receive a diagnostic lumbar puncture. Gallium Ga 67 scanning using single-photon emission CT sometimes can be useful in differentiating active lymphoma from fibrotic tissue, particularly when baseline scans reveal the presence of gallium-avid tumor, which can be reimaged at the completion of therapy.

Lymph node biopsy with attention to additional studies as indicated
 Complete blood and platelet counts
 Serum chemistry panel (electrolytes, renal and hepatic function, serum calcium)
 Lactate dehydrogenase level, β_2 -microglobulin level
 CT scan of chest, abdomen, and pelvis
 Bone marrow biopsy
 MRI of head and other locations*
 Bone scan*
 Lumbar puncture*
 SPECT gallium scan*

CT, computed tomography; MRI, magnetic resonance imaging;
 SPECT, single photon-emission computed tomography.
 * As indicated based on histologic subtype and presence of pertinent symptoms.

TABLE 233.3. DIAGNOSTIC AND STAGING INVESTIGATIONS FOR PATIENTS WITH NON-HODGKIN'S LYMPHOMAS

Staging is classified according to the Ann Arbor staging system, which was originally developed for Hodgkin's disease ([Chapter 232](#)). The combination of stage and histologic subtype of lymphoma guides stratification of patients for appropriate treatment. Previously abnormal tests should be repeated part way through therapy, at the completion of therapy, and at regular intervals thereafter. Patients failing standard therapies at any point in time should be considered for clinical trials of newer therapies.

Several prognostic factors are associated with poor outcomes in patients with NHL. Histologic transformation of follicular NHL was one of the first unfavorable prognostic factors identified. In one study, the median survival of patients with follicular lymphoma and subsequent transformation to a diffuse large cell lymphoma was 12 months, compared with 40 months for patients with de novo diffuse large cell lymphoma. Other characteristics associated with a poor outcome in many studies include advanced age, advanced stage, poor performance status or the presence of B symptoms, the presence of CNS or bone marrow involvement, the presence of bulky sites of tumor, an elevated LDH or β_2 -microglobulin level, cytogenetic abnormalities such as chromosome 17 abnormalities and slow tumor responsiveness to therapy.

The International Prognostic Index was developed in 1993 as a means to capture prognostic information in patients with intermediate-grade or high-grade NHL. A retrospective analysis was performed on patients who had been treated with anthracycline-based chemotherapy regimens. An index was derived that could stratify newly diagnosed patients into risk categories based on the number of independent risk factors present at diagnosis: age (≤ 60 years versus >60 years), stage (I or II versus III or IV), LDH concentration (normal versus $>$ normal), Eastern Cooperative Oncology Group (ECOG) performance status (0 or 1 versus 2, 3, or 4) and the number of extranodal sites of disease (≤ 1 versus >1). The probability of survival was grouped according to the number of adverse prognostic factors ([Fig. 233.1](#)). The principal clinical use of the International Prognostic Index has been the identification of patients at diagnosis who are unlikely to be cured with standard anthracycline-based chemotherapy and in whom trials of novel therapies are warranted.

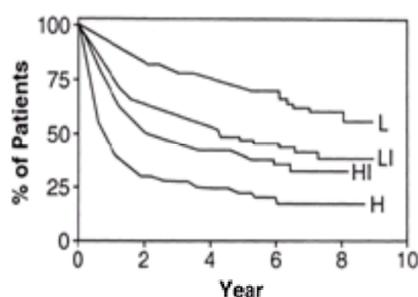

FIGURE 233.1. Survival according to risk groups defined by the International Prognostic Index. Patients are placed into four risk groups defined by the number of risk factors at diagnosis. L, low; LI, low intermediate; HI, high intermediate; H, high risk. (From Shipp MA, et al. A predictive model for aggressive non-Hodgkin's lymphoma: the International Non-Hodgkin's Lymphoma Prognostic Factors Project. *N Engl J Med* 1993;329:987, with permission.)

MANAGEMENT OF NON-HODGKIN'S LYMPHOMA

Treatment must be tailored to the individual patient and depends on the histologic subtype, stage, and other prognostic factors mentioned previously.

FOLLICULAR NON-HODGKIN'S LYMPHOMA

Localized (stage I or nonbulky stage II) follicular NHL is treated with radiation therapy, and approximately 40% to 50% of patients treated in this fashion remain disease-free at 10 years' follow-up. Patients with advanced disease (stage III or IV) are incurable with standard therapy but have a median survival of 8 years or more and generally have disease that is responsive to simple nontoxic chemotherapy regimens. However, overall survival is not known to be prolonged by the use of any form of standard chemotherapy. For this reason, a "watch and wait" approach is often offered to patients with advanced disease in whom no significant disease-related symptoms or organ dysfunction are present. When symptoms or organ dysfunction lead to the decision to begin treatment, single-agent therapy with oral alkylating agents, such as chlorambucil (Leukeran) or cyclophosphamide (Cytoxan), is often used.

Another initial therapy frequently used in this clinical setting is the CVP regimen of cyclophosphamide, vincristine, and prednisone. The use of aggressive combination chemotherapy regimens typically used for intermediate-grade and high-grade NHLs can lead to a more rapid therapeutic response in patients with low-grade lymphoma. Unfortunately, responses with any form of conventional chemotherapy are not durable, lasting a median of 2 years. Postchemotherapy maintenance interferon- α has been demonstrated to prolong disease-free and overall survival in randomized trials, but patients often find the associated flu-like symptoms difficult to endure. High-dose chemotherapy with autologous stem cell transplantation is now commonly used for the treatment of patients with refractory or relapsed follicular NHL. A lack of controlled trials in this area and the long natural history of the disease make it difficult to directly measure the magnitude of benefit associated with high-dose therapy. Extended follow-up of these patients is necessary to evaluate the curative potential of this approach.

Monoclonal antibodies directed against lymphocyte-specific antigens have been evaluated for the treatment of NHL and found to have potential especially for patients with relapsed low-grade or follicular lymphomas. These agents have been assessed both as isolated agents and as conjugates with toxins, chemotherapeutic agents, radioisotopes, or immunotherapeutic molecules. Rituximab, an unlabeled monoclonal antibody directed against the CD20 antigen has recently demonstrated response rates of approximately 50% (with a median duration of response of 10 to 12 months) in patients with relapsed low-grade or follicular lymphomas. Preliminary trials with radiolabeled antibodies for the treatment of low-grade NHL have also yielded promising results.

DIFFUSE LARGE B-CELL LYMPHOMA

The subtype of NHL, diffuse large B-cell lymphoma should be treated with curative intent. For the past two decades, combination chemotherapy has formed the basis of curative therapy for patients with this disease. First-generation chemotherapy regimens formulated in the early 1970s (e.g., CHOP, COMLA, and CHOP-Bleo; [Table 233.4](#)) were the first to produce long-term disease-free survival in a proportion of treated patients. Long-term follow-up from the original CHOP studies demonstrates that approximately one-third of patients are alive and disease-free a decade after treatment. Second- and third-generation regimens were developed by adding new agents to the original CHOP regimen, by taking advantage of alternative modes of administration, or by using alternating non-cross-resistant chemotherapeutic agents. These regimens include COP-BLAM, CAP-BOP, ProMACE-MOPP, m/M-BACOD, MACOP-B, and ProMACE-CytaBOM ([Table 233.4](#)).

Regimen	Drugs Used
CHOP	Cyclophosphamide, doxorubicin, vincristine, prednisone
CHOP-B	Cyclophosphamide, doxorubicin, vincristine, prednisone, bleomycin
COP-BLAM	Cyclophosphamide, vincristine, prednisone, bleomycin, lomustine, procarbazine
CAP-BOP	Cyclophosphamide, doxorubicin, procarbazine, bleomycin, vincristine, prednisone
ProMACE-MOPP	Prednisone, methotrexate, cyclophosphamide, doxorubicin, procarbazine, bleomycin, vincristine, procarbazine
m/M-BACOD	Methotrexate, bleomycin, cyclophosphamide, vincristine, doxorubicin, procarbazine
MACOP-B	Methotrexate, doxorubicin, cyclophosphamide, vincristine, procarbazine, bleomycin
ProMACE-CytaBOM	Prednisone, methotrexate, cyclophosphamide, doxorubicin, procarbazine, bleomycin, cytarabine
VACOP-B	Vincristine, doxorubicin, cyclophosphamide, vincristine, procarbazine, bleomycin
DHAP	Doxorubicin, high-dose cyclophosphamide, procarbazine
MINE	Methotrexate, high-dose cyclophosphamide, procarbazine
ESAP	Etoposide, high-dose cyclophosphamide, procarbazine
IMVP-16	Ifosfamide, methotrexate, etoposide

TABLE 233.4. COMBINATION CHEMOTHERAPY REGIMENS FOR LYMPHOMAS

Patients with localized (stage I or nonbulky stage II) disease are generally treated with short-course combination chemotherapy and involved-field irradiation. This results in long-term disease-free survival in approximately 70% to 80% of patients. Patients with bulky stage II, stage III, or stage IV disease have 5-year survival rates of 30% to 50% in most chemotherapy series. A definitive large, multicenter, randomized trial published in 1993 compared the four most popular combination chemotherapy regimens: CHOP, m-BACOD, MACOP-B, and ProMACE-CytaBOM. At 3 years' follow-up, the time to treatment failure and overall survival rates were no different for the four treatment arms. CHOP was associated with a trend toward less treatment mortality and, as such, has become the generally accepted standard combination chemotherapy regimen for these patients.

Lymphoma in certain anatomical locations necessitates additional therapy. For example, NHL in the testicle, paranasal sinuses, and epidural spaces can be associated with CNS relapse, and CNS prophylaxis should be used in these patients. Irradiation of the contralateral testicle is necessary for patients with primary testicular NHL.

Patients with recurrent diffuse large B-cell lymphoma have a poor prognosis with routine salvage chemotherapy. Multiagent chemotherapy regimens such as DHAP, MINE, IMVP-16, and ESAP ([Table 232.4](#)) have been evaluated in this setting. Despite a 20% to 30% complete response rate with most of these regimens, less than 5% of the patients are long-term disease-free survivors. A randomized trial (known as the Parma trial) comparing high-dose chemotherapy with autologous bone marrow transplantation was published in 1995. Patients with relapsed intermediate-grade or high-grade lymphoma were treated with two courses of conventional salvage chemotherapy. The patients responding to initial chemotherapy were then randomized to receive further conventional salvage chemotherapy or high-dose chemotherapy with autologous bone marrow transplantation. At 5 years' follow-up, patients randomized to high-dose chemotherapy/autologous bone marrow transplantation had a superior event-free (46% versus 12%) and overall (53% versus 32%) survival, and these differences have been sustained with further follow-up. This trial essentially established high-dose chemotherapy/autologous transplantation as the standard of care for patients with chemosensitive relapsed intermediate-grade or high-grade NHL.

In many transplantation centers, patients with poor prognostic features at diagnosis as established by the International Prognostic Index have been treated with high-dose chemotherapy/autologous stem cell transplantation in first partial or complete response to improve the long-term outlook. Some evidence suggests that outcomes are superior in patients who receive high-dose chemotherapy/autologous stem cell transplantation. For example the largest such study randomized poor-risk patients 55 years of age or younger to consolidative high-dose chemotherapy/autologous bone marrow transplantation in first complete remission. Patients with two or more adverse risk factors by the International Prognostic Index randomized to high-dose chemotherapy/autologous bone marrow transplantation had a superior disease-free (59% versus 39%) and overall (65% versus 52%) survival at 5 years after transplantation.

Alternative therapies that are being evaluated for patients who are not transplantation candidates include infusional chemotherapy, modulation of the multidrug resistance gene (*PGY*), and monoclonal antibody therapy alone or with conjugated toxins, chemotherapy, or radiolabeled isotopes.

LYMPHOBLASTIC LYMPHOMA

Intensive chemotherapeutic regimens similar to those used in acute lymphoblastic leukemia patients produce the best long-term disease-free survival for patients with lymphoblastic lymphomas. Because of the propensity for CNS relapse, CNS prophylaxis (intrathecal chemotherapy and craniospinal irradiation) is a routine part of most treatment regimens. Particularly in adult patients, bone marrow involvement, CNS involvement, and elevated LDH levels at the time of diagnosis are poor prognostic signs. For patients with these poor prognostic features, many transplantation centers advocate high-dose chemotherapy with autologous stem cell transplantation as consolidative therapy. Some series have suggested that the use of a human leukocyte antigen (HLA)-identical sibling donor results in an increased chance of long-term disease-free survival in young patients.

CONCLUSION

The management strategy for patients with newly diagnosed or relapsed NHL is formulated on the basis of the histologic subtype of the disease, the results of staging investigations, and the presence or absence of the previously outlined prognostic factors. This approach for the selection of therapy ensures delivery of the best possible treatment for each patient.

CHAPTER 234: PLASMA CELL DISORDERS

PHILIP R. GREIPP

[Incidence and Epidemiology](#)
[Etiology](#)
[Pathogenesis](#)
[Specific Plasma Cell Disorders](#)
[Conditions Associated with Monoclonal Gammopathy](#)

The principal plasma cell disorders are multiple myeloma (MM), monoclonal gammopathy of undetermined significance (MGUS), macroglobulinemia of Waldenström, and amyloidosis of the light-chain type. They arise when an abnormal clone of plasma cells produces a monoclonal immunoglobulin (M protein). The M protein is often first discovered on a screening serum electrophoresis. It assumes the shape of a monoclonal peak on a serum electrophoresis densitometric tracing and is often referred to as an *M spike*. Immunoelectrophoresis or immunofixation of the serum proves the suspected protein as monoclonal, having a single IgG, IgA, IgM, IgD, or IgE immunoglobulin heavy-chain class and a single kappa (k) or lambda (λ) isotype immunoglobulin light chain.

In an asymptomatic patient with a small amount of IgG or IgA M protein (less than 2 g per deciliter), the most likely diagnosis is monoclonal gammopathy of undetermined significance (MGUS). This most often represents a “benign” condition, which remains stable during the patient's lifetime, but in 25% of patients it can also be a precursor to a serious disorder such as multiple myeloma (MM). Less commonly, amyloidosis of the light-chain type may develop ([Chapter 235](#)).

A small monoclonal protein of the IgM type in an asymptomatic person most often represents MGUS. It may also be a precursor to macroglobulinemia, malignant lymphoma, chronic lymphocytic leukemia, or a chronic lymphoproliferative disorder. These disorders are discussed in [Chapter 228](#) and [Chapter 236](#).

INCIDENCE AND EPIDEMIOLOGY

Twenty-five percent of MGUS patients eventually develop MM or another serious plasma cell disorder at the rate of 1% per year. In order of frequency, patients with MGUS have IgG, IgM, IgA, or IgD M protein in the serum and either a k or λ light chain as part of the immunoglobulin molecule. Monoclonal gammopathy increases with age. It is uncommon in persons younger than 40 years of age. The annual incidence of MM is 3 to 4 cases per 100,000 persons with a 2:1 male predominance. As in other B-cell malignancies, the death rate from MM appears to be increasing. MM is projected to cause 14,000 deaths in the United States. It accounts for 1% of all malignancies and 2% of all cancer deaths. The median age is 60 to 65 years in referral populations and 75 years in the general population. MM is two times more common among blacks than whites, regardless of economic environment; this suggests a possible genetic or biologic predisposition.

ETIOLOGY

The causes of monoclonal gammopathy and myeloma are unknown. Although MGUS and MM have been reported in twins, family members, and spouses, no broad-based genetic predisposition or familial tendency is established. MGUS occurs more frequently among patients with HIV infection and those who have had bone marrow transplantation, suggesting that immune dysregulation can provide the milieu for the development of MGUS. Correlations with radiation or pesticide exposure have been challenged. Findings of herpes simplex virus HSV8 in dendritic cells and the detection of other viruses raise the possibility of viral oncogenesis.

PATHOGENESIS

In MM, cytokines mediate myeloma cell proliferation and bone destruction. Interleukin-1b (IL-1b) is produced by myeloma cells, and it can increase marrow stromal cell production of IL-6. In turn, IL-6 can stimulate proliferation of susceptible myeloma cells, block their apoptosis, and activate osteoclasts. Resulting pure “punched-out” lytic bone lesions are typical of MM. In about 15% of patients with MM, osteoporosis and compression fractures without radiographic bone lesions may develop. Hypercalcemia occurs in about 20% of patients owing to rapid loss of bone mineral. Renal failure in MM is associated with higher urinary excretion of monoclonal light chain (Bence Jones proteinuria), typically more than 1 g of protein in a 24-hour collection. Nephrotoxic light chains can concentrate in the renal medulla and form protein casts with Tamm–Horsfall mucoprotein. Flattened tubular epithelium, protein casts, and foreign-body giant cells characterize the myeloma kidney, which is especially susceptible to the effects of hypercalcemia, dehydration, x-ray contrast media, and nephrotoxic medications. Excess intake of vitamin C acidifies the urine and can cause Bence Jones protein casts and renal failure.

Myeloma plasma cells often have an immature appearance. Plasmablastic features suggest a poor prognosis. A high plasma cell proliferation rate, measured using the plasma cell labeling index (PCLI), defines MM as separate from MGUS and suggests a poor prognosis. A high level of IL-6 in the serum or plasma suggests more advanced MM. C-reactive protein is made by the liver in response to IL-6 and serves as a surrogate for IL-6 measurement. b₂-Microglobulin levels, which are elevated in patients with advanced myeloma, also convey a poor prognosis.

Myeloma cell surface adhesion molecules such as CD56 interact with marrow stromal cells, providing myeloma cells with a selective growth advantage by placing them close to the source of needed cytokines.

Because myeloma cells proliferate too slowly to produce metaphases for standard cytogenetic analysis, cytogenetic abnormalities, which contribute to MM progression, have been observed in only 20% of cases. Loss of chromosome 13 or a portion of it is associated with a poor prognosis. Fluorescence in situ hybridization (FISH) for interphase cells detects such abnormalities more sensitively than standard cytogenetics and in the near future will detect critical translocations. Molecular abnormalities contribute to myeloma progression by dysregulation of the *p53* and *bcl2* genes late in the disease. Like IL-6, these abnormalities decrease apoptosis, or programmed cell death. IL-1b upregulation is an important step between MGUS and overt MM. A combination of cytogenetic and molecular abnormalities leads to an expansion of the myeloma cell clone. *Ras* mutations can further increase the expansion of the myeloma cell clone. Abnormal gene expression causing glucocorticoid and multidrug resistance lead to a refractory, progressive, and terminal phase of the disease.

Infections are related to low levels of normal immunoglobulins and a defective primary antibody response to new antigen exposures. After chemotherapy, neutropenia and more deeply impaired T-cell immunity predispose to more infections.

The differential diagnosis of monoclonal gammopathies depends on the understanding of the disorders listed in [Table 234.1](#) and [Table 234.2](#). The algorithm shown in [Figure 234.1](#) can be used as a guide to evaluate the most common monoclonal gammopathies.

Monoclonal gammopathy of undetermined significance
Smoldering multiple myeloma
Multiple myeloma
Solitary plasmacytoma
Macroglobulinemia
Primary amyloidosis
Heavy-chain diseases (γ, α, and μ)
Cryoglobulinemia (types I and II)

TABLE 234.1. PRINCIPAL DISORDERS ASSOCIATED WITH MONOCLONAL GAMMOPATHY

Light-chain deposition disease
Renal glomerular deposition of monoclonal light chain (usually λ)

Adult-acquired Fanconi's syndrome
Renal tubular deposition of monoclonal light chain (usually κ)

Scleromyxedema (ie, papular mucinosis or lichen myxedematosus)
Mucinous deposition in the skin (usually IgG λ)

Peripheral neuropathy (usually IgM)

Osteosclerotic myeloma
Single or multiple osteosclerotic bone lesions (usually λ)
Associated POEMS of angiocentric follicular lymph node hyperplasia

Cold agglutinin disease
IgM κ on erythrocytes

Systemic capillary leak syndrome
Usually an IgG κ M protein with episodic hypotension and hemocoagulation

Acquired C₁-esterase inhibitor syndrome
Often an IgM λ protein with associated angioedema and episodic abdominal pain

Acquired von Willebrand disease
Usually IgM, with typical platelet defect of von Willebrand

— Ig, immunoglobulin; κ , kappa; λ , lambda; POEMS, polyneuropathy, organomegaly, endocrinopathy, M protein, and skin changes.

TABLE 234.2. DISORDERS ASSOCIATED WITH MONOCLONAL GAMMOPATHY

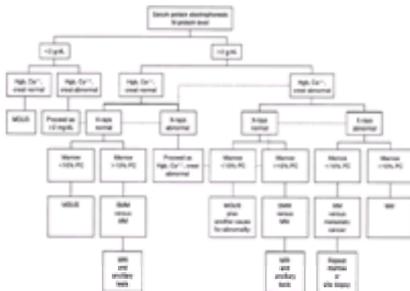

FIGURE 234.1. An algorithm for the differential diagnosis of monoclonal gammopathy (IgG, IgA types), including stepwise evaluation for patients with small (less than 2 g per deciliter) and larger (more than 2 g per deciliter) M-protein levels. Other ancillary tests refer to the C-reactive protein level, β_2 -microglobulin level, plasma cell labeling index (PCLI), and test for circulating plasma cells. Patients with more than 2 g per deciliter of serum M protein should have a 24-hour urine protein electrophoresis. If Bence Jones protein is more than 5 g in 24 hours, proceed as if the Hgb, Ca^{++} , and Creat values are abnormal. Ca^{++} , serum calcium level; *Creat*, serum creatinine level; *Hgb*, hemoglobin level; *M protein*, monoclonal protein; *MGUS*, monoclonal gammopathy of undetermined significance; *MM*, multiple myeloma; *MRI*, magnetic resonance imaging; *PC*, plasma cells; *SMM*, smoldering multiple myeloma.

SPECIFIC PLASMA CELL DISORDERS

MONOCLONAL GAMMOPATHY OF UNDETERMINED SIGNIFICANCE

Clinical Findings

Patients with MGUS are asymptomatic. No associated abnormalities are seen on physical examination. MGUS is often coincidentally found with other diseases, including heart disease, cancer, and diabetes, which are common in older populations in whom MGUS is most prevalent. Symptoms such as bone pain, fatigue, and symptoms of hypercalcemia or renal insufficiency are absent in MGUS, and their unexplained presence suggests MM.

Laboratory Findings

A small monoclonal spike (less than 2 g per deciliter) on the serum protein electrophoresis of an asymptomatic patient supports a diagnosis of MGUS rather than MM. An M-protein concentration in the serum greater than 2 g per deciliter suggests the need to rule out MM. The urine should be examined by electrophoresis of a 24-hour collection for any patient with a serum M-protein concentration greater than 2 g per deciliter or whose urinalysis reveals proteinuria. A large spike on the urine protein electrophoretic tracing with a urine M-protein level greater than 300 mg per 24 hours suggests the need to rule out MM.

Serum special protein studies, including immunoelectrophoresis, immunofixation, and more recently developed capillary electrophoresis with immunosubtraction occasionally show free monoclonal light chain in the serum (Bence Jones proteinemia), which is not apparent on the standard electrophoresis. This strongly suggests MM or amyloidosis. Such patients also have high levels of free κ or γ monoclonal light chain in the urine (Bence Jones proteinuria).

Anemia, hypercalcemia, and renal insufficiency are absent in the patient with MGUS. A bone survey shows no lytic lesions. Osteoporosis suggests the need to rule out MM, but it may be coincidental because of the age of the population involved. The bone marrow always shows less than 10% plasma cells. The PCLI of the marrow plasma cells is invariably very low, and circulating plasma cells are typically absent. Measurement of normal immunoglobulins is rarely helpful. They can be suppressed in MGUS or MM. C-reactive protein and β_2 -microglobulin levels are rarely helpful in differentiating MGUS from early-stage MM.

Optimal Management

If no symptoms or laboratory findings suggest MM, amyloidosis, or another monoclonal gammopathy-associated condition, no further diagnostic studies are needed. Patients with MGUS should be followed up by serial electrophoresis at 3- to 6-month intervals until their M-protein level is stable, then at least annually thereafter. Quantitative immunoglobulin levels of IgG, IgA, or IgM are helpful, especially if the spike is too small or difficult to measure on electrophoresis. An increase greater than 0.5 g in the serum electrophoretic spike or an increase in the quantitative immunoglobulin level during follow-up for the appropriate M protein suggests the need to rule out MM. A similar increase in an IgM-type protein suggests lymphoma, chronic lymphocytic leukemia, or macroglobulinemia, topics covered in other chapters.

Accurate differentiation of MGUS from MM can prevent unnecessary complications of treatment. If unexplained anemia, hypercalcemia, or renal insufficiency is present, x-ray films of the axial skeleton, skull, and proximal long bones should be obtained to search for lytic lesions. Bone marrow aspiration and biopsy are also indicated. Measurement of the PCLI and assessment of circulating plasma cells can be very useful in more difficult diagnostic situations.

SMOLDERING AND INDOLENT MULTIPLE MYELOMA

Clinical Findings

Smoldering and indolent multiple myeloma lie between MGUS and MM. Unlike MGUS, patients with smoldering multiple myeloma (SMM) have a higher level of M protein in the serum (often more than 3 g per deciliter) and a higher number of plasma cells in the marrow (higher than 10%). Patients are asymptomatic, and their disease is not progressive, so one can observe the patient without treatment for years. Affected patients may have mild nonprogressive anemia but no bone lesions, hypercalcemia, or renal failure. Disease of asymptomatic patients who have scattered small bone lesions that are not progressive has been called stage I or indolent multiple myeloma (IMM). Most IMM patients progress to overt MM in less than 1 year. Eventual development of overt MM is to be expected in patients initially diagnosed with SMM or IMM, but the interval varies from months to many years.

SMM or IMM patients are asymptomatic. Physical examination reveals no abnormalities. Bone pain, fatigue, or symptoms of unexplained hypercalcemia or renal insufficiency suggests a diagnosis of MM.

Laboratory Findings

In addition to a higher serum M-protein spike and more than 10% plasma cells in the marrow with aggregates of plasma cells on the marrow biopsy, a 24-hour urine collection usually shows less than 500 mg of M protein. A higher level suggests overt MM. Some patients with less than 3 g per deciliter of M protein have more than 10% plasma cells in the marrow. These can also be classified as SMM. The PCLI is low, usually 0.0% to 0.2%, and circulating plasma cells are less than 3×10^6 per liter. The bone density is normal or borderline, and the MRI of the lumbar spine is normal. Mild anemia may exist and remain stable for years. Although bone fractures, hypercalcemia, and renal insufficiency constitute evidence of overt MM, idiopathic osteoporosis, hyperparathyroidism, and other occult renal disease must be considered in the differential diagnosis.

Optimal Management

Patients with SMM are followed up more closely than are patients with MGUS. A reasonable approach is to perform serum electrophoresis at 3-month intervals the first year and, if stable, at 6-month intervals thereafter. A second bone survey and marrow examination should be done if the M-protein level increases. A complete blood count and chemistry profile with serum calcium and creatinine should be done at least twice each year. Careful attention should be given to any symptoms that may indicate MM.

Early chemotherapy in asymptomatic MM does not improve survival, and the use of alkylating agent-based chemotherapy can cause pancytopenia, cytogenetic abnormalities, myelodysplastic syndrome, or acute leukemia. Although the overall risk of these problems is only 2% or 3%, the risk increases with time, reaching 10% at 10 years. Bisphosphonate therapy may prevent progression of bone disease. Observation is sometimes the best course.

The use of MRI of the lumbar spine is especially helpful when osteoporosis is evident on plain x-rays. If the diagnosis of idiopathic osteoporosis versus MM cannot be resolved, bisphosphonate therapy such as pamidronate and close follow-up is usually the best alternative.

MULTIPLE MYELOMA

Clinical Findings

Unlike MGUS and SMM, the plasma cell clone in MM expands progressively and produces one or more of the following: bone lesions, anemia, renal failure, or hypercalcemia. De novo plasma cell leukemia is a particularly malignant form of myeloma. Bone lesions are less common, and patients often have hepatosplenomegaly—findings uncommon in typical MM. Confirmation of a diagnosis of MM requires a finding of more than 10% plasma cells in the marrow aspirate or aggregates of monoclonal plasma cells on the marrow biopsy. If the malignant plasma cell proliferation cannot be found in the marrow, a site-directed biopsy of a plasmacytoma plus other lytic lesions satisfies diagnostic criteria.

The typical course of MM lasts 3 to 4 years. There is wide variation in survival, ranging from only a few weeks or months in 10% of patients to more than 10 years in 5% of patients. The cause of death is usually infection or bleeding associated with a chemotherapy resistant state.

Most patients with MM are anemic. They can present with pallor, fatigue, and shortness of breath. Most patients also have bone lesions, which manifest as movement-related bone pain. Bone tenderness or pathologic fractures of the vertebrae, ribs, or sternum may occur with little or no trauma. Bone pain can be dismissed as musculoskeletal pain for months before diagnosis. Hypercalcemia may develop, causing a loss of appetite, somnolence, nausea, vomiting, constipation, dehydration, or renal failure. Absence of significant anemia or bone lesions does not preclude the diagnosis of MM.

Recurrent infection with capsular organisms, including *Streptococcus pneumoniae*, *Staphylococcus epidermidis*, and *Haemophilus influenzae*, occur in less than 10% of patients. Patients with pneumonia may develop meningitis because of immune impairment. Standard immunization does not prevent *S. pneumoniae* infection. Gram-negative bacterial infections are common during the course of MM because of the effects of chemotherapy and neutropenia.

Bleeding in the initial months of MM is uncommon. A bleeding diathesis later in the course of the disease may result from interference of the M protein with coagulation factors, combined with thrombocytopenia due to chemotherapy superimposed on diminished marrow reserves.

Amyloidosis may occur in 10% of cases of myeloma, but usually the diagnosis is incidental with no symptoms or complications.

Laboratory Findings

Serum and urine immunoelectrophoresis and immunofixation are done in all cases. A serum monoclonal protein is present in 85% of patients with MM, and a urine monoclonal protein is found in 75%. Ten percent of these may lack the characteristic spike on electrophoresis of the serum and urine. For about 1% to 2% who have no M protein detected in the serum or urine by any method, the disease is called *nonsecretory* or, very rarely, *nonproducer myeloma* in which the malignant plasma cells are negative for cytoplasmic immunoglobulin by immunocytochemistry.

A bone survey including radiographs of the skull, axial skeleton, ribs, sternum, shoulder and hip girdles, and proximal long bones show characteristic lytic bone lesions in two-thirds of patients with MM. Osteoporosis and lytic lesions plus an M protein alone are insufficient criteria for the diagnosis of MM. MRI of the spine or CT scan of a suspected area may be needed to demonstrate bone lesions.

Accurate diagnosis depends on the demonstration of an M protein in the serum or urine, accompanied by more than 10% plasma cells in the marrow aspirate or aggregates of plasma cells in the biopsy sample, and demonstration of bone lesions, anemia, hypercalcemia, or renal failure. The average bone marrow examination demonstrates 30% plasma cells. Sheets of plasma cells replace the marrow in advanced disease. Rarely, fibrosis is present. Amyloidosis is found on the marrow biopsy in a small percentage of patients and is most often clinically inconsequential. About 2% of patients present with plasma cell leukemia, defined as more than 2,000 circulating plasma cells per cubic millimeter. In advanced disease, the blood smear may show a leukoerythroblastic reaction.

Hypercalcemia (calcium level higher than 12 g per deciliter) occurs in one of ten patients, and renal failure (creatinine greater than 2 mg per deciliter) in one of six patients. Fifty percent of patients have an elevated serum b_2 -microglobulin level, which correlates with high tumor burden or renal insufficiency. Confirmatory tests include the PCLI and determination of circulating plasma cells.

Laboratory findings have yielded a staging system that reflects the tumor burden. Patients with stage I disease have a hemoglobin concentration greater than 10 g per deciliter, normal calcium, no bone lesions or a solitary lesion, an IgG level less than 5 g per deciliter, an IgA level less than 3 g per deciliter, and urine light-chain values less than 4 g per 24 hours. Patients with stage III disease have a hemoglobin concentration less than 8.5 g per deciliter, a calcium level greater than 12 g per deciliter, multiple lytic lesions, an IgG level greater than 7 g per deciliter, an IgA level greater than 5 g per deciliter, and a urine light-chain value greater than 12 g per 24 hours. Patients with intermediate values have stage II disease. Patients without and with renal insufficiency are classified, respectively, as A or B. An improved prognostic system relies on measurement of PCLI and b_2 -microglobulin. The serum C-reactive protein level and soluble IL-6 receptor level also appear to be independent prognostic factors.

Optimal Management

Optimal management of a patient with MM depends on a prompt, accurate diagnosis and appropriate use of chemotherapy, radiation therapy, stem cell transplantation, management of bone disease, pain management, and psychologic support. Much of the improvement in survival observed during the last decade resulted from prompt recognition of complications and better supportive therapy. The patient and physician need to be aware of the symptoms of MM complications and their treatment.

Long-term disease control rather than cure is the goal of standard and even transplantation therapy regimens. Chemotherapy usually reduces the tumor burden, but most patients have residual disease. A plateau reached in most patients is marked by a stable decrease in the level of M protein. During this plateau, chemotherapy may be discontinued, and the M-protein level assayed regularly. The choice to use interferon in prolonging this phase should be weighed against the side effects it

produces. Survival is not improved by maintenance interferon. Eventual relapse is the rule, and the chance for prolonged survival depends on whether the patient's myeloma is sensitive to second-line chemotherapy.

For patients over age 70 years who are not candidates for transplantation, simple melphalan (Alkeran) and prednisone chemotherapy produces an objective response in about 50% of patients. An objective response is defined as a reduction of the serum M-protein levels by more than 50% and a disappearance of the urine M protein. The dosage of melphalan is 0.15 mg per kilogram per day for 7 days, administered with 60 mg of prednisone daily for 7 days, cycled every 6 weeks. Although the objective response rate with combination chemotherapy may be higher than with melphalan and prednisone, there appears to be little survival advantage. However, combination chemotherapy may be advantageous for rapidly lowering the tumor burden. Disadvantages include side effects, expense, and more infections in older or infirm persons.

Precautions and prophylaxis against infection may improve outcome. Administration of trimethoprim-cotrimoxazole during the first 3 months of treatment, when the risk of infection is highest, is a reasonable approach, especially with combination chemotherapy regimens. Ciprofloxacin (500 mg twice daily) can be substituted. Granulocyte colony-stimulating factor may be used, but its comparative effectiveness is not proved, and it is costly. Penicillin VK (500 mg twice daily) taken orally prevents the recurrent *S. pneumoniae* infections that occur in less than 10% of patients.

Radiation therapy is used for locally threatening lesions. About 5% of MM patients develop spinal cord compression during the course of their disease. Prompt recognition of the symptoms and signs can prevent major disability. These include severe unremitting back pain, especially nerve root (radicular) pain, unilateral or bilateral numbness of the lower extremities, paresis or paralysis, urinary or bowel control problems, hyperreflexia, and pathologic reflexes. Myeloma is exquisitely sensitive to radiation therapy. Local recurrence is rare. Residual tumor mass, if any, is often dormant or caused by persistent amyloid in the mass. Fields and doses of radiation should be limited to control the locally threatening tumor and to avoid permanent effects on normal marrow. Radiation may be necessary for painful localized lesions in other bones, but it should be reserved for symptoms that pose threats to life or that might cause long-term disability.

Surgical internal fixation may be necessary in the case of impending fracture of a long bone. The most reliable sign of impending fracture is persistent pain. An orthopedist who has experience with MM should be consulted, and appropriate conservative measures, such as bracing for refractory pain or other support measures, or surgery should be chosen after considering the patient's long-term outlook and the degree of the threat posed by localized tumor growth. Oral calcium supplements, fluoride, and vitamin D do not adequately prevent fractures. Bisphosphonates, although costly, have been proved to prevent fractures and should be used for an indefinite period of time for any patients with myeloma bone disease.

Early recognition and treatment of hypercalcemia help to prevent renal insufficiency. Appropriate initial treatment includes high-dose corticosteroids and vigorous hydration to initiate a diuresis. Patients initially may have a large initial intravascular volume deficit that must be replaced. If saline diuresis has been initiated, natriuretic diuretics may be administered to enhance calcium excretion. Intravenous bisphosphonates are effective in treatment of hypercalcemia.

Renal insufficiency is a serious but often reversible complication of MM. Causes include light-chain proteinuria, hypercalcemia, hyperuricemia, and hyperviscosity caused by very high levels of M protein. Aggravating factors include infections, dehydration, use of contrast dyes, nephrotoxic antibiotics, and excess doses of vitamin C. Prevention requires avoidance of these factors. Treatment includes vigorous intravenous hydration and discontinuation of nephrotoxic agents. Allopurinol, alkalinization of the urine, and plasmapheresis may be of benefit. Hydration and diuresis are the most important measures. Dialysis is rarely needed, and patients who require hemodialysis generally have more aggressive and resistant myelomas.

Patients younger than 70 years of age healthy enough to undergo the rigors of intensive therapy should be considered candidates for peripheral stem cell transplantation (PSCT) from the outset. After an initial period of cytoreductive chemotherapy with vincristine, doxorubicin (Adriamycin), and dexamethasone (VAD) or a similar regimen, stem cell harvest is carried out. Harvested cells are then cryopreserved in liquid nitrogen for immediate PSCT. Alternatively, standard chemotherapy can be given and PSCT reserved later for relapsed disease. MM treatment-related mortality in most centers is less than 5%. Intensive therapy and PSCT are attractive because they achieve a greater reduction in tumor burden and a higher complete response (CR) rate averaging 25% compared with the lower complete response rates obtained with standard chemotherapy. Patients who achieve CR live longer than other responding patients. Patients with primarily resistant disease on VAD chemotherapy may also respond particularly well to stem cell transplantation compared with the response from standard chemotherapy.

Allogeneic transplantation has a higher treatment-related mortality rate than autologous stem cell transplantation. In addition to a 30% to 40% mortality rate in the first 6 months, there is risk of developing severe chronic graft-versus-host disease. Allogeneic transplantation is restricted to centers where outcome is reported and special studies are conducted to reduce morbidity and mortality. Enthusiasm for potential cure by autologous and allogeneic transplantation is tempered by the reality that relapses occur in most cases. New agents and modalities holding promise are thalidomide, other antiangiogenic approaches, immunomodulation, and vaccination.

Pain management and psychologic support are important in patients with MM. A patient needs to know that response to treatment yields longer survival, often many years. Patients should know that other approaches are available in case of relapse. The availability of clinical trials should be stressed before treatment is started. Ideally, patients should assume a role in the choice of initial treatment. They should be guided toward developing an awareness of the importance of prompt treatment of complications. Patients should be told that they could live a normal life during the stable phase of the disease. With the support of analgesics, most patients afflicted with even the most severe bone pain can maintain activity levels that encourage better bone mineralization. They can increase fluid intake to prevent dehydration and reduce the risk of renal damage. Such patients can learn to promptly recognize and report fever or other evidence of infection.

SOLITARY PLASMACYTOMA

Most patients with solitary plasmacytoma have a single solitary plasmacytoma of bone (SPB), and some have an extramedullary plasmacytoma (EMP). Most have a monoclonal protein in the serum or urine. They do not fulfill criteria for MM, because they do not have anemia, disseminated bone lesions, hypercalcemia, or renal insufficiency and because they have less than 10% plasma cells in the marrow. Although most patients with SPB remain asymptomatic after initial treatment, about one-third develop MM an average of 4.5 years after initial diagnosis of SPB. About 40% are disease-free at 10 years. EMP can affect almost any organ. Some patients with EMP later develop local spread rather than overt MM.

Clinical Findings

The findings in SPB depend on the site of involvement. SPB most commonly affects the vertebrae but may also affect the ribs, scapulas, pelvis, and skull or any medullary site. Involvement of adjacent bone and tissue sites by direct extension does not constitute evidence of MM. Spinal cord compression and its attendant clinical symptoms and signs are potential complications that must be detected early and treated on an emergency basis.

Laboratory Findings

Evaluation of patients with suspected SPB should include serum and urine electrophoresis and immunofixation, bone radiographs, a complete blood count, a blood chemistry panel, and a marrow examination. Unlike patients who have MM, the spike in the serum of patients with SPB is small and usually disappears with treatment. Patients do not have major light-chain proteinuria. Hemoglobin, calcium, and creatinine levels are normal. Bone x-ray films fail to reveal additional bone lesions. The marrow examination usually detects no monoclonal plasma cells, but if they are present, the patient is likely to require chemotherapy for myeloma within only a few years.

Optimal Management

A patient with a SPB and an M protein does not satisfy criteria for MM, even with a small percentage of monoclonal plasma cells in the marrow. Chemotherapy should not be given as part of initial treatment for SPB. Many patients with SPB are given chemotherapy, but local irradiation alone may bring about long-term control without recurrence. Unlike the palliative irradiation used for controlling locally threatening disease in patients with MM, the goal in patients with SPB is cure. Radiation fields should generously encompass the known area of involvement, and full doses should be given.

The patient's prognosis depends on the biology of solitary plasmacytoma more than its size or extent. Morphologic immaturity of the plasmacytoma is not a negative prognostic factor for progression to overt MM. The presence of monoclonal plasma cells in the marrow or persistent M protein in the serum or urine suggests that the patient will eventually develop MM. Patients remain at risk of MM for years. Local recurrence is extremely rare after local irradiation or complete surgical resection.

These patients should be followed up in the same manner as those with SMM.

HEAVY-CHAIN DISEASES

Heavy-chain diseases are rare variants of monoclonal gammopathies that are characterized by the production by plasma cells of abnormal heavy chains of immunoglobulin. Immunoelectrophoresis and immunofixation may show that monoclonal heavy chains migrate differently from the migration of associated monoclonal light chains. This usually reflects critical deletions in coding the heavy chain to which the light chains are normally covalently linked. The underlying disorder varies.

Clinical Findings

The clinical spectrum of the heavy-chain diseases varies from that of a collagen vascular disorder to a lymphoma. Most common in the United States is γ heavy-chain disease, corresponding to IgG monoclonal gammopathy. Patients characteristically have hepatosplenomegaly or lymphadenopathy. Sometimes, they have pharyngeal involvement and uvular swelling (Franklin's disease). Usually, no free light chain is produced, and the course is extremely varied. The α heavy-chain disease, corresponding to IgA monoclonal gammopathy, is seen mainly in the Mediterranean area. Patients have abdominal nodal involvement, small-bowel involvement, and associated malabsorption. In μ heavy-chain disease, the presentation varies from lymphoma-like disease to that of chronic lymphocytic leukemia.

Laboratory Findings

A small, broad-based spike may be easily missed on electrophoresis. Lytic bone lesions are uncommon.

Optimal Management

Mediterranean lymphoma or a heavy-chain disease can cause malabsorption. Treatment varies from antibiotics for certain patients to cytotoxic therapy as for low-grade lymphoma. The response rate is high and the subsequent course highly variable. Cures are rare.

CRYOGLOBULINEMIA

Cryoglobulins precipitate from serum at reduced temperatures in vitro and may redissolve on rewarming. Type I cryoglobulinemia consists of a monoclonal protein, frequently IgM. The clinical picture varies from MGUS lymphoma or macroglobulinemia in the case of IgM M proteins to myeloma in the case of IgG or IgA M proteins. Type II cryoglobulinemia consists of a monoclonal immunoglobulin, usually IgM, which forms complexes with polyclonal immunoglobulin, usually IgG, and binds and removes complement causing low levels of C3 and C4. High rheumatoid factor levels are common. Type III cryoglobulins are characteristically polyclonal IgM immunoglobulin complexed with polyclonal IgG immunoglobulin.

Clinical Findings

Patients with type I cryoglobulinemia have acral cyanosis and even infarction if the cryoglobulin precipitates near body temperature. Most patients are asymptomatic. Cryocrits may be very high without any symptoms.

Patients with type II or mixed cryoglobulinemia develop vasculitides, with involvement of the skin, kidneys, and peripheral neuropathy. The clinical syndrome resembles immune complex disease, and complement levels may be low.

Type III cryoglobulins occur secondary to underlying infections, such as mononucleosis.

Laboratory Findings

Immunoelectrophoresis of redissolved cryoglobulin identifies the type of cryoglobulin. Thermal insolubility assays are useful in type I cryoglobulinemia to predict whether the patient will have symptoms.

Optimal Management

Patients with symptomatic type I cryoglobulinemia may require treatment for the underlying lymphoma or myeloma. Patients with type II or mixed cryoglobulinemia may benefit from corticosteroids and cytotoxic therapy. Interferon therapy may control disease without the long-term negative effects of cytotoxics and corticosteroids. Patients with type III cryoglobulinemia are rarely symptomatic and seldom require treatment.

CONDITIONS ASSOCIATED WITH MONOCLONAL GAMMOPATHY

[Table 234.2](#) lists other conditions associated with monoclonal gammopathy. Renal insufficiency in association with monoclonal gammopathy may be caused by amyloidosis of the light-chain type ([Chapter 235](#)), adult-acquired Fanconi's syndrome, or light-chain deposition disease. These disorders can overlap and mimic MM because of the finding of renal failure and increased plasma cells in the marrow associated with a monoclonal gammopathy, but most patients do not develop overt MM. They may live for years without requiring chemotherapy.

A full description of each of these syndromes is beyond the scope of this chapter. Most patients with one of these syndromes should be observed without treatment. Chemotherapy should be given only if the patient has overt systemic myeloma or if the risk of the disease outweighs the risk of chemotherapy-induced myelodysplasia and acute leukemia.

CHAPTER 235: AMYLOIDOSIS

ROBERT A. KYLE

[Incidence and Epidemiology](#)
[Etiology](#)
[Pathogenesis and Pathophysiology](#)
[Clinical Findings](#)
[Laboratory Findings](#)
[Strategies for Optimal Care](#)

Amyloid is a substance that consists of fibrils. It appears homogeneous and amorphous under a light microscope and stains pink with hematoxylin and eosin. With polarized light, amyloid stained with Congo red produces apple-green birefringence. Linear, nonbranching, aggregated fibrils 7.5 to 10 nm wide and of indefinite length are seen with an electron microscope.

INCIDENCE AND EPIDEMIOLOGY

The types and distribution of amyloidosis are shown in [Fig. 235.1](#). The age- and sex-adjusted annual rate of primary amyloidosis (AL) in Olmsted County, Minnesota, is 0.89 cases per 100,000 persons. Approximately 2,450 new cases occur annually in the United States. The median age at diagnosis is 64 years, but only 1% of patients are younger than 40 years.

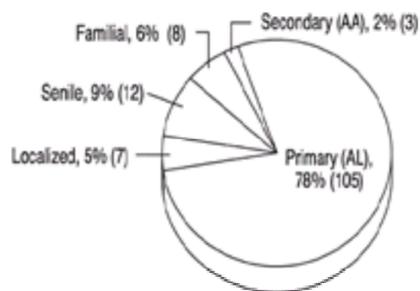

FIGURE 235.1. Types of amyloidosis among 135 cases diagnosed in 1997. (Modified from Kyle RA, Gertz MA. Primary systemic amyloidosis: clinical and laboratory features in 474 cases. *Semin Hematol* 1995;32:45–59, with permission of W.B. Saunders Co.)

ETIOLOGY

The cause of AL is unknown. Secondary amyloidosis (AA) is associated with an inflammatory process such as rheumatoid arthritis or its variants, inflammatory bowel disease (especially Crohn's disease), or bronchiectasis. In some parts of the world, tuberculosis and leprosy are major causes. Amyloidosis rarely is associated with hypernephroma, macroglobulinemia, Hodgkin's disease or other lymphomas, or heavy-chain diseases.

PATHOGENESIS AND PATHOPHYSIOLOGY

In AL, the amyloid fibrils consist of the NH₂-terminal amino acid residues of the variable portions of a monoclonal k or y light chain. AL is closely related to multiple myeloma, and it is difficult to differentiate AL from multiple myeloma with amyloidosis. Because the prognoses are similar, both should be considered AL. In AA, the main component of the amyloid fibril is protein A, which is derived from serum amyloid A protein and is not related to any known immunoglobulin. The amyloid fibrils in familial amyloidosis consist of transthyretin. More than 50 point mutations of transthyretin have been recognized. Fibrinogen, apolipoprotein A-I, gelsolin, lysozyme, cystatin-C, and b protein also may be associated with familial amyloidosis. The amyloid fibrils in senile amyloidosis consist of normal transthyretin. Among patients undergoing long-term hemodialysis or peritoneal dialysis, periarticular or bony deposition of amyloid fibrils consisting of β₂-microglobulin often develops. Localized amyloid most often produces carpal tunnel syndrome. The catabolism or breakdown of amyloid fibrils is an important factor in pathogenesis, but little is known of this process. Amyloid P component, a glycoprotein, and glycosaminoglycans are present in amyloid deposits, but their functions are unknown.

CLINICAL FINDINGS

PRIMARY AMYLOIDOSIS

Weakness, fatigue, and weight loss are the most common features of AL. Purpura, particularly in the periorbital and facial areas, occurs among 15% of patients. Light-headedness, syncope, change in the tongue or voice, jaw or hip claudication, paresthesias, dyspnea, and edema are the most frequent symptoms. The liver is palpable in almost one-fourth of patients, but the spleen is palpable in only 5%. Macroglossia occurs in about 10%. Nephrotic syndrome or renal failure affects more than one-fourth of patients at diagnosis. Congestive heart failure, carpal tunnel syndrome, sensorimotor peripheral neuropathy, and orthostatic hypotension are other important features ([Fig. 235.2](#)). The presence of one of these syndromes and a monoclonal protein in the serum or urine are strong indications of AL, and appropriate biopsies are needed for diagnosis.

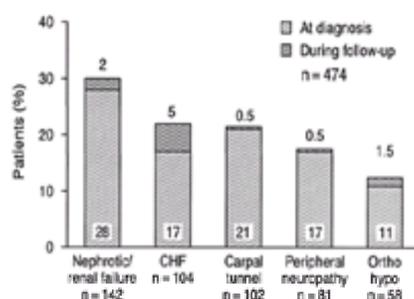

FIGURE 235.2. Frequency of amyloid syndromes at diagnosis of primary amyloidosis and during follow-up care. CHF, Congestive heart failure; Ortho hypo, orthostatic hypotension. (From Kyle RA, Gertz MA. Primary systemic amyloidosis: clinical and laboratory features in 474 cases. *Semin Hematol* 1995;32:45–59, with permission of W.B. Saunders Co.)

SECONDARY AMYLOIDOSIS

At diagnosis, more than 90% of patients with secondary amyloidosis have renal insufficiency or nephrotic syndrome. Gastrointestinal involvement often is manifested as a malabsorption syndrome. Nausea and vomiting from pseudoobstruction may occur. In contrast to AL, AA rarely involves the heart and peripheral nerves.

FAMILIAL AMYLOIDOSIS

For clinical purposes, familial amyloidosis can be classified most easily as neuropathic, cardiopathic, or nephropathic. The neuropathic type is characterized by sensorimotor peripheral neuropathy beginning in the lower extremities and by autonomic dysfunction, disturbances of bladder and gastrointestinal function, and vitreous opacities. Carpal tunnel syndrome may be a major feature. Some patients do not have symptoms until the sixth or seventh decade of life. Most patients described have been from Portugal, Sweden, and Japan. Familial Mediterranean fever is characterized by recurrent episodes of fever and abdominal pain and results in nephrotic syndrome or renal insufficiency. Hypertension and renal failure are the main features of amyloidosis in other families. The heart may be the main organ of amyloid deposition among families from Denmark, the Appalachian region of the United States, and many other parts of the world.

SENILE SYSTEMIC AMYLOIDOSIS

Patients with senile systemic amyloidosis usually have congestive heart failure. Atrial fibrillation is common. Echocardiography shows findings consistent with amyloidosis, and a biopsy reveals amyloid consisting of normal transthyretin. It is important to recognize these patients, because the survival period is much better than it is for AL (60 months versus 5 months) and because patients with senile systemic amyloidosis should not receive chemotherapy.

DIALYSIS-ASSOCIATED AMYLOIDOSIS

Patients undergoing long-term hemodialysis or peritoneal dialysis often have carpal tunnel syndrome and pain involving the shoulders, hands, wrists, hips, and knees. Deposition of amyloid in bones commonly produces radiolucencies.

LABORATORY FINDINGS

PRIMARY AMYLOIDOSIS

Anemia is not a prominent feature of AL, but when present, it is usually a result of multiple myeloma, renal insufficiency, or gastrointestinal bleeding. Thrombocytosis occurs among 10% of patients. Serum creatinine level is higher than 2.0 mg per deciliter among 20% of patients. For one-half of patients, serum protein electrophoresis shows a modest localized band or spike (median, 1.4 g per deciliter). A monoclonal protein is found in the serum and the urine of more than 70% of patients. γ Light chains are twice as common as k light chains. A monoclonal protein is found in the serum or urine in 90% of patients with AL. The bone marrow contains 5% or less plasma cells in almost one-half of patients.

Low voltage or characteristics of anteroseptal infarction, arrhythmia, and heart block are common electrocardiographic features. The echocardiogram is abnormal among two-thirds of patients. The main features are increased thickness of the left and right ventricular walls, abnormal myocardial texture (granular sparkling), atrial enlargement, valvular thickening and regurgitation, pericardial effusion, and abnormal diastolic and ultimately reduced systolic ventricular function.

The diagnosis depends on the demonstration of amyloid deposits ([Fig. 235.3](#)). Results of abdominal fat aspiration or bone marrow biopsy are positive among 90% of patients. If these sites are normal, tissue should be obtained from the rectum or a possibly involved organ such as the kidney, liver, heart, or sural nerve. A monoclonal population of bone marrow plasma cells or a monoclonal protein in serum or urine occurs among 98% of patients with AL.

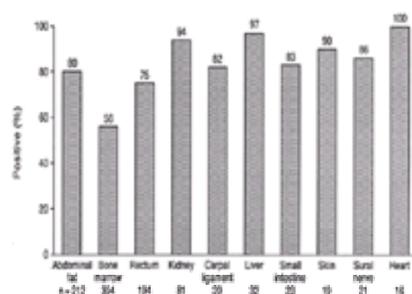

FIGURE 235.3. Results of biopsy among patients with primary amyloidosis. (From Kyle RA, Gertz MA. Primary systemic amyloidosis: clinical and laboratory features in 474 cases. *Semin Hematol* 1995;32:45–59, with permission of W.B. Saunders Co.)

SECONDARY AMYLOIDOSIS

Serum creatinine level is increased among two-thirds of patients with secondary amyloidosis. Eighty-seven percent of Mayo Clinic patients had more than 1 g of protein in 24-hour collections of urine. Serum albumin level was reduced among almost 90% of patients, but alkaline phosphatase level was increased among only 14%. Results of organ biopsy among patients with AA are similar to those among patients with AL.

FAMILIAL AMYLOIDOSIS

The laboratory findings among patients with neuropathic and cardiopathic amyloidosis are nondescript. Renal insufficiency and nephrotic syndrome frequently occur among persons with nephropathic amyloidosis. The diagnosis depends on the demonstration of amyloid. The incidence of positive biopsy results for bone marrow and rectum are similar to those in AL. The type of transthyretin mutation must be determined.

STRATEGIES FOR OPTIMAL CARE

PRIMARY AMYLOIDOSIS

In a series of 474 patients with AL seen within 1 month of diagnosis at the Mayo Clinic from 1981 to 1992, the median duration of survival was 13 months. The median survival period was 4 months for patients with congestive heart failure and 2 years for those with nephrotic syndrome or renal failure. Therapy for AL is unsatisfactory. Treatment should be attempted with alkylating agents known to be effective against plasma cell proliferative processes, because the amyloid fibrils consist of the variable portion of a monoclonal light chain. My colleagues and I demonstrated that melphalan and prednisone produce a significantly longer survival period than does colchicine (18 versus 9 months). We found no difference in survival time in a prospective study comparing melphalan and prednisone with a combination of alkylating agents. Intensive therapy consisting of high-dose chemotherapy followed by rescue with peripheral stem cells shows some promise. A useful treatment option may be 4'-iodo-4'-deoxyrubicin (I-DOX), which has an affinity for amyloid fibrils.

SECONDARY AMYLOIDOSIS

The median duration of survival is approximately 2 years for AA. Treatment depends on the underlying disease. Resorption of amyloid after therapy for osteomyelitis, tuberculosis, or empyema has been reported. Renal transplantation is helpful.

FAMILIAL AMYLOIDOSIS

The median actuarial survival period for familial amyloidosis was 5.8 years in the Mayo series. Liver transplantation produces a dramatic reduction in variant transthyretin serum level. In theory this should stop further deposition of amyloid.

DIALYSIS-ASSOCIATED AMYLOIDOSIS

Renal transplantation often leads to dramatic improvement in joint symptoms. The use of a b2-microglobulin-absorbent column may be helpful.

CHAPTER 236: WALDENSTRÖM'S MACROGLOBULINEMIA

ROBERT A. KYLE

[Definition](#)
[Incidence and Epidemiology](#)
[Etiology](#)
[Pathogenesis and Pathophysiology](#)
[Clinical Findings](#)
[Laboratory Findings](#)
[Strategies for Optimal Care](#)

DEFINITION

Waldenström's macroglobulinemia (WM) is characterized by proliferation of lymphocytes and plasma cells that produce a large amount of IgM monoclonal protein. It has similarities to multiple myeloma, lymphoma, and chronic lymphocytic leukemia.

INCIDENCE AND EPIDEMIOLOGY

The incidence of WM was 0.34 cases per 100,000 white men and 0.17 cases per 100,000 white women in a Surveillance, Epidemiology, and End-Result (SEER) study. Approximately 1,400 cases occur in the United States each year. At the Mayo Clinic, WM is one-seventh as common as multiple myeloma. The median age in the Mayo Clinic series was 63 years (range, 30 to 89 years). The disorder rarely occurs before 40 years of age. About 60% of patients are male.

ETIOLOGY

The cause of WM is unknown. The condition has been recognized among first-degree relatives of several families and among monozygotic twins. In a case-control study, patients with WM were slightly better educated than controls, but there were no differences in sociodemographic factors, history of prior medical conditions, medication use, cigarette or alcohol consumption, specific occupational exposures, or employment in any particular industries or occupations. First-degree relatives appeared to have more diverse immunologic abnormalities than did controls.

PATHOGENESIS AND PATHOPHYSIOLOGY

WM is a monoclonal B-cell proliferative process in which lymphocytes or plasma cells produce an IgM monoclonal protein. WM is part of a spectrum that includes monoclonal gammopathy of undetermined significance of the IgM type, lymphocytic lymphoma or other malignant lymphoproliferative disorders, chronic lymphocytic leukemia, and primary amyloidosis. The monoclonal B cells always express monoclonal IgM of the same light-chain type as in the serum. Clonal chromosomal changes may be found, but no specific abnormality has been defined.

CLINICAL FINDINGS

Weakness and fatigue are the most common features of WM. Chronic nasal bleeding or oozing from the gums is characteristic, but postsurgical or gastrointestinal bleeding may occur. Blurring or loss of vision may be prominent. Dizziness, headache, vertigo, nystagmus, sudden deafness, ataxia, or diplopia may be present. Dyspnea and congestive heart failure may develop. Fever, night sweats, loss of weight, and recurrent infections may occur. Retinal vein engorgement and flame-shaped hemorrhages are common. Papilledema, somnolence, coma, and cerebral hemorrhage may develop in some cases. Although most patients have symptoms when the relative viscosity is more than 4 centipoises (cP), the correlation between serum viscosity and clinical manifestations is imprecise. Symptoms rarely are attributable to hyperviscosity if the relative viscosity is less than 4 cP. Bone pain is rare. About one-fourth of patients have hepatomegaly when WM is diagnosed. Splenomegaly and lymphadenopathy are slightly less common.

Diffuse pulmonary infiltrates, isolated masses, or pleural effusion may be a major manifestation. Diarrhea and steatorrhea from infiltration of monoclonal IgM rarely occur. Obstructive jaundice and portal hypertension have been reported. Although retroperitoneal and mesenteric lymphadenopathy often occur, they usually are asymptomatic. Renal insufficiency is uncommon. Nephrotic syndrome is rare in WM, but when present, it usually is caused by amyloidosis. Sensorimotor peripheral neuropathy is the most common neurologic manifestation. This may be caused by deposition of IgM or amyloid. Infiltration of the meninges rarely occurs.

LABORATORY FINDINGS

Most patients with symptomatic WM have anemia. Increased plasma volume is a frequent finding and is responsible for spuriously low hemoglobin and hematocrit levels. Rouleaux formation is prominent, and erythrocyte sedimentation rate usually is greatly increased. Lymphocytosis or monocytosis is a routine finding. Serum creatinine value almost always is normal.

Serum protein electrophoresis shows a sharp, narrow spike or dense band usually migrating in the g area. About 75% of the IgM proteins are k. The IgM level obtained by means of nephelometry often is 1,000 to 3,000 mg per deciliter more than that found with serum protein electrophoresis. The reduction in uninvolved IgG and IgA immunoglobulins is less striking than in multiple myeloma. About 10% of macroglobulins precipitate in the cold (cryoglobulinemia). A urinary monoclonal light chain is detected by means of immunofixation among 70% to 80% of patients. Fewer than 5% have lytic bone lesions.

A bone marrow aspirate often is hypocellular, but the biopsy specimen usually is hypercellular and extensively infiltrated with lymphoid or plasmacytoid cells. The presence of mast cells may help differentiate macroglobulinemia from myeloma or lymphoma.

STRATEGIES FOR OPTIMAL CARE

The diagnosis of WM depends on the presence of an IgM monoclonal protein and lymphocyte–plasma cell infiltration of the bone marrow that produces symptoms and physical findings of WM. The level of IgM protein is not helpful in predicting survival and is of importance only in producing the hyperviscosity syndrome. Patients with WM should not be treated unless they have symptoms. The median survival period is 5 years. Older age, loss of weight and other constitutional symptoms, low hemoglobin level, and the presence of cryoglobulinemia or cytopenia indicate shorter survival.

Plasmapheresis with a cell separator quickly alleviates the symptoms of hyperviscosity. Specific therapy should be directed against the proliferating lymphocytes and plasma cells. Chlorambucil given in a daily or intermittent course has been the usual treatment for more than three decades and produces an objective response among 70% of patients. Therapy should be continued until the IgM protein reaches a plateau level and constitutional symptoms have resolved. Because the response is slow, patients should be treated for at least 6 months before chlorambucil therapy is abandoned. The combination of vincristine, BCNU (carmustine), melphalan, cyclophosphamide, and prednisone is an alternative regimen. Interferon alfa-2 has produced benefit for some patients.

The nucleoside analogs fludarabine and 2-chlorodeoxyadenosine are reported to produce a response among as many as 80% of previously untreated patients. However, a large study involving 117 patients showed a response to fludarabine among only 34% of the patients. Only one-third of patients resistant to alkylating agents respond to the nucleoside analogs. Rituximab (Rituxan) produces a response among approximately one-half of patients.

CHAPTER 237: INHERITED DISORDERS OF BLOOD COAGULATION

DAVID GINSBURG

[Definition](#)
[Hemophilia](#)
[Von Willebrand Disease](#)
[Strategies for Optimal Care](#)
[Inherited Defects of Other Coagulation Factors](#)

DEFINITION

Hemostasis depends on a finely tuned balance among a large number of cellular and protein components of blood. The initial response to vascular injury is mediated by the interaction of platelets with specific plasma proteins and the vessel wall. Activation of the coagulation cascade leads to the deposition of fibrin, the principal structural component of the clot, and the fibrinolytic system coordinates subsequent dissolution of the clot. Inherited functional abnormalities at many points in this complex circuit can cause pathologic bleeding or thrombosis. Inherited disorders that lead to pathologic thrombosis (thrombophilia) are reviewed in [Chapter 240](#) and inherited abnormalities in platelet function in [Chapter 239](#). This chapter discusses inherited bleeding disorders caused by genetic deficiencies in coagulation factor function ([Table 237.1](#)). Although generally mild, the most common inherited bleeding disorder is von Willebrand disease (VWD), whereas hemophilia is the most frequent cause of a clinically severe hemorrhagic diathesis. Deficiencies of other clotting factors are considerably less common and can cause bleeding of varying severity.

Disorder	Inheritance	Prevalence	Clinical Features
Hemophilia A	X-linked recessive	1:5,000–10,000	Mild to severe hemorrhage, joint bleeds, and petechiae
Hemophilia B	X-linked recessive	1:10,000	Mild to severe hemorrhage, joint bleeds, and petechiae
von Willebrand disease (VWD)			
Type 1	Autosomal recessive	1:100–1,000	Mild bleeding, skin bruising, hematuria, epistaxis, menorrhagia
Type 2	Autosomal recessive	1:1,000,000	Severe bleeding, menorrhagia, joint bleeds
Type 2A, Type 2B	Autosomal recessive	1:1,000	Similar to Type 1 but petechiae more frequent; Type 2B also has epistaxis
Type 2C	Autosomal recessive	?	Similar to Type 1 but petechiae more frequent; Type 2C also has epistaxis
Other variants	Variable	None	Variable
Factor XI deficiency	Autosomal recessive	Common among Ashkenazi Jews	Similar to hemophilia, but mild
Factor XII deficiency (high molecular weight kininogen)	Autosomal recessive	Rare	Similar to hemophilia, but mild
Factor XIII deficiency	Autosomal recessive	Rare	Similar to hemophilia, but mild
Factor V deficiency	Autosomal recessive	Rare	Similar to hemophilia, but mild
Factor VII deficiency	Autosomal recessive	Rare	Similar to hemophilia, but mild
Factor X deficiency	Autosomal recessive	Rare	Similar to hemophilia, but mild
Factor XI deficiency	Autosomal recessive	Rare	Similar to hemophilia, but mild
Factor XII deficiency	Autosomal recessive	Rare	Similar to hemophilia, but mild
Factor XIII deficiency	Autosomal recessive	Rare	Similar to hemophilia, but mild
Factor VII deficiency	Autosomal recessive	Rare	Similar to hemophilia, but mild
Factor X deficiency	Autosomal recessive	Rare	Similar to hemophilia, but mild
Factor XI deficiency	Autosomal recessive	Rare	Similar to hemophilia, but mild
Factor XII deficiency	Autosomal recessive	Rare	Similar to hemophilia, but mild
Factor XIII deficiency	Autosomal recessive	Rare	Similar to hemophilia, but mild

TABLE 237.1. INHERITED DISORDERS OF BLOOD COAGULATION

HEMOPHILIA

Coagulation factors VIII and IX form a complex that activates factor X, leading to thrombin formation and deposition of a fibrin blood clot. Deficiency of factor VIII results in hemophilia A (classic hemophilia) and deficiency of factor IX in hemophilia B (Christmas disease). The factor VIII and factor IX genes both are located on the X chromosome, accounting for the typical X-linked inheritance of these two disorders.

INCIDENCE AND EPIDEMIOLOGY

Hemophilia A is the most common form. The prevalence is estimated at 1:5,000 to 1:10,000 male births. Approximately 80% to 90% of cases of hemophilia are classified as hemophilia A; the others are hemophilia B. Because of the X-linked inheritance, homozygous females (inheritance of two mutated copies of the *FVIII* or *FIX* gene) are exceedingly rare. Heterozygous female carriers should have approximately one-half of the normal factor level and generally have no symptoms. However, mild bleeding sometimes may be encountered, particularly in settings of unequal X chromosome inactivation.

Hemophilia occurs with similar prevalence in all populations. Approximately one-third of patients with hemophilia A or hemophilia B have “new mutations,” and thus there is no family history of hemophilia. Observation of marked bleeding among females or male-to-male transmission of factor VIII deficiency should raise the suspicion of another disorder, particularly the type 2N variant of VWD (see later).

ETIOLOGY AND PATHOGENESIS

Hemophilia A and hemophilia B are caused by mutations in the genes for factor VIII and factor IX, respectively. Deficiency of the corresponding protein causes decreased clot formation and abnormal bleeding, particularly after trauma, although spontaneous hemorrhage may also occur.

The severity of bleeding in both hemophilia A and hemophilia B can be correlated directly with the level of residual clotting factor activity ([Table 237.2](#)). Most patients have undetectable levels of factor activity (< 1%), and the hemophilia is classified as severe. Residual activity in the 1% to 5% range is classified as moderate hemophilia and in the 5% to 25% range as mild hemophilia. Severe hemophilia generally is recognized soon after birth or as soon as the child becomes active. Mild hemophilia may go undiagnosed until later in adult life or at the time of major surgery or trauma. The remarkable moderating effect of even small levels of residual factor VIII or factor IX activity on clinical severity forms the rationale for prophylaxis with intermittent factor replacement. This approach is becoming common practice in the management of newly diagnosed pediatric cases of severe hemophilia A.

Classification	Factor IX or Factor VIII Activity	Clinical Manifestation
Severe	<1%	Spontaneous hemorrhage beginning in early infancy; frequent hemarthroses and other serious hemorrhage
Moderate	1–5%	Hemorrhage after trauma; occasional spontaneous hemorrhage
Mild	5–25%	Bleeding generally only after severe trauma or surgery
	>25%	No substantial bleeding

TABLE 237.2. CLINICAL CLASSIFICATION OF HEMOPHILIA A AND B

Severe hemophilia is caused by genetic defects that disrupt the factor VIII or factor IX gene. These include deletions of part or all of the gene and point mutations that disrupt the protein coding sequence. Moderate and mild forms of hemophilia generally are associated with single amino acid substitutions that only partly compromise protein function.

CLINICAL FINDINGS

The clinical presentations of hemophilia A and hemophilia B are essentially indistinguishable, and the differential diagnosis is based entirely on the results of clotting factor activity assays. The diagnosis of hemophilia should be suspected in any boy with a severe congenital bleeding disorder and in older males with mild bleeding. Patients with mild hemophilia may have easy bruising and excessive bleeding after trauma or surgery. In contrast to the bleeding of VWD or primary disorders of platelet function, which is predominantly cutaneous or from mucosal surfaces, the bleeding of hemophilia is primarily localized to soft tissues or joints.

The most serious life-threatening complication is central nervous system bleeding, which can follow even minor trauma and may lead to death or severe disability. Central nervous system bleeding accounted for about 25% of deaths among patients with hemophilia before the AIDS era. Joint bleeding (hemarthrosis) occurs predominantly into the large joints. Though usually first recognized as mild pain and some limitation of motion, symptoms often increase over several hours and can cause severe pain with continued bleeding. Repeated injury can lead to chronic degenerative arthritis, frequently necessitating joint replacement in later adulthood. Large intramuscular bleeds can lead to compartment syndromes. Pharyngeal bleeding causing airway obstruction is a particularly serious complication. Large bleeds into soft tissues can be walled off to form large masses with a liquefied center, referred to as *pseudocysts*. Hematuria is a common problem among many patients with hemophilia at some time during their lives and may lead to ureteral obstruction due to clots. Median life expectancy for patients with hemophilia expanded dramatically from 11 or 12 years in the early 1900s to close to normal in the late 1990s.

The bleeding manifestations of hemophilia have been overshadowed by the profound infectious complications related to therapy. Most patients who received blood products for hemophilia before 1984 were exposed to HIV, and approximately 90% of the patients heavily exposed during that time have positive test results for the virus. Nearly two-thirds of this cohort have died. The prevalence of hepatitis also was nearly uniform among this patient population. Although over the past 15 years hemophilia care has been dominated by management of HIV complications, this trend is shifting gradually because the younger population, who began treatment after 1984, is generally virus free.

Another important complication of hemophilia treatment is the development of antibody inhibitors to the infused missing clotting factor (factor VIII or factor IX). These inhibitors, which develop in 10% to 20% of patients with hemophilia A and 5% to 6% of those with hemophilia B, can dramatically complicate therapy. Antibodies can reach extremely high titers, which can be difficult or impossible to overwhelm with high doses of factor replacement.

LABORATORY FINDINGS

Bleeding time, which is thought primarily to represent a measure of platelet plug formation, is normal in hemophilia A and hemophilia B. Prothrombin time is normal in both disorders, and activated partial thromboplastin time (aPTT) is moderately prolonged in the severe form of these disorders and at least mildly prolonged among patients with factor VIII or IX levels less than 30%. The critical diagnostic tests for both disorders are specific assays for factor VIII and factor IX procoagulation activity. Patients with severe hemophilia have less than 1% factor activity, levels in the range of 1% to 5% being classified as moderate and 5% to 25% as mild ([Table 237.2](#)). Levels in excess of 25% generally are associated with normal hemostasis. VWF activity and protein level (the latter sometimes mistakenly referred to as factor VIII-related antigen or factor VIII:R:Ag) are normal in hemophilia. The inhibitory antibodies that develop in some patients are quantified in Bethesda units. One unit corresponds to the amount of antibody needed to neutralize the clotting factor activity contained in 1 mL of normal blood.

DNA testing can be performed for mutations in both the factor VIII and the factor IX gene. However, the clinical diagnosis of hemophilia, prediction of severity, and therapy all are based on the factor VIII or factor IX clotting activity measurement. Approximately one-half of severe hemophilia A is caused by the same recurrent DNA inversion event, referred to as the *factor VIII gene inversion*. It usually is most effective to begin testing with a screen for this abnormality. In the one-half of patients with severe hemophilia who do not have the inversion, direct DNA sequencing of the 26 factor VIII gene exons identifies the responsible mutation in most instances.

Identification of the gene mutation can facilitate precise carrier determination and facilitate prenatal diagnosis when a pregnancy is at risk. In the few cases in which the actual mutation cannot be identified, prenatal diagnosis often is still possible with genetic linkage analysis. In the past, hemophilia A carrier status among at-risk female patients often was determined by means of measurement of factor VIII activity in comparison with levels of VWF, although the sensitivity and specificity of this determination were low. Carrier status now can be resolved much more accurately in most cases by means of DNA diagnosis.

STRATEGIES FOR OPTIMAL CARE

The foundation of management of severe hemophilia A and hemophilia B is replacement of the missing clotting factor. The products for replacement are rapidly changing and the best choice of product is generally left to a hemophilia specialist. In the past, factor VIII and factor IX concentrates were prepared by means of pooling blood from large numbers of donors followed by limited biochemical purification. It is these products that carried the tragic infectious risk for HIV infection and hepatitis. Since the mid 1980s, heat and detergent treatment appear to have eliminated the hepatitis and HIV risk, but the potential for infection with other as yet unidentified agents remains a serious concern. For this reason, most patients found to have hemophilia are treated with recombinant factor VIII or factor IX. However, the high cost and limited availability of these products restricts use to the acute management of profuse hemorrhage or prophylactic treatment before surgical procedures or after trauma.

Continuous prophylaxis among children with newly diagnosed hemophilia has become a more widespread approach. A factor VIII dose of 50 units per kilogram generally raises the factor VIII level from 0 to 100%. A level of factor VIII that is 50% or higher should be adequate for normal hemostasis, even under extreme circumstances. The half-life of factor VIII is approximately 8 hours, necessitating treatments several times per day or continuous infusion. Mild or moderate hemophilia A can sometimes be successfully managed with desmopressin (DDAVP), which can produce a two- to fivefold increase in factor VIII that lasts for several hours. Desmopressin is generally not effective in severe hemophilia. e-Aminocaproic acid can be effective in the management of dental or superficial bleeding.

Management of the inhibitory factor VIII antibodies that develop in 10% to 20% of cases is a challenge that generally requires the expertise of a specialist. Treatment approaches include immunosuppression, infusion of porcine factor VIII, and various tolerance-inducing regimens. Both hemophilia A and hemophilia B are primary targets of a variety of gene therapy approaches, and several clinical trials have been initiated. Comprehensive care of patients with hemophilia also requires the cooperative input of many specialists, including orthopedists and geneticists. Care often is coordinated through a comprehensive hemophilia center.

VON WILLEBRAND DISEASE

DEFINITION

von Willebrand disease (VWD) is closely related to hemophilia A; von Willebrand originally called it *pseudohemophilia*. VWD is caused by a deficiency of von Willebrand factor (VWF) a large, multimeric plasma glycoprotein that serves as a carrier for factor VIII and as an adhesive bridge between blood platelets and the vessel wall. Bleeding ranges from mild in the most common form (type 1) to potentially life threatening (with hemorrhagic complications that resemble those of severe hemophilia) in the rare severe form of VWD (type 3). The large number of identified variants of VWD has led to a confusing and complex nomenclature.

INCIDENCE AND EPIDEMIOLOGY

The mild form of VWD, type 1, is the most common inherited bleeding disorder. Results of several epidemiologic studies have suggested that as many as 1% to 3% of the general population may be affected. In many of these studies, the diagnosis was based on minimal reductions in laboratory values not necessarily associated with major bleeding. The prevalence of clinically significant VWD is probably closer 1:1,000. The situation is clearly complicated by the incomplete penetrance of VWD—that is, not all persons who inherit the genetic defect actually express clinically significant bleeding. The number of patients with symptoms is probably less than 60% of persons carrying a VWD genetic defect. Penetrance is greater among women because of the hemostatic stresses of pregnancy and menstruation; VWD is an important cause of menorrhagia. Type 1 VWD is autosomal dominant in inheritance, though because of reduced penetrance, less than 50% of offspring of an affected parent have appreciable bleeding. Accurate estimates of the frequency of VWD also are compounded by the extremely common and nonspecific nature of mild bleeding symptoms among the general population. For example, in some studies as much as 20% of the population reports symptoms such as easy bruising.

Type 3 VWD is associated with severe, life-threatening bleeding, similar to that observed in severe hemophilia. Type 3 VWD is estimated to occur with a frequency of approximately 1:1,000,000 and may be more common in Scandinavia, where it was first described. Parents of patients with type 3 VWD generally have no symptoms, leading to the classic description of the inheritance pattern as autosomal recessive. However, a subset of type 3 parents is found to have typical type 1 VWD. The

type 2 variants of VWD account for 20% to 30% of cases and are probably more highly penetrant. The inheritance of most type 2 VWD variants is autosomal dominant.

ETIOLOGY AND PATHOGENESIS

VWF is one of the largest proteins circulating in blood. It is formed from multimers of up to 100 identical subunits, ranging up to 20 million dalton in molecular mass. VWF serves as the adhesive link between blood platelets and the injured vessel wall and is critical for efficient formation of the initial platelet plug at sites of vascular injury. VWF also carries factor VIII and localizes it to sites of initial clot formation. VWF is produced by endothelial cells and platelets. Plasma VWF is derived exclusively from endothelial cells. Platelet VWF is stored in the platelet α -granule and is released during platelet activation.

VWD is generally the result of mutations within the VWF gene on chromosome 12. Type 1 and type 3 VWD are produced by mutations that completely disrupt the function of VWF, whereas the type 2 variants usually are caused by single-amino-acid substitutions that lead to mildly decreased or altered function. Patients with type 3 VWD generally have inactivating mutations in both copies of the VWF gene that cause production of very low or undetectable levels of VWF. Factor VIII is very unstable without VWF, and patients with severe VWD also have very low levels of factor VIII, contributing to the severe bleeding diathesis. Patients with type 1 VWD generally have VWF levels in the range of 20% to 50% of normal, associated with mild bleeding, and are generally presumed to carry an inactivating mutation in one copy of the VWF gene. The remaining VWF, though reduced in quantity, is qualitatively normal, accounting for the mild symptoms.

The type 2 VWD variants result from qualitative dysfunction of the VWF protein. Types 2A and 2B VWD are associated with loss of the largest and functionally most active VWF multimers. In type 2B this occurs because increased spontaneous affinity for the platelet surface leads to clearance of both platelets and VWF from plasma and loss of the large VWF multimers as well as thrombocytopenia.

Type 2N VWD is caused by mutations within the factor VIII binding domain of VWF, resulting in loss of factor VIII binding, although VWF platelet binding function is normal. Patients who are homozygous for a type 2N VWD mutation may resemble those with mild to moderate hemophilia A with normal VWF platelet binding function but a mild to moderately reduced factor VIII level. It is important to differentiate type 2N VWD from hemophilia A. This diagnosis should be suspected when a female patient has reduced factor VIII levels or when other aspects of inheritance are not consistent with an X-linked pattern.

In addition to mutations within the VWF gene, a variety of other genetic and environmental factors are known to affect levels of plasma VWF, including estrogen level, stress, and most notably ABO blood group. Patients with type O blood have average VWF levels 20% to 30% lower than those with type A, B, or AB blood. A number of other genetic factors undoubtedly modify the severity of VWD, but these remain to be identified.

Among patients with mild type 1 VWD, the modest reduction in factor VIII level probably only minimally contributes to bleeding and the primary pathologic finding relates to the corresponding quantitative decrease in platelet adhesion. This pathophysiologic mechanism explains why patients with VWD have bleeding different from that of patients with hemophilia.

CLINICAL FINDINGS

Unlike that of hemophilia, the bleeding of VWD is immediate and most prominent from mucosal surfaces. Bleeding generally is mild, except in type 3 disease. Nosebleeds are common, as are easy bruising, gastrointestinal bleeding, and excessive menstrual bleeding. Postpartum bleeding may occur, as may bleeding after trauma or surgery. Bleeding into joints or deep tissue as in hemophilia generally does occur in VWD, except among patients with type 3 VWD, who also have markedly reduced levels of factor VIII.

LABORATORY FINDINGS

The laboratory diagnosis of VWD is considerably more complex and less reliable than the simple factor assays that are the hallmark of hemophilia diagnosis. As a result of the limitations of laboratory testing, along with the incomplete penetrance and variable expression of VWD, many instances of mild VWD are incorrectly diagnosed or not diagnosed at all. Because of the frequency of VWD, many patients with mild or questionable bleeding histories are incorrectly given this diagnosis. Nonetheless, VWD is the most likely diagnosis for any patient with a mild congenital bleeding disorder, particularly when the disorder is associated with a family history that indicates autosomal dominant inheritance.

Prothrombin time and aPTT are generally normal, except among patients with type 3 VWD, among whom a marked reduction in factor VIII can lead to prolongation of aPTT. The bleeding time is expected to be prolonged in VWD but is a notoriously unreliable screening test with frequent false-positive and false-negative findings. For this reason, many experts discourage the use of bleeding time as a routine screening test. The standard evaluation for VWF consists of a battery of three laboratory tests: VWF activity (also called *ristocetin cofactor activity*, because it is based on the platelet aggregation induced by the antibody ristocetin in the presence of VWF), factor VIII coagulation activity, and VWF antigen level (previously called factor VIII-related antigen). As for all other clotting factors, these activities are expressed as a percentage of a pooled normal control (normal defined as 100%) or units (one unit is defined as the activity in 1 mL of control plasma).

Among patients with typical type 1 VWD, all three assays (factor VIII activity, VWF activity, and VWF antigen) generally are similarly decreased to the range of 20% to 50% of normal. Unfortunately, there is extensive overlap in observed values between patients and healthy persons, because the normal range for all of these factors is approximately 50% to 150%. For this reason, repeated testing often is necessary, and the diagnosis should generally not be made or excluded on the basis of a single measurement.

Specialized testing is needed to identify the type 2 variants of VWD. Analysis of VWF multimers generally is performed only in a reference laboratory. A normal distribution of multimer size is expected with type 1 VWD whereas selective loss of large multimers occurs in type 2A and type 2B. Diagnosis of type 2N VWD requires measurement of factor VIII VWF binding and again is performed only in a few reference laboratories. Diagnosis of type 2B VWD requires a specialized ristocetin-induced platelet aggregation study (RIPA) and must be differentiated from a closely related disorder, pseudo-VWD. The latter disorder is caused by mutations in the platelet receptor for VWF (GPIb).

Although DNA analysis of mutations within the VWF gene has the potential to be of great diagnostic value, this study is currently only available in research laboratories. The mutations responsible for most common type 2 VWD variants are known, although only a few type 1 mutations have been identified. Though not currently available outside research laboratories, prenatal diagnosis can be performed by means of mutation detection or linkage analysis, but is generally only indicated for type 3 VWD.

STRATEGIES FOR OPTIMAL CARE

Desmopressin can produce a two- to threefold increase in plasma levels of VWF and factor VIII that can last for 4 to 12 hours. Because the toxicity of this drug is modest, desmopressin has become a mainstay for the management of mild VWD. Desmopressin can be administered by means of intravenous bolus injection and is now available in a nasal spray. The increase in VWF occurs promptly, and adequate levels often can be maintained with repeated dosing once or twice per day, although tachyphylaxis can occur. Accurate diagnosis is essential, because desmopressin may be relatively contraindicated in the management of type 2B VWD. In type 2B disease, increased release of abnormally reactive VWF may exacerbate thrombocytopenia and clinical bleeding. However, this view is controversial, and some patients with type 2B VWD have been successfully treated with desmopressin. Desmopressin is generally not effective therapy for type 2A or type 3 VWD.

Patients with severe VWD (type 3) often need treatment with factor replacement. Unfortunately, a recombinant VWF product is not available. Treatment is limited to selected factor VIII concentrates prepared from pooled plasma that contain large amounts of VWF, such as humate P. Patients also can be treated with fresh frozen plasma or cryoprecipitate, although efforts should be made to minimize exposure to these plasma products, which may still carry high risk for viral infection. The fibrinolytic inhibitor *e*-aminocaproic acid may be useful in reducing mucosal bleeding among VWD patients, particularly after dental extractions. Estrogens and oral contraceptives increase VWF levels and can be useful for treatment of women, particularly for menorrhagia. This effect also decreases the risk for profuse bleeding during pregnancy, though postpartum bleeding is common.

INHERITED DEFECTS OF OTHER COAGULATION FACTORS

Other coagulation factor deficiencies are considerably less common than hemophilia or VWD. However, they have a wide range of clinical manifestations, from asymptomatic laboratory abnormality to severe, life-threatening hemorrhage. For most of these disorders, a purified or dedicated factor concentrate is not available and treatment is thus limited to replacement with fresh frozen plasma or other general measures.

DISORDERS OF FIBRINOGEN

A variety of disorders of fibrinogen caused by mutations within the a, b, or g chain genes have been reported. Because balanced synthesis of all three chains is needed for functional fibrinogen, an abnormality in any one chain can cause reduced or absent fibrinogen synthesis or synthesis of dysfunctional fibrinogen. These disorders are called *hypofibrinogenemia*, *afibrinogenemia*, and *dysfibrinogenemia*, respectively. The inheritance of afibrinogenemia is autosomal recessive, and, although rare, life-threatening hemorrhage similar to that associated with hemophilia can occur. Despite the absence of any detectable fibrinogen, bleeding severity is surprisingly variable. Some patients have only mild to moderate symptoms. Bleeding in hypofibrinogenemia is uncommon, unless the fibrinogen level is less than 50 mg per deciliter. Treatment is with cryoprecipitate, which contains large amounts of fibrinogen.

Dysfibrinogenemia is caused by single-amino-acid substitutions within one of the three fibrinogen chains; the substitutions lead to abnormal fibrinogen function. These disorders can be associated with pathologic bleeding or thrombosis, more often the latter. Inheritance usually is autosomal dominant, and the diagnosis should be suspected when assays of fibrinogen function give markedly lower levels than those obtained with chemical or immunologic methods.

FACTOR XI DEFICIENCY

Factor XI deficiency is autosomal recessive in inheritance and is particularly common for Ashkenazi Jews, among whom the prevalence has been estimated to be as high as 1:190. One-half of all patients are in this population, two mutations accounting for most instances. Unlike the situation for hemophilia, plasma factor XI level is a poor predictor of bleeding severity; marked bleeding occasionally occurs among heterozygotes. Most patients are only mildly or moderately affected; bleeding is most common after surgical procedures and dental extractions. This diagnosis often is detected with a prolonged screening aPTT and confirmed with a factor XI clotting activity assay.

DEFICIENCY OF FACTOR XII, PREKALLIKREIN, AND HIGH-MOLECULAR-WEIGHT KININOGEN

All three of these disorders are associated with marked prolongation of aPTT but no clinically significant bleeding. They are primarily identified through routine screening with aPTT before a surgical procedure. Factor XII deficiency may be associated with increased risk for thrombosis, although this has not been confirmed. Factor XII is the most common of these three disorders; the others represent rare case reports. No specific therapy is necessary.

DEFICIENCY OF OTHER COAGULATION CASCADE FACTORS

Deficiency of factor X, factor VII, factor V, and factor II (prothrombin) are all very rare, but they cause bleeding similar to that of hemophilia. The genes for all these factors are located on autosomes, and inheritance is autosomal recessive. Factors II, VII, and X (along with factor IX) are all vitamin K–dependent proteins the levels of which are reduced by vitamin K deficiency or treatment with warfarin. Rare cases of patients with combined deficiency of all of the vitamin K–dependent factors have been reported and are caused by defects in vitamin K metabolism or in the g-carboxylase enzyme itself. Accurate diagnosis of all these conditions depends on specific activity assays for each of the coagulation factors.

Autosomal dominant inheritance of factor V deficiency restricted to the platelet (factor V Quebec) is known to be caused by a generalized enhancement of proteolysis within the platelet rather than a specific mutation within factor V. Combined deficiency of both factors V and VIII has been identified in a number of families, particularly of Middle East origin. The levels of both factors are reduced to the 5% to 25% range. This autosomal recessive disorder is now known to be caused by, in most instances, mutations in the *ERGIC-53* gene, a component of the endoplasmic reticulum to Golgi transport pathway.

FACTOR XIII DEFICIENCY

Factor XIII deficiency is autosomal recessive in inheritance and is caused by mutations in either the A or B subunits, each encoded by a different gene. Factor XIII cross links fibrin and stabilizes the blood clot. Because initial clot formation is normal, bleeding generally does not occur until late, when the less stable clot is prematurely lysed. This delayed pattern of bleeding is characteristic. Serious bleeding can occur, and the diagnosis often is made on the basis of prolonged umbilical cord bleeding. Results of routine coagulation tests are normal, although a specific clot solubility test can be used to identify this defect. Treatment is with fresh frozen plasma or cryoprecipitate.

DEFECTS IN THE FIBRINOLYTIC SYSTEM

The fibrinolytic system acts through an independent series of steps to activate the proteolytic enzyme plasmin, which degrades the fibrin blood clot to counterbalance the coagulation cascade. Abnormalities of two regulatory inhibitors in this pathway have been associated with inherited bleeding, although both conditions are rare. α_2 -Antiplasmin is the specific inhibitor of plasmin itself. Autosomal recessive deficiency has been reported in several families, and it causes a mild to moderate bleeding disorder. Genetic deficiency of plasminogen activator inhibitor 1 (PAI-1), the primary inhibitors of the plasminogen activators tissue plasminogen activator (tPA) and urokinase (uPA), has also been reported. PAI-1 deficiency has been identified primarily among the Amish population, where it may be a fairly common mutation. Homozygous patients with the deficiency have mild to moderate bleeding, particularly after trauma. Both PAI-1 and α_2 -antiplasmin deficiency often can be effectively managed with inhibitors of the fibrinolytic system such as e-aminocaproic acid.

CHAPTER 238: ACQUIRED DISORDERS OF BLOOD COAGULATION

ALVIN H. SCHMAIER

[Disorders Associated with a Prolonged Activated Partial Thromboplastin Time and Prothrombin Time](#)
[Disorders Associated with a Prolonged Activated Thromboplastin Time or Prothrombin Time](#)
[Disorders Associated with an Abnormal Bleeding Time Only](#)
[Disorders Associated with Abnormal Bleeding but Normal Screening Tests](#)

The most common forms of bleeding that physicians encounter are acquired disorders of blood coagulation. These entities occur frequently and often are encountered in the hospital practice of the internist. They commonly arise not as primary disorders themselves but as secondary manifestations of a primary disease or as result of therapy for an underlying disorder. Thus they often are iatrogenic, and the physician must be vigilant to prevent them. The diagnostic approach to acquired disorders of blood coagulation follows from the same method that one would use for all bleeding states. Careful analysis of results of screening tests for bleeding disorders (prothrombin time, activated partial thromboplastin time, platelet count, bleeding time, and fibrinogen level) and an understanding of the patient's underlying illness often point to the nature of the acquired disorder of blood coagulation. The bleeding associated with these entities can be profuse or mild, or there may be no bleeding at all. Recognition of the cause of an acquired bleeding disorder should lead to prompt therapy.

A physical examination for bleeding disorders is useful but seldom provides enough information for a diagnosis. In general, defects in plasma proteins become manifest as intramuscular hematomas, retroperitoneal hematomas, and intraarticular hemorrhage. Defects in number and quality of platelets can cause petechiae on the conjunctiva, soft and hard palate, and anterior portions of the arms and legs. Hemorrhagic bullae of the soft palate are characteristic of severe thrombocytopenia. Easy bruising on the skin of the upper arms and chest without recognition of recent trauma and ecchymosis around venipuncture sites also characterize disorders of platelet and von Willebrand's factor. Often only evaluation of routine coagulation screening tests alerts the physician to an acquired bleeding disorder. Activated partial thromboplastin time (aPTT) and prothrombin time (PT) together or alone help detect all known bleeding disorders caused by plasma proteins except for factor XIII deficiency and defects or deficiencies in a₂-antiplasmin, plasminogen activator inhibitor 1, and a₁-antitrypsin Pittsburgh. Platelet count and bleeding time are used to detect quantitative or qualitative defects in platelets and von Willebrand's factor. Thus with the results of a few inexpensive laboratory studies, the physician gains great diagnostic insight.

DISORDERS ASSOCIATED WITH A PROLONGED ACTIVATED PARTIAL THROMBOPLASTIN TIME AND PROTHROMBIN TIME

The most common acquired disorders of blood coagulation become manifest with a prolonged PT and aPTT ([Table 238.1](#)). These entities include anticoagulation, disseminated intravascular coagulation (DIC), liver disease, vitamin K deficiency, massive transfusion, and a number of rare disorders caused by acquired inhibition or deficiency of various coagulation proteins.

Prolonged PT and aPTT
Use of anticoagulants
Disseminated intravascular coagulation
Liver disease
Vitamin K deficiency
Massive transfusion
Rare acquired inhibition of coagulation proteins
Paraproteinemia
Cryofibrinogenemia
Systemic amyloidosis
Inhibitors of factors V, VIII, X
Antiphospholipid syndrome
Prolonged aPTE, Normal or Prolonged PE, Normal PT
Acquired inhibition of factor VIIIc
Acquired inhibition of factor IXc or factor XIc
Acquired inhibition of factor VIIc
Abnormal Bleeding Time but Normal PT and aPTT
Acquired von Willebrand's disease
Uremia
Use of medications
Abnormal Bleeding but Normal Bleeding Time, PT, and aPTT
Inhibitors to factor XIII
— Antiplasmin deficiency

PT, prothrombin time; aPTT, activated partial thromboplastin time.

TABLE 238.1. APPROACH TO ACQUIRED BLEEDING DISORDERS

ANTICOAGULATION

By far the most common defects in the coagulation system among patients in hospitals is related to therapeutic anticoagulation. Anticoagulants are widely pervasive in the treatment of patients with thrombotic disorders and those undergoing interventional procedures. Use of these agents is growing in the practice of medicine, and the number of agents also is increasing. Standard heparin functions as an anticoagulant by potentiating the naturally occurring plasma protease inhibitor antithrombin to inhibit coagulation factors IIa (thrombin), Xa, IXa, VIIa, XIa, XIIa, and kallikrein. The protection against thrombosis provided by heparin is mostly caused by the ability of the drug to inhibit factors IIa and Xa. Heparin mostly prolongs aPTT but in high enough concentrations also prolongs PT.

Low-molecular-weight forms of heparin mostly inhibit factor Xa. They cannot be monitored with PT or aPTT, but if the plasma level is sufficiently high, they prolong both times. Hirudin (an active site thrombin inhibitor) and danaparoid sodium (a heparinoid factor Xa inhibitor) also prolong both the aPTT and PT.

The oral anticoagulant warfarin inhibits two enzymes in vitamin K metabolism. The inhibition decreases the amount and uncarboxylated forms of coagulation factors II, VII, IX, X, protein C, and protein S. Decarboxylated vitamin K–dependent proteins are unable to bind to cell membranes to be activated. Warfarin anticoagulation mostly prolongs the PT, but because it inhibits factor IX synthesis and activity, it also prolongs aPTT at therapeutic concentrations when stable levels are achieved.

Bleeding during anticoagulant therapy occurs when there is a site for bleeding. Bleeding occurs most commonly among elderly patients and may be associated with cerebral amyloid angiopathy. It also can occur within 2 weeks after a surgical procedure. The addition of drugs that interfere with hemostasis increases risk for bleeding. Acquisition of blood through anticoagulated indwelling lines and catheters is a common cause of abnormal results of coagulation screening tests among hospitalized patients.

Treatment of patients with bleeding caused by use of anticoagulants can be a serious problem. Standard heparin has a short half-life of 1 hour; therefore stopping the drug usually corrects the problem within 4 hours. If need be, heparin can be neutralized with protamine sulfate, but excess protamine sulfate can function as an anticoagulant itself. Warfarin anticoagulation is more difficult. It takes 5 days to bring about anticoagulation with warfarin because of the long half-lives of factors X and prothrombin. It also takes 5 days to correct the effect of warfarin in a nutritionally replete person with normal liver function. For asymptomatic prolongation of PT or an increase in international normalized ratio, merely withholding the drug is sufficient. Vitamin K infusion (5 to 10 mg) shortens or corrects an abnormal PT within 4 to 12 hours if liver function is normal.

Serious bleeding can be corrected with fresh frozen plasma infusion. Life-threatening bleeding or intracranial bleeding can be corrected with infusion of vitamin K–dependent concentrates with a goal of 50% normal levels of factors. Low-molecular-weight forms of heparin have much longer half-lives, 3 to 18 hours depending on the preparation. Excessive anticoagulation with these agents theoretically can be corrected with protamine sulfate. Low-molecular-weight forms of heparin are eliminated through renal excretion and therefore the doses should be reduced in the treatment of patients with kidney disease. Danaparoid sodium, a heparinoid, has an 18-hour half-life. It is not corrected with protamine sulfate. Patients with serious bleeding associated with this agent need supportive care until the drug is metabolized. Hirudin has a short half-life (2 hours) and is eliminated renally. Doses of this drug have to be markedly reduced in the care of patients with renal dysfunction. Patients with abnormal bleeding can only be given supportive care. It is important to remember that some of these patients may be taking platelet inhibitors (aspirin, thienopyridines) which also contribute to abnormal bleeding. Platelet transfusion sometimes can be helpful to control abnormal bleeding in the care of these patients.

DISSEMINATED INTRAVASCULAR COAGULATION

DIC is a clinicopathologic syndrome that is not a specific disease but is a manifestation of an underlying disorder. Recognition that a patient has DIC obligates the physician to search for an underlying medical disorder. In simplest terms, DIC can be described as a loss of balance between procoagulant (clot forming) and fibrinolytic (clot lysing) capacities. In biochemical terms, DIC is the loss of balance between the main clotting enzyme, thrombin, and the main enzyme of fibrinolysis, plasmin. The clinical and laboratory manifestations of DIC reflect the multiple actions of thrombin and plasmin. The degree to which thrombin or plasmin is formed depends on the inciting etiologic factor, the acuteness of the initiating event, and the clearance of activated products of coagulation and fibrinolysis.

The clinical manifestations of DIC follow from the inciting etiologic factor and the degree to which thrombin or plasmin is formed. DIC can become manifest as an acute hemorrhagic event as result of excessive fibrinolysis from plasmin formation. It also can manifest itself as a subacute or chronic illness that becomes manifest as venous thrombosis caused by a procoagulant state due to excessive thrombin formation. In the acute, hemorrhagic variety of DIC, patients have mucosal bleeding, skin ecchymosis especially around venipuncture sites, and petechiae. What is seen on the skin mirrors what is found diffusely in the body—multiple punctate hemorrhage in all tissues, including the brain. In the subacute or chronic form of DIC, evidence of venous or arterial thrombosis may be the only manifestation of the disorder.

DIC results from tissue injury of any cause. The many and varied causes of DIC can be classified according to the appearance of an acute, hemorrhagic disorder or a subacute, thrombotic disorder (Table 238.2). In acute, hemorrhagic DIC, the clinical and laboratory features develop rapidly over a period of time ranging from a few hours to days. The inciting etiologic factors usually are infection, obstetric complications, malignant disease, or gross tissue injury. Unlike acutely ill patients with complicating DIC, other patients may have a mild or protracted clinical course of consumption of coagulation factors or even subclinical disease with signs and symptoms that can be referred to thrombosis. These illnesses often are associated with malignant disease or vasculitis. They manifest themselves with fibrin deposition in the intravascular compartment that causes venous thrombosis, marantic endocarditis, and arterial embolism.

Acute DIC
Infection: gram-positive and gram-negative septicemia, typhoid fever, Rocky Mountain spotted fever, viremia, infestation with parasites
Obstetric complications: abruptio placentae, amniotic fluid embolism, hypertonic saline abortion, eclampsia
Malignant disease: acute promyelocytic leukemia
Tissue injury: snake bite, necrotizing enterocolitis, freshwater drowning, heat stroke, brain and crush injury, renal homograft rejection, dissecting aortic aneurysm, hemolytic transfusion reaction
Other causes: homozygous protein C and S deficiency, factor V Leiden, severe liver disease, heparin-induced thrombocytopenia and thrombosis syndrome

Subacute or Chronic DIC
Malignant disease: mucin-producing adenocarcinoma
Obstetric complications: retained dead fetus
Vascular disorders: connective tissue disorders, giant cavernous hemangioma, chronic renal disease, venous thrombosis, pulmonary embolus, marantic endocarditis, arterial embolization

TABLE 238.2. DIFFERENTIAL DIAGNOSIS AND CLINICAL CLASSIFICATION OF DISSEMINATED INTRAVASCULAR COAGULATION

The laboratory diagnosis of DIC follows from the screening assays used in hemostasis (Table 238.3). If results of two of these tests are abnormal, the diagnosis of DIC is possible. If results of three of these tests are abnormal, the diagnosis of DIC is probable; if results of all screening tests are abnormal (PT, aPTT, platelet count, fibrinogen), the diagnosis is likely. In rare instances, such as after a timber rattlesnake bite or therapeutic thrombolysis, results all of these tests can be abnormal without DIC. The diagnosis of DIC is confirmed with a test that specifically shows plasmin and thrombin formation. Measurement of D-dimer is the confirmatory test for DIC. D-dimer is plasmin-liberated, insoluble cross-linked fibrin produced by prior thrombin cleavage of fibrinogen that has formed a neoantigen between the two D domains of fibrin. A positive D-dimer result a priori indicates DIC because it demonstrates the simultaneous formation of thrombin and plasmin. Measurement of fibrin degradation (split) products (FDPs) shows only plasmin-cleaved insoluble cross-linked fibrin, soluble fibrin, or fibrinogen. It does not indicate prior thrombin formation. In most instances a positive FDP result indicates DIC, but the FDP result can be positive from thrombolytic therapy, liver disease, and resolving hematoma without DIC. Measurement of soluble fibrin monomer is another confirmatory test. A positive result indicates that thrombin has been formed and fibrinogen has been cleaved. In acute DIC, fibrin monomer may be very transient and completely proteolyzed and thus not detected.

Screening Assays

Prothrombin time
Activated partial thromboplastin time
Platelet count
Fibrinogen

Confirmatory Tests

D-dimer
Fibrin degradation products
Fibrin monomer

TABLE 238.3. DIAGNOSIS OF DISSEMINATED INTRAVASCULAR COAGULATION

The first principle in therapy for DIC is to manage the underlying cause. Infections are managed with the appropriate antibiotics; obstetric complications are managed with the appropriate surgical treatment, and recognized cancer is managed with chemotherapy. Once treatment has been directed at the primary illness, therapy can be directed at the DIC itself. Before embarking on additional treatment, the physician always must carefully weigh the expected outcome with the possible benefits of therapy. The first principle is to replace the missing factor or factors. If a patient is depleted in fibrinogen, administration of cryoprecipitate is appropriate. If the patient has thrombocytopenia, platelet replacement is indicated; fresh-frozen plasma also may be helpful. Infusion of fresh frozen plasma may allay the illness because there are excess plasma protease inhibitors in plasma to “cool” the active proteases of DIC. If a patient with self-limited DIC has acral cyanosis and digital ischemia, standard heparin therapy may be instituted once the patient has received replacement therapy. In these cases, full-dose anticoagulation is not the goal. Standard heparin usually is given at one-fourth the usual dose (4 to 5 units per kilogram per hour as a constant infusion) without a large intravenous loading dose. This lowered amount of heparin is sufficient to inhibit factor X activation and thus block further thrombin formation.

LIVER DISEASE

Liver disease can manifest a variety of coagulation protein disorders. All coagulation proteins (II, VII, IX, X, fibrinogen, prekallikrein, high-molecular-weight kininogen, XI, XII, XIII), anticoagulants (protein C, protein S), fibrinolytic protein (plasminogen), and plasma protease inhibitors (antithrombin, C₁ inhibitor, a₂antiplasmin) are synthesized in the liver. Prekallikrein is the first protein in the liver whose synthesis is decreased in liver disease. Fibrinogen usually is the last protein the synthesis of which is lost in liver disease. Dysfibrinogenemia frequently is associated with liver disease. Patients with liver disease have reduced clearance of activated coagulation proteins. Patients with liver disease and cirrhosis experience hypersplenism, which manifests itself with thrombocytopenia. Some patients with liver disease have increased bleeding because of reductions in the amounts of hemostatic proteins and platelets and from anatomic lesions (gastritis, esophageal varices, peptic ulcer, hemorrhoids) related in part to portal hypertension and abuse of alcohol.

The earliest stages of liver disease are associated with a prolonged PT and later a prolonged aPTT. With disease progression and the appearance of dysfibrinogenemia, thrombin time lengthens and fibrinogen level decreases. FDP levels may rise because of reduced clearance, and platelet count may fall. Hemostatic abnormalities may be treated with vitamin K and fresh frozen plasma. If surgery is planned and a patient has thrombocytopenia, massive platelet

transfusion may be necessary, although platelet transfusion usually is not helpful because the enlarged spleen serves as a reservoir for the transfused platelets. Cryoprecipitate therapy is useful to manage severe fibrinogen deficient states. Successful liver transplantation ameliorates these problems.

VITAMIN K DEFICIENCY

Vitamin K has a critical role in amino terminal carboxylation reactions (the addition of carboxy groups on the γ -carbon of glutamic acid residues, γ -carboxyglutamic acid) of the so-called vitamin K-dependent proteins. This reaction is essential for these proteins to interact with lipid surfaces and cell membranes to participate normally in hemostatic reactions. Vitamin K, a lipid-soluble vitamin, is provided by dietary intake of leafy green vegetables and by synthesis of intestinal flora. The body has a 1-month store of this vitamin. Deficiency of vitamin K can be caused by anatomic lesions that cause the small intestine to be bypassed, malabsorption, biliary tract obstruction, and rarely by a reduction in dietary intake. The last cause usually occurs among nutritionally depleted persons with alcoholism or patients in hospitals who have received intravenous nutrition for more than 1 month without vitamin K replacement. Antibiotics also interfere with the growth of intestinal bacteria and impair vitamin K synthesis and oral absorption. The oral anticoagulant warfarin also interferes with the metabolism and function of vitamin K. Bleeding associated with vitamin K deficiency, which includes warfarin treatment, indicates that there is a bleeding site. It is incumbent on the physician to search for that site rather than to fully ascribe the bleeding to the vitamin K deficiency.

MASSIVE TRANSFUSION

Massive blood transfusion associated with trauma or surgery can lead to an acquired bleeding state. Infusion of a volume of fluid greater than 1.5 times the patient's blood volume in 24 hours can cause coagulopathy as the result of plasma dilution and increased concentration of the anticoagulant sodium citrate dextrose circulating in the patient's blood. Increased numbers of packed red cells and crystalloid infusion can dilute circulating platelets, and the dilution contributes to the problem. Plasmapheresis and extracorporeal circulation for cardiac surgery and respiratory failure without adequate fresh frozen plasma replacement also can decrease the level of plasma coagulation factors. In general it is useful to give one unit of fresh frozen plasma and one ampule of calcium gluconate for every 4 to 5 units of packed red cells given to patients in a short period of time.

RARE ACQUIRED INHIBITORS OF COAGULATION PROTEINS

Patients with hypergammaglobulinemic states (multiple myeloma, Waldenström's macroglobulinemia) acquire bleeding disorders. Immunoglobulin binds to fibrinogen and other coagulation proteins to interfere with their function. The presence of functionally abnormal fibrinogen (dysfibrinogenemia) is common in these patients, as is other nonspecific evidence of coagulation protein inhibitors. Primary therapy is management of the underlying disease. Plasmapheresis is useful for rapid correction of the hypergammaglobulin defect and for cessation of abnormal bleeding.

The presence of antibodies to fibrinogen that interfere with its function is not infrequent. Antibodies that interfere with fibrinopeptide A release can be associated with bleeding. These patients have prolonged thrombin and reptilase times. Antibodies to fibrinopeptide B release can cause strikingly long PT and aPTT but no bleeding history. Patients have abnormal thrombin times but normal reptilase times.

Systemic primary amyloidosis or amyloidosis associated with multiple myeloma has been associated with isolated deficiencies of factor X. Combined deficiencies of factors IX and X occasionally have been seen among patients with amyloidosis. The cause of this phenomenon is not completely known. Some patients have responded to splenectomy; others have responded to melphalan and prednisone therapy. The presence of antibodies to factor X has been reported. Bleeding is controlled with prothrombin complex concentrates.

Heparin-like or heparinoid-like anticoagulants have developed spontaneously in patients as a manifestation of underlying hematologic malignant disease (plasma cell dyscrasia, lymphoma, leukemia). Management of the underlying disease may ameliorate the condition. Isolated coagulation factor inhibitors of factor V are rare but serious and often lethal disorders. These inhibitors usually are present in older patients. Some cases may be iatrogenic as a result of the use in surgery of topical bovine thrombin contaminated with bovine factor V. Factor V deficiency also has been reported to occur with chronic myelogenous leukemia. Isolated hypoprothrombinemia can occur among patients with antiphospholipid antibody syndrome.

Antiphospholipid syndrome frequently becomes manifest as a prolonged aPTT and PT, especially if the reagent for the latter study has a lower international sensitivity index. The most common sign of the presence of antiphospholipid antibodies is an isolated prolonged aPTT. Antiphospholipid antibodies are heterogenous, being directed to acidic and neutral phospholipids, phospholipids in complex with various proteins (prothrombin, kininogen, prekallikrein, factor XI), or β_2 -glycoprotein I. Antiphospholipid antibodies may prevent annexin V, a membrane anticoagulant, from binding to endothelial cells and thus indirectly promoting prothrombinase activity. In general, the presence of antiphospholipid antibodies is not associated with bleeding unless there is associated hypoprothrombinemia and thrombocytopenia. They also are associated with various degrees of severity of thrombosis.

DISORDERS ASSOCIATED WITH A PROLONGED ACTIVATED THROMBOPLASTIN TIME OR PROTHROMBIN TIME

Acquired disorders of coagulation with bleeding associated with a prolonged aPTT but a normal PT usually are spontaneous inhibitors of factor VIII:c. Each of us apparently has the potential to produce inhibitors to factor VIII:c. Spontaneous factor VIII:c inhibitors develop in immunosuppressed persons—patients with B-cell malignant disease, those with systemic lupus erythematosus or another connective tissue disorder, pregnant women, elderly patients, persons who take certain medications (penicillins, sulfa drugs, phenytoin), and patients with hemophilia A. A patient without hemophilia who has acute bleeding and a high titer (more than 5 Bethesda units) can be treated with activated prothrombin complex concentrates or porcine factor VIII:c. Among patients with an inhibitor but no evidence of acute hemorrhage, immunosuppressive therapy with cyclophosphamide (Cytoxan), vincristine, and prednisone is successful in 80% of cases.

Inhibitors to factor IX are present in only about 5% of patients with hemophilia B. They are quite rare among healthy persons. Large gene deletions have been reported to occur among patients with hemophilia B who have spontaneous inhibitors. Isolated deficiency of factor IX has been reported with Gaucher's disease. Specific inhibitors to factor XI have been recognized most commonly among patients with lupus anticoagulants. Three patients with factor XI deficiency were found to have inhibitors to factor XI; two of the inhibitors were against the high-molecular-weight kininogen-binding site on factor XI. Spontaneous inhibitors to factor VII have been found in a patient with lung cancer. The only initial sign was isolated prolongation of PT.

DISORDERS ASSOCIATED WITH AN ABNORMAL BLEEDING TIME ONLY

Acquired bleeding disorders with prolonged bleeding times but normal PT and aPTT usually arise from inhibitors to von Willebrand factor or result from uremia. Acquired von Willebrand disease has been associated with use of medications (procainamide, valproic acid), connective tissue disorders, lymphoproliferative disorders, and a variety of tumors. Antibodies can be directed to von Willebrand factor itself or platelet glycoprotein Ib/IX/V complex. Patients with acute and chronic renal failure can have multiple causes of bleeding. No one mechanism can explain all causes of bleeding. Patients with uremia often have ecchymosis, muscular hematomas, gastrointestinal bleeding, and oozing on the mucosal surfaces. For many of these patients severe anemia contributes to the bleeding tendency.

Medications are common causes of abnormal bleeding. Aspirin is widely used as primary and secondary prevention of acute coronary syndromes and stroke. Some persons are quite sensitive to the antiplatelet effect of aspirin and have spontaneous bleeding. The thienopyridines (ticlopidine, clopidogrel) are antiplatelet agents that inhibit the expression of the adenosine diphosphate (ADP) receptor on platelets. With the wide use of these medications in cardiovascular medicine, increased bleeding will occur when these patients receive additional anticoagulants. Abnormal bleeding among patients taking the irreversible platelet inhibitors aspirin and the thienopyridines is best managed by means of platelet transfusions.

DISORDERS ASSOCIATED WITH ABNORMAL BLEEDING BUT NORMAL SCREENING TESTS

Inhibitors to factor XIII have occurred among patients with factor XIII deficiency who have received multiple transfusions. Many of these patients were receiving isoniazid when the inhibitor developed. α_2 -Antiplasmin is a serine protease inhibitor of plasmin. In acute promyelocytic leukemia primary fibrinolysis develops as a result of membrane expression of annexin II on the membrane of acute leukemic cells. An increase in annexin II on leukemic cell membranes increases plasminogen activation and causes acquired deficiency of α_2 -antiplasmin. The congenital form of α_2 -antiplasmin deficiency is associated with bleeding that does not cause abnormal results of screening tests. Thrombocytopenia often occurs with acute promyelocytic leukemia, and evidence of DIC frequently also is present. The bleeding in acute promyelocytic leukemia is best controlled with transfusion support and heparin. Data suggest that *all-trans*-retinoic acid actually down-regulates tissue factor

and annexin II on leukemic cells to control bleeding independently of replacement therapy and heparin.

CHAPTER 239: DISORDERS OF PLATELET FUNCTION

KEITH R. MCCRAE AND SANFORD J. SHATTIL

[Normal Platelet Function](#)
[Classification of Disorders of Platelet Function](#)
[Therapy for Platelet Function Disorders](#)

Platelets arrest hemorrhage by adhering to the wall of damaged blood vessels and aggregating to form the primary hemostatic plug. Activated platelets, damaged endothelial cells, and other cells within the vessel wall participate in secondary hemostasis by providing a membrane surface on which coagulation proteins can assemble, interact, and produce a fibrin plug. Even in the absence of overt vessel damage, platelets are involved in maintaining the integrity of the vascular endothelial lining. Each of these functions may become inadequate in the presence of thrombocytopenia or a qualitative disorder of platelet function.

The clinical hallmarks of platelet dysfunction are bleeding from the skin and mucous membranes (epistaxis, gingival bleeding, menorrhagia), excessive posttraumatic or postoperative hemorrhage, and a prolonged bleeding time. All of these events reflect inadequate formation of the primary hemostatic plug. Disturbances of the role of platelets in maintaining vascular integrity may account for the development of petechiae, which are pinpoint hemorrhages in the skin or mucous membranes. These occur most commonly on the distal lower extremities or other dependent areas under increased hydrostatic pressure. Although hemorrhage involving larger and deeper areas of the skin (purpura and ecchymoses) may occur, these lesions are less specific than are petechiae as an indicator of platelet-type bleeding. Spontaneous hemorrhage into muscles or joints is not a feature of platelet dysfunction and suggests a defect in the formation or stability of the fibrin plug.

A bleeding time test is used clinically as a measurement of platelet plug formation. With a blood pressure cuff on the arm set at 40 mm Hg, a 1-mm deep incision is made on the volar surface of the forearm with a disposable, spring-triggered device, and the duration of bleeding is assessed. Bleeding time, which normally ranges from 2 to 9 minutes, usually is prolonged when there is a disorder of platelet function. However, the results of this test have not been shown to be a predictor of surgical bleeding and do not replace the need for meticulous history taking in screening for hemostatic defects.

The bleeding history is the most important screening test for platelet function defects. In the history interview one should attempt to obtain qualitative and quantitative information about earlier bleeding episodes. For example, reports of easy bruising are common and subjective and may or may not indicate an underlying problem. Oral bleeding can continue for as long as 24 hours after molar extraction even among persons with normal bleeding profiles. In contrast, bleeding that necessitates transfusion after minimal trauma or surgery is abnormal. Whereas bleeding of recent onset generally suggests an acquired defect in platelet function, a family history of bleeding suggests an inherited disorder, the diagnosis of which may be facilitated by pedigree analysis. Patients always must be questioned about the use of prescription and nonprescription drugs, because many such medications markedly alter platelet function. If a disorder of platelet function is suspected on the basis of the history and a prolonged bleeding time, additional laboratory studies are warranted to make a specific diagnosis and plan therapy.

NORMAL PLATELET FUNCTION

A discussion of platelet dysfunction is facilitated by an understanding of platelet anatomy and biochemistry. A platelet is enveloped by a plasma membrane that invaginates extensively into the cytoplasm to form a surface-connected open canalicular system. This membrane consists predominantly of a bilayer of phospholipid and cholesterol and contains numerous integral and peripheral membrane glycoproteins. Some of these glycoproteins mediate the interaction of the platelet with its environment and have been assigned Roman numerals on the basis of molecular weight. Several cytoskeletal proteins are closely associated with the cytoplasmic surface of the membrane, and these may be involved in a number of membrane functions, including control of cell shape. Platelets also contain a calcium-sequestering vesicular organelle called the *dense tubular system*, mitochondria, and four distinct types of storage granules. Electron-dense granules (d granules) contain serotonin and metabolically inactive adenosine diphosphate (ADP). a Granules contain several proteins, including fibrinogen, von Willebrand factor (VWF), thrombospondin, platelet-derived growth factors, vascular endothelial cell growth factor, and platelet factor 4. The membrane of the a granule also contains a glycoprotein, P-selectin, which is expressed on the cell surface after platelet secretion and may be involved in the interaction of activated platelets with other cells in a vascular wound. Finally, I-granules contain lysosomal enzymes, and microperoxisomes contain catalase.

Platelet adhesion refers to the contact and spreading of platelets on the wall of a damaged blood vessel. Adhesion is promoted by red blood cells, in part through rheologic effects, and is mediated by interactions of platelets with substances in the subendothelial matrix. Platelets contain binding sites for a number of matrix proteins, including collagen, fibronectin, vitronectin, VWF, and laminin. In the capillary microcirculation, where blood shear rates are high, interactions between VWF and the platelet glycoprotein Ib/IX/V complex promotes initial platelet adhesion. VWF is a 225-kD protein synthesized by endothelial cells and megakaryocytes, where it undergoes a series of posttranslational modifications, including formation of large multimers with molecular weights ranging from 0.8 to 20×10^6 kD. VWF multimers are released constitutively from endothelial cells into the vessel lumen and are deposited abluminally into the subendothelial matrix. The multimers also are stored within endothelial cells and may be released in response to certain stimuli. Although the VWF molecule contains distinct binding domains for platelets and collagen, it normally circulates in plasma in a conformational state that does not interact with circulating platelets. However, subendothelial VWF remains in an active conformation, perhaps through conformational changes induced after its binding to collagen. After vessel damage, exposed VWF within the subendothelial matrix binds to platelets; the larger VWF multimers are more effective in this regard.

Interactions between VWF and platelets occur largely through platelet GpIb, a 170-kD integral membrane protein composed of a 143-kD a subunit disulfide-linked to a 23-kD b subunit, the subunits arising from separate genes. GpIb normally forms a complex with a smaller, 17-kD membrane protein, GpIX, and an additional surface glycoprotein, GpV. Approximately 25,000 molecules of GpIba, GpIbb, and GpIX are expressed on the surface of each platelet with one-half as many molecules of GpV, for a putative overall stoichiometry for the GpIba-Ibb-IX-V complex of 2:2:2:1. In vitro, compounds such as ristocetin and botrocetin stimulate the binding of VWF to the complex, causing platelet agglutination; this property is used diagnostically to assess the function of VWF and platelet GpIb.

Binding of platelets to VWF leads to rolling adhesion to the vessel wall, and induces signaling events that lead to inside-out activation of integrin α IIb β 3, also called platelet GpIIb-IIIa, the platelet fibrinogen receptor (see later). α IIb β 3 may then mediate stronger, stationary adhesion through interactions with VWF and perhaps other matrix proteins containing Arg-Gly-Asp sequences. Adhesion of platelets to exposed collagen also occurs through interactions with platelet collagen receptors, including the integrin α 2 (GpIa, molecular weight 168 kD) β 1 (GpIIa, molecular weight, 130 kD) complex and glycoprotein VI (61 kD).

After adhering to the wall of a damaged vessel, platelets must aggregate to form the primary hemostatic plug. *Platelet aggregation* requires the binding of extracellular fibrinogen to α IIb β 3 (molecular weights 142 and 99 kD, respectively, for the α IIb and β 3 chains). Although approximately 80,000 α IIb β 3 molecules are on the surface of each platelet, the fibrinogen receptor function is not expressed until the platelet is activated by an agonist, an event that occurs through several interrelated pathways. Activation of α IIb β 3 after binding of an agonist to platelets involves specific conformational changes in the integrin complex. Each activated α IIb β 3 complex binds a single fibrinogen molecule in a calcium-dependent manner. Because the fibrinogen molecule is dimeric, fibrinogen may bind to receptors on adjacent activated platelets, resulting in receptor bridging and platelet-to-platelet aggregation. In addition to binding fibrinogen, activated α IIb β 3 can bind VWF, which may play an accessory role in platelet adhesion. VWF also may bind to activated α IIb β 3 and support platelet aggregation when fibrinogen is lacking.

Platelet activation and inside-out signaling are initiated by the binding of agonists such as thrombin, collagen, ADP, and epinephrine to specific receptors on the platelet surface membrane. When platelets are stirred in an aggregometer, weak agonists such as epinephrine and ADP can stimulate activation of α IIb β 3 and promote fibrinogen binding and the formation of small, or first-wave, platelet aggregates that may undergo disaggregation. If the concentration of a weak agonist is sufficiently high, the aggregating platelets produce and release thromboxane A_2 . This endogenously formed agonist in concert with ADP secreted from d granules promotes further α IIb β 3 activation, platelet secretion, and formation of large, irreversible, second-wave aggregates. These aggregates are stabilized by thrombospondin secreted from a granules. Exposure of functional α IIb β 3 also is stimulated by strong agonists such as thrombin, which directly stimulates thromboxane A_2 synthesis and granule secretion without the need for initial aggregation. Although collagen does not directly stimulate aggregation, it induces production of endogenous platelet thromboxane A_2 , induces granule secretion, and therefore induces a delayed aggregation response.

Platelet secretion requires a contractile response involving actin and myosin and the fusion of granule membranes with the plasma membrane. These processes are initiated by the agonist-induced activation of two phospholipid-cleaving enzymes, phospholipase C and phospholipase A_2 . One or more heterotrimeric guanine nucleotide binding proteins (G proteins) are interposed between agonist receptors and the phospholipases. G_q appears particularly important in this regard.

Phospholipase C converts phosphatidylinositol 4,5-bisphosphate to diacylglycerol and inositol 1,4,5-triphosphate, and each of these reaction products stimulates platelet secretion. Diacylglycerol activates protein kinase C, which phosphorylates proteins involved in the secretory response. Inositol-1,4,5-triphosphate stimulates calcium release from the dense tubular system, causing a rise in cytoplasmic free calcium and activation of calcium-dependent enzymes such as phospholipase A₂ and myosin light-chain kinase. Phospholipase A₂ releases arachidonic acid from phospholipids, promoting the synthesis of prostaglandins and thromboxane A₂. These reactions stimulate platelet activation, but the overall activation state of the platelet depends on the balance between stimulatory and inhibitory influences. The latter include prostacyclin from endothelial cells and prostaglandin D₂ (PGD₂) from platelets, which bind to their platelet membrane receptors and stimulate adenylate cyclase. That process increases intracellular concentrations of cyclic adenosine monophosphate (cAMP), which maintains platelets in the resting state. Endothelial cells may regulate platelet activation through the release of an ecto-ADPase.

Platelet procoagulant activity refers to the capability of platelets to support several key coagulation reactions, especially intrinsic pathway–mediated activation of factor X, and the conversion of prothrombin to thrombin. The platelet facilitates these reactions by providing a surface on which coagulation enzymes, substrates, and cofactors interact. Platelet procoagulant activity is markedly increased on activation by thrombin or collagen and is accounted for, at least in part, by exposure of acidic phospholipids on the surface of activated platelets and small membrane vesicles released from these cells.

CLASSIFICATION OF DISORDERS OF PLATELET FUNCTION

Defects in platelet adhesion, aggregation, and procoagulant activity may be inherited or acquired. Inherited defects ([Table 239.1](#)) usually have a predominant effect on only one of these functions, so classification is based on the underlying functional defect. Of the inherited platelet function disorders, von Willebrand disease and platelet activation defects are most prevalent, whereas storage pool disorders are less common, and membrane glycoprotein deficiencies are rare. In contrast, acquired conditions that impair platelet function often affect adhesion, aggregation, and procoagulant activity simultaneously, and in many such cases the precise underlying pathophysiologic mechanism is difficult to discern. It is most useful at present to classify acquired platelet function defects in the context of their associated clinical setting ([Table 239.2](#)). Ingestion of aspirin and other nonsteroidal anti-inflammatory drugs is the most common cause of acquired platelet dysfunction and of platelet dysfunction overall.

Pathophysiologic Mechanism	Specific Disorder
Disorders of Platelet Adhesion	
Defects of adhesive proteins	von Willebrand disease
Defects of adhesion receptors	Bernard–Soulier syndrome Platelet-type von Willebrand disease Glycoprotein IIb/3a or Gp VI deficiency
Disorders of Platelet Aggregation	
Deficiency of the ligand (fibrinogen)	Afibrinogenemia
Defects of the receptor (Gp IIb/3a)	
Defects of Gp IIb/3a quantity or quality	Glanzmann thrombasthenia and variants
Defects of Gp IIb/3a activation	Platelet activation defects; Barter's syndrome
Storage pool defects	Storage pool disease (α and α-storage pool diseases); gray platelet syndrome; Scott syndrome
Disorders of Platelet Procoagulant Activity	

TABLE 239.1. INHERITED DISORDERS OF PLATELET FUNCTION

Drugs That Affect Platelet Function
Nonsteroidal anti-inflammatory drugs
β-Lactam antibiotics
ADP-receptor antagonists
Ticlopidine
Clopidogrel
Glycoprotein IIb/3a receptor antagonists
Abciximab (ReoPro)
Eptifibatid (Integrilin)
Tirofiban (Aggrastat)
Others
Miscellaneous drugs
Systemic Conditions That Affect Platelet Dysfunction
Chronic renal disease
Cardiopulmonary bypass
Antiplatelet antibodies
Disseminated intravascular coagulation
Hematologic Diseases That Affect Platelet Dysfunction
Acute myelogenous leukemia, myelodysplastic syndromes, myeloproliferative disorders
Multiple myeloma and other B-cell neoplasms
Antiplatelet antibodies

TABLE 239.2. ACQUIRED DISORDERS OF PLATELET FUNCTION

INHERITED DISORDERS OF PLATELET FUNCTION

Disorders of Platelet Adhesion

von Willebrand Disease

von Willebrand disease and platelet-type von Willebrand disease are discussed in [Chapter 237](#).

Bernard–Soulier Syndrome

Bernard–Soulier syndrome is a rare disorder transmitted in an autosomal recessive manner. Consanguinity is frequent in affected families. Homozygotes or compound heterozygotes experience menorrhagia and recurrent mucocutaneous, posttraumatic, or postoperative bleeding, which may be variable in severity but can be life threatening. The first bleeding episode occurs in infancy or childhood, sometimes after circumcision. In addition to a prolonged bleeding time, patients with this disorder have giant platelets on a peripheral blood film (many as large or larger than red blood cells). These persons also have mild to moderate thrombocytopenia, which in some cases is caused by shortened platelet survival. Heterozygotes do not have a bleeding tendency or thrombocytopenia, although their platelets may be larger than normal.

The main functional abnormality in Bernard–Soulier syndrome is impaired adhesion of platelets to the subendothelial matrix. This defect is the result of a marked deficiency or absence of the GpIb-IX-V complex, and the deficiency causes impaired interaction of platelets with subendothelial VWF. Bernard–Soulier syndrome should be suspected when there are giant platelets on a blood smear and when ristocetin does not induce platelet agglutination in the presence of normal VWF. The diagnosis is confirmed by means of measurement of GpIb and GpIX electrophoretic and immunologic techniques. Heterozygotes have about one-half the normal levels of GpIb-IX-V.

Several molecular defects that underlie the platelet phenotype in Bernard–Soulier syndrome have been characterized. Most of these are point mutations in GpIba that lead to specific amino acid substitutions, although in one case a point mutation leading to premature chain termination has been described. In some cases, deletions in the GpIb coding sequence have led to frameshift mutations. Similar mutations have affected the genes for GpIba and GpIX, although Bernard–Soulier syndrome caused by mutations in the gene for GpV has not been reported. The expression of unaffected subunits of the GpIb-IX-V complex (for example, GpIba and GpIbb in the case of a GpIX mutation) and GpV also is markedly reduced in platelets from patients with Bernard–Soulier syndrome. Although this observation remains unexplained, efficient expression of GpIba, GpIbb, or GpIX in vitro occurs only in the presence of a gene that encodes at least one other member of the complex. Though GpV is not needed for expression of the other proteins, its expression is enhanced in their presence. These studies suggest that association of the GpIba, GpIbb, and GpIX subunits during or soon after synthesis and insertion into the endoplasmic reticulum facilitates their transport to the cell surface. The abnormal morphologic features of Bernard–Soulier platelets also suggest that the proper assembly of this complex plays a role in platelet and megakaryocyte development. Bernard–Soulier platelets also display delayed aggregation in response to thrombin, perhaps because GpIb-IX-V may mediate platelet activation by low

concentrations of thrombin, and are resistant to damage by quinine- or quinidine-dependent antiplatelet antibodies, which are specific for an epitope consisting of the drug bound to the GpIb-IX-V complex.

Integrin α 1 (Glycoprotein Ia) or Glycoprotein VI Deficiency

Studies have begun to define the role of integrin α 2b1 (GpIa-IIa) and GpVI in adhesion to and activation of platelets by collagen. Binding of collagen to each of these sites may induce platelet activation, although different pathways appear to be involved. For a patient whose platelets contained only 10% of the normal levels of GpVI, platelet adhesion and spreading was reduced only modestly, although platelet aggregation and ATP release after exposure to collagen were absent. These observations suggest that platelet α 2b1 is primarily involved in adhesion and arrest of platelets under flow conditions, whereas GpVI may largely function as a signaling receptor. GpVI is physically associated with the platelet Fc receptor γ chain, a signal-generating subunit of the Fc receptor. Src family kinases are associated with the GpVI-FcR- γ complex and may be involved in platelet activation occurring through this pathway.

Patients with deficient collagen receptor expression have a mild bleeding tendency and prolonged bleeding time consistent with that of a platelet adhesion disorder. Platelets from such persons display diminished adhesion to or spreading on subendothelial collagen but are fully responsive to other agonists. Little information is available concerning the molecular defects that underlie diminished expression or function of these receptors. However, a linked polymorphism in the coding regions of the α ₂ integrin gene at nucleotides 807 (C or T) and 873 (G or A) has been described in which carriers of the C₈₀₇G₈₇₃ allele express higher levels of α 2b1 and may be at greater risk for the development of myocardial infarction at a young age. In vitro platelets from these persons adhere more rapidly to type I collagen at high shear rates.

Disorders of Platelet Aggregation

Decreased platelet aggregation may be caused by (a) quantitative or qualitative abnormalities of platelet allb β 3 (thrombasthenia) or (b) decreased activation of allb β 3 caused by a platelet biochemical defect or storage pool deficiency.

Glanzmann Thrombasthenia

Glanzmann thrombasthenia is an autosomal recessive disorder characterized by a prolonged bleeding time, absent platelet aggregation, and mucocutaneous or posttraumatic bleeding. The bleeding diathesis is severe in many patients, although some patients have no excessive bleeding throughout their lives. For most patients, hemorrhage is sporadic and unpredictable; however, childhood epistaxis and vaginal bleeding at menarche or parturition represent serious risks. Glanzmann thrombasthenia usually is diagnosed before the age of 5 years, and although some authorities believe that its severity tends to decrease in later life, this opinion may simply represent a decreased incidence of minor trauma among adults. The disease is rare in most areas of the world (for example, 1 case per million in Scandinavia), but some populations have a high incidence, such as Jordanian Arabs and Jewish emigres from Iraq.

In the classic form of Glanzmann thrombasthenia there is a marked deficiency or absence of platelet allb β 3. Many patients have an associated decrease in the content of a granule fibrinogen, although plasma fibrinogen is normal. As a result of the deficiency of allb β 3, activated platelets are not capable of binding fibrinogen and cannot aggregate to form the platelet plug. Thrombasthenic platelets, however, can undergo a normal secretory response and can adhere to the vessel wall, although defects in platelet spreading have been described. The diagnosis is established with detection of a near absence of agonist-induced platelet aggregation and of allb β 3 by means of electrophoretic and immunologic techniques. The platelets of persons heterozygous for this disorder contain about one-half the normal amount of allb β 3, and these persons generally do not have a bleeding diathesis. Thrombasthenic platelets are deficient in the Bak (Lek) antigen, normally found on integrin allb, and the PL^A and YUK antigens, normally found on integrin b β .

Integrins allb and b β 3 are the products of separate genes on chromosome 17. Numerous studies have identified several molecular defects leading to the development of Glanzmann thrombasthenia. These lesions may involve the genes that encode either integrin allb or integrin b β 3 and at this point appear to involve each of these genes with approximately equal frequency. Most reported lesions have been either small deletions or substitutions of one base pair, which in some cases have involved splice donor sites, although larger deletions of up to 4.5 kb have been characterized. Most patients with Glanzmann thrombasthenia appear to be compound heterozygotes, although some persons with homozygous defects have been identified. These defects may be particularly common among Iraqi Jews with thrombasthenia, who often display a characteristic 11 base pair deletion in exon 12 of integrin b β 3.

As observed with mutations in proteins composing the GpIb-IX-V complex, platelets from patients with thrombasthenia who have mutations that affect only one member of the allb β 3 complex contain smaller amounts of the other member as well. The reduction in cell surface expression of integrin allb or b β 3 often is markedly greater than the total platelet content of these proteins. These findings suggest that proper complex formation between the two integrin chains must occur in the endoplasmic reticulum for the intact complex to be properly processed and transported to the cell surface. Proper complex formation may depend on each protein's assuming a particular folding pattern, which depends on the ability of the protein to bind specific chaperone proteins.

A mutation instructive with respect to the mechanisms of fibrinogen receptor activation has been a single base pair substitution in the cytoplasmic domain of integrin b β 3. Platelets from this patient exhibited variant thrombasthenia in that they contained immunologically reactive allb and b β 3 chains but did not bind fibrinogen or aggregate after platelet activation. Expression of this mutated receptor in stable cell lines has confirmed the importance of the cytoplasmic domain of integrin b β 3 in mediating inside-out signaling and activating allb β 3 receptor. Additional rare patients with variant thrombasthenia caused by other mutations or deletions in allb β 3 have been described.

Prolonged bleeding time and decreased platelet aggregation also may occur in congenital afibrinogenemia. The aggregation defect is generally mild, in part because VWF can bind to integrin allb β 3 after platelet activation and support aggregation.

Platelet Activation Defects

This group of inherited disorders is characterized by diminished platelet aggregation and secretion in response to one or more agonists. Unlike allb β 3 in Glanzmann thrombasthenia and its variants, allb β 3 in these defects is quantitatively and qualitatively normal. Some clinical platelet activation defects can be subtle. Bleeding time may be normal or only slightly prolonged, and the bleeding history may be mild or intermittent. If these patients ingest aspirin, however, their bleeding times may become inordinately prolonged, and they may also bleed excessively after surgical procedures.

Activation defects often are referred to as aspirin-like and represent a number of poorly defined abnormalities in the metabolic pathways responsible for stimulus-response coupling. In theory, the functional defect can be caused by an abnormality of agonist receptors, transducing elements (G proteins), enzymes, or intracellular second messengers necessary for optimal allb β 3 activation, cell aggregation, and secretion. In some families, specific deficiencies of or mutations in agonist receptors (e.g., thromboxane A₂ receptors) or enzymes (e.g., cyclooxygenase or thromboxane synthetase) have been found. Other patients have been described whose platelets were unable to elevate intracellular ionized calcium levels after exposure to thrombin. These defects were not caused by deficiencies of thromboxane production or insensitivity to inositol 1,4,5-triphosphate but were postulated to be caused by deficiency or dysfunction of phospholipase C. In type I glycogen storage disease, a platelet activation defect is presumed to be related to chronic hypoglycemia and a decrease in the amount of metabolic adenosine triphosphate (ATP) available to support cell activation.

Bartter's syndrome is a rare disorder associated with renal juxtaglomerular hyperplasia, hypokalemia, hypertension, and increased blood levels of renin, angiotensin II, and aldosterone. Patients do not have a great deal of bleeding, but they may have a slightly prolonged bleeding time and decreased platelet aggregation in response to ADP and epinephrine. The platelets are intrinsically normal, but activation appears to be partially inhibited by a plasma factor the identity and mechanism of action remain to be determined.

Storage Pool Diseases

Storage pool diseases are a heterogeneous group of disorders characterized by a decrease in the number or content of platelet storage granules. It is presumed that these disorders are caused by a defect in megakaryocyte granule formation or in the synthesis or uptake of substances by the granules. The associated bleeding diathesis may be minimal to moderate in severity. An isolated deficiency of dense granules (d storage pool disease) and a combined deficiency of a granules and dense granules (ad storage pool disease) are transmitted in an autosomal dominant manner. d Storage pool disease also may be associated with other congenital anomalies, such as Hermansky-Pudlak syndrome (tyrosine-positive oculocutaneous albinism, ceroidlike pigment in macrophages, autosomal recessive inheritance);

Chediak–Higashi syndrome (oculocutaneous albinism, abnormally large granules in many cell types, recurrent pyogenic infections, autosomal recessive inheritance); Wiscott–Aldrich syndrome (eczema, thrombocytopenia, recurrent infections, X-linked recessive inheritance); and TAR syndrome (thrombocytopenia and absent radii, either inherited or acquired in utero).

In d or ad storage pool diseases, hemostasis is impaired because the secretory response is inadequate, leading to formation of a smaller than normal platelet aggregate in the hemostatic plug. In vitro there is an absence of the second wave of platelet aggregation. This is largely caused by a reduction in the amount of ADP released from d granules. The diagnosis is confirmed with detection of a reduction in the amount of platelet d granule substances (ADP) or a granule substances (platelet factor 4, VWF, multimerin, or b-thromboglobulin). Pure a granule deficiency is a rare autosomal recessive trait associated with the presence of large platelets, mild thrombocytopenia, diminished second-wave platelet aggregation, and mild reticulin fibrosis in the marrow. It is called *gray platelet syndrome* because of the characteristic lack of blue granularity of the platelets on Romanovsky-stained blood smears. Although gray platelets are deficient in many a granule substances, they do appear to contain the membranes of a granules. The defect in intracellular membrane structure and function present in gray platelets appears to be specific for megakaryocytes, because the endothelial homologues of platelet a granules, Weibel–Palade bodies, are present in the endothelial cells of these patients in normal amounts and have a normal content of VWF and P-selectin. Isolated microsomes from platelets of patients with the gray platelet syndrome display abnormalities in ionized calcium transport, which may be associated with deficiencies in the phosphorylation of specific proteins that regulate this process.

Disorders of Platelet Procoagulant Activity

Only a few patients with a primary deficiency of platelet procoagulant activity have been described. This disorder has been called *Scott syndrome*. Because such an abnormality primarily affects formation of fibrin rather than of the platelet plug, bleeding time is normal. Persons with this disorder may have spontaneous intramuscular hematomas and episodic but severe bleeding after tooth extractions, surgical procedures, and parturition. Serum prothrombin time is used as a screening test. In this test, when the patient's blood is allowed to clot in a test tube, prothrombin is converted to thrombin inefficiently, leaving residual amounts of the prothrombin in the serum. As a result, a prothrombin time subsequently performed on the patient's serum is shorter than that of control serum. Pedigree analysis of a single family with this disorder suggests that Scott syndrome may be inherited in an autosomal recessive manner.

When studied in vitro, platelets from patients with Scott syndrome do not express a procoagulant surface after activation. This is the result of failure of exposure of acidic phospholipid on the surface of activated platelets and platelet-derived microvesicles. Normal amounts and activity of a phospholipid scramblase protein that accelerates transbilayer migration of phospholipid have been found in platelets, red blood cells, and lymphocytes from patients with Scott syndrome. Thus the pathogenesis of this disorder remains uncertain. Because platelet procoagulant activity is normally increased after platelet activation by thrombin or collagen, many other inherited and acquired disorders of platelet function may be associated with a secondary deficiency of platelet procoagulant activity.

ACQUIRED DISORDERS OF PLATELET FUNCTION

Drugs That Affect Platelet Function

Aspirin and Other Nonsteroidal Anti-inflammatory Drugs

Aspirin acetylates and irreversibly inhibits cyclooxygenase, the enzyme that converts arachidonic acid to prostaglandin endoperoxides. As a result, platelets cannot undergo a secretory response or second wave of aggregation in response to the presence of ADP and epinephrine. The cyclooxygenase in circulating platelets is inhibited almost completely after ingestion of a single 300 to 600 mg dose of aspirin or after ingestion of only 30 mg of aspirin per day for several days. Because platelets circulate for 7 to 10 days, aspirin may affect platelet function for as long as a week after it is discontinued. Although aspirin usually prolongs the bleeding times of healthy persons to about twice baseline value, this change usually is of little clinical consequence. Among persons with other hemostatic defects, however, aspirin may drastically prolong bleeding time and exacerbate the bleeding diathesis. Nonsteroidal anti-inflammatory agents such as indomethacin, ibuprofen, and phenylbutazone inhibit cyclooxygenase reversibly. Unlike those of aspirin, the effects of these drugs subside once the drugs are eliminated from the circulation. Acetaminophen does not affect platelet function in conventional doses.

Ticlopidine and Clopidogrel

Other drugs that inhibit platelet aggregation include the thienopyridines ticlopidine and clopidogrel. The mechanism of action of these drugs, although incompletely understood, appears to involve inhibition of the binding of ADP to the low-affinity type 2 platelet purinergic receptor. As a result, the drugs inhibit ADP-induced platelet aggregation. Aggregation in response to other platelet agonists such as collagen, thromboxane, thrombin, and platelet-activating factor also is inhibited at submaximal agonist concentrations. These drugs prolong bleeding time in a dose- and time-dependent manner, generally to a greater extent than does aspirin. Maximal prolongation of the bleeding time takes 4 to 7 days, although some investigators have suggested that clinical responses may occur more rapidly. Bleeding times take as long as 10 days to normalize after discontinuation of ticlopidine or clopidogrel. This finding suggests that the effects of these agents on platelet aggregation are irreversible. Administration of these agents in combination with aspirin may cause synergistic inhibition of platelet aggregation.

Inhibition of platelet aggregation by ticlopidine is responsible for the ability of this agent to reduce the incidence of (a) recurrent stroke, transient ischemic attacks, or primary cerebrovascular events among patients with peripheral arterial atherosclerotic disease, (b) vascular death or myocardial infarction among patients with unstable angina or peripheral arterial atherosclerosis, (c) coronary and peripheral arterial stent thrombosis, and (d) saphenous vein graft occlusion after coronary artery bypass surgery. Although ticlopidine may be a marginally more effective inhibitor of in vivo platelet function than is aspirin, toxicity has limited its applicability. Ticlopidine is associated with a 1% incidence of severe neutropenia, a 0.02% incidence of thrombotic thrombocytopenic purpura, rare cases of aplastic anemia, and frequent dermatologic and gastrointestinal side effects. The results of the CAPRIE trial (Clopidogrel versus Aspirin in Patients at Risk of Ischaemic Events) suggest that clopidogrel may have similar efficacy as ticlopidine and have led to the recent U.S. Food and Drug Administration approval of this agent for secondary prevention of vascular events among patients with symptomatic atherosclerosis (recent ischemic stroke, myocardial infarction within 35 days, or documented peripheral arterial disease). To date use of clopidogrel has not been associated with an increased incidence of neutropenia, though rare cases of thrombotic thrombocytopenic purpura have been reported.

Integrin α IIb β 3 Inhibitors

A diverse family of drugs is emerging that directly inhibits platelet aggregation by means of interfering with the binding of fibrinogen to α IIb β 3. The prototype of this family is abciximab (ReoPro), a human–murine chimeric Fab fragment derived from a monoclonal antibody that inhibits fibrinogen binding to α IIb β 3 and inhibits platelet aggregation. Abciximab cross-reacts with a related integrin, α _v β ₃, which also is expressed at low levels in platelets and at higher levels in vascular smooth muscle and endothelial cells. In several studies, abciximab has significantly reduced the incidence of death, myocardial infarction, and the need for subsequent revascularization procedures among patients undergoing coronary angioplasty. A significant reduction in mortality was found after follow-up periods that exceeded 3 years among patients who received abciximab in the EPIC trial (Evaluation of 7E3 for the Prevention of Ischemic Complications) ([Fig. 239.1](#)). These observations confirm the role of platelet aggregation in the morbidity and mortality associated with angioplasty. Results of other studies suggest that abciximab may be a promising agent in therapy for acute stroke.

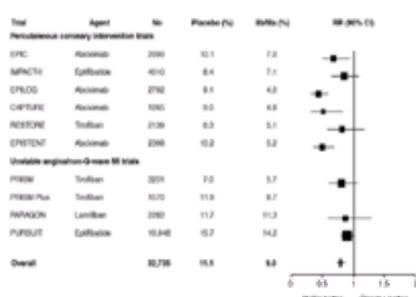

FIGURE 239.1. Death or nonfatal myocardial infarction outcomes at 30 days in 10 randomized, placebo-controlled trials of glycoprotein (Gp) IIb/IIIa blockers. Risk ratio (RR) with 95% confidence interval (CI), size of RR box being proportional to total sample size. Frequency of death or nonfatal myocardial infarction in columns 4

and 5. Overall (all 10 trials) benefit of GpIIb-IIIa blockade is highly significant (RR = 0.79; 95% CI, 0.73 to 0.85; $p < 10^9$). (From Topol EJ, Byzova TV, Plow EF. Platelet GpIIb-IIIa blockers. *Lancet* 1999;353:227–231, with permission.)

Eptifibatide (Integrilin) is a cyclic heptapeptide containing a Lys-Gly-Asp sequence based on that in the snake venom disintegrin barbourin. The sequence of eptifibatide resembles that of a region within the carboxy terminus of the fibrinogen g chain that mediates binding of fibrinogen to allbb3. Eptifibatide rapidly inhibits platelet aggregation and causes mild prolongation of bleeding time after infusion into humans. Tirofiban (Aggrastat) is a small-molecule peptidomimetic, the structure of which was designed to mimic that of the Arg-Gly-Asp sequence within fibrinogen, VWF, and other allbb3 ligands. Tirofiban inhibits the binding of fibrinogen to allbb3 and reversibly inhibits platelet aggregation. Eptifibatide and tirofiban markedly decrease the incidence of death, myocardial infarction, and the need for additional coronary intervention among patients with unstable angina or non-Q-wave myocardial infarction, effects that have persisted in follow-up periods of 6 months (Fig. 239.1). An orally available peptidomimetic allbb3 antagonist, lamifiban, has shown promise in phase III clinical studies (Fig. 239.1), and other oral agents have entered earlier phases of development.

In early studies, parenteral allbb3 inhibitors appeared to be responsible for a high incidence of bleeding complications. Results of subsequent studies showed that these complications were primarily attributable to excessive doses of heparin administered concurrently. The rate of bleeding complications decreased significantly in later trials of weight-adjusted heparin dosing. No increased incidence of intracerebral hemorrhage has been observed with these drugs, and emergency coronary artery bypass grafting has been performed without excessive bleeding complications. Thrombocytopenia develops among 0.5% to 1.0% of treated patients, possibly because of the exposure of ordinarily cryptic epitopes on allbb3 after binding of the drug. The safety of long-term allbb3 inhibition has not yet been fully assessed.

Miscellaneous Drugs

Many drugs can affect platelet function in vitro, although relatively few prolong bleeding time. Large doses of carbenicillin, other penicillins, and the cephalosporin moxalactam prolong bleeding time and affect platelet aggregation in a dose-dependent way. This effect begins within hours of drug administration and may last for several days after the drug is discontinued. Severe bleeding caused solely by this effect is uncommon, however. In vitro, high concentrations of penicillins impair the interaction of agonists with the platelet surface membrane, but the mechanism of the effects in vivo is not clear. Bleeding time also may be prolonged among some persons receiving conventional doses of heparin, presumably because this drug reduces the component of platelet activation normally mediated by thrombin. Dextran and large doses of the plasma expander hydroxyethyl starch may prolong bleeding time among some patients, but bleeding is uncommon unless other hemostatic defects are present. Fibrinolytic agents, such as streptokinase or tissue plasminogen activator, may affect platelets by stimulating the production of plasmin. Under some conditions in vitro, plasmin may impair platelet function by causing an increase in fibrin degradation products and by cleaving platelet GpIb and allbb3, although the contribution of platelet dysfunction to the efficacy or the hemorrhagic side effects of fibrinolytic therapy has not been determined.

Systemic Conditions That Affect Platelet Function

Many patients with uremia have a prolonged bleeding time and defective platelet adhesion, aggregation, and procoagulant activity. Hemorrhagic manifestations appear less common than do in vitro platelet abnormalities and may include epistaxis, bleeding from puncture sites, gastrointestinal and genitourinary bleeding, and subdural hematoma. The pathogenesis of the platelet defect is not clear but is most likely multifactorial and involves the actions of dialyzable and nondialyzable uremic toxins. A defect in platelet adhesion is supported by results of studies demonstrating deficient shear-induced platelet aggregation of uremic platelets. Platelets from patients with uremia exhibit a reduced agonist-dependent release of arachidonic acid from membrane phospholipids, and uremic plasma stimulates the production of prostacyclin, a potent inhibitor of platelet activation, by endothelial cells.

Decreased levels of platelet ADP and ATP have been described in some studies. Rheologic factors related to anemia also contribute to the bleeding diathesis of patients with uremia because the prolonged bleeding time may improve when anemia is corrected. The plasma of patients with uremia contains elevated levels of L-arginine, the precursor of the potent vasodilator and inhibitor of platelet adhesion and aggregation, nitric oxide (NO). Uremic platelets generate more NO and contain higher levels of cyclic guanosine monophosphate (GMP), a second messenger of NO, than do control platelets, and uremic plasma stimulates the production of NO from cultured endothelial cells. The potential role of NO in uremia-induced platelet dysfunction is supported by the observation that the bleeding time of uremic rats normalizes after treatment with *N*-monomethyl-L-arginine, a potent inhibitor of NO synthesis. In addition to platelet dysfunction, factors such as uremic serositis or heparin anticoagulation during dialysis may be a predisposing factor for bleeding among patients with renal disease. The prolonged bleeding time and bleeding diathesis associated with uremia often improve with dialysis.

Cardiopulmonary Bypass

A prolonged bleeding time develops among almost all patients during cardiopulmonary bypass but usually reverses within 4 hours of the procedure. For some patients, the prolonged bleeding time may persist and be associated with substantial postoperative bleeding. The platelet defect in these patients is multifactorial and not adequately explained by the moderate thrombocytopenia that frequently occurs or the heparin administered during the procedure. Results of some studies suggest that during cardiopulmonary bypass, a percentage of both GpIb and allbb3 may be lost from the platelet surface. The potential mechanisms accounting for this loss are uncertain and may reflect the effects of either mechanical trauma from turbulence and shear stress within the extracorporeal oxygenator or those of proteolytic enzymes, such as plasmin, activated during the bypass procedure. With respect to the latter, observations that protease inhibitors such as aprotinin or ϵ -aminocaproic acid may reduce blood loss during cardiopulmonary bypass or, as has been found in some studies, diminish the bypass-associated reduction in platelet GpIb suggest the involvement of plasmin in the induction of postbypass platelet dysfunction. The bypass procedure also may activate platelets, as suggested by the observations that platelets from patients undergoing cardiopulmonary bypass express increased amounts of P-selectin and that levels of P-selectin and b-thromboglobulin are elevated in the plasma of these patients. The use of iloprost, a prostacyclin analog, and echistatin, a disintegrin peptide that inhibits allbb3-mediated platelet aggregation, shows promise in preventing pathologic platelet activation during cardiopulmonary bypass. However, the utility of inhibiting platelet activation in diminishing the overall morbidity associated with cardiopulmonary bypass is uncertain at this time.

Antiplatelet Antibodies

Immunoglobulin molecules can bind to the platelet surface in several pathologic conditions, including immune thrombocytopenic purpura, systemic lupus erythematosus, and platelet alloimmunization, resulting in accelerated platelet destruction and thrombocytopenia. Some patients with circulating antiplatelet antibodies also may have impaired platelet aggregation and a prolonged bleeding time, even when thrombocytopenia is modest or absent. In a few cases, the IgG purified from the patient's plasma or eluted from the platelets inhibited aggregation of normal platelets. Abnormal aggregation may be related to an acquired form of storage pool disease caused by antibody-mediated platelet activation and secretion occurring in vivo. In one report, platelets in immune thrombocytopenic purpura exhibited an activation defect manifested by diminished conversion of arachidonic acid to thromboxane A₂. Results of experiments with an ex vivo perfusion system have indicated that some antiplatelet antibodies also may inhibit adhesion of platelets to the subendothelial matrix. Several patients have been described who had autoantibodies with specificity for GpIb-IX-V or allbb3 or that caused an acquired form of Bernard–Soulier syndrome or thrombasthenia.

After repeated platelet transfusions, alloantibodies to GpIb or allbb3 develop in some patients with the inherited forms of Bernard–Soulier syndrome or Glanzmann thrombasthenia, respectively. Such antibodies may limit the efficacy of subsequent transfusions by reducing the function or survival of donor platelets. In one case of a woman with Bernard–Soulier syndrome, an alloantibody with specificity for the GpIb-IX complex was able to cross the placenta during pregnancy and cause neonatal alloimmune thrombocytopenia.

Disseminated Intravascular Coagulation

Diminished platelet aggregation is but one of several hemostatic defects in disseminated intravascular coagulation (DIC) and may be caused by a combination of severe fibrinogen depletion and inhibition of fibrinogen binding by high concentrations of fibrin degradation products. The hemorrhagic diathesis in this disorder usually is dominated by abnormalities in coagulation and fibrinolytic proteins, as well as thrombocytopenia, rather than platelet dysfunction per se.

Hematologic Diseases That Affect Platelet Function

Acute Myelogenous Leukemia, Myelodysplastic Syndromes, and Chronic Myeloproliferative Disorders

Platelet dysfunction occurs among some patients with acute myelogenous leukemia, myelodysplastic syndromes, and chronic myeloproliferative disorders, particularly essential thrombocythemia, myelofibrosis with myeloid metaplasia, and polycythemia vera. A number of intracellular and membrane defects have been reported that are presumed to be caused by platelets arising from a neoplastic clone. The pattern of abnormality varies from patient to patient, however, and none of the functional defects is a reliable predictor of hemorrhage. In rare instances acquired forms of von Willebrand disease or Bernard–Soulier syndrome have occurred. In most of these disorders, thrombocytopenia usually is a more important cause of bleeding than is platelet dysfunction. An exception is essential thrombocythemia, in which bleeding may occur in association with an elevated platelet count (>400,000 per milliliter), even in the presence of a normal bleeding time. Patients with essential thrombocythemia also may have digital ischemia (erythromelalgia) or other vascular ischemic syndromes caused by microvascular platelet occlusion.

Bleeding and thrombotic complications may improve when the platelet count is lowered by means of plateletpheresis or chemotherapy. Aspirin may be useful in the management of digital ischemia but should be avoided in the care of bleeding patients or those with active peptic ulcer disease. Results of some studies suggest that low doses of aspirin (75 to 100 mg per day) may be as effective as larger doses in reducing thrombotic complications and are accompanied by a lower incidence of bleeding. Essential thrombocythemia must be differentiated from secondary thrombocytosis, because elevated platelet counts in the latter are not associated with platelet dysfunction. Secondary thrombocytosis may occur in several settings, including hemolysis, iron deficiency anemia, aftermath of splenectomy, carcinoma, chronic inflammatory disorders, and transient rebound thrombocytosis after marrow suppression. The presence of other features of a myeloproliferative syndrome in essential thrombocythemia can be helpful in the differential diagnosis. These include splenomegaly, leukocytosis, and histologic features of bone marrow that demonstrate reticulin fibrosis and large clusters of megakaryocytes. When these clues are not present, documentation of decreased platelet aggregation in response to agonists such as epinephrine support a diagnosis of essential thrombocythemia.

Multiple Myeloma and Other B-cell Neoplasms

Prolonged bleeding time occurs among some patients with plasma cell neoplasms, such as multiple myeloma and Waldenstrom's macroglobulinemia. Platelet dysfunction may cause serious bleeding for some patients with these disorders. In these situations, the paraprotein appears to be responsible. Although a direct effect on one or more membrane proteins is suspected, the mechanism has not been characterized in most patients. As do rare patients with autoimmune thrombocytopenia, some patients with multiple myeloma may have acquired thrombasthenia caused by a paraprotein that specifically reacts with allbb3 and inhibits fibrinogen binding. Acquired von Willebrand disease has been reported among a small number of patients with multiple myeloma and other B-cell neoplasms. Rare patients with monoclonal antithrombin antibodies also have been described.

Bleeding among patients with monoclonal gammopath, particularly those with Waldenstrom's macroglobulinemia and IgM paraproteins, is more often a manifestation of the hyperviscosity syndrome than of platelet dysfunction per se. In either case, bleeding resolves after reduction of the paraprotein through plasmapheresis or chemotherapy.

THERAPY FOR PLATELET FUNCTION DISORDERS

GENERAL PRINCIPLES

Once the diagnosis of platelet dysfunction is made and the underlying defect established, an appropriate therapeutic strategy must be formulated to deal with a bleeding episode or to prevent hemostatic failure during surgery. Treatment must be individualized on the basis of variables such as the severity of the underlying platelet defect, the degree of stress that will be placed on the hemostatic system, and the efficacy and risks of a particular form of treatment. The physician must educate the patient to avoid aspirin and other platelet-inhibiting drugs, particularly before surgery.

Although the bleeding time is a useful test for evaluating patients for disorders of platelet function, it is affected by a number of technical variables that influence its sensitivity. Studies have shown that bleeding time is not clinically useful in finding individuals in unselected populations who are at greatest risk for surgical bleeding. Although a normal bleeding time, properly measured, gives reasonable assurance that the patient's ability to form a platelet plug is clinically sufficient, the significance of a prolonged bleeding time is far less certain and depends on whether the patient has a history that suggests a bleeding disorder. It is reasonable to use bleeding time as an indicator of the effect of therapy on patients with an inherited platelet function defect or to evaluate patients with a history of bleeding who may have a congenital or acquired disorder of platelet dysfunction. Results of studies suggest that automated platelet analyzers such as the PFA-100 device may have equal and perhaps better sensitivity and specificity than bleeding time for the detection of clinically significant platelet dysfunction. However, the utility of this technology awaits additional testing in expanded clinical settings.

Many defects of platelet function are mild, and clinical judgment must be brought to bear on therapeutic decisions. For example, when a patient with a clinically mild platelet defect is to undergo a minor surgical procedure or when meticulous hemostasis can be obtained with local measures, attempts to normalize bleeding time with platelet transfusions or other potentially toxic therapy are unwarranted.

MANAGEMENT OF THE UNDERLYING DISEASE

The most rational therapeutic approach to platelet dysfunction is to treat the patient for the underlying disease. The platelet dysfunction associated with systemic lupus erythematosus, lymphoma, plasma cell neoplasia, DIC, myeloproliferative disorders, or the presence of antiplatelet antibodies usually improves with successful therapy for the underlying disorder. Potentially life-threatening bleeding associated with multiple myeloma can be controlled successfully with plasmapheresis to remove the offending paraprotein. Acute episodes of bleeding in essential thrombocythemia may respond to plateletpheresis and pharmacologic suppression of platelet production. In afibrinogenemia or von Willebrand disease, replacement therapy with cryoprecipitate or factor VIII preparations rich in multimeric VWF may be warranted. Management of von Willebrand disease is discussed in [Chapter 237](#).

In uremia, a prolonged bleeding time per se is not an indication for treatment. If the patient has clinically significant bleeding, intensive dialysis may be useful. Desmopressin (DDAVP) has been reported to shorten bleeding time for 50% to 75% of patients. Some of these patients have subsequently undergone surgical procedures without undue hemorrhage, although no results of controlled trials of this therapy have been reported. The drug has been well tolerated in a dose of 0.3 µg per kilogram given intravenously over 15 to 30 minutes and has been successfully administered through the subcutaneous and intranasal routes, although absorption may be erratic with intranasal administration. Facial flushing, mild tachycardia, water retention, and hyponatremia are potential side effects. Caution in the use of this drug in the care of elderly patients with symptomatic atherosclerotic cardiovascular disease is warranted. The drug has been reported to precipitate myocardial ischemic episodes. The efficacy of desmopressin in therapy for uremia may reflect its ability to induce the release of VWF and factor VIII from tissue stores; however, it is unlikely that this is the only mechanism involved since levels of these proteins in patients with uremia are generally normal or elevated. The shortening of the bleeding time induced by desmopressin generally lasts for several hours after the infusion, and the drug has sometimes been administered repeatedly at 12- to 24-hour intervals, although tachyphylaxis may develop after several doses. Furthermore, because desmopressin is not efficacious for all patients, a therapeutic trial before surgery is indicated.

An additional treatment that may shorten bleeding time among adult patients with uremia who are undergoing dialysis is conjugated estrogens (0.6 mg per kilogram per day for 5 days intravenously or 50 mg per day by mouth). Although the mechanism of action of these agents is obscure, bleeding time may improve after the first dose, and the effect may persist for several days. The bleeding times of many patients with uremia also may improve after the hematocrit rises to greater than 30% with administration of red blood cell transfusions or recombinant erythropoietin. This improvement may reflect rheologic effects, although elevation in the hematocrit also has been reported to enhance platelet adhesion in d storage pool disease, perhaps because of shear-induced release of red cell ADP.

ADJUNCTIVE THERAPIES

Platelet transfusion is indicated for severe bleeding due to intrinsic platelet defects such as Glanzmann thrombasthenia, Bernard–Soulier syndrome, storage pool disease, and cardiopulmonary bypass. The increased use of platelet function inhibitors, particularly allbb3 blockers, in the care of patients with cardiovascular disease will likely lead to increased bleeding among some patients. Because specific antagonists of these agents are not available, treatment of such persons once alternative causes of bleeding are excluded should include platelet transfusion. The number of transfused platelets needed to secure hemostasis must be determined empirically and depends variables such as the patient's blood volume, the severity of the underlying defect, the functional integrity and life span of the donor platelets, and the presence of alloantibodies. Because of the inherent dangers associated with blood transfusion and the development of refractoriness after multiple

transfusions, platelet transfusions should be reserved for situations in which they are clearly indicated.

In a number of uncontrolled and placebo-controlled studies, use of desmopressin successfully shortened the bleeding time for at least one-half of patients with inherited or acquired disorders of platelet function, including storage pool disease, platelet activation defects, and aspirin ingestion. The drug has not been efficacious in the treatment of patients with Glanzmann thrombasthenia, although bleeding time is shortened transiently among some patients with Bernard–Soulier syndrome. The mechanisms by which these effects are mediated are not clearly defined, and additional experience is needed to determine the precise mechanisms of action and overall efficacy of desmopressin to manage bleeding among patients with platelet function disorders. Prednisone, 20 to 50 mg per day for 3 days, has been reported to improve bleeding time among some patients with platelet activation defects. The mechanism is equally obscure.

Women with menorrhagia associated with defects of platelet function may benefit from hormonal therapy. Local hemostatic agents, such as topical thrombin, adsorbable collagen hemostat, or mouth rinses with tranexamic acid may alleviate bleeding during dental extractions. Prophylactic oral administration of antifibrinolytic agents such as *e*-aminocaproic acid or tranexamic acid may be useful in the treatment of patients with von Willebrand disease or hemophilia who are undergoing dental extractions. These agents may precipitate thrombosis among patients with DIC and should not be used in their care.

CHAPTER 240: THROMBOTIC DISORDERS

JOEL S. BENNETT

[Definition](#)
[Incidence and Epidemiology](#)
[Etiology](#)
[Pathogenesis and Pathophysiology](#)
[Optimal Management](#)

DEFINITION

Thrombotic disorders, the most common causes of morbidity and mortality in Western civilization, result from the formation of fibrin or platelet thrombi. Thrombi form when the normal hemostatic balance that maintains the fluidity of blood shifts to favor their formation. The composition of thrombi reflects the nature of the blood flow conditions in which they form. Under the high shear conditions found on the arterial side of the circulation, thrombi are composed primarily of platelets (white thrombi). Under the low shear conditions found in the venous circulation, thrombi are composed primarily of fibrin and entrapped erythrocytes (red thrombi).

INCIDENCE AND EPIDEMIOLOGY

Arterial thrombosis is most often a complication of atherosclerotic vascular disease and, as such, the most common cause of death in the United States. Coronary artery thrombosis results in approximately 800,000 new and 450,000 recurrent myocardial infarctions per year and resulted in 498,000 deaths in 1989. The prevalence of cerebrovascular disease in 1989 was 10 per 1,000 population, leading to 147,000 deaths. Venous thromboembolism affects 1 per 1,000 people annually. Pulmonary embolism is the most serious complication of this disorder, but because the diagnosis of pulmonary embolism may be difficult to establish and its occurrence frequently is overlooked, accurate data regarding its incidence are difficult to obtain. It has been estimated that there are 50,000 deaths from pulmonary embolism annually. Moreover, because only 10% of episodes of pulmonary embolism are fatal, the annual incidence of pulmonary embolism is probably close to 500,000. Evidence of pulmonary embolism is found in 25% to 30% of routine autopsies, which suggests that even this figure is an underestimate. Pulmonary embolism is also a major cause of postpartum and postoperative deaths. It accounts for 4,000 to 8,000 such deaths annually and in 1 to 2 deaths per 1,000 patients over age 40 undergoing major surgery.

ETIOLOGY

Thrombotic disorders are the result of inherited disorders of the hemostatic system ([Table 240.1](#)) or stem from other disorders ([Table 240.2](#)). Although arterial thrombosis most often derives from atherosclerosis, it also can be a complication of homozygous and heterozygous homocystinemia, arteritis, myeloproliferative disorders, thrombotic thrombocytopenic purpura (TTP), heparin-induced thrombocytopenia (HIT), and the antiphospholipid antibody syndrome.

Arterial thrombosis
Homocystinemia
Venous thrombosis
ATIII deficiency
Protein C deficiency
Protein S deficiency
Factor V Leiden
Prothrombin G20210A
Homocystinemia
Dysfibrinogenemia
Plasminogen deficiency

Nephrotic syndrome
Antiphospholipid antibody syndrome
Paroxysmal nocturnal hemoglobinuria

TABLE 240.2. ACQUIRED DISORDERS THAT CAUSE THROMBOSIS

The predilection to venous thrombosis is termed *thrombophilia* and occurs most often in patients with malignancy, in immobilized medical and surgical patients, in women who are pregnant or taking oral contraceptives, and in patients with the nephrotic syndrome, the antiphospholipid antibody syndrome, and paroxysmal nocturnal hemoglobinuria. In many patients, especially those who experience venous thrombosis at a young age, thrombophilia may be familial in origin. In 5% to 10% of these patients, there are abnormalities in proteins that control coagulation, including deficiencies of antithrombin (AT), protein C (PC), or protein S (PS). Approximately 40% of patients with venous thrombosis, 50% to 60% of patients with a family history of venous thrombosis, and 2% to 5% of normal individuals are resistant to the anticoagulant effect of activated PC (APC), most often owing to a polymorphism of the factor V (FV) molecule termed *factor V Leiden*. A relatively common genetic variation in the 3' untranslated region of the prothrombin gene, prothrombin G20210A, is also associated with a moderate risk of venous thrombosis, as is an increased plasma concentration of the sulfur-containing amino acid homocysteine. Rarely, thrombophilia results from dysfibrinogenemia and abnormalities of fibrinolysis.

PATHOGENESIS AND PATHOPHYSIOLOGY

ARTERIAL THROMBOSIS

In the arterial circulation, the formation of a thrombus recapitulates the formation of a normal hemostatic plug. Platelets do not interact with the endothelial lining of blood vessels. When the arterial endothelium is breached, however, platelets adhere to connective tissue in the subendothelial matrix. Although platelets can adhere to collagen, fibronectin, and laminin in the matrix when the shear stress is high, adherence requires the presence of von Willebrand factor. Concurrently, platelets in the vicinity of the wound are stimulated by agonists, such as thrombin and ADP. This results in the binding of fibrinogen or von Willebrand factor to glycoprotein IIb/IIIa (GpIIb-IIIa) complexes on the surface of these platelets. The GpIIb-IIIa-bound protein then cross-links these platelets into aggregates that bind to the layer of adherent platelets, forming a hemostatic plug or an occlusive thrombus. Stimulated platelets also secrete ADP stored in their dense granules to amplify the

aggregation process and convert arachidonic acid released from membrane phospholipid to thromboxane A₂, a potent platelet agonist and vasoconstrictor.

Platelet thrombi form on the surface of atherosclerotic plaques when there is extensive endothelial cell denudation. More often, thrombi result from disruption of the plaque and exposure of blood to highly thrombogenic material in the plaque interior. Plaque disruption occurs most often at the junction of the fibrous cap of the plaque and normal intima. This permits blood to enter the lipid pool in the plaque interior and leads to the formation of a platelet-rich thrombus. An extension of the thrombus composed of densely packed fibrin may reenter the vessel lumen and partially or totally occlude the flow of blood. A partially occlusive thrombus can embolize to produce vascular occlusion downstream or organize to increase arterial narrowing. An occlusive thrombus produces tissue infarction unless adequate collateral blood flow has developed.

Many patients homozygous for cystathionine b-synthase (CBS) deficiency die of vascular disease before the age of 30. The basis for their predisposition to premature atherosclerosis and arterial thrombosis is unknown. Approximately one-third of some cohorts of patients with premature atherosclerosis also have lesser degrees of hyperhomocystinemia after methionine loading, suggesting that hyperhomocystinemia is an independent risk factor for vascular disease. Arteritis due to collagen-vascular diseases, such as systemic lupus erythematosus (SLE), can produce widespread recurrent arterial thrombi. The arterial and venous thromboses associated with the myeloproliferative disease polycythemia vera result from the increased blood viscosity and thrombocytosis that accompany this disease. Arterial and venous thromboses are also a feature of essential thrombocythemia and result from the increased number of abnormal platelets that characterize this disorder. Paradoxically, two thrombocytopenic syndromes (TTP and HIT) are associated with thrombosis rather than bleeding. TTP is characterized by widespread arteriolar platelet thrombi that cause evanescent symptoms of ischemia. Arterial and, occasionally, venous thrombosis develops in a minority of patients with HIT and can lead to stroke, myocardial infarction, or the need for amputation of an extremity. The antiphospholipid antibody syndrome is associated with both arterial and venous thrombosis and is discussed in the next section.

VENOUS THROMBOSIS

Venous thrombi are composed primarily of fibrin and entrapped erythrocytes and result from a series of biochemical reactions that begin with the exposure of tissue factor in a damaged vessel and lead to the sequential activation of coagulation factor X (FXa), cleavage of prothrombin by FXa to liberate thrombin, and cleavage of fibrinogen by thrombin to produce fibrin monomers. Fibrin monomers spontaneously polymerize into strands of fibrin that are irreversibly cross-linked by thrombin-activated factor XIII to produce an insoluble clot. Fibrin clots eventually are removed by the enzyme plasmin or organized by connective tissue. Because thrombin is directly responsible for the conversion of fibrinogen to fibrin, its generation from prothrombin and its activity in plasma are carefully regulated. The predominant inhibitor of thrombin and FXa activity in plasma is AT, the protein that mediates the anticoagulant effect of heparin and a member of the serpin family of protease inhibitors.

Two other proteins that limit the generation of thrombin from prothrombin are present in plasma. The production of sufficient FXa by activated factor IX (FIXa) to cleave prothrombin at a physiologically relevant rate and the cleavage of prothrombin itself require activated factor VIII (FVIIIa) and activated factor V (FVa), respectively. A complex formed by APC and PS acts as a brake on thrombin production by enzymatically cleaving both FVIIIa and FVa. Sensitive assays have shown that small amounts of FXa and thrombin are generated continuously in normal individuals, but their activities are controlled by AT and the APC-PS complex to prevent the formation of fibrin thrombi. Consequently, thrombosis can occur either when the production of FXa and thrombin is enhanced or when the activity of the control proteins is diminished.

Antithrombin Deficiency

AT irreversibly inhibits thrombin and FXa (as well as FIXa and factors XI and XII) by forming a covalent complex at the active site of each coagulation factor. Heparin binds to AT and accelerates its function approximately 1,000-fold by inducing a conformational change in the molecule. Abnormalities of AT are inherited in an autosomal dominant fashion and have been detected in about 5% of individuals with venous thrombosis who are less than 45 years old. There are two types of inherited AT deficiency. Type I deficiency is characterized by an equivalent decrease in the concentration and activity of AT in plasma, indicating reduced protein synthesis from one or both AT genes. In type II deficiency, however, AT activity is reduced out of proportion to its plasma concentration, reflecting synthesis of a defective protein. Although thrombosis due to AT deficiency affects one in 2,000 to 5,000 individuals, the prevalence of AT deficiency in the general population approaches 0.2% to 0.4%. Thus, additional factors appear to be required to induce thrombophilia in AT-deficient individuals.

The AT activity in the plasma of individuals heterozygous for AT deficiency is generally 50% of normal. The incidence of venous thrombosis in these individuals is about 50%. Thrombosis develops spontaneously in half of these individuals and is associated with other predisposing factors in the remainder. In two-thirds of patients, thrombosis is recurrent and is associated with pulmonary embolism in 40%. There is a single case report of two homozygous neonates with type I deficiency, suggesting that homozygous type I deficiency is incompatible with survival beyond the neonatal period. The predisposition to thrombosis in patients with type II deficiency varies with the type of AT mutation. Mutations involving the protease binding site predispose to thrombosis, whereas mutations affecting the heparin binding sites, at least in heterozygous individuals, do not. However, individuals who are homozygous for the latter mutations have thrombophilia.

AT deficiency can be acquired. The concentration of AT occasionally declines after acute thrombosis but frequently decreases during the course of disseminated intravascular coagulation (DIC). Diminished AT concentrations also can result from liver disease because of decreased synthesis, from the nephrotic syndrome because of urinary loss, and with the use of oral contraceptives or other estrogen-containing drugs. The concentration of AT does not change substantially during pregnancy.

Protein C Deficiency

PC is a vitamin K–dependent zymogen that is converted to an active enzyme by thrombin bound to the endothelial cell membrane protein thrombomodulin (TM). When thrombin is generated from prothrombin, a portion of it binds to TM. Thrombin bound to TM is no longer able to cleave fibrinogen but converts PC to APC. APC, in turn, forms a complex with PS and intact FV to suppress further thrombin generation by inactivating FVIIIa and FVa. Thus, PC-deficient individuals are prone to thrombosis because they are unable to suppress thrombin generation adequately. PC deficiency is inherited as an autosomal dominant disorder, and heterozygotes with 50% levels of PC are at risk for thrombosis. Heterozygous individuals are usually asymptomatic until the third decade of life, when they begin to experience thrombosis, most often involving the veins in the legs. There is also a reported association between thrombotic stroke in young adults and PC deficiency.

Although heterozygous PC deficiency has a prevalence of one in 200, penetrance of the disorder varies. While up to 75% of individuals in some affected families have experienced thrombosis, members of other affected families are asymptomatic. Obligate heterozygous family members of infants with homozygous PC deficiency and purpura fulminans also have been asymptomatic. Like AT deficiency, additional factors may be required to induce thrombophilia in PC-deficient kindreds. Two types of PC mutations have been described. The more common type I mutation leads to a decline in PC synthesis, whereas type II mutations result in the synthesis of a functionally defective protein. Homozygous or doubly heterozygous PC deficiency with PC concentrations of less than 1% has been described in newborns and results in fatal purpura fulminans unless PC replacement is promptly initiated.

Acquired PC deficiency develops in the context of liver disease because of decreased synthesis. DIC and the adult respiratory distress syndrome result in PC deficiency by increasing consumption. Vitamin K antagonists, such as warfarin, lower the concentration of functional PC in plasma by inhibiting its γ -carboxylation in the liver. The administration of warfarin to patients heterozygous for PC deficiency has been associated infrequently with the development of skin necrosis. This occurs because the half-life of PC, like that of factor VII (FVII), is short (about 6 to 12 hours), while the half-life of the other vitamin K–dependent clotting factors is considerably longer. Thus, the administration of warfarin, especially in high loading doses, produces a transient hypercoagulable state, an effect exaggerated in individuals who are PC deficient.

Protein S Deficiency

PS is a vitamin K–dependent cofactor for the APC-mediated cleavage of FVIIIa and FVa. Normally, 60% of the PS in plasma is bound to C4b-binding protein (C4bBP). Because the unbound fraction is the cofactor for APC, PS measurements must differentiate between free and C4bBP-bound PS. C4bBP is an acute-phase reactant; changes in its concentration alter the concentration of free PS. Hereditary deficiency of PS predisposes to thrombosis and is inherited in an autosomal dominant fashion with an estimated prevalence of one in 20,000. The clinical manifestations of heterozygous PS deficiency are similar to those of PC deficiency, including an association with arterial thrombosis in young individuals. The total PS concentration of heterozygotes is approximately 50% of normal (type I), but deficiency states have been described in which the total PS concentration is normal while the free fraction is diminished (type II). Type III PS deficiency is due to the synthesis of a

dysfunctional protein. Severe homozygous PS deficiency can result in neonatal purpura fulminans.

Acquired PS deficiency results from liver disease, DIC, pregnancy, and oral contraceptive use. The reduced concentrations of free PS that arise after acute thromboembolic disease, in part due to increases in C4bBP, make a diagnosis of PS deficiency difficult to establish at this stage of the disease. The concentration of functional PS declines with warfarin therapy, with a half-life of about 42 hours. Nevertheless, a case of warfarin-induced skin necrosis in a PS-deficient patient has been reported.

Factor V Leiden

Approximately 40% of patients with venous thromboembolism who are not AT, PC, or PS deficient are resistant to the ability of purified APC to prolong the activated partial thromboplastin time (aPTT). In thrombophilic families, the prevalence of this abnormality can reach 50% to 60%. In more than 90% of cases, APC resistance is due to an Arg506@Gln polymorphism in the FV molecule (FV Leiden). Because Arg506 is one of the APC cleavage sites in FV, FV Leiden is less sensitive than normal FV to inactivation by APC. The thrombophilia in families with FV Leiden is inherited as an autosomal dominant disorder: 30% of the heterozygotes and 44% of the homozygotes in these families have experienced one or more thromboembolic episodes. Looked at another way, heterozygosity for FV Leiden increases the risk of venous thrombosis five- to tenfold, while homozygosity raises this risk by a factor of 50 to 100. Furthermore, the relative risk of venous thromboembolism in relatives of patients heterozygous for FV Leiden has been reported to be 4.2, with the annual incidence increasing from 0.25% at ages 15 to 30 to 1.1% in individuals older than 60. Because the prevalence of FV Leiden in white populations may be as high as 2% to 5%, it is likely to be a significant second risk factor for thrombosis in individuals otherwise prone to thrombosis. For example, the risk of venous thromboembolism in women taking oral contraceptives is magnified about eightfold by the presence of FV Leiden. On the other hand, the polymorphism is rare or absent in African, Chinese, Japanese, and Native American populations.

Prothrombin G20210A

Because prothrombin is the precursor for thrombin, an analysis of the prothrombin gene as a candidate gene for venous thrombosis revealed that a G to A polymorphism at the last position (20210) of its 3' untranslated region was associated with an increase of about 25% in the plasma concentration of prothrombin and a 2.8- to 4.8-fold rise in the relative risk of venous thrombosis. In white populations, heterozygosity for prothrombin G20210A is present in 1% to 2% of healthy individuals and in 4.6% to 7.9% of patients with venous thrombosis. Like FV Leiden, prothrombin G20210A is rare in individuals of African, Asian, or Native American origin. Prothrombin G20210A also has been reported to be a risk factor for cerebral venous thrombosis, more frequently in women using oral contraceptives; for myocardial infarction in young women, especially those with other risk factors for coronary artery disease; and for cerebrovascular ischemic disease in younger patients.

Homocystinemia

An increased plasma concentration of the sulfur-containing, potentially toxic amino acid homocysteine, a product of methionine metabolism, is a risk factor for both premature atherosclerosis and deep venous thrombosis. It has been estimated that 10% of the risk for coronary artery disease may be attributable to homocysteine and that homocysteine concentrations in patients with symptomatic vascular disease are 31% greater than in normal controls. The homocysteine concentration in cells and plasma is controlled by two biochemical reactions: remethylation of homocysteine to methionine by sequential reactions involving the enzymes N_5,N^{10} -methylene tetrahydrofolate reductase (MTHFR) and methionine synthase (the latter requiring vitamin B₁₂ as a cofactor) and transsulfuration, in which homocysteine condenses with serine to form cystathionine in a reaction catalyzed by the vitamin B₆-dependent enzyme CBS. Homozygous deficiency of CBS or MTHFR leads to congenital homocystinuria with plasma homocysteine concentrations as high as 400 μ mol/L.

Approximately 50% of patients with congenital homocystinuria have a thromboembolic event before the age of 30, with a mortality rate of 20%. Smaller increases in plasma homocysteine are present in individuals who are either heterozygous for CBS deficiency or homozygous for the common thermolabile MTHFR C667T variant when their plasma folate concentrations are low. In these individuals, there is a graded relationship between plasma homocysteine concentration and the risk of coronary artery disease, stroke, and death. Homocysteine concentrations above the 95th percentile for normal controls also have been reported to raise the risk for deep venous thrombosis by a factor of 2.5. Supplementing the diet of MTHFR C667T homozygotes with folate decreases their plasma concentration of homocysteine. Whether fortification of cereal grain products with folate to prevent congenital neural tube defects will have a beneficial effect on the overall incidence of thrombotic disorders remains to be determined.

The Antiphospholipid Antibody Syndrome

This refers to the association of lupus anticoagulants (LACs) and anticardiolipin antibodies (ACAs) with venous and arterial thrombosis. LACs are IgG and IgM antibodies directed against the anionic phospholipid component of the aPTT and prothrombin time (PT) clotting assays and prolong these assays. Although these antibodies were described first in patients with SLE, in whom they can be detected in 30% to 50% of cases, they also are found in patients with other chronic autoimmune disorders; patients taking such drugs as procainamide, phenothiazines, hydralazine, and quinidine; patients recovering from acute viral infections; patients infected with HIV; women with histories of several spontaneous abortions; and patients with prolonged aPTTs (as an incidental finding). While LACs prolong the aPTT, and occasionally the PT, they are not associated with bleeding unless they are accompanied by significant prothrombin deficiency or thrombocytopenia.

ACAs react with cardiolipin, the phospholipid antigen for the serologic testing for syphilis, but ACAs differ from reagin, the antiphospholipid antibody found in syphilis. Purified ACAs do not interact with phospholipid unless the lipid is complexed with the plasma protein b₂-glycoprotein I, suggesting that the antigens they recognize reside on a lipoprotein complex. ACAs are detectable in about 40% of patients with SLE and in patients with many of the same conditions in which LACs are found. There is as yet no satisfactory explanation for the association of LACs and ACAs with thrombosis, however. It remains to be determined whether LACs and ACAs are actually pathogenic or are simply markers of a hypercoagulable state.

A history of thrombosis can be established for 30% to 40% of patients with SLE and LACs and/or ACAs and in 15% to 30% of patients with LACs and/or ACAs but without SLE. LACs and ACAs that arise after acute infection or drug ingestion usually are not associated with thrombosis. Venous thrombosis typically affects the lower extremities but may involve unusual sites, such as the hepatic veins, cerebral venous sinuses, or the axillary veins. Arterial thrombosis can result in strokes, transient ischemic attacks, or gangrene of the extremities or digits. Thromboembolic disease associated with nonbacterial aortic and mitral valve vegetations has been reported, as has the concurrence of livedo reticularis and cerebrovascular disease (Sneddon syndrome). Patients with histories of venous thrombosis tend to have recurrent venous thrombi, while patients with histories of arterial thrombosis tend to have recurrent arterial thrombi. There is also an association between persistently positive results on tests for LACs and ACAs in women with SLE and recurrent fetal loss, presumably owing to thrombosis of placental vessels and placental infarction. It is not clear whether such an association exists for women without SLE.

Rare Causes of Thrombophilia

A minority of the reported cases of congenital dysfibrinogenemia are associated with thrombosis. There is no ready explanation for thrombosis in most of these cases, but in several, defective thrombin binding to the abnormal fibrinogen was thought to increase the concentration of free thrombin; in others, defective plasminogen activation or fibrinolysis has been detected. Although thrombophilia has been associated with abnormalities of plasminogen and abnormal fibrinolysis, the contribution of the abnormalities to thrombosis remains to be established.

OPTIMAL MANAGEMENT

The clinical and laboratory findings and strategy for treating patients with thrombosis are discussed in [Chapter 219](#). Drugs that are useful for treating patients with thrombosis are discussed in the next sections. The goal of medical management of arterial thrombosis is to prevent recurrence using drugs that inhibit platelet function. In specific circumstances, fibrinolytic agents have been administered to directly lyse arterial thrombi.

ANTIPLATELET AGENTS

Aspirin remains the antiplatelet agent of choice, and there is substantial evidence for its benefit in lowering the incidence of arterial occlusion. Aspirin inhibits platelet function by irreversibly inactivating the enzyme cyclooxygenase. Because platelets are unable to synthesize new cyclooxygenase, the effect of aspirin persists for the life of the platelet. Inactivation of platelet cyclooxygenase prevents synthesis of prostaglandin endoperoxides and thromboxane A₂ and inhibits platelet responses

requiring these substances. A single 100-mg dose of aspirin almost completely inhibits platelet thromboxane synthesis. The effect of lower aspirin doses is cumulative, and 30 to 50 mg daily will completely inhibit thromboxane synthesis by 7 to 10 days. Side effects of aspirin are primarily gastrointestinal irritation and bleeding. A small increased incidence of hemorrhagic strokes was observed in one clinical trial.

Alternatives to aspirin are the thienopyridines ticlopidine and clopidogrel, drugs that primarily inhibit ADP-induced platelet aggregation. In contrast to aspirin, the onset of action of these drugs is delayed, limiting their usefulness in acute situations. Their effect also persists for 4 to 10 days after they are stopped. Ticlopidine has a number of serious side effects, including neutropenia in 2% to 3% of patients and rare cases of aplastic anemia; moreover, a number of reports have associated its use with the development of TTP. These side effects have not been attributed to clopidogrel, but it has been used for a shorter period of time. Drugs that inhibit platelet aggregation directly by antagonizing GpIIb-IIIa are beneficial in improving the outcome of angioplasty in patients with acute coronary syndromes. Their utility and safety in other syndromes associated with arterial thrombosis and when given over the long term remain to be determined.

THROMBOLYTIC AGENTS

Thrombolytic agents, such as streptokinase, urokinase, recombinant tissue plasminogen activator (rtPA), and anisoylated plasminogen streptokinase activator complex, catalyze the conversion of the zymogen plasminogen to the fibrinolytic enzyme plasmin and have been used to lyse arterial and venous thrombi. Because tPA converts fibrin-bound plasminogen to plasmin, it was hoped that rtPA would be clot specific, but this is not the case; at clinically effective doses, each drug cleaves fibrinogen as well as fibrin. The use of a thrombolytic agent within 4 to 6 hours of the onset of a myocardial infarction results in coronary artery reperfusion in 50% to 80% of cases and reduces mortality rates by 30% to 55%. Local thrombolytic therapy is an alternative to surgery in selected cases of peripheral artery occlusion. Thrombolytic therapy is the treatment of choice for massive pulmonary embolism and submassive embolism superimposed on chronic cardiopulmonary disease, with an overall success rate of 80% to 90%. The role of thrombolytic therapy in the management of deep venous thrombosis of the lower extremities is unclear, because the risk of hemorrhage is greater with the use of these agents than with conventional anticoagulants and because it has not been shown to prevent the postphlebotic syndrome. It is an option for treatment of subclavian or axillary vein thrombosis.

The major hazard of thrombolytic therapy is hemorrhage due to lysis of physiologic as well as pathologic blood clots. The reported incidence of bleeding ranges from 5% to 40%, including a 0% to 2% incidence of intracranial bleeding. Absolute contraindications for thrombolytic therapy include active bleeding and damage and disturbances of the central nervous system. Relative contraindications include surgery or trauma within 10 days, arterial punctures, gastrointestinal ulcer disease, known coagulation or platelet disorders, severe hypertension, hepato-renal insufficiency, pregnancy, and subacute bacterial endocarditis.

Venous thrombosis is treated by anticoagulation. Anticoagulation also has been used to prevent recurrence or extension of arterial thrombi. Acute venous thrombosis is treated initially with heparin. Heparin also is used as prophylaxis against venous thrombosis in hospitalized patients at risk for thrombosis. The oral anticoagulant warfarin is administered for prophylaxis against venous thrombosis in outpatients.

HEPARIN

Heparin is a highly sulfated glycosaminoglycan that is extracted from tissues rich in mast cells. Commercial heparin is extracted from bovine lung or pork intestine and is a heterogeneous preparation of sugar fragments whose molecular weights range from 3,000 to 30,000. The anticoagulant function of heparin stems from its ability to potentiate the function of AT. Heparin binding to AT is mediated by a specific sequence of five sugar residues that is found in only 30% of heparin molecules.

Heparin is not absorbed orally and must be administered intravenously or subcutaneously. Both its anticoagulant activity and duration of action increase disproportionately with dose: the half-life of an i.v. dose of 100 U per kilogram is approximately 60 minutes, while the half-life of an i.v. dose of 400 U per kilogram is about 150 minutes. Heparin is cleared primarily by the reticuloendothelial system, though a small amount is excreted in the urine. Heparin is not transported across the placenta and can be used safely in pregnant women. When heparin is used to treat acute venous thrombosis, it generally is administered by continuous i.v. infusion at a dose sufficient to prolong the mean control aPTT by 1.5 to 2.5 times. This usually requires a dose of about 30,000 U per 24 hours, preceded by a bolus dose of 5000 U. Heparin also can be given by subcutaneous injection at 12-hour intervals. When heparin is used as prophylaxis against venous thrombosis and pulmonary embolism, it is given at a fixed dose of 5,000 U subcutaneously every 8 to 12 hours and generally does not prolong the aPTT. Although this regimen is effective in most instances, it is not effective after orthopedic procedures and hip fractures; a regimen adjusted to keep the aPTT at the upper limit of normal is required.

Heparin that is depolymerized or fractionated into fragments of 4,000 to 6,500 MW (low-molecular-weight heparin, or LMWH) preferentially catalyzes the inactivation of FXa instead of thrombin by AT. LMWH has a number of potential therapeutic advantages over unfractionated heparin: greater and predictable bioavailability, a half-life of 2 to 4 hours after i.v. injection and 3 to 6 hours after subcutaneous injection, and dose-dependent clearance. Thus, it has been used frequently without laboratory monitoring. LMWH has been administered in fixed daily or twice-daily subcutaneous doses to prevent venous thrombosis in general surgery patients, in patients undergoing hip surgery, and in patients with stroke and spinal injury. It also has been used to treat venous thrombosis and has been given to patients with unstable angina and ischemic stroke. In each of these circumstances, it has proved to be at least as effective and safe as unfractionated heparin. Moreover, LMWH may be useful for the outpatient management of venous thrombosis, bypassing the considerable costs of hospitalization.

The principal side effect of therapy with unfractionated heparin and LMWH is hemorrhage, which occurs in 2% to 7% patients. When bleeding is mild, it is usually sufficient to simply stop the drug. If bleeding is severe, the anticoagulant effect of unfractionated heparin can be reversed by an i.v. infusion of protamine sulfate in a ratio of 1 mg protamine per 100 U of heparin. Protamine sulfate also neutralizes the anti-thrombin activity of LMWH, but it is less effective in reversing its anti-FX activity. Thus, the reliability of protamine sulfate in reversing the anticoagulant effect of LMWH is less certain. HIT due to anti-heparin antibodies develops in approximately 1% of patients receiving heparin by any route, usually within 5 to 10 days of the initial dose. HIT generally is not associated with hemorrhage, but because a small number of patients with HIT experience thrombi, it is an indication for discontinuing heparin. The incidence of HIT is thought to be lower in patients receiving LMWH. Long-term heparin administration to pregnant women can cause osteoporosis and spontaneous vertebral fractures, but this complication may also be less frequent in women given LMWH.

ORAL ANTICOAGULANTS

Oral anticoagulants are vitamin K antagonists and lessen the plasma concentration of the functional forms of FVII, FIX, and FX and prothrombin (factor II). They also decrease the plasma concentration of functional PS and PC. Vitamin K is an essential cofactor for the γ -carboxylation of a number of amino-terminal glutamic acids of these coagulation factors. The γ -carboxylated glutamic acids interact with calcium, and, in their absence, the coagulation factors are biochemically inactive. During γ -carboxylation, vitamin K is oxidized from a hydroquinone to an epoxide and must be regenerated to a hydroquinone for further γ -carboxylation to occur. The two enzymes involved in regenerating vitamin K hydroquinone (vitamin K epoxidase and vitamin K reductase) are inhibited by vitamin K antagonists.

Warfarin, a 4-hydroxycoumarin, is the most commonly used oral vitamin K antagonist. Warfarin is absorbed almost completely from the gastrointestinal tract, and 97% is bound to albumin. Only the free fraction of warfarin is biochemically active. Warfarin is metabolized in the liver by enzymes of the cytochrome P450 system, and its plasma half-life is 36 to 42 hours. After warfarin ingestion, the levels of functional prothrombin, FVII, FIX, and FX decline according to their half-lives in plasma. FVII declines first (half-life of 6 hours), FIX and FX decline next (half-lives of 24 hours), and prothrombin declines last (half-life of 72 hours). The decline of functional PC (half-life of 6 to 12 hours) is similar to that of FVII, while the decline in PS is considerably slower (half-life of 42 hours).

Warfarin usage is complicated by the effect of exogenous factors on its metabolism ([Table 240.3](#)). Fat malabsorption enhances the anticoagulant effect of warfarin by impairing vitamin K absorption, while increased intake of foods rich in vitamin K is inhibitory. The resin cholestyramine binds warfarin in the gastrointestinal tract, preventing its absorption. Drugs that induce the synthesis of cytochrome P450 enzymes in the liver lessen the effect of warfarin by increasing its metabolism. Conversely, the effect of warfarin is enhanced by drugs that displace it from albumin and temporarily increase its free concentration or directly interfere with its metabolic clearance by the liver.

Drugs That Increase Warfarin Activity and Prolong Prothrombin Time	
Acetaminophen	Miconazole
Allopurinol	Naloxone
Amiodarone	Orlistat
Anabolic steroids	Phenibutazone
Antibiotics that depress the intestinal flora	Phenytoin
Chloramphenicol	Proxycam
Chlorpropamide	Quinine
Cimetidine	Sulfapyrazole
Ceftriaxone	Sulfonamides
Disulfiram	Tamoxifen
Erythromycin	Thyroid hormone
Fluconazole	Tolbutamide
Isoniazid	Trimethoprim-sulfamethoxazole
Ketoconazole	Vitamin E (tocopherol)
Drugs That Decrease Warfarin Activity and Shorten Prothrombin Time	
Barbiturates	Griseofulvin
Carbamazepine	Haloperidol
Chlorbutolone	Oral contraceptives
Cholestyramine	Vitamin K

TABLE 240.3. DRUGS THAT INFLUENCE THE ANTICOAGULANT ACTIVITY OF WARFARIN

Warfarin is given to patients with venous thrombosis, after treatment with heparin, to prevent recurrence of the thrombosis and to patients with chronic atrial fibrillation and prosthetic heart valves to prevent embolization. It has been used to prevent stroke and pulmonary embolism in patients with myocardial infarction, but its efficacy in preventing reinfarction is not clear. The warfarin dosage is regulated by measuring the PT. Because PT measurements depend on the potency of the thromboplastin used for the test, the PT has been standardized by comparing the potency of various thromboplastins with a thromboplastin standard. This comparison is termed the International Sensitivity Index, or ISI. PT values are now reported as the International Standardized Ratio, or INR [INR = (measured PT/control PT)^{ISI}]. This represents the PT ratio that would have been obtained if the standard thromboplastin had been used. INRs recommended to prevent recurrent venous thromboembolism and embolization in patients with chronic atrial fibrillation are 2.0 to 3.0, while INRs of 3.0 to 4.0 have been recommended to prevent embolization from mechanical heart valves. Small doses of warfarin, on the order of 1 mg daily, have been reported to be effective in preventing thrombosis in subclavian vein catheters and as prophylaxis after gynecologic surgery.

Bleeding occurs in 5% to 10% of patients treated with warfarin when the INR is within the therapeutic range and in a higher percentage when the INR is excessive. When bleeding develops in a patient whose INR is in the therapeutic range, the presence of a structural lesion should be considered. When mild bleeding is associated with an excessive INR, it may be necessary only to withhold warfarin until the INR declines into the therapeutic range. When bleeding is severe, defective coagulation can be corrected immediately by the transfusion of fresh frozen plasma. In the most severe cases, the warfarin effect also should be reversed by administering vitamin K. It should be remembered that vitamin K may make the patient resistant if warfarin therapy is reinstated. Rarely, the initiation of warfarin therapy causes severe skin necrosis. Some, but not all, patients with skin necrosis are heterozygous for PC or PS deficiency. In patients with known PC deficiency, skin necrosis has been prevented by heparin administration during the initiation of warfarin therapy. Warfarin crosses the placenta and can lead to fetal bleeding. It also can cause a form of embryopathy characterized by nasal hypoplasia and stippled epiphyses when it is administered during the first trimester and possibly central nervous system abnormalities when it is administered during any trimester. Consequently, heparin is the preferred anticoagulant during pregnancy. Warfarin does not have an anticoagulant effect on breast-fed infants.

[Thalassemia Syndromes](#)
[Strategies for Optimal Care](#)

Disorders that affect the structure, function, or production of hemoglobin are called *hemoglobinopathies*. Hemoglobinopathies usually are inherited as mutations within the globin gene clusters, but rare acquired hemoglobinopathies can be caused by toxic exposures or hematologic neoplasms. These conditions range in severity from asymptomatic laboratory abnormalities to death in utero. In many geographic areas, these disorders represent serious public health problems. Because the pathophysiologic mechanism is uniquely well understood at the molecular level, hemoglobinopathies serve as the paradigm for understanding the physiologic consequences of deranged gene function. In this chapter, the molecular basis, pathophysiologic mechanism, and clinical features of selected hemoglobinopathies are considered.

ESSENTIAL BIOLOGIC FEATURES OF HUMAN HEMOGLOBINS

HEMOGLOBIN STRUCTURE

Several different hemoglobins are produced during embryonic, fetal, and adult life ([Table 241.1](#)). Each consists of a tetramer of globin polypeptide chains: a pair of α -like chains and a pair of non- α chains. The main adult hemoglobin, HbA, has the structure $\alpha_2\beta_2$. Within each chain is a single heme moiety consisting of a protoporphyrin IX ring that forms a complex with a single iron atom in the ferrous state (Fe^{2+}). The heme moiety is situated within each globular polypeptide chain in a manner optimal for reversible binding of oxygen. Each heme moiety can bind a single oxygen molecule, and every molecule of hemoglobin can transport up to four oxygen molecules.

Name of Hemoglobin	Subunit Structure	Time of Expression
Hemoglobin Portland	$\zeta_2\gamma_2$	Embryonic life
Hemoglobin Gower I	$\zeta_2\epsilon_2$	Embryonic life
Hemoglobin Gower II	$\alpha_2\epsilon_2$	Embryonic life
Hemoglobin F	$\alpha_2\gamma_2$	Fetal life ^a
Hemoglobin A ₂	$\alpha_2\delta_2$	Minor adult hemoglobin
Hemoglobin A	$\alpha_2\beta_2$	Major adult hemoglobin

^aProduced in small amounts in a limited subpopulation of cells (F cells) in adults.

TABLE 241.1. COMPOSITION OF NORMAL HUMAN HEMOGLOBINS

The *primary structures* (amino acid sequences) of the various globins are highly homologous to one another, suggesting that all of the proteins arose from a common ancestral gene. Each globin has a largely helical *secondary structure*. About 80% of each polypeptide exists in the form of an α helix. The non- α chains contain eight helical segments, designated A through H, as shown in [Fig. 241.1](#). The helices fold into three-dimensional globular *tertiary structures* that are remarkably similar for the α and non- α globins ([Fig. 241.1](#)).

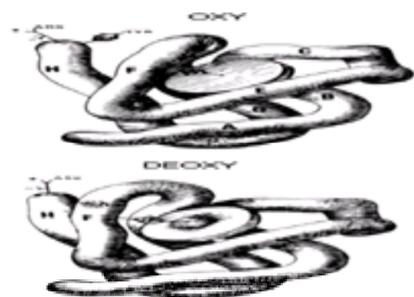

FIGURE 241.1. The helical and globular structure of the α -globin chain. Schematic shows the ways in which the folding of globin-chain amino acid sequences produces a hydrophobic pocket into which heme can be inserted. Iron atoms are maintained in an optimal configuration for reversible oxygen binding.

The exterior surface of the globin polypeptide chains are enriched in polar (hydrophilic) amino acids that enhance solubility. The interior is composed almost exclusively of nonpolar groups that form a cleft between the E and F helices into which the heme ring is deeply buried. This heme pocket is lined with hydrophobic groups that exclude water from the vicinity of the heme, allowing numerous noncovalent, hydrophobic, weak bonds to form and stabilize the interaction between heme and globin chains. A histidine in the F helix, called histidine F8, forms a strong covalent bond with the heme iron as a result of this configuration. These features are important for normal solubility and oxygen-binding properties of the hemoglobin molecule.

The *quaternary structure* of normal adult HbA has been characterized in considerable detail. The tetramer actually consists of two $\alpha\beta$ dimers. The two α chains in the complete tetramer do not interact directly with each other. Rather there are numerous tight interactions ($\alpha_1\beta_1$ contacts) between the α and β chains within each dimer. The two chains within each dimer interact at points that remain relatively fixed during the complex conformational changes that accompany binding and release of oxygen. The complete tetramer is held together by interfaces ($\alpha_1\beta_2$ contacts) between the α -like chain of one dimer and the non- α chain of the other dimer. These contact points undergo large shifts during binding and release of oxygen.

The conformational changes that occur during binding and release of oxygen have been studied extensively. It is sufficient to understand that the hydrophilic surface amino acids, the hydrophobic amino acids lining the heme pocket, the F8 histidine, and the amino acids that form the $\alpha_1\beta_1$ and $\alpha_1\beta_2$ contact points represent critical positions. Mutations in these strategic regions tend to be the ones that alter clinical behavior.

FUNCTION OF HEMOGLOBIN

Hemoglobin functions effectively as an oxygen carrier in humans because it can bind efficiently to oxygen at the P_{O_2} of the alveolar capillary bed, retain the bound oxygen as the red blood cells (RBCs) traverse the circulation, and unload this oxygen to the tissues at the modestly lower oxygen tensions of tissue capillary beds.

The ability of hemoglobin to fulfill the body's requirements for oxygen acquisition and delivery over a relatively narrow range of oxygen tensions results from a property inherent in the tetrameric arrangement of heme and globin subunits within the hemoglobin molecule. This property has been called *cooperativity* or *heme-heme interaction*.

The importance of heme-heme interaction in generating the normal oxygen dissociation curve of HbA is shown in [Fig. 241.2](#). Monomeric globin-like peptides, such as individual globin subunits or myoglobin, are useless as oxygen carriers. These proteins acquire oxygen readily but can release it only at low oxygen pressures that are incompatible with life. In contrast, the hemoglobin tetramer exhibits an S-shaped oxygen dissociation curve. At low oxygen tensions, the hemoglobin is fully deoxygenated. As the oxygen tension rises, increases in oxygen binding occur slowly at first. As soon as some oxygen has been bound by the hemoglobin molecule, there is an abrupt increase in the slope of the curve. This cooperative or autocatalytic mechanism causes hemoglobin molecules that have bound some oxygen to develop a higher oxygen affinity, greatly accelerating their ability to combine with more oxygen.

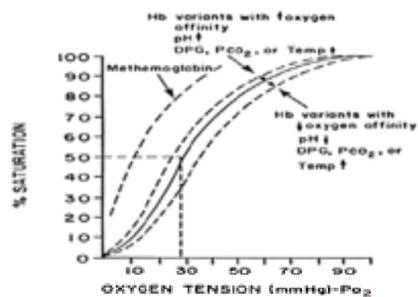

FIGURE 241.2. The oxygen dissociation curve of hemoglobin. Drawing shows the sigmoidal oxygen-binding curve of normal hemoglobin (*solid line*) and changes in dissociation that cause a shift to the left (increased oxygen affinity) or a shift to the right (decreased oxygen affinity), as indicated by the *dashed lines*. The far left shift, caused when hemoglobin is converted to methemoglobin, is indicated by an additional *dashed line*. The P_{50} value of the hemoglobin dissociation curve is used as an indication of oxygen affinity. The *right-angled dashed lines* indicate that the P_{50} value is measured as the partial pressure of oxygen at which a particular hemoglobin preparation is 50% saturated with oxygen.

The cooperative nature of oxygen binding has been extensively studied with x-ray crystallography. The complete deoxy form is stabilized by several strong salt bonds (electrostatic bonds), which must be broken before the first oxygen molecule can bind to heme. Because the transition to the oxyhemoglobin state requires breaking of these bonds, the first oxygen to bind to the hemoglobin molecule must overcome much resistance. After one oxygen molecule has bound, however, the bonds are broken. Oxygen affinity then approaches that of the individual subunits and causes a marked increase in the slope of the oxygen-binding curve. This results in the physiologically more useful S-shaped oxygen equilibrium curve, along which substantial amounts of oxygen loading and unloading can occur over a narrow range of oxygen tensions.

The oxygen affinity of normal hemoglobin is affected by several factors. The classic effect of pH on oxygen affinity is known as the Bohr effect. It is caused by the stabilizing action of protons on the deoxy conformation. Deoxyhemoglobin binds protons more readily than does oxyhemoglobin because it is a weaker acid. At low pH, hemoglobin has a lower oxygen affinity, facilitating delivery of oxygen to tissues.

Small molecules, called *allosteric effectors*, alter oxygen affinity of hemoglobin. The most important physiologic regulator of hemoglobin function in humans is 2,3-diphosphoglycerate (2,3-DPG). 2,3-DPG is generated as an intermediate of glycolysis in RBCs. Formation and destruction of this substance are enzymatically regulated and can be adjusted to changing physiologic conditions. Binding stabilizes the deoxy state. High levels of 2,3-DPG or other conditions that increase affinity for 2,3-DPG lower oxygen affinity. HbA has a reasonably high affinity for 2,3-DPG, and its affinity for oxygen can be affected by this molecule. In contrast, HbF, the main fetal hemoglobin, has little ability to bind 2,3-DPG. HbF tends to have higher oxygen affinity *in vivo* because of its failure to interact with 2,3-DPG.

For the purpose of understanding hemoglobinopathies, it is sufficient to know that the structure-function considerations outlined provide an exquisitely adaptive form of oxygen binding. Proper oxygen transport depends on the tetrameric structure of the proteins, proper arrangement of charged amino acids, and interaction with low-molecular-weight substances such as protons or 2,3-DPG.

DEVELOPMENTAL BIOLOGY OF HUMAN HEMOGLOBINS

Different types of hemoglobin predominate at different developmental stages. Hemoglobin synthesis begins at about the fifth to seventh week of gestation. RBCs first appear in yolk sac erythroblastic islands; these cells, called the *primitive cell line*, are large and nucleated. The predominant hemoglobins produced are Hb Portland ($\alpha_2\gamma_2$), Hb Gower I ($\alpha_2\varepsilon_2$), and Hb Gower II ($\alpha_2\varepsilon_2$). Embryonic hemoglobins have little clinical significance after birth.

Erythropoiesis shifts to the liver at 10 to 11 weeks of gestation, coincident with a transition from predominance of embryonic hemoglobins to predominance of fetal hemoglobin (HbF: $\alpha_2\gamma_2$). HbF is a heterogeneous mixture of two hemoglobins; they differ in the composition of the γ -chain component. The γ chains have alanine, and δ chains have glycine at position 136. Production shifts to bone marrow during the sixth to seventh month of gestation, but HbF continues to predominate until about 38 weeks of gestation, when a switch (HbF@HbA switch) to predominant synthesis of adult hemoglobin (HbA: $\alpha_2\beta_2$) occurs.

The regulation of hemoglobin switching remains incompletely understood. It is clear that the expression of the β -globin genes is regulated by three types of elements: promoters immediately upstream of the coding sequences, enhancers present within or downstream of the structural genes, and the series of hypersensitive sites far upstream from the β -globin gene that are referred to as the *locus control region* (LCR). Although the LCR is critical for the high level of expression of the different globin genes, the process of hemoglobin switching can take place in transgenic mice in the absence of LCR sequences. There is considerable evidence that hemoglobin switching is mediated by a variety of different processes such as stage-specific silencing, stage-specific activation mediated by transcription factors such as erythroid Kruppel-like factor (EKLF), and competition between the promoters of the different globin genes for *cis* interaction with the LCR. In spite of considerable advances that have led to the identification of many of the crucial elements necessary for appropriate hemoglobin switching, it is still not possible to reconstruct a complete mechanism that would explain all the intricacies of this highly regulated process.

HEMOGLOBIN F SYNTHESIS DURING POSTNATAL LIFE

The small amounts of HbF produced during postnatal life are confined to a small subpopulation of RBCs called F cells. The number of F cells produced and the HbF content of each F cell appear to be genetically determined. Although F cells express few other features of fetal cells, they seem to be distinct from true fetal RBCs.

F cells are produced by the complex kinetics of the erythroid pool of progenitor cells. Results from a number of laboratories have suggested that the most immature committed erythroid precursors (BFU-e) undergo a series of proliferative and differentiating cell divisions before they enter the pool of the more differentiated progenitors poised to become proerythroblasts. To a first approximation, the most immature or undifferentiated BFU-e retain the highest potential to express fetal hemoglobin in adults. Under normal conditions of erythropoiesis, these cells continue to proliferate slowly and to differentiate into more mature BFU-e before being recruited into the pool of maturing progenitors (CFU-e and proerythroblasts). By this time, they have largely lost their ability to produce fetal hemoglobin. Only a small number of early BFU-e are recruited into the maturing pool, accounting for the small number of F cells produced under normal conditions.

Under conditions of marked erythroid stress, such as chronic congenital hemolytic anemia or recovery from bone marrow transplantation or chemotherapy, many BFU-e are recruited into the maturing pool of progenitors before they have had the chance to undergo the differentiating cell divisions. These cells retain considerable potential to produce fetal hemoglobin, resulting in higher than normal levels of HbF in clinical conditions characterized by marked erythroid stress. The molecular mechanisms mediating these complex events remain obscure. Nonetheless, it is believed that this phenomenon may explain, at least in part, the increased levels of HbF among patients with sickle cell disease treated with hydroxyurea. The same is true of the activation of HbF production with injections of high doses of

recombinant erythropoietin. The expression of the fetal globin genes can be increased in postnatal life by treatment with agents such as butyrate, which can inhibit histone deacetylase and modify the structure of chromatin.

GENETICS AND BIOSYNTHESIS OF HUMAN HEMOGLOBIN

Production of the various human hemoglobins is controlled by two tightly linked gene clusters (Fig. 241.3). The α -like globin genes are clustered on chromosome 16 and the non- α genes on chromosome 11. The α -like cluster consists of two α -globin genes and a single copy of the ζ gene. The non- α gene cluster consists of a single ϵ gene, the ζ^G and ζ^A fetal globin genes, and the adult δ and β genes. Interspersed among the globin genes are pseudogenes that have been inactivated by mutations that prevent their expression.

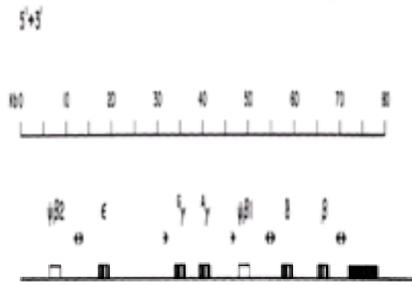

FIGURE 241.3. Structural organization of the non- α -globin gene cluster. Diagram shows the approximate topography of non- α -globin genes as they are arrayed along chromosome 11. The entire cluster is about 80 kb long. The gene loci are diagrammed as alternating patterns of introns and exons. *Open boxes* represent two pseudogenes, labeled yb1 and yb2. These are inactive remnants of globin genes that have become nonfunctional during evolution. The *arrows* pointing in the forward and reverse directions indicate repetitive sequence elements that are scattered throughout both globin gene clusters. The *large solid box* indicates a distinctive repetitive element downstream of the globin gene clusters. A strong enhancer that controls tissue-specific expression of the gene cluster is located within this region. The α -globin gene cluster has similar topography. A region about 10 kb upstream of the ϵ gene has been shown to promote maximal rates of globin gene expression.

In most respects, the functional anatomy of globin genes is typical of eukaryotic genes (Fig. 241.4). Each globin gene contains two intervening sequences (introns) interspersed among three blocks of sequence (exons) that ultimately code for messenger RNA. The non- α globin genes contain a small (130 bases) and a large (900 to 1,100 bases) intervening sequence. Both of the intervening sequences in the α - and ζ -globin genes are small (100 to 200 bases).

FIGURE 241.4. Anatomic features of the β -globin gene. Bar diagram shows the position of the anatomic features listed below each type of signal.

Flanking sequences at each end of the genes are important for regulating function of the genes. Immediately upstream (39 to 70 bp) are typical eukaryotic promoter elements necessary for the assembly of the transcription initiation complex, which includes RNA polymerase. Regions 100 to 300 bases upstream are important for proper developmental expression. The sequences in these regions are moderately well conserved among the globin gene clusters of several species. Sequences in the 5' flanking region of the γ genes and the β genes appear to be crucial for the correct developmental regulation of these genes. Important elements that function as classic enhancers have been identified in the 3' flanking regions of the β -globin gene. All these regulatory regions exist in erythroid cells in a relatively open chromatin configuration that is characterized by increased DNase sensitivity. The LCR more than 50 kilobases upstream of the β -globin gene consists of five sites characterized by a higher level of sensitivity to DNase and is called *HS1* to *HS5*. Deletion of some or all of these HS elements causes complete silencing of the β -globin gene and manifests as β - or $\delta\beta$ -thalassemia.

The regulatory DNA sequences within and upstream of the globin gene cluster are called *cis*-acting elements. They achieve their biologic effects through interaction with *trans*-acting factors, which are nuclear DNA binding proteins that bind specifically to these sequences, promoting or inhibiting transcription. Several transcription factors that bind to sequences in the globin gene promoters and enhancers have been identified. Some of these are ubiquitous transcription factors that are present both in erythroid and nonerythroid cells (e.g., Sp1 and YY1), whereas others are more or less limited to erythroid cells (e.g., GATA-1, NFE-2, and EKLF). These erythroid-specific factors appear to be involved in regulating the expression of other erythroid genes such as the genes that encode the enzymes of the heme biosynthetic pathway.

It is especially relevant to the discussion of the thalassemia syndromes to emphasize that the final product of the process, the hemoglobin tetramer, is highly soluble, whereas the individual globin chains are insoluble. To avoid precipitation and denaturation of monomeric globin chains, it is essential that α and non- α globins be synthesized in equal amounts. When globin chain synthesis is balanced, each newly synthesized α - or non- α -globin chain has an available mate with which to pair. The mechanisms responsible for maintaining the delicate balance between the expression of the α - and non- α -globin genes in normal RBCs is poorly understood. This delicate balance is disturbed when the α - or non- α -globin genes carry mutations that interfere with their expression. The pathophysiologic mechanism of the thalassemia syndromes involves imbalance of globin chain synthesis. The imbalance causes precipitation of unpaired chains and premature destruction of the RBCs.

The production of normal RBCs requires the coordinated expression of the globin genes and of all the genes responsible for heme and iron metabolism. Although it is clear that the genes that encode globin and the heme biosynthesis enzymes are regulated by shared erythroid-specific transcription factors, the mechanism responsible for the coordinated expression of these genes is still poorly understood. Disorders in which iron or the protoporphyrin component of heme are deficient generally cause secondary reduction in the level of globin synthesis. For complex reasons, a mild imbalance in globin chain synthesis also occurs; α -chain synthesis is more impaired by heme or iron deficiency than is β -chain synthesis. In other words, anemia characterized by deficiency of iron or heme tends to be mildly α -thalassemic. Because imbalances in this regulatory scheme occur frequently in a variety of conditions such as thalassemia, iron deficiency anemia, and disorders of heme biosynthesis, it can be inferred that the normal regulatory mechanisms are rather easily disrupted.

DETECTION AND CHARACTERIZATION OF HEMOGLOBINOPATHIES

Of the many methods available for hemoglobin analysis, two electrophoretic techniques are in routine clinical use. For routine or screening tests, most clinical laboratories perform electrophoresis at pH 8.6 on cellulose acetate membranes; this method is especially simple, inexpensive, and reliable. Agar gel electrophoresis at pH 6.1 in citrate buffer (citrate agar method) often is needed to detect the abnormal hemoglobins. Neither method can completely resolve all known hemoglobin variants. Comparison of results obtained from the same patient in each system usually allows the physician to diagnose most hemoglobinopathies unambiguously. The two electrophoretic methods should be regarded as complementary. In each case, the hemoglobins migrate toward the cathode. Cellulose acetate separations

STRUCTURALLY ABNORMAL HEMOGLOBINS

SICKLE CELL SYNDROMES

The sickle cell syndromes are caused by a mutation in the b-globin gene that changes the sixth amino acid from glutamic acid to valine. HbS ($\alpha_2\beta_2^{6\text{Glu}\rightarrow\text{Val}}$) exhibits normal behavior when oxygenated, but deoxy HbS polymerizes reversibly to form a gelatinous network of fibrous polymers called *tactoids*. These tactoids exert deleterious effects on the circulating RBCs, including stiffening of the membrane, increased viscosity, dehydration due to potassium leakage and calcium influx, and distortion of morphologic features that produces the sickle shape that characterizes these syndromes (Fig. 241.5). Sickle cells lose pliability and cannot traverse small capillaries. The altered membrane of sickled RBCs is sticky and adheres to endothelial cell walls with a tenacity that further impedes flow through the microvasculature.

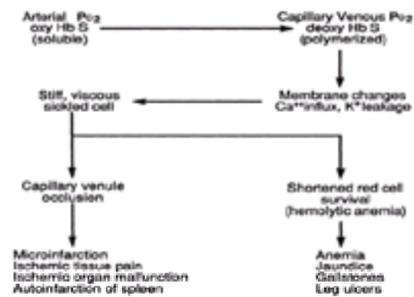

FIGURE 241.5. Pathophysiologic mechanism of sickle cell anemia. Diagram summarizes the pathogenesis of the two features of sickle cell disease—hemolytic anemia and vaso-occlusive crises.

Sickling has two main pathophysiologic consequences. First, the abnormal sickle cells are destroyed by the spleen, and hemolytic anemia occurs. The presence of anemia can be beneficial in sickle cell disease because it reduces total blood viscosity and improves blood flow to the periphery. Therefore the mere presence of anemia in sickle cell disease is not an indication for transfusion therapy. Second, the sickle cells clog small capillaries and venules. Tissue supplied by the occluded vessels becomes ischemic, provoking symptoms ranging from pain to end-organ damage. This veno-occlusive component of the disease usually dominates the clinical signs and symptoms. Prominent manifestations include ischemic pain (painful crises) and ischemic malfunction or frank infarction in the spleen, central nervous system, bones, liver, kidneys, and lungs. The finding that sickle RBCs adhere to the endothelium, particularly in acute vaso-occlusive crises, suggests that the adhesive mechanisms themselves may be targets for new therapies. Several sickle syndromes occur as the result of inheritance of HbS from one parent and another hemoglobinopathy, such as b-thalassemia or HbC ($\alpha_2\beta_2^{6\text{Glu}\rightarrow\text{Lys}}$) from the other parent. The prototype disease, sickle cell anemia, is the homozygous state for HbS. The sickling syndromes are considered in [Chapter 245](#) and are not discussed further here.

UNSTABLE HEMOGLOBINS

Unstable hemoglobins are produced by an amino acid substitution that renders the hemoglobin less soluble or more susceptible to oxidation. Both a- and b-globin variants can cause this condition. The mutations that produce insoluble hemoglobins tend to alter the helical segments, such as Hb Genova ($\beta^{28\text{Leu}\rightarrow\text{Pro}}$), to interfere with contact points between the a and b subunits, such as Hb Philly ($\beta^{35\text{Tyr}\rightarrow\text{Phe}}$), or to disrupt interactions of the hydrophobic pockets of the globin subunits with heme, such as Hb Köln ($\beta^{98\text{Val}\rightarrow\text{Met}}$).

Precipitation of hemoglobin in circulating RBCs produces intracellular inclusions called *Heinz bodies*, which are readily detectable with supravital dyes such as crystal violet. This method is the basis of a diagnostic test for Heinz body hemolytic anemia. The spleen attempts to remove these inclusions, and pitted, rigid cells form that eventually become sequestered and produce hemolytic anemia. Patients with severe forms of this anemia need long-term transfusion support. Splenectomy often is effective for relief of anemia. Leg ulcers and premature gallbladder disease occur frequently.

Unstable hemoglobins are rare compared with sickle cell anemia and thalassemia. They occur sporadically in many ethnic groups, often by means of spontaneous new mutations. The heterozygous state often is symptomatic, because large numbers of Heinz bodies form even when the unstable variant accounts for only one-half of the total hemoglobin. Most of the symptomatic unstable hemoglobins are b-globin variants, because sporadic mutations affecting the a-globin loci would usually involve only one of the four alleles, generating only 20% to 30% abnormal hemoglobin. The propensity of unstable hemoglobins to precipitate is exaggerated with oxidative stress, such as infection or exposure to oxidizing drugs such as quinine.

HEMOGLOBINS WITH ALTERED OXYGEN AFFINITY

High-affinity hemoglobins, such as Hb Zurich ($\beta^{\text{His}\rightarrow\text{Arg}}$), have high avidity for oxygen, causing the oxygen dissociation curve to shift to the left. These hemoglobins bind oxygen readily but are not likely to deliver the oxygen to tissues at normal capillary oxygen pressures. The resultant mild tissue hypoxia leads to inappropriately high RBC production and polycythemia. In extreme cases, hematocrits of 60% to 65% can occur. High-affinity variants are caused by several forms of mutations that alter interactions within the heme pocket, disrupt the Bohr effect or salt-bond site, or impair the interaction of HbA with 2,3-DPG. Because 2,3-DPG lowers the oxygen affinity of HbA, reduced 2,3 DPG-binding causes an effective increase in oxygen affinity. The presence of high-affinity hemoglobins should be considered in the case of patients with unexplained erythrocytosis. In some cases, the elevated hematocrit can increase blood viscosity and produce hyperviscosity symptoms. Phlebotomy is then needed.

Low-affinity hemoglobins, such as Hb Kansas ($\beta^{102\text{Asn}\rightarrow\text{Thr}}$), usually produce misleading laboratory abnormalities and physical findings but no symptoms. These hemoglobin variants bind sufficient oxygen in the lungs despite their lower oxygen affinity to achieve full saturation; however, at capillary oxygen tensions, they release excessive amounts of oxygen. These patients can deliver normal amounts of oxygen at hematocrits that indicate anemia and can have pseudoanemia. Capillary hemoglobin desaturation can be sufficiently dramatic that more than 5 g per deciliter of unsaturated hemoglobin is present in the vascular beds, producing clinically apparent cyanosis. Despite these findings, patients usually need no specific treatment.

METHEMOGLOBINEMIA

Methemoglobin is generated by oxidation of the iron moieties to the ferric state. Methemoglobin has such high oxygen affinity that almost no oxygen is delivered to tissues. Methemoglobin levels greater than 50% to 60% of total hemoglobin produce fatal tissue hypoxia. Methemoglobin also has a characteristic bluish-brown muddy color that causes patients to appear cyanotic.

Congenital methemoglobinemia is caused by mutations that interact with the heme pocket to favor stabilization of iron in the ferric state, such as HbM Iwate ($\alpha^{87\text{His}\rightarrow\text{Tyr}}$), or by inherited deficiency of the enzyme that reduces methemoglobin to hemoglobin, such as methemoglobin reductase, nicotinamide adenine dinucleotide phosphate (NADP), or diaphorase. Acquired methemoglobinemia is caused by exposure to toxins that oxidize heme iron, notably nitrate and nitrite-containing compounds. Patients with congenital methemoglobinemia rarely need treatment. Patients with nitrate or nitrite poisoning, if sufficiently severe, need therapy with ascorbic acid and methylene blue.

TREATMENT OF PATIENTS WITH UNSTABLE HEMOGLOBINS, HIGH-AFFINITY HEMOGLOBINS, AND METHEMOGLOBINEMIA

Diagnosis of the presence of an *unstable hemoglobin variant* should be suspected when a patient has nonimmune hemolytic anemia, jaundice, splenomegaly, or premature biliary tract disease. Unstable hemoglobins, like other congenital hemolytic states, are part of the differential diagnosis of neonatal jaundice. Most cases of

hemolytic anemia due to the presence of unstable hemoglobins are detected during infancy. Some mildly unstable variants may become manifest in adult life with mild to moderate anemia or only with unexplained reticulocytosis, hepatosplenomegaly, premature biliary tract disease, or leg ulcers. Because these variants frequently are caused by spontaneous mutation, a family history of anemia may not exist. A peripheral blood smear often shows anisocytosis, abundant cells with punctate inclusions, and irregular shapes (poikilocytosis).

The two best tests for diagnosing unstable hemoglobins are the Heinz body preparation and the isopropanol or heat stability test. The latter test is used to assess the ability of hemoglobin to remain in solution when heated or exposed to a mildly nonpolar solvent. Many unstable Hb variants are not detected with electrophoresis; they migrate in a position indistinguishable from that of HbA. The result of electrophoresis often is normal. The test is useful for confirmation but not as a ruling-out strategy.

Young children with severe hemolytic anemia caused by the presence of unstable hemoglobins may need transfusions for the first 3 years of life, because splenectomy before 3 to 4 years of age is associated with immune deficit. Splenectomy is the therapy of choice thereafter. Most patients have marked improvement. Rare patients may need lifelong transfusion support. Even after splenectomy, patients should be observed for signs of cholelithiasis and leg ulcers. Splenectomy should be considered in the care of patients with the secondary complications of chronic hemolysis, even if anemia is absent.

Many unstable hemoglobins precipitate more rapidly when subjected to oxidative stress. Principles of management that apply to glucose-6-phosphate dehydrogenase deficiency are applicable to the care of patients with unstable hemoglobins, even after splenectomy.

The presence of *high-affinity hemoglobin variants* should be suspected when a patient has unexplained erythrocytosis. The best test for confirmation is measurement of P_{50} . A significant left shift (lower numeric value of the P_{50}) suggests the possibility of the presence of high-affinity hemoglobin. The most important confounding variable is tobacco smoking. Carbonmonoxy-hemoglobin level frequently is elevated in heavy smokers and causes the P_{50} to fall.

Many high-affinity hemoglobins produce no symptoms, but rubor or plethora may be apparent. When the hematocrit exceeds 55% to 60%, headache or other symptoms of high blood viscosity and sluggish flow may occur. These patients may benefit from judicious phlebotomy. The guiding principle of phlebotomy should be to improve oxygen delivery by reducing blood viscosity and increasing blood flow. Erythrocytosis represents an appropriate attempt to compensate for the impaired oxygen delivery of the abnormal variant. Overzealous phlebotomy may stimulate increased erythropoiesis or aggravate symptoms by thwarting this compensatory mechanism. Phlebotomy should be directed at improvement of symptoms and viscosity, not at restoration of a normal hematocrit.

The presence of *low-affinity hemoglobins* should be suspected when a patient has cyanosis or a low hematocrit for no reason that is apparent after thorough evaluation. The P_{50} test can confirm the diagnosis. Awareness of the diagnosis, counseling, and reassurance are the interventions of choice.

The presence of *methemoglobin* should be suspected when a patient appears cyanotic but has a PaO_2 sufficiently high that hemoglobin should be fully saturated with oxygen. It may not be possible to ascertain whether a patient has ingested nitrite or another oxidant; some exposures may be inapparent to the patient, and others may be caused by suicide attempts. Methemoglobin gives a characteristic muddy appearance when blood is drawn. The test of choice to establish the diagnosis is measurement of methemoglobin content, which can readily be performed on an emergency basis in most clinical laboratories.

Congenital methemoglobinemia almost never necessitates therapy. Acquired methemoglobinemia may be associated with symptoms of cerebral ischemia if levels exceed 15% to 20%. Levels greater than 60% usually are lethal. Emergency therapy for methemoglobinemia involves intravenous injection of 1 mg per kilogram of methylene blue. Management of milder cases and follow-up therapy for severe cases can be achieved with oral methylene blue (60 mg three to four times a day) or ascorbic acid (300 to 600 mg a day). Methylene blue can induce hemolysis in patients with glucose-6-phosphate dehydrogenase deficiency.

THALASSEMIA SYNDROMES

The thalassemia syndromes are inherited disorders of α - or β -globin chain biosynthesis. There are two major consequences of reduced synthesis of a specific globin chain. First, the reduced supply of globin diminishes production of hemoglobin tetramers, causing hypochromia and microcytosis. Second, unbalanced synthesis of α and β subunits occurs because impaired synthesis of one chain is not associated with comparable reductions in synthesis of the other globin. Unpaired globin chains accumulate: α chains in β -thalassemia and β chains in α -thalassemia. The pathophysiologic process of thalassemia is dominated by the behavior of these unpaired chains. Clinical severity varies widely depending on the degree to which the synthesis of the affected globin is impaired and on modifying factors, such as altered synthesis of other globin chains or coinheritance of other abnormal globin alleles.

β -THALASSEMIA SYNDROMES

β -Thalassemia may be caused by mutations that affect every step in the pathway of globin gene expression: transcription, processing of the mRNA precursor, translation, and posttranslational integrity of the β -polypeptide chain (Fig. 241.6). Complete deletion of the β -globin gene alone has not been encountered, but complex deletions removing two or more non- α genes and partial deletion of the β -globin gene do account for rare cases. Other mutations alter promoter regions, polyadenylation signals, the translation initiator codon, and other steps in the synthetic pathway. The most common forms of β -thalassemia are caused by mutations that impair splicing of the mRNA precursor into mature mRNA in the nucleus or prevent translation of the mRNA in the cytoplasm.

FIGURE 241.6. β -Thalassemia may be caused by mutations that affect every step in the pathway of β -globin gene expression: transcription, processing of the mRNA precursor, translation, and posttranslational integrity of the β -polypeptide chain. *Circled numerals* at various positions of the gene diagram at the top indicate the positions within the gene at which structural lesions are located. The lesions, numbered 1 through 11 down the left side, show the fine structure of these mutations.

Other less common but informative thalassemia mutations have been described. The patient may have a severe β -thalassemia phenotype, but the β -globin gene and its promoters are present and have entirely normal nucleotide sequences. This thalassemia phenotype may be caused by deletion of the LCR sequences needed for high levels of expression in developing RBCs. These LCR sequences are located thousands of bases upstream from the ϵ -globin gene of the β -globin gene cluster.

In each β -thalassemia syndrome, inadequate amounts of hemoglobin tetramers are produced because the supply of β globin is reduced. Hypochromia and microcytosis result. Among heterozygotes (β -thalassemia trait), this is the only abnormality, and the anemia is minimal. Unbalanced α - and β -globin accumulation also occurs. Excess α -globin chains accumulate because the α -globin genes continue to be expressed at a normal level. These α -globin chains are highly insoluble. They precipitate in early erythroblast precursors of homozygotes, forming inclusion bodies that exert toxic effects, killing most erythroblast precursors in the marrow. Massive ineffective erythropoiesis results. Few of the proerythroblasts beginning erythroid maturation in the bone marrow survive. The occasional RBC that survives and makes it out of the bone marrow bears a burden of inclusion bodies. These cells are sequestered in the spleen. The RBC life span is shortened, producing severe hemolytic anemia.

These factors combined produce profound deficits in the oxygen-carrying capacity of the blood. Erythropoietin is produced in an attempt to stimulate compensatory

erythroid hyperplasia, but the marrow response is sabotaged by the inclusion body–mediated ineffective erythropoiesis. Profound anemia persists despite massive bone marrow expansion, driving erythroid hyperplasia to still higher levels and becoming so exuberant in some cases that masses of extramedullary erythropoietic tissue form in the abdomen or pelvis.

Massive bone marrow expansion has adverse effects on growth and development. Children with thalassemia have characteristic chipmunk facies owing to maxillary marrow hyperplasia and frontal bossing. Thinning and pathologic fracture of the long bones and vertebrae caused by cortical invasion by erythroid elements and profound growth retardation and endocrine deficiencies are common. Hemolytic anemia causes hepatosplenomegaly and high-output congestive heart failure. The metabolic drain caused by the conscription of so many caloric resources for erythroid hyperplasia leads to inanition, susceptibility to infection, and in the most severe cases, death during the first 20 years of life. Treatment with RBC transfusions sufficient to maintain a hematocrit of more than 30% improves oxygen delivery, suppresses the excessive ineffective erythropoiesis, and prolongs life. Without aggressive iron chelation therapy, complications of chronic transfusion therapy, notably iron overload, usually prove fatal before the age of 30 years.

The severity of b-thalassemia varies markedly among patients. Many factors contribute to this clinical heterogeneity. Individual alleles vary with respect to severity of the biosynthetic lesion. Other modulating factors ameliorate the burden of unpaired a-globin inclusion bodies. Coinheritance of the a-thalassemia trait reduces clinical severity by restricting production of excess a-globin. High levels of fetal hemoglobin expression persist to various degrees in b-thalassemia. g-Globin gene expression supplies g chains as a substitute for b chains, simultaneously generating more functional hemoglobin and reducing the a-globin inclusion burden. This marked clinical heterogeneity has led to adoption of the terms *b-thalassemia major* and *b-thalassemia intermedia*. Patients with b-thalassemia major need intensive transfusion support to survive. Patients with b-thalassemia intermedia have somewhat milder clinical complications and can survive without transfusion. *b-Thalassemia minor* is the term sometimes used to describe asymptomatic b-thalassemia among heterozygotes (b-thalassemia trait).

a-THALASSEMIA SYNDROMES

The four classic types of a-thalassemia are a-thalassemia-2 trait, in which one of the four a-globin genes fails to function; a-thalassemia-1 trait, with two dysfunctional genes; HbH disease, with three genes affected; and hydrops fetalis with Hb Bart's with all four genes defective. These syndromes usually are caused by deletion, respectively, of one, two, three, or all four of the a genes (Fig. 241.7). Deletions of a-globin genes are much more common than deletions of b-globin genes because duplication of the a-globin genes on chromosome 16 causes a marked increase in the risk of homologous recombination. Nondeletion forms of a-thalassemia have been described. They are caused by mutations similar to those described for b-thalassemia.

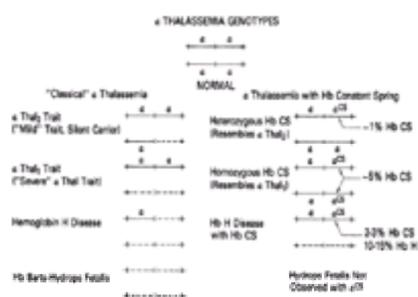

FIGURE 241.7. Classic forms of a-thalassemia with and without the Hb Constant Spring type of hemoglobin. *Top*, Normal duplicated a-globin genes (four gene loci per diploid cell). *Left*, The four classic forms of a-thalassemia that produced through deletion of one, two, three, or all four loci. *Right*, a-Thalassemia syndromes caused by Hb Constant Spring.

a-Thalassemia-2 trait is an asymptomatic, silent carrier state produced through deletion or dysfunction of a single a-globin gene. a-Thalassemia-1 trait is caused by deletion or dysfunction of two a-globin genes. Offspring from one person with a-thalassemia-2 trait and another with a-thalassemia-1 trait can have a form of thalassemia more severe than that caused by either trait alone, called *HbH disease*. In Asian and Mediterranean populations, a deletion that removes both genes from the same chromosome (*cis*-deletion) is common, as is homozygosity for a-thalassemia-2 (*trans*-deletion). Both produce asymptomatic hypochromia and microcytosis.

HbH disease usually is caused by coinheritance of the *cis*-a-thalassemia-1 deletion and a-thalassemia-2 trait. HbA production is only 25% to 30% of normal; unpaired g chains accumulate during gestation, and unpaired b chains accumulate during adult life. The unpaired b-globin chains are somewhat more soluble than the a-globin chains that accumulate in b-thalassemia, forming recognizable b₄-tetramers called HbH. HbH forms very few inclusions in erythroblasts; rather, it precipitates from circulating RBCs. Patients with HbH disease usually have the clinical signs and symptoms of thalassemia intermedia characterized by a moderately severe hemolytic anemia with relatively mild ineffective erythropoiesis. Patients with HbH disease often survive into adult life and usually are not dependent on blood transfusions.

Hydrops fetalis with Hb Bart's is caused by total absence of a-globin synthesis caused by the homozygous state for the a-thalassemia-1 *cis*-deletion. No physiologically useful hemoglobin is produced beyond the embryonic stage. Free g globin accumulates, forming tetramers called *Hb Bart's*. Hb Bart's has an extraordinarily high oxygen affinity, comparable with that of myoglobin. It binds oxygen delivered to the placenta but delivers almost none of it to fetal tissues. Severe anemia and asphyxia occur at the tissue level, causing profound edema (hydrops), congestive heart failure, and death in utero. Advances in prenatal diagnosis and the early institution of intrauterine blood transfusions have allowed a small number of live births. Unfortunately, most of the infants have permanent damage to the central nervous system.

a-Thalassemia-2 trait is common among people of African descent, with a gene frequency of 15% to 30% in some populations. The *cis*-a-thalassemia-1 deletion almost never occurs, however. Although a-thalassemia-2 and the *trans* form of a-thalassemia-1 are common, HbH disease and hydrops fetalis are almost never encountered among blacks.

THALASSEMIC STRUCTURAL VARIANTS

Thalassemic structural variants are abnormal hemoglobins characterized by a biosynthetic defect and abnormal structure. The few examples considered herein are either particularly instructive examples or are clinically relevant because they are common.

Hemoglobin Lepore

Hb Lepore— $\alpha_2(\text{db})_2$ —is the prototype of a group of hemoglobinopathies characterized by fused globin chains. These hemoglobinopathies are caused by unequal crossover and recombination events that fuse the proximal end of one gene with the distal end of a closely linked gene downstream. During meiosis, mispairing and crossover of the highly homologous d and b genes can occur, resulting in a Lepore chromosome that contains only the fused db gene and an anti-Lepore chromosome that contains the reciprocal fusion product (bd) and intact b- and d-globin genes.

Lepore globin is synthesized in small amounts because the fusion gene is under the control of the d-globin promoter, which normally sustains transcription at only 2% to 5% the level of the b-globin promoter. Because there are no other b-like globin genes on this chromosome, patients with Hb Lepore have the phenotype of b-thalassemia, differentiated by the added presence of 2% to 10% Hb Lepore and slightly increased levels of HbF in the 3% to 5% range. Anti-Lepore globin is not associated with thalassemia because of the presence of an intact b-globin gene on the same chromosome. Heterozygotes for Hb Lepore have the clinical phenotype of b-thalassemia trait; homozygotes behave as patients with homozygous b-thalassemia. Compound heterozygotes for Hb Lepore and a classic b-thalassemia allele also can have severe thalassemia. The presence of Hb Lepore should be suspected when a person with hypochromic microcytic RBCs also produces an abnormal hemoglobin that migrates in the position of HbS on routine electrophoretic gels.

Hemoglobin E

HbE ($\alpha_2\beta_2^{26\text{Glu}\rightarrow\text{Lys}}$) is extremely common in Cambodia, Thailand, and Vietnam. Heterozygotes resemble persons with mild b-thalassemia trait. Homozygotes have somewhat more marked abnormalities but no symptoms. Compound heterozygotes for HbE and a b-thalassemia gene can have b-thalassemia intermedia or b-thalassemia major, depending on the severity of the coinherited thalassemic gene. HbE is mildly unstable, but this instability by itself is insufficient to greatly affect the life span of RBCs. The high frequency of the presence of HbE gene may be a result of the thalassemia phenotype associated with its inheritance.

The only nucleotide sequence abnormality found in the β^E gene is the base change in codon 26 that causes the amino acid substitution. This mutation occurs at a cryptic RNA splice site. It alters the consensus sequence surrounding a potential GT donor splice site, activating the site. Alternate splicing at this position occurs 40% to 50% of the time, generating a structurally abnormal globin mRNA that cannot be translated. The 40% to 50% of mRNA precursors spliced at the normal sites generate functional mRNA that is translated into β^E globin because the mature mRNA carries the base change that alters codon 26.

HbE is important because it is so common in Southeast Asian populations. However, the prevalence of this gene in some parts of the United States has increased markedly with the increase in migration of Asians to the United States. For example, HbE has become the most common mutant hemoglobin detected in California. Genetic counseling of persons at risk should be directed at avoidance of the interaction between HbE and b-thalassemia, rather than HbE homozygosity. HbE is an instructive example of the pleiotropic mechanisms by which single mutations can give rise to a genetic disease.

HEREDITARY PERSISTENCE OF FETAL HEMOGLOBIN

The term *hereditary persistence of fetal hemoglobin* (HPFH) refers to a group of rare disorders characterized by continued synthesis of high levels of HbF in adult life. Patients have no deleterious effects, even when all the hemoglobin produced is HbF. These patients demonstrate convincingly that prevention or reversal of the fetal to adult hemoglobin switch would provide efficacious therapy for sickle cell anemia and b-thalassemia. Two main types of HPFH have been described. *Pancellular HPFH* is characterized by high levels of fetal hemoglobin synthesis and uniform distribution of HbF among all RBCs. *Heterocellular HPFH* is caused by inherited increases in the number of F cells.

Pancellular HPFH is divisible into two classes. The *deletion* forms are caused by large (80- to 100-kb) deletions within the b-globin gene cluster that appear to bring potent enhancer sequences into the proximity of the g-globin genes, promoting their high expression. In *nondeletion* HPFH, single-base changes occur in the proximal promoter regions of the affected g-globin gene, resulting in overexpression in adult life.

Most cases of heterocellular HPFH appear to be caused by mutations outside the b-globin gene cluster on chromosome 11. In some families, HbF is elevated only when factors that produce erythroid stress, such as sickle cell anemia, are present. The latter mechanism appears to account for the high levels of fetal hemoglobin in areas such as the eastern provinces of Saudi Arabia, where sickle cell disease is phenotypically very mild.

ACQUIRED HEMOGLOBINOPATHIES

The two most important acquired hemoglobinopathies are carbon monoxide poisoning and methemoglobinemia. Abnormalities of hemoglobin biosynthesis have been described in blood dyscrasias. An elevated HbF occasionally accompanies proliferation of an abnormal clone in myelodysplastic syndromes. Some patients with erythroleukemia and myeloproliferative disorders may have a mild form of HbH disease. The abnormalities frequently are restricted to one or a few clones of abnormal RBCs and are not severe enough to alter the course of the underlying disease.

MANAGEMENT OF THALASSEMIA

The diagnosis of b-thalassemia major usually is apparent during infancy and childhood. Severe anemia is accompanied by the characteristic signs of massive ineffective erythropoiesis with hepatosplenomegaly, profound microcytosis, characteristic results of a blood smear, and elevated levels of HbF, HbA₂, or both. These children should be cared for in consultation with a hematologist. Most need long-term transfusion therapy. Hypertransfusion should be directed at maintenance of a hematocrit greater than 27% to 30% so that erythropoiesis is suppressed. Splenectomy often is needed; it usually is performed if the annual transfusion requirement, expressed as volume of RBCs per kilogram of body weight, increases more than 50%. In most other respects, management is largely supportive. Folic acid supplements may be useful. Vaccination with Pneumovax in anticipation of eventual splenectomy is advised, as is close monitoring for infection, leg ulcers, and biliary tract disease. Early endocrine evaluation for glucose intolerance, thyroid dysfunction, and delayed onset of puberty or secondary sexual characteristics is indicated. Many patients have endocrine deficiencies as a result of iron overload.

Patients with b-thalassemia intermedia have the same signs and symptoms as those with b-thalassemia major but can survive without long-term transfusion. Management is particularly challenging because a number of factors can aggravate the anemia, including infection, onset of puberty, and development of splenomegaly and hypersplenism. Some patients benefit from splenectomy. The expanded erythron can cause absorption of excessive dietary iron and hemosiderosis, even without transfusion.

b-Thalassemia minor (thalassemia trait) usually is asymptomatic. The hallmark is profound microcytosis with only minimal or mild anemia. Mean corpuscular volume is rarely greater than 75 fL; hematocrit rarely is less than 30% to 33%. Hemoglobin electrophoresis classically reveals an elevated HbA₂ level (3.5% to 7.5%), but HbF, rather than HbA₂, may be elevated if the patient has db-thalassemia. The peripheral blood smear shows hypochromia and microcytic RBCs with many target cells. Reassurance, genetic counseling, and patient education usually are all that is needed. Patients with b-thalassemia trait should be alerted to the fact that their blood profile resembles that of iron deficiency and can be misdiagnosed. They should eschew routine use of iron. Iron deficiency can develop as among other persons, however, such as during pregnancy or from chronic bleeding. These patients should not be given the impression that iron is never appropriate.

The RBCs of persons with a-thalassemia trait are hypochromic, but the patients usually do not have anemia. HbA₂ and HbF levels are normal. The patients usually need only genetic counseling. Hydrops fetalis rarely is associated with survival beyond the perinatal period. HbH disease resembles b-thalassemia intermedia with the added complication that the HbH molecule behaves as a moderately unstable hemoglobin. Patients with HbH disease should undergo splenectomy if excessive anemia or a transfusion requirement develops. Oxidative drugs should be avoided. In severe cases of HbH disease, iron overload and death may happen in early adulthood.

Antenatal diagnosis of thalassemia syndromes is readily available, even though the techniques are used in clinical practice at only a few centers throughout the world. The best tests involve direct analysis of genes for specific mutations that predominate in a given area. Molecular epidemiologic studies have allowed investigators to identify the five to seven mutations that usually account for 90% to 99% of patients at risk in a given geographic area. These methods have dramatically reduced the incidence of homozygous thalassemia births in Greece, Sardinia, Cyprus, and parts of Italy. DNA diagnosis is based on polymerase chain reaction amplification of fetal DNA obtained through amniocentesis or chorionic villus biopsy followed by hybridization to allele-specific oligonucleotide probes. The probes can be designed to detect simultaneously the subset of mutations that account for 95% to 99% of the instances of b-thalassemia that occur in a particular ethnic group.

STRATEGIES FOR OPTIMAL CARE

The management of specific hemoglobinopathies is described earlier. A few important situations or new approaches to these disorders are as follows.

MANAGEMENT OF TRANSFUSIONAL HEMOSIDEROSIS

Long-term blood transfusion is associated with many untoward complications: blood-borne infection, alloimmunization, and iron overload. Iron overload can be lethal to patients undergoing long-term transfusion. Thalassemia and other forms of anemia associated with accelerated erythropoiesis predispose patients to more rapid development of iron overload than situations in which the erythron is not expanded, such as aplastic anemia and pure RBC aplasia. The expanded erythron provokes excessive absorption of dietary iron, exacerbating the hemosiderosis.

Healthy persons need 1 to 2 mg elemental iron each day, an amount readily delivered in most diets. A unit of packed RBCs contains 250 to 300 mg iron (1 mg per

milliliter), and a single transfusion of two units of packed RBCs is about equal to a 1- to 2-year intake of iron. There are no mechanisms for increasing the excretion of iron beyond normal daily losses. Iron rapidly accumulates in patients undergoing long-term transfusion therapy.

Transfused iron is at first safely sequestered in the form of ferritin and hemosiderin, but patients who receive more than 100 units of packed RBCs usually have symptoms of iron overload, such as endocrine dysfunction, glucose intolerance, delayed puberty, cirrhosis of the liver, and cardiomyopathy. The diagnosis is made by means of assessment of ferritin level or liver biopsy, which shows parenchymal and reticuloendothelial iron. There are other accurate and noninvasive methods for assessing iron in the liver, such as use of a superconducting quantum-interference device (SQUID). However, such instruments are not widely available around the world. Cardiac toxicity includes early development of pericarditis and later dysrhythmia and pump failure. The onset of clinically apparent pump failure is an ominous finding, often presaging death within a year.

Therapy for iron overload is largely ineffective after symptoms have become apparent. It is essential to anticipate the need for long-term transfusion support and to institute therapy with iron-chelating agents relatively early in life. The only approved and available iron chelator is deferoxamine mesylate (Desferal). This drug is extremely expensive, however, and poorly absorbed from the gastrointestinal tract. Its iron-binding kinetics are such that chronic, slow, subcutaneous infusion of the drug is necessary. In effect, patients benefit most from iron chelation therapy if a chelator is present most of the time in the bloodstream. The constant presence of the drug improves the efficiency of chelation and protects tissues from occasional releases of the most toxic fraction of iron—low-molecular-weight iron—which may not be sequestered by protective proteins.

Oral iron-chelating agents such as deferiprone have shown considerable promise in early clinical trials. However, long-term trials have raised some doubts about the efficacy and safety of these drugs. Thus the role of these new agents in the management of iron overload in thalassemia remains to be determined. The only currently established method for iron chelation, however, is long-term subcutaneous infusion of deferoxamine mesylate through a metered pump. Patients vary greatly in their ability to excrete iron when treated with deferoxamine mesylate. Candidates should first be given a test dose, and iron excretion in the urine should be monitored for 24 hours. Long-term therapy varies greatly with respect to dose and scheduling of pumping time among different medical centers. Specific recommendations cannot be provided herein. Patients should be treated in consultation with a center that has expertise in this area.

Long-term use of high doses of deferoxamine mesylate is occasionally associated with the development of cataracts and deafness. Local skin reactions, including urticaria, are common, but there are few other acute side effects. Skin reactions usually can be managed with antihistamines. Intensive iron chelation therapy is effective in the sense that negative iron balance can be achieved, even in the face of a high transfusion requirement. However, restoration of iron balance does not ensure prevention of long-term morbidity and mortality among patients undergoing long-term transfusion therapy. Patients with β -thalassemia major appear to have a significant survival advantage when therapy is started before 5 to 8 years of age. Irreversible end-organ damage may start at relatively modest levels of iron overload, even if symptoms do not appear for many years thereafter. Most experts recommend institution of therapy early in the course of a long-term transfusion regimen because it seems clear that iron toxicity can begin even at early stages.

EXPERIMENTAL THERAPIES FOR HEMOGLOBINOPATHY

Several new approaches to definitive treatment of hemoglobinopathy are being actively investigated. These include bone marrow transplantation, gene therapy, and pharmacologic induction of HbF synthesis. Bone marrow transplantation has been used to treat a large number of patients with β -thalassemia and a small number of patients with sickle cell anemia. Bone marrow transplantation replaces the patient's stem cells with cells capable of producing adequate amounts of normal hemoglobin. The outcome is excellent when the procedure is performed early in the course of disease before end-organ damage occurs. Cure is achieved among more than 90% of patients. When the procedure is performed in centers with considerable experience in bone marrow transplantation, the mortality is less than 10%. Even a low mortality such as this is difficult to accept, however, in the care of patients with nonmalignant disorders when survival into adult life is possible with conventional therapy.

Gene therapy in which a normal β - or γ -globin gene is inserted into the genome of the patient's own hematopoietic stem cells is another therapeutic modality that might provide cures for patients with hemoglobin disorders. Although the human β -globin gene was one of the first human genes used in retroviral gene transfer experiments, application of this new technology to gene therapy for thalassemia and sickle cell disease has been exceptionally difficult. The earlier generations of globin retroviral vectors suffered from genetic instability and low titers and gave rise to low-level expression of the transferred β -globin gene in transduced erythroid cells. The efficiency of gene transfer into nondividing hematopoietic stem cells was disappointingly low. Several groups of investigators have solved the problems of genetic instability, low titers, and low-level expression in transduced cells. However, the problem of low efficiency of retrovirus-mediated gene transfer into nondividing hematopoietic stem cells has remained intractable. The development of lentivirus-type vectors that can transduce nondividing cells offers considerable hope for solving the problem of low efficiency of gene transfer into hematopoietic stem cells. Once this is achieved, gene therapy should become a therapeutic option for patients with hemoglobin disorders.

Patients with β -chain hemoglobinopathy could be effectively treated by means of reestablishment of high levels of fetal hemoglobin synthesis. The clinical well-being of patients with hereditary persistence of fetal hemoglobin validates this strategy. Initial attempts to stimulate HbF synthesis were based on the fact that the γ -globin genes were found to be heavily methylated in adult erythroid cells. Methylation of the GC base pairs in 5' regions of genes has been known for some time to correlate with inactivation of expression of many genes. In experimental systems and in laboratory animals, administration of 5'-azacitidine, a drug that inhibits methylation of genes, was shown to markedly stimulate HbF synthesis. A short-term clinical trial with this agent to treat patients with thalassemia had the same effect. One patient needed no transfusions during the short course of the study. Unfortunately, 5'-azacitidine is too toxic and carcinogenic for wide use, especially in the care of children.

The augmentation of fetal hemoglobin synthesis obtained with 5'-azacitidine could be replicated by other chemotherapeutic agents such as hydroxyurea, which does not have any DNA-hypomethylating activity. Cytotoxic agents such as hydroxyurea and cytarabine promote high levels of HbF synthesis by means of stimulating proliferation of the primitive HbF-potent progenitor cell population (F-cell progenitors), accounting for increased levels of fetal hemoglobin. The mechanisms by which these events occur remain mysterious. In a randomized, placebo-controlled, multicenter clinical trial, the use of hydroxyurea led to a decrease in the incidence of the two most common complications of sickle cell disease (vaso-occlusive crises and acute chest syndrome). Although hydroxyurea has also shown some HbF-inducing activity in patients with β -thalassemia, no dose regimen has been identified yet that corrects the anemia and ameliorates the clinical manifestations of the disease. In spite of encouraging results of therapy for sickle cell disease with hydroxyurea, there are some lingering concerns about long-term toxicity of a DNA-damaging agent such as hydroxyurea. Butyrate belongs to a group of short-chain fatty acids that are also capable of stimulating HbF production in tissue culture cells and in several animal species. Results of the initial short-term human study with butyrate were encouraging. Results of a longer study showed loss of the initial HbF response after extended therapy with continuous high doses of arginine butyrate. The use of newer therapeutic regimens based on pulse or intermittent administration of butyrate caused sustained induction of HbF among most patients with sickle cell disease. It is still not clear whether butyrate will have similar activity in patients with β -thalassemia.

APLASTIC CRISIS AMONG PATIENTS WITH HEMOGLOBINOPATHY

Patients with chronic hemolytic anemia rely on high levels of erythropoiesis. Because of the shortened life span of their circulating RBCs, even transient depression of erythropoiesis can profoundly aggravate anemia. Healthy persons can tolerate suppression of erythropoiesis for several days without serious effects, because less than 1% of the circulating RBCs are replaced every day. Patients with hemolytic anemia sometimes have an alarming decline in hematocrit during and immediately after acute illnesses. These hypoplastic crises usually are transient and self-correcting before intervention is needed. These events probably represent an exaggerated manifestation of the suppression of bone marrow function that occurs in almost everyone during acute inflammatory illnesses. They can occur repeatedly during adult and childhood years.

Aplastic crisis refers to a profound cessation of erythroid activity among patients with chronic hemolytic anemia. It is associated with a rapidly falling hematocrit. Episodes usually are self-limited. Aplastic crises are caused by infection with a particular strain of parvovirus, B19A. Children with this viral infection usually develop permanent immunity. Aplastic crises do not often reoccur and are rare among adults. Management requires close monitoring of hematocrit and reticulocyte count. If anemia becomes symptomatic, transfusion support is indicated. Most crises resolve within 7 to 14 days.

CHAPTER 242: IRON DEFICIENCY AND IRON LOADING ANEMIAS

KENNETH R. BRIDGES

[Iron Deficiency](#)
[Iron Overload](#)

IRON DEFICIENCY

Iron deficiency is a leading cause of anemia, affecting more than one-half billion people worldwide. Among adults, blood loss nearly invariably is the culprit. The high demand for iron that accompanies neonatal and adolescent growth spurts occasionally produces iron deficiency among children. Nevertheless, blood loss is the most frequent cause of iron deficiency for this group as well. Body iron stores for women normally vary between 1 and 2 g, whereas men average 3 to 4 g. The liver is the site of most stored iron. Depletion of iron stores precedes impaired production of iron-containing proteins, the most prominent of which is hemoglobin. The two important stages of iron deficiency are (a) depletion of iron stores without anemia and (b) depletion of iron stores with anemia. Therapy for iron deficiency cannot be comfortably undertaken until the cause of the iron deficit is ascertained.

ETIOLOGY

Abnormal Iron Uptake from the Gastrointestinal Tract

Although iron is the second most abundant metal in the earth's crust, its low solubility makes acquisition for metabolic use a challenge. Iron is not maintained in an easily absorbed form in the absence of gastric acid. Surgical interventions, such as vagotomy or hemigastrectomy for peptic ulcer disease, formerly were the major causes of impaired gastric acidification with secondary iron deficiency. Today the use of histamine H₂ blockers and acid pump blockers to manage peptic ulcer disease and acid reflux is among the most common causes of defective iron absorption. Although this complication is infrequent, use of these medications is widespread. Consequently, the likelihood of physicians' encountering secondary iron deficiency with use of these medications is rising.

The impaired function of the gastric parietal cells associated with pernicious anemia not only reduces production of intrinsic factor but also lessens gastric acidity. Impaired iron absorption can result. In addition, the megaloblastic enterocytes absorb iron poorly. Frank iron deficiency can accompany the anemia produced by cobalamin deficiency.

Disruption of the Enteric Mucosa

Some disorders, such as Crohn's disease, disrupt the integrity of the enteric mucosa and hamper iron absorption. Occult gastrointestinal bleeding exacerbates the problem of iron balance. Sprue, both the tropical and the nontropical variety (celiac disease), also can interfere with iron absorption. The disease can be mild to the point that it produces few or no symptoms. A gluten-free diet improves bowel function for many such patients, and anemia is corrected.

Blood Loss

Blood loss is the world's leading cause of iron deficiency. Menstrual blood loss is the primary physiologic cause of blood loss. Bleeding into the gastrointestinal tract is the most common cause of pathologic blood loss. Structural defects that bleed into the gastrointestinal tract can be malignant, such as adenocarcinoma of the colon, or benign, such as duodenal peptic ulcer. The rate of blood loss frequently is so low that symptoms of severe anemia are the first indication of bleeding.

The world's leading cause of gastrointestinal blood loss is parasitic infestation. Hookworm infection, caused primarily by *Necator americanus* or *Ancylostoma duodenale*, affects more than one billion people, most in tropical or subtropical areas. Daily blood loss exceeds 11 million liters. *Trichuris trichiura*, or whipworm, is believed to infest the colons of 600 to 700 million persons, about 10% to 15% of whom have iron deficiency. Urinary blood loss usually is sufficiently alarming that patients seek medical attention before substantial iron deficiency develops. Although pulmonary blood loss sufficiently severe to produce iron deficiency occurs, the phenomenon is distinctly rare, (as in chronic infection that causes bronchiectasis).

Chronic intravascular hemolysis occasionally produces iron deficiency due to loss of iron into the urine. Paroxysmal nocturnal hemoglobinuria is a classic but uncommon culprit in this regard. Two proteins in the circulation, haptoglobin and hemopexin, guard against such losses. The former complexes tightly with any hemoglobin in the plasma and is cleared by the liver. The latter binds free heme in the circulation to form a complex that also is cleared by the liver. The binding capacity of these two proteins is relatively low, however. Chronic intravascular hemolysis can overwhelm these two systems, allowing renal filtration of hemoglobin dimers (molecular weight 32 kd). The renal tubule cells absorb the hemoglobin dimers, digest the protein, and retain the iron as hemosiderin. When the tubule cells slough into the urine, the hemosiderin can be detected by means of Perls' Prussian blue staining. Intravascular hemolysis can be documented long after the event because renal tubule cells are not shed completely for weeks.

CONSEQUENCES OF IRON DEFICIENCY

Although anemia is the problem most prominently linked to iron deficiency, the condition produces a wide range of abnormalities, depending on its severity and duration. Some of these abnormalities, such as cognitive dysfunction among children, have been recognized only recently.

Anemia

Microcytic, hypochromic anemia impairs tissue oxygen delivery and produces weakness, fatigue, palpitations, and light-headedness. The rate at which anemia develops greatly influences the severity of the symptoms. Very severe anemias, for example, a hemoglobin level of 4 or 5 g per deciliter, occurs among some patients who have iron deficiency caused by slow, chronic bleeding. Often these patients report only mild fatigue. Among older patients, angina from cardiac ischemia can be the first symptom of iron deficiency.

Thalassemia trait is sometimes confused with iron deficiency. Iron deficiency unevenly alters the size of red blood cell. Electronic blood analyzers are used to determine mean corpuscular volume and the range of variation in red cell size (expressed as red blood cell distribution width, RDW). RDW, which is measured with every electronically processed complete blood cell count, is normal among patients with thalassemia trait but is high among those with iron deficiency. Other common features of thalassemia trait are basophilic stippling and the presence of target cells. These characteristics are not sufficiently unique, however, to differentiate thalassemia trait from iron deficiency.

Growth and Developmental Retardation

Iron deficiency with or without concomitant anemia commonly impairs growth and intellectual development among children. Current data indicate that some of the injury is irreversible. Concomitant lead exposure can further hamper the psychological development of these children. The mechanism by which iron deficiency impairs neurologic function is unknown. Many enzymes in neural tissue require iron for normal function. The cytochromes involved in energy production, for example, predominantly are heme proteins. Iron deficiency may impair cytochrome synthesis and produce an energy deficit during the formative years of neural cell growth and development.

The effect of iron deficiency on childhood growth is difficult to separate from overall nutritional deficiency. The high prevalence of childhood iron deficiency among less affluent people has yoked deficiencies of iron and general nutrients. When the two factors are separated, correction of iron deficiency improves growth independently of nutritional status.

Epithelial Changes

Iron deficiency alters the gastrointestinal tract, reflecting the enormous proliferative capacity of this organ. Some patients have angular stomatitis and glossitis with painful swelling of the tongue. The flattened, atrophic lingual papillae make the tongue smooth and shiny. A rare complication of iron deficiency is Plummer–Vinson syndrome with formation of a postcricoid esophageal web. Long-standing, severe iron deficiency affects the cells that generate the fingernails and produces koilonychia, or spooning. The nail substance is so soft, that ordinary pressure on the fingertips, as occurs with writing, produces a concave deformity. Most of these abnormalities are now uncommon among industrialized nations.

Miscellaneous

Pica occurs variably among patients with iron deficiency. The precise pathophysiologic mechanism of the syndrome is unknown. Patients consume unusual items, such as laundry starch, ice, and soil clay. Both clay and starch can bind iron in the gastrointestinal tract, exacerbating the deficiency.

Unexplained thrombocytosis occurs frequently with platelet counts of 500,000 to 700,000 cells per femtoliter. Megakaryocytes and normoblasts are derived from a common committed progenitor cell, the colony-forming unit–granulocytic, erythroid, myelomonocytic. Thrombopoietin, the molecule that stimulates megakaryocyte growth and platelet production, is structurally homologous to erythropoietin, the molecule that promotes red blood cell development. Some investigators have speculated that elevated levels of erythropoietin among patients with iron deficiency anemia might modestly increase platelet production by cross-reacting with the thrombopoietic receptor. Results of investigations with recombinant human erythropoietin and thrombopoietin, however, indicate little cross-reactivity.

DIAGNOSIS OF IRON DEFICIENCY ANEMIA

Iron deficiency anemia lowers the number of circulating red blood cells, a feature of all types of anemia. The red blood cells are microcytic (usually less than 80 fL) and hypochromic. The quantity of the iron-carrying protein, transferrin, in the circulation increases 50% to 100% over baseline. The quantity of iron on transferrin can decrease by as much as 90%. Consequently transferrin saturation frequently declines from its usual 30% to less than 10%. The most useful single laboratory value for the diagnosis of iron deficiency may be plasma ferritin level. Plasma ferritin level often falls to less than 10% of baseline level with substantial iron deficiency.

Other phenomena, such as chronic inflammation with rheumatoid arthritis, perturb the plasma values of iron, transferrin, and ferritin and complicate the diagnosis of iron deficiency among these patients. The situation is further obscured by the fact that chronic inflammation per se can produce anemia. Newer tests, such as assay of circulating transferrin receptors, sometimes can help with the diagnosis of iron deficiency. If all else fails, bone marrow biopsy with Prussian blue staining for iron is the touchstone for the diagnosis.

THERAPY FOR IRON DEFICIENCY

The most important steps in the evaluation and management of iron deficiency are identifying the cause of the deficiency and correcting the abnormality. Malignant disease of the gastrointestinal tract is the haunting specter among adults with iron deficiency. After the cause of the iron deficiency has been ascertained, oral iron supplementation replaces stores most efficiently.

Oral Iron Supplementation

Oral iron supplementation is the ideal way to replace iron stores because the body's normal mechanisms are used. The shortcoming is the limited capacity of the gastrointestinal tract for iron absorption. Only about 5 to 10 mg of elemental iron is absorbed, even when 50 or 100 mg is presented to the gastrointestinal lumen. Most orally consumed iron flows untouched through the alimentary tract. Replenishing a 2,000 mg iron deficit can take most of a year. With ongoing blood loss, replacement of stores with oral iron becomes a Herculean task. Many if not most patients do not comply with such a prolonged medical regimen ([Table 242.1](#)).

Noncompliance
Ongoing blood loss
Insufficient duration of therapy
High gastric pH
Antacids
Histamine H₂ blockers
Gastric acid pump inhibitors
Inhibition of iron absorption and utilization
Lead
Aluminum intoxication (hemodialysis patients)
Chronic inflammation
Neoplasia
Incorrect diagnosis
Thalassemia
Sideroblastic anemia

TABLE 242.1. CAUSES OF POOR RESPONSE TO ORAL IRON

Parenteral Iron Replacement

Parenteral iron is available either as iron dextran or iron saccharide (commonly ferric polymaltose). Only iron dextran is available in the United States, whereas both forms are available throughout most of the rest of the world. Iron saccharide complexes are superior to iron dextran because they produce fewer side effects. Parenteral administration of iron is indicated when (a) oral iron is poorly tolerated, (b) rapid replacement of iron stores is needed, or (c) gastrointestinal iron absorption is compromised. Iron dextran can be administered by means of intramuscular or intravenous injection. A test dose of 10 mg iron should be given and the patient observed by a physician for 30 minutes to rule out an anaphylactic reaction to the medication (such reactions are infrequent). About 10% to 15% of patients experience transient mild to moderate arthralgia the day after intramuscular or intravenous administration of iron-dextran. Acetaminophen usually effectively relieves the discomfort. In uncomplicated cases of iron deficiency, intravenous replacement produces subjective improvement in a few days. Peak reticulocytosis occurs after about 10 days, and complete correction of the anemia can take 3 to 4 weeks.

FUNCTIONAL IRON DEFICIENCY

With steady-state erythropoiesis, iron and erythropoietin flow to the bone marrow at constant, low rates. Among patients with end-stage renal disease, recombinant human erythropoietin (rHepo) is administered in intermittent surges, most commonly as intravenous boluses. The resulting kinetics of erythropoiesis are markedly unphysiologic and strain the production process. Erythropoietin, the accelerator of erythroid proliferation is not coordinated with the supply of iron, the fuel for erythroid proliferation. This imbalance almost never occurs naturally. The rHepo jars previously quiescent cells to proliferate and produce hemoglobin. The requirement for iron jumps dramatically and outstrips the rate of delivery by transferrin. The late arrival of newly mobilized storage iron does not prevent production of hypochromic cells. This is functional iron deficiency or iron-erythropoietin kinetic imbalance. Functional iron deficiency is a major cause of erythropoietin resistance among patients with end-stage renal disease.

IRON OVERLOAD

ETIOLOGY

Transfusional Iron Overload

A unit of blood (250 mL) contains about 225 mg iron. The iron is an integral component of the heme in hemoglobin and cannot be removed from the blood. Senescent

red blood cells are destroyed by reticuloendothelial cells, primarily in the liver and spleen. The iron from the hemoglobin is not excreted. The elements either is used to make new red blood cells or is placed in storage (primarily in the liver). Among patients with transfusion-dependent anemia, nearly all of the iron from the transfused red blood cells goes into storage and eventually produces severe iron overload.

Erythroid Hyperplasia

The connection between hematopoiesis and iron absorption is most strikingly apparent among patients with ineffective erythropoiesis. Disorders such as β^+ thalassemia (thalassemia intermedia) or sideroblastic anemia increase the fractional absorption of ingested iron. Patients often have iron overload without transfusion. The mechanism by which bone marrow activity modulates gastrointestinal iron absorption is unclear. Without some compounding variable, such as hereditary hemochromatosis trait, iron loading without transfusion is uncommon in conditions such as sickle cell disease or hereditary spherocytosis, in which the increase in erythroid activity is less dramatic.

CONSEQUENCES OF IRON OVERLOAD

The effect of iron overload on some organs, such as the skin, is trivial, whereas hemosiderotic harm to other organs, such as the liver, can be fatal. Few unique symptoms precede advanced injury. Abdominal discomfort, lethargy, and fatigue are common but nonspecific characteristics. Dyspnea with exertion and peripheral edema indicate cardiac compromise and advanced iron loading.

Liver

As the main site of iron storage, the liver is a conspicuous victim of iron overload. Mild to moderate hepatomegaly develops early and is followed by shrinkage caused by fibrosis and cirrhosis. Hepatic tenderness occurs inconsistently. Hematoxylin and eosin staining reveals a sepia pigment in the hepatocytes that Perls' Prussian blue staining unmasks as iron. Large deposits of iron develop in the Kupfer cells of patients with transfusional iron overload, reflecting the destruction of senescent erythrocytes by these cells. This iron redistributes to the tissues, producing organ injury that is almost identical to that in hereditary hemochromatosis. Long-standing iron overload frequently fosters micronodular cirrhosis. Hemosiderotic liver damage produces very little inflammation. Hepatic iron deposition and even fibrosis can develop with very little increase in serum transaminase levels. Disturbances in liver synthetic function indicate advanced disease.

Heart

Congestive cardiomyopathy is the most common cardiac defect that occurs with iron overload, but other problems have been described, including pericarditis, restrictive cardiomyopathy, and angina without coronary artery disease. The cumulative number of blood transfusions correlates strongly with functional cardiac derangements among children with thalassemia.

The findings at physical examination are surprisingly benign even among patients with heavy cardiac iron deposition. Once evidence of cardiac failure appears, however, heart function rapidly deteriorates often without response to medical intervention. Biventricular failure produces pulmonary congestion, peripheral edema, and hepatic engorgement. Vigorous iron extrication has occasionally reversed this potentially lethal cardiac complication.

The most useful noninvasive procedures are echocardiography for children and radionuclide ventriculography for adults. The echocardiographic abnormalities correlate roughly with the number of transfusions. Exercise radionuclide ventriculography is particularly sensitive in the detection of cardiac dysfunction among patients with iron overload.

Endocrine

Dysfunction of the endocrine pancreas is common among patients with iron overload. Some patients incur overt diabetes mellitus that necessitates insulin therapy. Disturbances in carbohydrate metabolism often are more subtle, however. An oral glucose tolerance test frequently unmasks abnormal insulin production in the absence of frank diabetes mellitus. Vigorous removal of the excess iron occasionally reverses the islet cell dysfunction. Exocrine pancreatic function, in contrast, usually is well preserved.

Pituitary dysfunction produces a plethora of endocrine abnormalities. Reduced gonadotropin levels are common. When the decrease in gonadotropin level is coupled with a primary reduction in gonadal synthesis of sex steroids, patients can suffer decreased libido or impotence. Although Addison's syndrome is uncommon with iron overload, production of corticotropin can be deficient. A metapyrone stimulation test shows delayed or diminished pituitary secretion of corticotropin.

Miscellaneous Abnormalities with Iron Overload

Hyperpigmentation is a nonspecific skin response to a variety of insults, including excessive exposure to ultraviolet light (tanning), thermal injury, and drug eruptions. Cutaneous iron deposition damages the skin and enhances melanin production by melanocytes. With particularly heavy iron overload, visible iron deposits sometimes appear in the skin as a grayish discoloration. Defective bone mineralization is a problem for patients with thalassemia. Osteoporosis weakens the bones, making the patients subject to fractures, both traumatic and pathologic. Arthropathy, a common feature of hereditary hemochromatosis, is rare among patients with transfusional iron overload due to acquired anemias. Other troubling musculoskeletal problems include severe, recurrent cramps and disabling myalgia. Muscle biopsy shows iron deposits in the myocytes, but the pathophysiologic connection between the pain and the cramps is unclear.

Iron Overload and Opportunistic Infections

Withholding iron from potential pathogens is one strategy used in host defense. The extremely high affinity of transferrin for iron coupled with the fact that two-thirds of the iron binding sites of the protein normally are unoccupied essentially eliminates free iron from plasma and extracellular tissues. Both transferrin and the structurally related protein lactoferrin are bacteriostatic in vitro for many bacteria. The very high transferrin saturations that occur among patients with iron overload compromise the bacteriostatic properties of the protein. Iron sequestration is not a frontline defense against microbes. Therefore iron overload does not produce the susceptibility to infection that occurs with defects in more central systems (chronic granulomatous disease, for example.) Nevertheless, a number of infections, often with unusual organisms, have been reported among patients with iron overload ([Table 242.2](#)).

Bacterial

Listeria monocytogenes
Yersinia enterocolitica
Salmonella typhimurium
Klebsiella pneumoniae
Vibrio sputorum
Escherichia coli

Fungal

Cunninghamella bertholathae
Rhizopus oryzae
Mucor species

TABLE 242.2. INFECTIONS ASSOCIATED WITH IRON OVERLOAD

THERAPY FOR IRON OVERLOAD

Phlebotomy is the most effective means of removing excess iron. This option is not available to transfusion-dependent patients and is available to few patients with

ineffective erythropoiesis. For patients with transfusional iron overload, chelation is the only available treatment.

Parenteral Chelation Therapy

Desferrioxamine (desferoxamine mesylate) is the most widely used chelator in the management of transfusional iron overload. Several characteristics of the drug place severe constraints on its use. First, absorption from the gastrointestinal tract is limited, dictating parenteral administration. Second, a bolus of the compound is excreted from the circulation with a half-life of only about 10 to 15 minutes. The chelator binds little or no iron during this time. Therefore slow, continuous parenteral administration is required. Third, desferrioxamine irritates tissues, meaning that only a small amount can be administered at a given site.

The practical translation is a drug given by means of continuous subcutaneous infusion with a rate-controlled pump. Skin irritation, manifested as raised, painful, erythematous welts, is less severe among children than among adults but is troublesome nevertheless. Patients can minimize but not eliminate the problem by rotating the infusion site daily. The infusion is given over 12 to 16 hours, allowing freedom from the pump for part of the day. Iron mobilization often falls to unacceptable levels when the infusion time is less than 12 hours. Desferrioxamine therapy is most effective when the pump is used daily. Few patients can conform to such a rigid schedule. The infusion should be conducted at least 5 days a week, however.

Otovestibular toxicity occurred in one group of children treated with doses of desferrioxamine that exceeded 150 µg per kilogram in some instances. Full recovery followed cessation of treatment. The drug produced no problems when reinitiated at a level of 25 to 50 µg per kilogram per day. Long-term chelation therapy with desferrioxamine sometimes produces bone disease. Chelation of minerals needed to form hydroxyapatite in developing bone is the presumed cause of this complication.

Oral Chelation Therapy

An orally effective iron chelator would be nirvana for patients with transfusional iron overload. None of the many agents advanced to date has met the exacting requirements for effective treatment. Only one drug occupies the field of competition, 1,2-dimethyl-3-hydroxypyrid-4-one, also called L1 or deferiprone. After early initial promise, L1 became embroiled in controversy. The issue at the center of the storm is whether L1 prevents progression of hepatic damage. Different groups of investigators have reached diametrically opposed conclusions with essentially the same data. This controversy, along with the infrequent but serious granulocytopenia that occurs with administration of the drug clouds the future of L1.

CHAPTER 243: MEGALOBLASTIC ANEMIAS

RALPH CARMEL

Normal Biochemistry and Physiology

[Etiology](#)
[Clinical Findings](#)
[Laboratory Findings](#)
[Optimal Management](#)

Megaloblastic anemia is a very characteristic disturbance of hematopoiesis that gives rise to large cells (macrocytosis) combined with nuclear abnormalities. All blood cell lines are affected—indeed, all dividing cells, such as skin and intestinal cells, show the same defect.

Several pathologic processes can produce megaloblastic anemia, but the most common by far are deficiencies of folate or cobalamin (vitamin B₁₂). These vitamin deficiencies are being identified with increasing frequency in patients who have little or no anemia, due, in part, to more sophisticated diagnostic approaches and earlier recognition.

NORMAL BIOCHEMISTRY AND PHYSIOLOGY

FOLATE

Biochemistry

Folic (pteroylglutamic) acid becomes metabolically active only upon reduction to tetrahydrofolic acid (THF) by dihydrofolate reductase (Fig. 243.1, reaction 1). Moreover, active folates have up to seven γ -carboxyl-linked glutamic acid side chains. This polyglutamated state enhances folate binding to enzymes and thus folate's coenzyme activity. It also is the usual intracellular form of folate because the highly polar polyglutamate side chain promotes cellular retention of the folate. Folates in the plasma are largely monoglutamates.

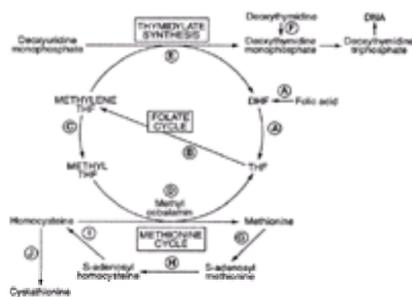

FIGURE 243.1. Folate metabolism and its interrelations with DNA synthesis (*top*) and cobalamin and homocysteine (*bottom*). This diagram includes only selected folate pathways in human beings. 1, Two steps in the reduction of folic acid and dihydrofolate to tetrahydrofolate (THF), mediated by dihydrofolate reductase. 2, The generation of 5, 10-methylene THF, coupled to serine-glycine metabolism. 3, Reaction mediated by 5, 10-methylene THF reductase; this reaction is augmented when methionine and S-adenosylmethionine production falls, as might occur in cobalamin deficiency, and thus potentiates the “methyl THF trap”. 4, Reaction mediated by methionine synthase (homocysteine:methionine methyltransferase); it requires methylcobalamin and is the focal point of the methyl THF trap hypothesis. 5, *De novo* synthesis of thymidine, mediated by thymidylate synthase. 6, Salvage pathway of thymidylate synthesis, mediated by thymidine kinase. 7, In addition to its remethylation to methionine (reaction 4), homocysteine is also metabolized to cystathionine; the initial reaction in the transsulfuration pathway is mediated by cystathionine b-synthase and pyridoxal phosphate.

The main metabolic function of folate involves one-carbon unit transfers. Several amino acid conversions require folate; an important one is the methylation of homocysteine to methionine, with 5-methyl THF as a cosubstrate for methionine synthase (Fig. 243.1, reaction 4). Folate is also involved in purine synthesis. The clinically most apparent role, however, is in the methylation of deoxyuridine monophosphate to thymidine monophosphate by thymidylate synthase, which requires 5,10-methylene THF (Fig. 243.1, reaction 5). It is the compromise of this reaction in folate deficiency that leads to megaloblastic anemia. Precisely how the compromised reaction does so is unclear, because the diminished thymidylate synthesis appears to be compensated by the salvage pathway (Fig. 243.1, reaction 6), but there may be different thymidylate pools. Moreover, the deoxyuridine excess, along with the thymidylate insufficiency, promotes misincorporation of uracil in place of thymidine into DNA.

Nutrition, Absorption, and Metabolism

Folate derives its name from the leafy vegetables that are rich in it; many other foods, such as meat, dairy products, cereals, and flour, are also good sources. To avoid deficiency, adults normally require about 0.2 mg of folate daily. Total body stores vary but are about 10 mg. Thus, daily turnover is 1% to 2% of stores.

Food folate, largely reduced and usually methylated, is labile. For example, cooking fish, frying meat, or boiling vegetables can decrease the folate content of these foods by 50% to 90%. Even simple storage can diminish the folate content of some foods. Such information must be considered in assessing the adequacy of a patient's dietary intake. Moderate fortification with folate of all cereal-grain products was mandated by the Food and Drug Administration in 1998.

Dietary folate is absorbed after its polyglutamate side chain is converted by folate conjugase to the monoglutamate form, which more readily crosses membranes. Most nonmethylated folate is also converted to methyl THF during absorption. Medicinal folic acid is absorbed to a large extent by a different process than is food folate. The efficiency of absorption depends on the form of folate, but usually more than 60% is absorbed; the process is an active, saturable one, and it is most efficient in the jejunum.

Absorbed methyl THF enters cells for use or is recycled to the liver for storage or enterohepatic recirculation by way of bile. Most folate in the blood at any time, therefore, represents recently absorbed folate and is largely methyl THF.

Two folate-binding protein activities exist in plasma. One involves low-affinity, nonspecific binding promoted by various proteins. The second is a specific protein with a high affinity for mostly oxidized rather than reduced folates and a low binding capacity. The physiologic roles of these proteins are uncertain. The nonspecific binder may prevent renal loss of folate.

Folate is ultimately degraded, and some of it may be lost through the urine. Biliary loss appears to be relatively minor.

COBALAMIN

Biochemistry

Cobalamins are corrinoids (compounds that contain a porphyrin-like corrin ring with a central cobalt atom) that have a 5,6-dimethyl benzimidazole side chain. The

major physiologic cobalamins are hydroxocobalamin, methylcobalamin, and 5'-deoxyadenosyl cobalamin. By International Union of Pure and Applied Chemistry-International Union of Biochemistry nomenclature, *vitamin B₁₂* refers specifically to cyanocobalamin, a cobalamin with a cyanide moiety attached to its central cobalt, a form found only in medicinal preparations.

Cobalamins are known to take part in only two reactions in humans. First, 5'-deoxyadenosyl cobalamin is the coenzyme for methylmalonyl CoA mutase in the isomerization of methylmalonyl CoA to succinyl CoA, as part of mitochondrial propionate metabolism. Methylmalonic acidemia is a useful indicator of cobalamin deficiency.

The second reaction involves methylcobalamin as a cofactor in the methylation of homocysteine to methionine, in which methyl THF is converted to THF (Fig. 243.1, reaction 4). This key role has many important ramifications. Cobalamin deficiency impairs the demethylation of methyl THF, thus inducing a block in folate metabolism. This forms the basis of the "methyl THF trap" hypothesis. The resulting depletion of 5,10-methylene THF, needed for reaction 5 in Fig. 243.1, explains why cobalamin deficiency leads to megaloblastic anemia. It also explains why therapy with folic acid, by temporarily bypassing the block, can transiently correct the megaloblastic anemia of cobalamin deficiency (Fig. 243.1, reactions 1, 2 and 5). Probably related to the increase of the largely monoglutamated methyl THF, cellular accumulation of folates also becomes impaired in cobalamin deficiency; tissue folate levels, including red cell folate, fall while serum levels rise. Another ramification of the trap is that hyperhomocysteinemia and partial methionine deficiency can result, along with impaired generation of S-adenosylmethionine, a universal methyl donor; these changes are now thought to have many important consequences.

Nutrition, Absorption, and Metabolism

Cobalamin is synthesized by bacteria. Humans usually acquire it secondhand from animals that have ingested these bacteria and stored the cobalamin. The best food sources are meats, seafood, and products of animals, such as dairy products and eggs. Vegetables and fruits are poor sources, as are cereals, rice, flour, and nuts. The daily cobalamin requirement is thought to be 1 to 5 µg, and the usual North American diet provides more than that. Because of cobalamin's specific, saturable absorption, no more than 1 to 2 µg is absorbed in any one meal. Total body stores are estimated at 2 to 10 mg. Thus, daily turnover is only about 0.1% of stores.

Cobalamin assimilation follows the sequence of events in Figure 243.2. Ingested vitamin is split from its food binding by pepsin at a low pH. It is then bound by one of two binding proteins. The ultimately important binder is intrinsic factor. This glycoprotein is secreted by the gastric parietal cell in great excess over requirements. The other binding protein, R binder or haptocorrin, is secreted by glandular epithelial cells, such as those in the salivary gland. This glycoprotein is a less specific binder than intrinsic factor in that it also binds nonfunctional corrinoids. R binder binds cobalamin preferentially in the stomach at low pH but is then degraded in the jejunum by pancreatic proteases. Its cobalamin, thus released, is then bound by intrinsic factor.

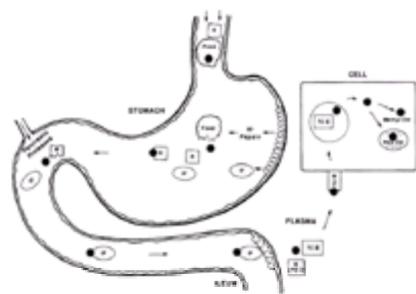

FIGURE 243.2. Sequence of events in cobalamin assimilation and use. Filled circles, cobalamin; R, salivary R binder; IF, intrinsic factor; TC II, transcobalamin II; R(TC I), plasma R binder (transcobalamin I); Methyl Cbl, methylcobalamin; Ado Cbl, 5'-deoxyadenosylcobalamin. (Modified from Carmel R. Clinical and laboratory features of the diagnosis of megaloblastic anemia. In: Lindenbaum J, ed. *Nutrition in hematology*. New York: Churchill Livingstone, 1983, with permission.)

Considerable enterohepatic recirculation of cobalamin occurs by way of biliary R binder, whose cobalamin is presumably released by pancreatic protease activity and transferred to intrinsic factor.

The intrinsic factor–cobalamin complex attaches to specific receptors for intrinsic factor on ileal epithelial cell membranes. These receptors are particularly numerous in the distal ileum. The complex is internalized, after which the cobalamin is exported from the ileal cell into the circulation.

In the bloodstream, cobalamin is bound by either of two binding proteins. Transcobalamin II binds cobalamin as it exits from the ileal cell and very quickly delivers it to all cells by way of specific receptors for transcobalamin II on their membranes. Without this binder, cellular uptake of cobalamin is inadequate. After internalization, the cobalamin becomes available as a coenzyme in the cytoplasm or mitochondria. On the other hand, transcobalamin I, the plasma representative of the R binder family, carries circulating cobalamin with a half-life of 9 to 10 days, without delivering it to cells. As a result, most measurable cobalamin in the plasma is normally attached to it, but its function is unknown; desialylated transcobalamin I may ultimately be involved nonspecifically in the hepatobiliary clearance of the vitamin.

The binding proteins are of additional interest in their own right. Plasma levels of transcobalamin I and its bound cobalamin are consistently elevated in chronic myelogenous and acute promyelocytic leukemias and sometimes in other conditions. Plasma transcobalamin II behaves like an acute phase reactant.

Various nonfunctional corrinoid analogues are found in the blood. Their source is unknown, but intestinal bacteria synthesize them and some multivitamin preparations are rich in them. Their role, deleterious or otherwise, is also uncertain.

ETIOLOGY

COBALAMIN (VITAMIN B12) DEFICIENCY STATES

The disorders presented here follow the assimilation sequence for cobalamin in Figure 243.2. Because of the large body reserves of cobalamin, virtually all disorders take several years to produce clinically obvious deficiency. Increasingly often now, they are diagnosed before the symptoms of deficiency appear.

Dietary Insufficiency

The great margin of safety provided by the 1,000: 1 ratio of body stores to daily requirements, combined with unimpaired reabsorption of biliary cobalamin, explains why dietary insufficiency rarely causes cobalamin deficiency in the United States. Cobalamin deficiency does not occur in general malnutrition such as among homeless persons with alcoholism or malnourished patients with renal failure or cancer. For a deficiency to develop, one must be a particularly strict vegetarian for many years, usually avoiding eggs and dairy products not to mention cobalamin supplements. Even patients who meet all the criteria for dietary insufficiency usually have coexisting malabsorptive disorders that explain their deficiency on closer examination.

Nevertheless, marginal cobalamin status may well be common in vegetarians. Even if megaloblastic anemia is rare, low serum cobalamin levels have been described in several surveys. The one type of patient who often exhibits overt signs of deficiency, especially neurological signs, is the infant born to and nursed by a vegan mother; interestingly, the mother usually has no symptoms.

Disorders of the Stomach

Pernicious Anemia

Pernicious anemia is the most common cause of clinically overt cobalamin deficiency. Despite its hematologic name, it is really a gastroenterologic entity defined by malabsorption of cobalamin due to failure of the stomach to secrete intrinsic factor. One can have pernicious anemia without being anemic.

Classical, or Addisonian, pernicious anemia features severe atrophic gastritis in which autoimmune phenomena are prominent. The gastritis often spares the antrum (type A gastritis) and gastrin levels usually are elevated. Achlorhydria is universal, but the crucial defect is loss of intrinsic factor secretion by the parietal cell. Although there is still no evidence that they are pathogenic, circulating antibodies to the H⁺,K⁺-ATPase of parietal cells (55% to 90% of cases) and the cobalamin-binding site of intrinsic factor (55% to 75% of cases) are often present.

Pernicious anemia is typically a disease of the elderly person of northern European ancestry but is found in all races. Moreover, pernicious anemia can occur in younger people; occurrence in the third or fourth decade of life is especially common among black women. When the disease occurs in children or teenagers, it is called *juvenile pernicious anemia* (not to be confused with congenital pernicious anemia, a hereditary disorder without atrophic gastritis). Pernicious anemia shows a slight female preponderance.

The gastric defect is irreversible. The vitamin deficiency that it produces, however, is easily reversed and does not recur as long as maintenance therapy with cobalamin is given. A small source of risk for increased mortality is the predisposition to gastric cancer, estimated at two to five times that of the general population. An initial endoscopy is generally favored but the value of aggressive screening programs with periodic endoscopic examination is not established. Gastric carcinoids may be even more common but usually have a benign course. Other diseases that coexist with pernicious anemia more often than expected include autoimmune endocrinopathies (hypothyroidism, hyperthyroidism, diabetes mellitus, hypoparathyroidism, Addison's disease) and various immunologic disorders (hypogammaglobulinemia, [in which gastric cancer occurs particularly often], myasthenia gravis, vitiligo, autoimmune hemolytic anemia, and immune thrombocytopenic purpura). Of these, thyroid disease is by far the most common and may precede, follow, or coexist with pernicious anemia. Iron deficiency also is common in patients with pernicious anemia.

Postgastrectomy State

Cobalamin deficiency develops in 15% to 30% of patients who undergo subtotal gastrectomy. Loss of intrinsic factor can occur as a result of atrophic gastritis in the remnant stump. Bacterial overgrowth in the upper intestine may also contribute to the malabsorption. However, malabsorption limited to food-bound cobalamin is much more common and is discussed in the following section. Iron deficiency occurs frequently and can mask the hematological changes of cobalamin deficiency; folate deficiency may also coexist.

Other Gastric Diseases

Cobalamin deficiency can result from extensive infiltrative disease of the stomach and the attendant loss of intrinsic factor. Deficiency has also been described after gastric stapling or bypass for obesity.

The concept that atrophic gastritis leads to cobalamin malabsorption and deficiency only if intrinsic factor secretion is lost (pernicious anemia) is no longer tenable. Patients who have lost only acid and pepsin secretion absorb free cobalamin adequately. However, they may not always be able to liberate, and thus absorb, cobalamin from food or attached to protein, a defect identified only by modifications of the standard absorption test. This form of malabsorption has been described in patients with achlorhydria associated with gastritis, patients who have undergone subtotal gastrectomy or vagotomy, and patients taking acid-suppressive drugs. Food-cobalamin malabsorption accounts for 25% to 40% of cases of low cobalamin levels where the Schilling test result, which measures only absorption of free cobalamin, is normal.

Hereditary Disorders

Congenital pernicious anemia produces cobalamin deficiency because of a selective failure to secrete intrinsic factor or the secretion of an abnormal intrinsic factor. The stomach is otherwise morphologically and functionally intact. No autoimmune phenomena are seen, and the patient is not at increased risk for gastric cancer. Although the patients usually come to medical attention in the first few years of life, some are first diagnosed in adolescence or even adulthood.

Disorders of the Intestinal Lumen

Bacterial Contamination of the Intestine

The small intestine can become overgrown with bacteria that take up cobalamin. This bacterial overgrowth can result from blind loops, large diverticula, strictures, or disorders of bowel motility. Increased bacterial counts in the upper intestine may be seen in patients with gastric achlorhydria but are of uncertain significance. Bacterial contamination can produce cobalamin deficiency before any other intestinal symptoms or signs are apparent. Treatment includes antibiotic therapy, but unless the underlying cause of the bacterial overgrowth can be reversed, recurrence is common.

Tapeworm Infestation

Diphyllobothrium latum avidly takes up cobalamin. The greater the number of parasites, the more likely there is to be cobalamin deficiency. The major source of the tapeworm is poorly cooked fish from infested lakes. The disorder is rare in the United States.

Pancreatic Insufficiency

Pancreatic insufficiency produces an abnormal cobalamin absorption test result in about half of patients. The cause is the unavailability of pancreatic proteases to degrade the R binder to which cobalamin initially binds in the stomach. As a result, less vitamin becomes available for binding to intrinsic factor. Nevertheless, deficiency rarely develops, perhaps because pancreatic replacement therapy usually is given before cobalamin deficiency supervenes.

Gastrinoma

The Zollinger–Ellison syndrome can produce cobalamin malabsorption. The low intestinal pH inhibits intrinsic factor attachment to ileal receptors.

Disorders of the Ileum

Acquired Diseases Involving the Ileum

Nearly any disease involving enough of the ileum, especially the distal ileum, can produce cobalamin malabsorption. Cobalamin deficiency can be the first manifestation of tropical sprue, which may appear long after emigration from the endemic area and is often combined with folate deficiency. Loss of ileum due to surgical resection or diversion (e.g., the Kock pouch) or due to damage after pelvic radiotherapy can also produce malabsorption. Low serum cobalamin levels occur in 15% to 25% of patients with AIDS, and ileal malabsorption can be demonstrated in some of these cases.

Drugs, Toxins, and Nutritional Deficiency

Alcohol and many drugs (e.g., neomycin, biguanides, colchicine, slow-release potassium chloride, cholestyramine, and para-aminosalicylic acid) can impair cobalamin absorption. Absorption tests can become abnormal within a week or two of beginning drug therapy. Actual cobalamin deficiency is uncommon, however, because the drugs are rarely taken long enough to deplete stores.

Cobalamin deficiency itself sometimes produces megaloblastic changes in intestinal epithelial cells. The transient ileal malabsorption of cobalamin (i.e., even when exogenous intrinsic factor is supplied in the Schilling test), seen in 40% to 75% of patients with pernicious anemia, has been attributed to this phenomenon. The malabsorption normally reverses with cobalamin therapy after a few days or weeks. When the ileal malabsorption takes several months to reverse, it seems more

plausible to implicate coexisting small bowel disorders.

Hereditary Disorders

In congenital malabsorption of cobalamin (Imerslund–Gräsbeck syndrome), malabsorption is limited to cobalamin only. The genetic defect is thought to involve the ileal receptor for intrinsic factor, cubilin, which is also found in kidney tubular cells. Mild proteinuria occurs in nearly all cases. Deficiency of the vitamin usually appears in the first few years of life but is sometimes delayed until the second decade. Malabsorption also accompanies hereditary transcobalamin II deficiency. This seems to be due to the inability of absorbed cobalamin to leave the ileal cell.

Disorders of Transport, Metabolism, and Utilization

Nitrous Oxide Exposure

Nitrous oxide inactivates cobalamin by oxidizing cob(I)alamin and inactivates methionine synthase (Fig. 243.1, reaction 4). Repeated exposure produces megaloblastic anemia and neurologic symptoms, with the latter often predominating. Cobalamin levels are usually normal and methylmalonic acidemia cannot always be demonstrated, so that the diagnosis of cobalamin abnormality can be difficult to make unless a history of exposure is elicited. Transient exposure during routine anesthesia produces no clinical sequelae unless a coexisting cobalamin deficiency has been overlooked.

Transcobalamin II Deficiency

Congenital deficiency of this crucial transport protein produces a life-threatening cellular depletion of cobalamin early in life. Serum cobalamin levels are usually, but not invariably, normal. Occasional cases may not be diagnosed until the second decade of life, but these usually are patients who had been misdiagnosed and inadequately treated earlier. Curiously, neurologic disturbances are not initially prominent in most patients. However, some patients have developed such deficits, perhaps as a result of inappropriate folate therapy.

R Binder (Transcobalamin I) Deficiency

Because most cobalamin circulates in the blood attached to transcobalamin I, absence of the binder produces low serum levels of the vitamin even though cellular levels are adequate. The binder appears to have no other role in cobalamin metabolism, and these patients are nondeficient and asymptomatic (although one patient had unexplained, progressive myelopathy and dysarthria). The patients usually are discovered by accident because of an unexplained low serum cobalamin level. Absence of R binder in both blood and secretions such as saliva establishes the diagnosis. Deficiency of lactoferrin, which, like transcobalamin I, originates in neutrophil specific granules, coexists in some cases.

Inborn Errors of Metabolism

Recognition of abnormalities that interfere with cellular cobalamin activity begins with the demonstration of methylmalonic acidemia, homocysteinemia, or both, but the biochemical and clinical defects vary. Some disorders with abnormality limited to the 5'-deoxyadenosyl cobalamin-mediated reaction feature only acidosis, methylmalonic acidemia, and perhaps developmental problems (as in *cbIA* and *B* mutations). Others have defective methylcobalamin activity as well (*cbIC*, *D*, and *F* mutations); these patients usually have homocysteinemia in addition to methylmalonic acidemia. Their clinical pictures have ranged from mild neurologic symptoms appearing in adolescence to severe hematologic and neurologic abnormalities terminating in death in infancy. Thrombotic complications sometimes occur. In the *cbIE* and *G* mutations, only methylcobalamin activity is impaired; homocysteinemia occurs without methylmalonic acidemia, and patients have hematologic and neurologic manifestations. The inborn errors should be considered in children who have developmental or neurologic problems as well as in children who have megaloblastic anemia. Some of the disorders may first be detected in adolescence or young adulthood.

Miscellaneous

Aging and mild cobalamin deficiency

Although the causes vary, low cobalamin levels occur in about 10% of the healthy elderly population. Most of the low levels are not accompanied by clinical symptoms or anemia but metabolic testing has shown evidence of cobalamin deficiency in 50% to 70% of cases. Food-cobalamin malabsorption explains 30% to 40% of these and pernicious anemia or ileal disease only about 10%; dietary insufficiency is rare.

FOLATE DEFICIENCY STATES

Deficiency of folate often is multifactorial in origin. In part this stems from the relative ease with which nutritional insufficiency can supervene in any illness. Alcohol and various drugs also have multiple effects on folate status that often are complicated by poor diet, coexisting disease, or the underlying illness for which the drugs are used. The disorders are presented here in the sequence of folate intake, absorption, and utilization.

Dietary Insufficiency

Poor dietary intake is the most common cause of folate deficiency. Because body stores are only about 100 times the daily requirement and because food folate is labile, significant tissue depletion can occur within a few months.

Certain factors potentiate the problem of poor or marginal intake. Chief among these is ingestion of alcohol. When combined with poor diet, alcohol use often has been implicated as the major cause of folate deficiency. Another potentiating factor can be an increased requirement for folate, which may strain body stores if the diet is marginal.

Disorders of Absorption

Diseases of the Small Intestine

Almost any condition involving enough of the upper small intestine can produce folate malabsorption. This includes sprue, infiltrative diseases, Whipple's disease, and resection of the small intestine. Bacterial contamination of the small intestine, however, does not produce folate deficiency, although it can produce cobalamin deficiency.

Drugs, Toxins, and Nutritional Deficiency

Several drugs and toxins have been associated with folate malabsorption. The chief one is alcohol (discussed in a later section). Sulfasalazine and para-aminosalicylic acid have been implicated in folate malabsorption. Malnutrition and its effects on the intestine also have been postulated to impair folate absorption.

Hereditary Disorders

The nature of the defect in congenital folate malabsorption is unknown, but it affects monoglutamate as well as polyglutamate absorption. A concurrent transport block into the cerebrospinal fluid has been implicated, perhaps explaining the frequent cerebral abnormalities these patients have in addition to their anemia.

Disorders of Transport, Metabolism, and Utilization

Alcohol

Alcohol has multiple effects on folate economy. Serum folate levels drop sharply with alcohol ingestion. Suggested mechanisms include impaired ability to form methyl THF in the liver, curtailed enterohepatic recirculation of folate, and increased urinary losses of folate. These putative defects are superimposed on the previously mentioned dietary insufficiency and on the possible absorptive defect. However, alcohol also can directly induce red cell macrocytosis that is not related to altered folate status and does not respond to folate therapy.

Drugs

Folate metabolism is a major target in antineoplastic therapy. Methotrexate inhibits dihydrofolate reductase ([Fig. 243.1](#), reaction 1), thus inhibiting the generation of metabolically active THF.

Several antibiotics, such as trimethoprim, sulfamethoxazole, and pyrimethamine, inhibit dihydrofolate reductase in microorganisms, but the human enzyme is much less susceptible. Triamterene, a pteridine derivative, and sulfasalazine, which also affects two other folate-related enzymes, inhibit dihydrofolate reductase. All these drugs can, on rare occasions, directly induce folate deficiency. Nevertheless, whenever deficiency occurs, the initial focus should be to find coexisting disorders such as malnutrition or other diseases that compromise folate status.

Patients receiving anticonvulsant therapy often become folate-deficient. The mechanism is unclear, and a poor diet often contributes to the deficiency. In addition to possibly impairing absorption, hydantoin may impair cellular folate metabolism.

Acute Folate Deficiency

Acute folate deficiency has been found among some patients in intensive care units. These patients develop cytopenia and megaloblastic bone-marrow changes, but the peripheral blood appearance is often unaltered and vitamin levels are normal. The cause of this syndrome of cellular folate depletion is unknown.

Hereditary Disorders

Hereditary folate metabolic disorders are often associated with cerebral abnormalities, such as retardation or seizures; megaloblastic anemia is not always present. Methylene THF reductase deficiency may be the most common disorder ([Fig. 243.1](#), reaction 3). It is associated with low serum folate levels due to impaired generation of methyl THF. Neurological symptoms are common, but megaloblastic anemia does not occur because methylene THF remains available for thymidine synthesis ([Fig. 243.1](#), reaction 5). The disorder has been found among teenagers as well as among younger children.

A milder genetic mutation producing a thermolabile methylene THF reductase is very common. It produces no symptoms but can contribute to mild hyperhomocysteinemia and perhaps an increased thrombotic risk.

Increased Requirements and Losses

Low folate levels are common in pregnancy. Megaloblastic anemia sometimes ensues, especially in the last trimester. Routine prenatal folate supplementation has decreased its incidence.

Folate requirements are increased in chronic hemolytic anemias and other chronic states of increased cell turnover. However, clinical deficiency from the increased demand alone is unusual, and it is wise to search for contributing problems. Controlled studies have not demonstrated any clinical benefit from the common practice of routinely giving folate prophylactically to patients with chronic hemolysis, such as those with sickle-cell anemia. Cobalamin levels should be checked first if folate supplementation is planned.

Increased folate losses have been described in patients undergoing dialysis for renal failure, and supplementation is routinely given.

OTHER CAUSES OF MEGALOBlastic ANEMIA

Megaloblastic changes are sometimes caused by mechanisms unrelated to either folate or cobalamin deficiency and do not respond to therapy with either vitamin.

Drugs and Toxins

Drugs that impair nucleoprotein synthesis directly, for example, antineoplastic drugs like 5-fluorouracil, cytosine arabinoside, and hydroxyurea, often produce megaloblastic changes and macrocytosis. Hypersegmentation of neutrophil nuclei occurs with steroid therapy and reverses with its discontinuation; the mechanism is unknown. Arsenic poisoning does not produce truly megaloblastic changes, but the nuclear fragmentation and increased mitoses that result can be confused with megaloblastic anemia.

Primary Disorders of the Hematopoietic Stem Cells

Many primary disorders of the hematopoietic stem cells are associated with macrocytosis ([Table 243.1](#)). Some, like the myelodysplastic syndrome, may also feature erythroid maturation changes that resemble those of megaloblastic anemia. Neutrophils may have hypersegmented nuclei in some myeloproliferative diseases.

TABLE 243.1. CAUSES OF MACROCYTOSIS

Hereditary Disorders Unrelated to Cobalamin or Folate

Orotic aciduria affects two enzymes in orotic acid metabolism. Among other features, severe megaloblastic anemia appears in the first year of life. The Lesch–Nyhan syndrome, a disorder of purine metabolism, sometimes produces megaloblastic anemia. Thiamine-responsive megaloblastic anemia, whose mechanism is unknown, may not produce anemia until late in childhood. Diabetes mellitus and sensorineural deafness are regular findings.

CLINICAL FINDINGS

The clinical expressions of cobalamin or folate deficiency are the same no matter what the underlying cause of the respective deficiency. Sometimes, however, especially in cobalamin deficiency, the only recognizable abnormality is simply a low vitamin level in the blood or metabolic evidence of insufficiency.

MEGALOBLASTIC ANEMIA

The severity of morphologic changes tends to correspond with the severity of anemia. All cells, whether precursors or mature cells, tend to be larger than normal. A nuclear–cytoplasmic asynchrony appears in the precursor cells. Erythrocytes are often oval in addition to being macrocytic, and there may be considerable poikilocytosis. Mature granulocytes have hypersegmented nuclei, and metamyelocytes and bands tend to be large with large, bizarrely shaped nuclei and abnormally fine chromatin. Hypersegmentation in granulocytes can be defined in several ways: the presence of at least one neutrophil with six or more nuclear lobes; the presence of more than 3% to 4% five-lobed neutrophils; or an increased neutrophil lobe average. Granulocytic changes occur early in deficiency and are found in nearly all cases, whereas erythroid abnormalities are sometimes partially masked (e.g., by coexisting iron deficiency) and macrocytosis may be absent.

Functionally, the anemia is primarily one of ineffective hematopoiesis. Up to 90% of the cells may die within the bone marrow. The resulting indirect hyperbilirubinemia and increased serum lactate dehydrogenase are often striking, unless the anemia is mild. Evidence of hemolysis, including low serum haptoglobin levels and hemosiderinuria, is sometimes seen but reticulocytosis does not occur.

Leukopoiesis and thrombopoiesis are also ineffective, and pancytopenia may occur. Granulocyte and platelet dysfunctions are sometimes demonstrable but rarely produce clinical manifestations.

NEUROLOGIC ABNORMALITIES

Cobalamin deficiency often produces characteristic and usually symmetric myelopathy and neuropathy. Pathologic examination shows axonal degeneration with loss of myelin. This predominates in the posterior and lateral columns in the upper thoracic spinal cord. Patchy changes may also be found in the brain. How the deficiency produces the neurologic lesions is unknown. Current evidence favors impaired homocysteine–methionine conversion with an altered S-adenosylmethionine/S-adenosylhomocysteine equilibrium as the key to the defect. Some patients have severe neurologic deficits with little or no evidence of hematologic abnormality, whereas in others the reverse is true.

The earliest symptom is usually paresthesia in the feet. Vibration and position sense become impaired. Deep tendon reflexes may be diminished. Later, ataxia and a positive Romberg's sign may appear. As the lesion progresses, the deficits ascend. Spasticity, increased deep tendon reflexes, and weakness appear as the lateral columns are involved. Ultimately, paraplegia, bladder atony, poor control of sphincters, and impotence may result.

Mild cerebral manifestations such as depression, memory impairment, and irritability are common. Electroencephalographic abnormalities are frequently demonstrable. Psychiatric symptoms, confusion, or dementia may appear. Rarely, the disturbances can include ophthalmoplegia and optic atrophy.

Folate deficiency does not produce the neurologic abnormalities that cobalamin deficiency does. Minor cerebral symptoms, such as irritability, memory loss and personality changes, may occur, however, and neuropathy has been described by some observers. The nature of these changes is unclear. Cerebral disturbances such as mental retardation, seizures, and psychosis are prominent in children with inborn errors of folate metabolism.

The neurologic deficits of cobalamin deficiency, unlike the hematologic ones, do not respond to folate therapy. Indeed, the risk is that they may progress unchecked while hematologic improvement occurs.

MISCELLANEOUS ABNORMALITIES

Some patients, especially those with cobalamin deficiency, may have glossitis and atrophy of the tongue papillae. Oral symptoms even predominate in some cases. Infertility has also been attributed to cobalamin deficiency. Other abnormalities that reverse with cobalamin therapy include unexplained weight loss, pigment changes in skin, hair, and nails, and low serum levels of bone alkaline phosphatase and osteocalcin.

Folate deficiency has been implicated in damage to fragile sites on chromosomes. Some studies have also described protection by folate supplementation against progression of cellular atypia to neoplasia, but the phenomenon is unclear. Periconceptional folate supplementation of the mother partially protects her fetus against neural tube defects. This effect, whose mechanism is unknown, prompted the recent fortification of all cereal-grain products with folate.

HYPERHOMOCYSTEINEMIA

Although asymptomatic per se, acquired as well as hereditary hyperhomocysteinemia may be clinically important. Epidemiologic evidence shows it to be, even when mild, a risk factor for thrombotic and arteriosclerotic disease. Studies are underway to determine if reducing homocysteine levels by vitamin therapy reduces the vascular risk. Hyperhomocysteinemia, which predominates in men and in the elderly, can be caused by folate, cobalamin, or pyridoxine deficiency ([Fig. 243.1](#)), by several enzyme deficiencies or by renal failure.

LABORATORY FINDINGS

DIAGNOSIS OF MEGALOBLASTIC ANEMIA

Classic megaloblastic anemia is easy to diagnose. The advent of electronic cell sizing has made macrocytosis instantly obvious in the routine blood cell count. Alertness to details optimizes diagnosis in the early phases of deficiency and in mild anemias, atypical presentations, and the presence of findings altered by coexisting problems. Macrocytosis typically precedes the anemia and can be invaluable in making an early diagnosis. Even a red blood cell mean corpuscular volume in the upper range of normal should be viewed with suspicion. Macrocytosis is not invariable, however; more than 25% of patients with pernicious anemia have normal or even low mean corpuscular volumes when first seen. Coexisting iron deficiency or thalassemia minor often is responsible for this, or the patient may simply have early deficiency or, for other, unknown reasons, may have only minimal hematologic abnormality. On the other hand, many nonmegaloblastic processes can also cause a high mean corpuscular volume ([Table 243.1](#)).

Neutrophil hypersegmentation is a sensitive index of the megaloblastic process. Hypersegmentation can also be found in nonmegaloblastic conditions, however, examples of which include myeloproliferative disease, corticosteroid therapy, and congenital hypersegmentation; it is nevertheless always advisable to demonstrate that vitamin deficiency does not coexist. The bone marrow aspirate is the court of last resort and should be examined before initiating therapy whenever the diagnosis is in doubt. However, megaloblastic changes may be subtle in mild or early deficiency, and megaloblastic erythroid changes may be blunted by coexisting iron deficiency.

Various features of the anemia can mimic other disorders. Pancytopenia is sometimes severe enough to be confused with aplastic anemia. The maturation abnormalities, particularly if accompanied by exuberant myeloid proliferation or transient red blood cell hypoplasia, have been mistaken for leukemia. Increased iron levels and abnormal sideroblasts can mimic sideroblastic anemia. The frequent hyperbilirubinemia, elevated lactate dehydrogenase, decreased haptoglobin, and hemosiderinuria may resemble primary hemolytic anemia.

DIAGNOSIS OF THE VITAMIN DEFICIENCY

For all practical purposes, megaloblastic anemia in adults is secondary to deficiency of folate, cobalamin, or both ([Table 243.2](#)). Cobalamin deficiency should also be considered in any patient with neuropathy, myelopathy, or cerebral disturbances, whether or not megaloblastic anemia is present.

	In Deficiency of		
	Cobalamin	Folate	Cobalamin and Folate
Serum cobalamin	↓	N-↓	↓
Serum folate	N-↓	↓	↓
Red blood cell folate	N-↓	↓	↓
Methylmalonic acid ^a	↑	N	↑
Homocysteine ^b	↑	↑	↑

N, normal level; ↓, decreased level; ↑, increased level.
^a Can be assayed in serum or urine.
^b Should be assayed in EDTA-anticoagulated plasma.

TABLE 243.2. LABORATORY DIAGNOSIS OF COBALAMIN AND FOLATE DEFICIENCY

Serum vitamin levels, even though they reflect body stores indirectly, are the mainstay of diagnosis. Indeed, low serum levels are sometimes the only evidence of deficiency. However, they are sometimes too sensitive (especially serum folate, which falls with poor intake within days) and at other times are falsely low ([Table 243.3](#) and [Table 243.4](#)). Although the lower the serum level, the more likely it is that a deficiency exists, even mildly decreased values require investigation. The burden of proof is always on the physician to demonstrate that deficiency is not present, given its treatability and the potentially serious consequences of failure to treat it. Serum cobalamin levels also tend to fall in folate deficiency, whereas serum folate tends to rise in cobalamin deficiency. Low levels of both vitamins may indicate combined deficiencies, especially in malabsorption syndromes.

Cobalamin Deficiency
Overt deficiency
 Adult or geriatric deficiency
 Latent pernicious anemia or other malabsorptive state, including food-cobalamin malabsorption
 "Old age"
 "Vegetarianism"
Unexplained but Sometimes Associated with Compromised Cobalamin Status
 Long-term dialysis for renal failure
 Hydronephrosis
 Cancer
 AIDS
Presumed not to Represent Cobalamin Deficiency
 Pregnancy (last trimester)
Folate deficiency
Transcobalamin I deficiency
 Multiple myeloma and Waldenström's macroglobulinemia
 Aplastic anemia
 Heavy chain leukemia
 Oral contraceptive use
 Severe iron deficiency
Artifact
 Radioactive serum (e.g., after isotopic scanning procedures)
 High-dose ascorbic acid ingestion

^a Only a few patients with dietary-related overt evidence of cobalamin deficiency.
^b Some patients in these categories can have coexisting cobalamin malabsorption and either clinically overt or mild, geriatric deficiency.

TABLE 243.3. CAUSES OF LOW SERUM COBALAMIN LEVELS

Folate deficiency
Low serum levels apparently not reflecting overt folate deficiency
 Transiently poor dietary intake without actual folate deficiency
 Sickle-cell anemia and other chronic hemolytic states
 Drug use (e.g., oral contraceptives, acetylsalicylic acid, alcohol)
 Idiopathic factors
Artifact
 Improper handling of specimen (e.g., long storage)
 Radioactive blood^a
 Folate-binding protein abnormality in renal failure^b
 Drugs that inhibit microbial growth (e.g., antibiotics)^b

^a Source of artifact only in radioisotopic assay.
^b Source of artifact only in microbiologic assay.

TABLE 243.4. CONDITIONS ASSOCIATED WITH LOW SERUM FOLATE LEVELS

Measuring tissue levels is an ideal goal but is impractical, aside from determining red cell folate levels. Red cell levels are truer indices of folate status than serum levels and are not immediately affected by vitamin therapy. Their chief shortcomings are laboratory performance problems and the fact that low levels often occur in cobalamin deficiency as well.

Metabolic tests are becoming increasingly useful. Elevated homocysteine levels are a helpful marker for folate or cobalamin deficiency but occur in other conditions too. High methylmalonic acid levels are relatively specific for cobalamin deficiency. Serum levels of both metabolites also rise in renal insufficiency, however. Some patients with cobalamin deficiency have abnormal metabolite levels even when their serum cobalamin levels are normal. Testing for these two metabolites is occasionally helpful in acquired vitamin deficiencies and is mandatory when considering hereditary disorders. Perhaps an even more sensitive test for both vitamin deficiencies, the deoxyuridine suppression test in bone marrow cells, which tests reactions 5 and 6 in [Fig. 243.1](#), is still a research tool.

DIAGNOSIS OF THE UNDERLYING DISEASE

Each of the two deficiencies has a distinct differential diagnosis. In cobalamin deficiency, the most common cause is pernicious anemia; for folic acid, it is dietary insufficiency, often combined with alcohol abuse. The temptation to automatically assume the most common diagnosis must be resisted, however.

Testing of cobalamin absorption is central to the diagnostic evaluation because nearly all cobalamin deficiency in the Western Hemisphere is either of gastric or intestinal origin. This is done by measuring the absorption of a small oral dose of radioactive cyanocobalamin. Radioactivity can be measured in urine (Schilling test), plasma, or feces, or whole-body retention can be measured. Each method has its advantages. The Schilling test is the most commonly used, but it requires a complete 24-hour urine collection and normal renal function. Pernicious anemia is diagnosed by an abnormal absorption test that is corrected by retesting with an oral dose of intrinsic factor. A popular version of the Schilling test combines both of the above steps but gives falsely normal results in 30% to 40% of cases due to isotope exchange.

The presence of anti-intrinsic factor antibody in the blood is diagnostically useful; it is rarely positive in patients without pernicious anemia, but an artifact can be produced if blood is sampled within 48 hours after a cobalamin injection is given. Antibody to parietal cells, on the other hand, is specific for atrophic gastritis, not pernicious anemia. High serum gastrin and low pepsinogen I levels occur in 80% to 90% of patients with pernicious anemia.

Malabsorption of food-bound cobalamin cannot be detected by standard absorption tests that use free cobalamin, such as the Schilling test. Absorption tests using cobalamin in scrambled egg yolk or bound to chicken serum have been devised but are still not widely available.

Diagnosing the cause of folate deficiency requires a good dietary history, evaluation for possible alcoholism, and a careful drug history. Malabsorption is responsible for 10% to 20% of cases. Because tests of folate absorption are not widely available, folate malabsorption is usually diagnosed indirectly by documenting other malabsorptive phenomena.

OPTIMAL MANAGEMENT

TREATING THE SYMPTOMS

Megaloblastic anemia responds rapidly to small doses of the appropriate vitamin. A single injection of cobalamin or one folic acid pill reverses megaloblastic erythropoiesis. A feeling of well-being often precedes hematologic response by days. Reticulocytosis begins within a day or two and peaks at 5 to 7 days, at which time the hemoglobin level begins rising noticeably, although hypersegmented neutrophils may persist for several weeks. With adequate treatment, the blood count should always become completely normal within 8 weeks.

Transfusion is rarely indicated, given its hazards, the well-compensated state of even severely anemic patients, and the responsiveness to vitamin therapy. If clinical findings necessitate transfusion, a unit of packed red blood cells should be given slowly and the patient reevaluated before proceeding.

Vitamin therapy can be safely deferred in most patients until the specific vitamin deficiency has been identified, but it can be started in an emergency as soon as the necessary diagnostic specimens have been obtained. The neurologic symptoms of cobalamin deficiency call for more urgent therapy, but there is no evidence that higher doses or more frequent injections are necessary. The completeness of the neurologic response is not as predictable as the hematologic response. The more extensive the neurologic involvement and the longer the symptoms have been present, the less likely it is that complete reversal will occur. Nevertheless, some degree of neurologic improvement is possible even in longstanding cases, although it may take 6 to 12 months to occur. In any case, neurologic dysfunction never progresses when therapy is given. Patients with spasticity, gait disturbances or bladder problems require early rehabilitative efforts.

TREATING THE VITAMIN DEFICIENCY

Before therapy is begun, it is essential to be sure of the diagnosis. Treatment of cobalamin deficiency with folic acid must be avoided. If both vitamins are given, proper diagnosis may become difficult if the initial test results are inconclusive. Giving both vitamins can also blur the specificity of the diagnosis in the patient's mind, if therapy is continued for long. The two main goals are to reverse the abnormalities produced by the deficiency and to prevent relapse. A third goal is to replete tissue stores and provide a reserve, although there is no evidence that fully repleted stores are essential to the patient's well-being.

Because cobalamin deficiency is usually due to malabsorption, therapy should be parenteral. Lifelong maintenance is required when the underlying disease is irreversible, as in pernicious anemia. Usual doses are 100 to 1000 µg; a smaller fraction of the 1000-µg dose, but a larger absolute amount, is retained. Cyanocobalamin is the common form of cobalamin used, but hydroxocobalamin is better retained and requires less frequent injections. Once repletion has been achieved, monthly maintenance injections can be given. However, individual requirements vary: some patients may need more frequent injections, whereas others can do with less frequent ones. Metabolic and transport blocks require very frequent injections. Oral cobalamin suffices in dietary insufficiency. It can be used even in malabsorption because a small fixed proportion is absorbed by mass action, but at least 100 µg must be taken daily, and its effectiveness must be continuously monitored.

Folate therapy can usually be given orally because most deficiencies are dietary in origin. Daily doses of 1 mg are sufficient and stores can be repleted within a few weeks. Long-term maintenance is necessary only when the underlying disorder cannot be reversed. Oral folic acid can often be absorbed normally even in malabsorption syndromes, but higher doses should be used.

TREATING THE UNDERLYING DISEASE

The underlying disease must always be identified. Several causes have their own specific therapy, such as antibiotics for bacterial contamination of the gut and gluten-free diets for sprue, and others have specific complications and prognostic implications. Vitamin therapy can be discontinued if the underlying disease has been reversed and does not recur.

COMPLICATIONS

Vitamin therapy itself has no complications (allergic reactions are rare), unless the wrong vitamin is given. Because a transient hematologic response can be obtained with folate in cobalamin deficiency while neurologic abnormalities continue to progress, this can be a serious problem. A more common occurrence is an incomplete hematologic response despite appropriate vitamin therapy. This is indicated by a blunted reticulocyte response during the first week or by failure of the blood count to become completely normal within 2 months and is almost always due to coexisting disorders. Iron deficiency often coexists and may initially be masked in untreated megaloblastic anemia, with completely normal blood and marrow tests of iron status.

Transfusion should be avoided whenever possible; volume overload is only one of the many risks involved.

Long-term complications are those related to the underlying disease itself. For example, in pernicious anemia, there are the increased risks of gastric cancer, carcinoid tumors, and immune endocrine disorders, particularly hypothyroidism.

PATIENT EDUCATION

Because cobalamin therapy usually becomes a lifelong concern, patient education is essential. Too many patients discontinue therapy once their symptoms disappear. Reinforcement and careful explanation of the nature of the underlying disease may help. Some patients can be taught to inject themselves, which saves costs and often improves compliance as well. Dietary education is essential in most cases of folate deficiency. Addressing alcohol problems is also important.

CHAPTER 244: HEMOLYTIC ANEMIAS

JOSEPH P. CATLETT

[Approach to the Patient](#)
[Specific Disorders](#)

APPROACH TO THE PATIENT

PRESENTATION

Hemolytic anemia may be defined as the premature destruction of erythrocytes occurring by a number of mechanisms. For this reason, the presenting signs and symptoms of hemolysis may vary from patient to patient, depending, in large part, on the mechanism of erythrocyte destruction and the acuteness of the process. Patients with chronic hemolytic anemias may be asymptomatic despite severe depression of the hematocrit, whereas patients with acute anemia may be at risk for circulatory failure. It is therefore important to obtain accurate clinical and laboratory information before proceeding to potentially inappropriate or unnecessary therapeutic interventions.

PATHOPHYSIOLOGY

Normal erythrocytes have a life span in the circulation of 100 to 120 days. The oldest 1% of the erythrocyte mass is destroyed in the spleen and replaced each day by the bone marrow. Newly released erythrocytes, known as *reticulocytes*, normally constitute about 1% of circulating erythrocytes and can be recognized in a blood film as large, bluish gray cells. Through progressive loss of membrane and intracellular organelles, reticulocytes are gradually “remodeled” in the spleen and microcirculation into a biconcave disk. The erythrocyte depends on the biochemical integrity of its membrane, the stability of its proteins and metabolic processes, and the fluidity of its cytoplasm to maintain a critical ability to deform itself to negotiate passages less than one-tenth its diameter. The biconcave disk shape of the resting erythrocyte confers optimal surface-to-volume ratio facilitating both gas exchange and deformation in the microcirculation. During flow, these cells transiently assume “teardrop” and “parachute” shapes. As the erythrocyte ages, it acquires a more spherical shape through gradual loss of metabolic activity, deformability, and membrane surface, and accumulates surface immunoglobulin.

The erythropoietic capacity of the bone marrow normally is capable of a sixfold increase in erythrocyte production to compensate for a proportional acceleration of hemolytic rate. Anemia results when the rate of erythrocyte destruction exceeds the erythropoietic capacity of the bone marrow.

Intrinsic hemolytic disorders primarily are inherited alterations of erythrocyte membrane, hemoglobin structure or synthesis, or enzyme activity. *Extrinsic* hemolytic states are largely acquired and include erythrocyte injury caused by antibody to erythrocyte antigens, complement, bacterial toxins, parasites, or physical injury within the circulation. Hemolysis may take place within the circulatory system (*intravascular* hemolysis) such as that due to a defective prosthetic heart valve or thrombotic thrombocytopenic purpura (TTP), or within the reticuloendothelial system, e.g., the spleen (*extravascular* hemolysis), such as is seen with hereditary spherocytosis (HS). In some hemolytic anemias, e.g., certain forms of immune hemolysis, both mechanisms are operative. A mechanistic classification of hemolytic anemias is shown in [Table 244.1](#).

Abnormalities of the erythrocyte membrane
Hereditary
Spherocytosis
Elliptocytosis
Acanthocytosis
Schistocytosis
Acquired
Acanthocytosis, stomatocytes, target cells (liver disease)
Ektinocytosis (uremia)
Paroxysmal nocturnal hemoglobinuria
Metabolic deficiencies of the erythrocyte
Hexose monophosphate shunt enzyme deficiencies
Glycolytic pathway enzyme deficiencies
Purine and pyrimidine metabolic abnormalities
Immune-mediated hemolytic anemia
Warm antibody-mediated
Cold agglutinin syndrome
Paroxysmal cold hemoglobinuria
Combined warm and cold antibody
DAI-negative autoimmune hemolysis
Drug-induced
Hemoglobinopathies and thalassemias
Physical erythrocyte injury
Fragmentation hemolysis
Microangiopathic
Cardiac and large-vessel disease
Thermal and chemical injury
Erythrocyte parasitization (malaria, bartonellosis, babesiosis)

TABLE 244.1. CLASSIFICATION OF HEMOLYTIC ANEMIAS BY MECHANISM OF ERYTHROCYTE INJURY

HISTORY AND PHYSICAL EXAMINATION

Historical data may be helpful in directing further evaluation and can include recurrent leg ulceration, pigmented gallstones requiring cholecystectomy at an early age, intermittent or chronic jaundice, intermittent dark urine, fevers, chills, fatigue, malaise, drenching night sweats, or weight loss. Acute hemolysis may follow self-administered or prescribed drug ingestion indicating the presence of an immune-mediated process or enzyme deficiency. Physical findings indicative of a hemolytic process may include jaundice, splenomegaly, hepatomegaly, petechial hemorrhages and purpuric lesions, or lymphadenopathy.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

The presence of hemolytic anemia should be determined first on the basis of simple laboratory tests. Unless an underlying deficiency is present, reticulocytosis is present on the blood film (termed *polychromasia*) with the absolute count usually in excess of 100,000 per microliter. In many cases of hemolysis, the lactic dehydrogenase (LDH) levels will be elevated along with varying degrees of indirect hyperbilirubinemia. Haptoglobin levels are depressed in intravascular and some cases of extravascular hemolysis, and free hemoglobin may be demonstrated in the plasma and urine. A direct antiglobulin (Coomb's) test (DAT) is positive for immunoglobulin, complement, or both in most instances of immune-mediated hemolysis. Review of the peripheral blood smear may also demonstrate the presence of *spherocytes*, or fragmented cells, termed *schistocytes*, which are seen in certain types of hemolysis (described later).

DIFFERENTIAL DIAGNOSIS

When hemolytic anemia is present, the differential diagnosis, as noted in [Table 244.1](#), should be reviewed and the necessary investigations performed to arrive at a precise diagnosis. The workup of each disorder will be described throughout this chapter.

STRATEGIES FOR OPTIMAL CARE MANAGEMENT

Establishing an accurate diagnosis is the key to the proper management of hemolytic anemia, regardless of the underlying cause. The optimal care of these patients depends on the underlying etiologic factors in the hemolytic process. However, certain therapies may be applicable to patients with hemolysis irrespective of its origin.

Management, Complications, and Pitfalls

Red blood cell transfusion often is indicated in patients with severe anemia. The decision to transfuse packed red cells in patients with hemolytic anemia has to be made in light of the known risks of transfusion, including febrile or allergic reactions, acute and delayed hemolytic transfusion reactions, and the transmission of infectious diseases. Long-term erythrocyte transfusion, more commonly necessary in congenital hemolytic anemias, may lead to iron overload (*transfusional hemosiderosis*) requiring iron chelation therapy. For patients with extrinsic hemolysis (e.g., microangiopathy, autoimmune hemolysis), the transfused cells can be

expected to have the same short survival suffered by the patient's own red cells. The presence of autoantibodies may render compatibility testing difficult (see later).

Oral folic acid in a dose of 1 mg per day is recommended initially since hemolysis increases the daily folic acid requirement and may deplete folic acid stores.

In patients with congenital hemolysis, gallstones may appear during adolescence and become symptomatic in early adulthood. Asymptomatic gallstones are often documented by ultrasound or other noninvasive testing. It is generally recommended that cholecystectomy be reserved for patients with symptomatic disease. Unfortunately, calcium bilirubinate gallstones, common in patients with chronic hemolysis, are not dissolved by chenodeoxycholic acid.

Indications for HOSPITALIZATION

Patients with severe symptomatic anemia, evidenced by dyspnea at rest, tachycardia, and hypotension, should be hospitalized for transfusion on an emergency basis. Those with high-output cardiac failure or impending circulatory collapse should be monitored in an intensive care setting. Most non-emergency transfusions can be done on an outpatient basis without undue complication.

Indications for REFERRAL

A patient with anemia unexplained by routine lab workup should be referred to a hematologist for further evaluation and management. For many patients, one or two visits will suffice to establish a diagnosis for which follow-up and management can be done by the primary care physician. The same can be said for stable or asymptomatic congenital disorders. For more acute disorders, such as active immune-mediated hemolysis or TTP, a hematologist should assume total care of these complex problems.

Cost-Effectiveness

It is difficult to gauge the cost-effectiveness of the many therapies used to treat hemolytic anemia. Certainly, in asymptomatic or minimally symptomatic patients who may have immune-mediated hemolysis, prednisone is more cost-effective than transfusion, when possible. Asymptomatic patients with chronic hemolytic processes usually do not require admission, despite a low hematocrit, and can safely be evaluated and treated on an outpatient basis. Many therapies that were once considered inpatient procedures, such as plasma exchange for relapsing TTP, can be safely done in a properly appointed ambulatory facility, thus avoiding hospital costs.

SPECIFIC DISORDERS

ABNORMALITIES OF THE ERYTHROCYTE MEMBRANE

Inherited Hemolytic Anemias Resulting from Membrane Protein Abnormalities

The erythrocyte membrane is formed by a lipid bilayer intercalated by membrane proteins. The bilayer is fluid in nature but is stabilized by its interaction with the membrane skeleton, a scaffold of proteins consisting mainly of spectrin, actin, and protein 4.1. This cytoskeleton is a major determinant of erythrocyte shape, strength, and flexibility. Numerous inherited and acquired alterations in erythrocyte membrane structure or intracellular content result in diminished deformability of the red cell with consequent accelerated hemolysis.

The molecular basis of erythrocyte membrane abnormalities can be divided into vertical and horizontal interactions. Vertical interactions are perpendicular to the plane of the membrane and stabilize the lipid bilayer. They involve interactions between spectrin, ankyrin (band 2.1; binds the lipid bilayer to the membrane skeleton), and ion transport channel (band 3); protein 4.1 and glycophorin C; and skeletal proteins with negatively charged lipids of the inner bilayer. Horizontal interactions are parallel to the plane of the membrane and support the structural integrity of the cells after their exposure to shear stress. These interactions involve the assembly of spectrin heterodimers into tetramers, the principal building blocks of the skeleton, and the binding of the distal ends of spectrin heterodimers with actin and protein 4.1.

Hereditary Spherocytosis

Definition

Hereditary spherocytosis (HS) is a common inherited hemolytic disorder of varying severity, characterized by spherocytosis on the blood smear, increased erythrocyte osmotic fragility, and a favorable clinical response to splenectomy.

Prevalence and Epidemiology

Reported in persons of most races, HS is the most common inherited anemia in patients of European descent, with an incidence of 1 in 2,000 among individuals in the United States and England. Despite the fact that the clinical severity of HS is highly variable among different kindreds, it is relatively uniform within a given family, where it is inherited in an autosomal dominant fashion. Recessively inherited HS has also been described, in some cases presenting with severe hemolytic anemia.

Etiologic Factors

Hereditary spherocytosis occurs as a result of a multistep process caused by an inherited deficiency or dysfunction of one of the skeletal proteins of the erythrocyte membrane including ankyrin, band 3, α -spectrin, β -spectrin, and protein 4.2 (pallidin) ([Table 244.2](#)). Accelerated erythrocyte destruction occurs in the spleen, where these intrinsically abnormal cells are retained and "conditioned." A combined deficiency of spectrin and ankyrin is found in most cases of HS, followed by deficiencies of band 3, spectrin only, and protein 4.2 (seen in the Japanese). Ankyrin "anchors" the spectrin-based skeleton to the intracellular portion of band 3. Multiple genetic defects are responsible for the array of protein abnormalities seen in HS; however, with few exceptions, mutations are private (unique for a given kindred).

Inheritance	Clinical Presentation	Reported Molecular Defect	Prevalence
Autosomal dominant	HS with minimal, mild to moderate hemolysis	Ankyrin	Probably common
Autosomal recessive	HS with severe hemolysis	β -spectrin	About 10% of all patients
	HS with mild to moderate hemolysis	α -spectrin	Probably rare
		4.2	Rare in whites, may be more common in Japan
		? Anion transport protein	

HS, hereditary spherocytosis.

TABLE 244.2. CLINICAL AND MOLECULAR HETEROGENEITY OF HEREDITARY SPHEROCYTOSIS

Pathogenesis

The pathophysiology of HS is thought to involve aberrant vertical interactions occurring between the spectrin-based cytoskeleton and the lipid bilayer. Because of the decrease in spectrin content, the density of the membrane skeletal monolayer is reduced, leading to a destabilization of the lipid bilayer and a release of lipids from

the membrane. This decrease in cell surface-to-volume ratio accounts for the spheroidal shape and decrease in deformability, which is diminished further by a high internal viscosity resulting from mild cellular dehydration. The red cells that are “conditioned” in the splenic pulp are considerably more osmotically fragile and more spherical. Some of the conditioned cells reappear in the peripheral circulation; their presence is suggested by a tail in the osmotic fragility curve, representing a subpopulation of the most fragile cells ([Fig. 244.1](#)). The primary cause of hemolysis is postulated to be entrapment of spherocytes in the splenic microcirculation and ingestion by splenic macrophages. Low pH, low glucose, and toxic free radicals released by macrophages have been postulated to contribute to the early demise of these red cells. Recent murine studies suggest that a membrane permeability defect may also exist.

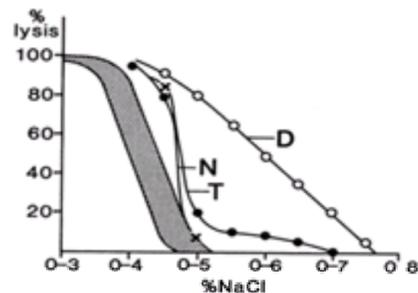

FIGURE 244.1. Different types of osmotic fragility curves in hereditary spherocytosis (HS). *N*, Normal-type curve, revealing an overall increase of osmotic fragility. Shaded area represents the normal range. *T*, Tailed curve, revealing a second population (a tail) of very fragile cells. *D*, Diagonal curve, in patients with severe HS, in whom the two cell populations are not easily separable. (Adapted from Dacie J. The haemolytic anaemias. In: *The hereditary haemolytic anaemias, vol 1. 3rd ed.* Edinburgh: Churchill Livingstone, 1985:114, with permission.)

Clinical Findings

The clinical manifestations of HS are highly variable and correlate with the severity of spectrin deficiency, ranging from an asymptomatic condition to severe, life-threatening hemolysis ([Table 244.2](#)). In its more common form, the clinical features include a mild, often compensated hemolytic anemia, acholuric jaundice, splenomegaly, and the presence of similar findings in one or more siblings, children, or parents of the patient. In some, the clinical expression is mild, with normal or slightly elevated serum bilirubin and reticulocyte counts, and only subtle changes in erythrocyte morphology. The disease may be discovered during evaluation of asymptomatic splenomegaly, a family study of a patient with more typical symptoms of the disease, or exacerbation of hemolysis secondary to infection. Rarely, the diagnosis may first be made in old age. There is evidence to support the presence of an asymptomatic carrier state.

HS should be distinguished from other spherocytic hemolytic anemias, such as autoimmune hemolytic anemia (AIHA), unstable hemoglobins, and the rare Rh deficiency syndrome. Spherocytes in HS usually can be distinguished from those in immunohemolytic anemia by their relatively uniform shape and increased hemoglobin concentration. Occasional spherocytes are also seen in patients with large spleens (i.e., cirrhosis, myelofibrosis) or in patients with microangiopathic anemias, but it is usually not difficult to distinguish these conditions from HS.

Aplastic crisis may occur in association with infection by parvovirus, which inhibits erythropoiesis in vitro and in vivo. The infection is asymptomatic or manifests as a flulike syndrome with fever, chills, mild respiratory symptoms, and a maculopapular rash on the face (slapped cheek syndrome), trunk, and extremities. Aplastic crisis should be differentiated from acute megaloblastic changes resulting from folate deficiency, such as during pregnancy, when the increased folate requirements of hyperplastic erythropoiesis are compounded by the high folate demands of the developing fetus. Bilirubin gallstones occur in more than half of all patients, including those with a relatively mild form of the disease. Other complications may include leg ulcerations or dermatitis, which heal quickly after splenectomy. Occasionally, extramedullary hemopoiesis, manifesting as a single mass or multiple masses, has been detected. Iron overload has been reported in several patients with HS who were heterozygous for human leukocyte antigen–linked hemochromatosis.

Laboratory Findings

Elevated unconjugated bilirubin, low haptoglobin, and reticulocytosis indicate hemolysis. The mean corpuscular hemoglobin concentration is increased, occasionally reaching 40 g per deciliter, which reflects mild cellular dehydration, and the erythrocyte volume is often inappropriately low considering the increase in reticulocytes, which have a larger volume than mature erythrocytes. Spherocytes are readily apparent only in more severe forms of the disease, whereas they can be missed in mild HS. In patients with severe or atypical forms of HS, additional morphologic abnormalities include surface spicules, irregular contour, and “pincered” erythrocytes with a mushroom-like appearance ([Fig. 244.2](#)).

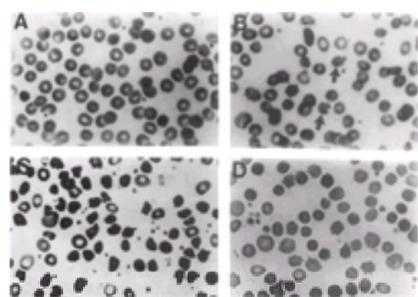

FIGURE 244.2. Blood films from patients with HS of varying severity. **A:** Typical HS. Although many cells have a spheroidal shape, some of them retain a central concavity. **B:** HS with pincered red blood cells (arrows). Occasional spiculated red blood cells also are present. **C:** Severe atypical HS due to a severe combined spectrin and ankyrin deficiency. In addition to spherocytes, many cells have an irregular contour. **D:** HS associated with abnormal b-spectrin that binds defectively to protein 4.1 (Spb-4.1). Some of the spherocytes have prominent surface projections, and resemble spherocanthocytes. (From Palek J. Anemias due to increased destruction of erythrocytes with abnormal shape and membrane defects. In: Williams WS, Beutler E, Ersler AJ, et al., eds. *Hematology*. New York: McGraw-Hill, 1989:558, with permission.)

The principal diagnostic test, erythrocyte osmotic fragility, measures the surface-to-volume ratio of the cells. Because their membranes are virtually unstretchable and impermeable to cations, erythrocytes act as nearly perfect osmometers—swelling in hypotonic solutions, then undergoing hemolysis after reaching a spheroidal shape. Because of a diminished surface-to-volume ratio, HS cells hemolyze more in hypotonic salt solutions than normal cells do ([Fig. 244.1](#)).

Deficiencies of one or more membrane proteins can be demonstrated in about 80% of cases by sodium dodecyl sulfate/polyacrylamide gel electrophoresis (SDS-PAGE) of erythrocyte membrane proteins or by radioimmunoassay.

Optimal Management

Patients with mild clinical features may require no specific therapy beyond folic acid supplementation. Splenectomy corrects the hemolytic anemia, but erythrocyte survival may remain slightly shortened in some patients. Spherocytosis becomes less prominent and osmotic fragility improves. Indications for splenectomy are somewhat controversial, but unequivocal criteria include severe symptomatic hemolytic anemia or its complications, particularly gallstones; mild hemolytic anemia in

association with gallstones; and a history of gallstones in similarly affected family members. Splenectomy is not recommended in patients with mild HS who do not have family histories of gallbladder disease because these patients tend to have relatively uneventful courses. Splenectomy failures may be due to an accessory spleen, which can occur in up to one-third of patients; accidental autotransplantation of splenic tissue into the peritoneal cavity at the time of splenectomy followed by the development (7 to 15 years later) of new splenic tissue (splenosis); or another concomitant hemolytic disorder.

Partial splenectomy (removal of 80% to 90% of splenic tissue), has been effective in decreasing the hemolytic rate while maintaining splenic phagocytic function and has been recommended in children, particularly transfusion-dependent infants. Prior to splenectomy, all patients should receive polyvalent vaccines against *Pneumococcus*, *Haemophilus influenzae*, and *Meningococcus*.

Because of a high prevalence of gallstones, all patients with HS should undergo periodic ultrasonographic examinations of the gallbladder. Patients in aplastic crisis from parvovirus or other infection should be supported with red cell transfusions until the crisis resolves.

Hereditary Elliptocytosis and Related Disorders

Definition

Hereditary elliptocytosis (HE) is a clinically, genetically, and biochemically heterogeneous group of inherited disorders, having in common elliptical erythrocytes. Three distinct subtypes have been described based on erythrocyte morphology. *Common HE*, the most prevalent form, is characterized by biconcave elliptocytes and, occasionally, rod-shaped cells, and, in its more severe form, designated hereditary pyropoikilocytosis (HPP), by poikilocytes, microspherocytes, and fragmented erythrocytes. *Spherocytic HE* is a phenotypic hybrid of HE and HS. *Stomatocytic HE*, also known as *Southeast Asian ovalocytosis* or *Melanesian ovalocytosis*, is characterized by "spoon-shaped" erythrocytes and other red cells that are more round and have a longitudinal or transverse slit ([Fig. 244.3](#)).

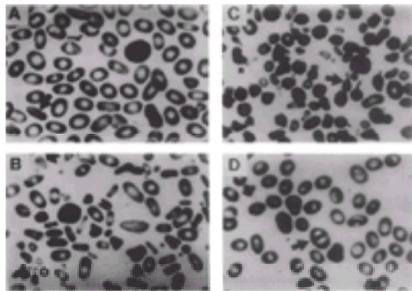

FIGURE 244.3. Blood films of patients with various forms of hemolytic elliptocytosis (HE). **A:** Dominantly inherited, mild, common HE. Note the predominant elliptocytosis with some rod-shaped cells (*arrows*) and the virtual absence of poikilocytes. **B:** Dominantly inherited severe HE. In addition to elliptocytosis, there are numerous small fragments and poikilocytes. **C:** Hereditary pyropoikilocytosis. The patient is a double heterozygote for mutant α -spectrin and a presumed synthetic defect of this protein. Note prominent microspherocytosis, micropoikilocytosis, and fragmentation. Only a few elliptocytes are present. Some poikilocytes are in the process of budding (*arrow*). **D:** Southeast Asian ovalocytosis. Most of the cells are oval, some of them containing a longitudinal slit or a transverse ridge (*arrow*). All blood smears were photographed at the same magnification ($\times 1000$).

Incidence and Epidemiology

The true incidence of HE is unknown since many individuals are asymptomatic, but it is estimated at 1 in 2,000 to 1 in 4,000 worldwide. It is considerably higher (1.2 in 2,000 to 2.4 in 4,000) in equatorial Africa. In Southeast Asia, the incidence of Southeast Asian ovalocytosis is as high as 30%. The inheritance characteristically is autosomal dominant, but occasional patients inherit HE from an asymptomatic carrier who has the same membrane protein mutation. The clinical severity is highly variable, reflecting heterogeneous molecular causes. HPP is inherited as an autosomal recessive disorder. Typically, one of the parents of the offspring with HPP carries an identifiable molecular defect (e.g., mutation of spectrin) and is asymptomatic or has mild HE, whereas the other asymptomatic parent does not have an identifiable molecular defect or carries an asymptomatic spectrin mutation. Genetic studies have linked HE to blood group antigens Rh and Duffy, the genes of which reside on the short arm of chromosome 1. The gene for Duffy blood group is close to that of α -spectrin, and the Rh gene is close to the region containing the gene for protein 4.1.

Etiologic Factors

The underlying defect involves dysfunction or a deficiency of one of the major skeletal proteins. The clinical expression of these defects is shown in [Table 244.3](#). The most common defects in HE are mutations of α - or β -spectrin. At the level of protein function, these abnormal spectrins are characterized by the inability of spectrin heterodimers to self-associate into tetramers. The second group consists of defects of protein 4.1. A total absence of protein 4.1 (homozygous condition) is associated with severe hemolytic HE, whereas a partial deficiency is associated with mild dominantly inherited HE. Several abnormal isoforms (increase or decrease in the size of the protein) have been reported. In a few patients with minimal HE, deficiency of glycophorin C has been detected.

Subtype	Genetic Basis	Clinical Features	Molecular Defect
Common HE	Autosomal dominant	Mild hemolysis, elliptocytes, rod-shaped cells	Mutations of α -spectrin or β -spectrin
Severe HE	Autosomal dominant	Severe hemolysis, elliptocytes, fragments, poikilocytes	Mutations of α -spectrin or β -spectrin
Hereditary pyropoikilocytosis (HPP)	Autosomal recessive	Severe hemolysis, microspherocytes, micropoikilocytes, fragmentation	Double heterozygosity for mutant α -spectrin and a synthetic defect
Southeast Asian ovalocytosis	Autosomal dominant	Ovalocytes, some with longitudinal or transverse slits	Mutations of protein 4.1

TABLE 244.3. CLINICAL AND MOLECULAR HETEROGENEITY OF HEREDITARY ELLIPTOCYTOSIS

Pathogenesis

In most patients with HE and HPP, the principal lesion involves horizontal membrane protein associations, namely, the spectrin dimer–dimer contact. This protein interaction, which is parallel to the plane of the membrane, maintains the structural integrity of the skeleton. The formation of elliptocytes is most likely a result of a permanent plastic deformation of the membrane skeleton. The elliptocytic shape is acquired in the circulation ([Fig. 244.3](#)), but the pathobiologic processes involved in this shape change are unclear. The clinical expression of HE is correlated directly with the severity of the spectrin dimer self-association defect as evidenced by the increase in the spectrin dimer percentage in the erythrocyte. Data suggest that the critical threshold of unassembled spectrin in the cell is 40% to 50%, above which patients exhibit severe hemolysis.

Clinical Findings

Common HE can be divided into several subgroups based on clinical severity. The most common is mild HE, an asymptomatic condition discovered during routine blood film evaluation. Some of these patients do not have clinical evidence of hemolysis, and their erythrocyte survival may even be normal. Others, although clinically asymptomatic, have laboratory evidence of mild compensated hemolysis. Transient hemolysis develops in some patients with mild HE when the “minimal” HE defect is augmented by superimposed events such as viral, bacterial, or protozoal infection; renal transplant rejection; splenomegaly; B₁₂ deficiency; or even normal pregnancy. In addition to elliptocytes and rod-shaped cells, blood films of such patients show considerable poikilocytosis. The underlying cause of increased hemolysis is not known. The prevailing hypothesis proposes that the marginally unstable erythrocytes of HE are damaged by the excessive shear stress of an altered microcirculation. There are several reports of HE with moderate to severe chronic hemolytic anemia requiring splenectomy. Some of these patients have a homozygous form of the disease, whereas in others, hemolytic HE is inherited through several generations. Asymptomatic carriers, with α -spectrin mutations involving the spectrin heterodimer association site, also have been reported. Typically, such patients are the parents (or siblings) of patients with HPP or, occasionally, HE.

HPP is an autosomal recessive disorder characterized by a severe hemolytic anemia with striking micropoikilocytosis and microspherocytosis with a mean corpuscular volume as low as 50 μm^3 . Patients with HPP are heterozygous for an α - or β -spectrin mutation associated with defective spectrin self-association and another defect possibly involving spectrin synthesis, which leads to a superimposed partial deficiency of spectrin. The same phenotype has been described in patients who are compound heterozygotes or homozygotes for one or two α -spectrin mutations; the concomitant spectrin deficiency presumably results from instability of one of these spectrin mutants. HPP is predominantly a disease of the black race, but it also has been seen in nonblacks. HPP represents a subset of HE: some of the relatives of HPP probands may have mild HE and carry identical α -spectrin mutations; however, the defect is more severe in HPP, where it is present in conjunction with a partial spectrin deficiency.

Spherocytic HE, also known as HE with spherocytosis or hemolytic hereditary ovalocytosis, is characterized by the presence of occasional spherocytes on the blood film and an increased osmotic fragility. These patients often have a clinically apparent hemolytic anemia in spite of relatively subtle changes in erythrocyte morphology.

Southeast Asian ovalocytosis is common (15% to 30%) among aboriginal populations of Malaysia, Melanesia, and possibly Indonesia. The condition is asymptomatic and appears to confer resistance to invasion by several strains of malarial parasites.

These disorders should be distinguished from other conditions in which elliptocytes and poikilocytes are commonly encountered, including iron deficiency, thalassemias, megaloblastic anemias, myelofibrosis, myelophthisic anemias, myelodysplastic syndromes, and pyruvate kinase deficiency. However, in these conditions, the quantity of elliptocytes in the peripheral smear seldom exceeds 60%.

Laboratory Findings

The percentage of elliptocytes on the blood film of a patient with a biochemically defined molecular defect of skeletal proteins is highly variable, ranging from 15% to 100%. A positive family history is more important for the diagnosis of HE than is any precise percentage of elliptocytes; therefore, evaluation of the peripheral blood smear, together with study of other family members, represents an essential step in diagnosis. Osmotic fragility is normal in mild forms of common HE but is increased in spherocytic HE, common HE with severe hemolysis, and HPP, reflecting the presence of spheroelliptocytes, microspherocytes, and fragments. In HPP, erythrocytes fragment and their mutant spectrin denatures at temperatures of 45°C to 46°C, whereas this same process occurs in normal cells at 49°C to 50°C. Thermal instability also has been detected in heterozygous patients with HE who carry spectrin mutations.

Techniques for diagnosing these conditions involve the separation of membrane proteins by SDS-PAGE, which can detect deficiencies or defects based on migration patterns. In patients with common HE, mutations of the spectrin protein are present in roughly 60%, and most can be detected readily by this method. An increased fraction of unassembled, dimeric spectrin also typically is present in erythrocyte extracts.

Optimal Management

For patients who manifest hemolytic disease, treatment with splenectomy in a fashion similar to that used for HS reverses the anemia. HPP and hereditary stomatocytosis may also respond partially to splenectomy.

Acanthocytosis

Definition

Spur cells, or acanthocytes (from the Greek *acantha*, or thorn), are erythrocytes with multiple irregular projections that vary in width, length, and surface distribution (Fig. 244.4). They were first described in a patient with atypical retinitis pigmentosa, a progressive ataxic neuropathy, and fat malabsorption in whom subsequent studies showed congenital absence of b-lipoproteins. Acanthocytes also are seen in certain inherited neurologic disorders without abetalipoproteinemia (chorea–acanthocytosis syndrome), in association with the McLeod phenotype, and as an acquired disorder (see later).

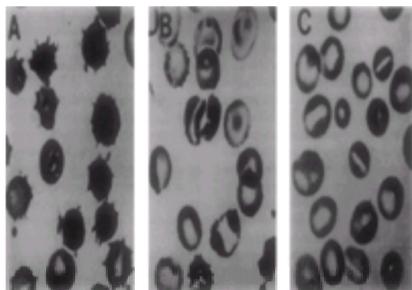

FIGURE 244.4. Blood films of patients with liver cirrhosis and spur cell anemia (A), hereditary xerocytosis (dessiccocytosis; B), and stomatocytosis (hydrocytosis; C). (Adapted from Cooper RA, Kimball DB, Durocher JR. The role of the spleen in membrane conditioning and hemolysis of spur cells in liver disease. *N Engl J Med* 1974;290:1279; and Lande WM, Mentzer WC. Hemolytic anaemia associated with increased cation permeability. *Clin Haematol* 1985;14:89, with permission.)

Etiologic Factors

Both *abetalipoproteinemia* and *chorea–acanthocytosis syndrome* are inherited as autosomal recessive disorders. Acanthocytes have been described in association with markedly reduced red cell expression of Kell antigens, referred to as the *McLeod phenotype*, which is inherited in an X-linked fashion.

Pathogenesis

The primary molecular defect in *abetalipoproteinemia* involves a congenital absence of apolipoprotein-b in plasma. Consequently, all plasma lipoproteins containing this apoprotein and plasma triglycerides are nearly absent, and plasma cholesterol and phospholipid levels are markedly reduced. Plasma sphingomyelin is relatively increased at the expense of phosphatidylethanolamine. Bone marrow erythrocyte precursors have normal morphologic characteristics. The acanthocytic shape becomes progressively more apparent as the red cells mature and age in the circulation. The most striking abnormality of the acanthocyte membrane in *abetalipoproteinemia* is an increase in membrane sphingomyelin. This phospholipid is located predominantly in the outer hemileaflet of the membrane bilayer, and the excess sphingomyelin causes an expansion of its surface area that probably is responsible for the surface irregularities.

In the McLeod phenotype, the acanthocytic lesion is directly related to the absence of the Kx antigenic substance, a precursor molecule necessary for Kell antigen expression. However, the molecular basis of acanthocytosis in the McLeod syndrome is unknown.

The mechanism of acanthocytosis in chorea–acanthocytosis syndrome is unknown, but a recent report suggested an abnormality of the anion transport protein (band 3).

Clinical and Laboratory Findings

Abetalipoproteinemia manifests in the first month of life by steatorrhea. Retinitis pigmentosa (often resulting in blindness) and progressive neurologic abnormalities, characterized by ataxia and intention tremors, develop between ages 5 and 10 years, with death occurring in the second or third decade. Hematologic manifestations include mild normocytic anemia with acanthocytosis (50% to 90%) and normal to slightly elevated reticulocyte counts. Patients may have nutritional deficiencies (iron, folate) from fat malabsorption, resulting in more severe anemia.

Chorea–acanthocytosis syndrome is a disease of adult onset characterized by progressive neurologic dysfunction with orofacial dyskinesia, limb chorea, neurogenic muscle hypotonia and atrophy. Hematologic manifestations are minimal and include a variable percentage of acanthocytes on the peripheral smear without anemia.

In some cases, the McLeod phenotype coexists with chronic granulomatous disease of childhood, retinitis pigmentosa, and Duchenne's muscular dystrophy. The genetic loci of these disorders are in proximity of the p21 region of the X chromosome. Therefore, males are affected, and carrier females can be identified by flow cytometric analysis for Kell blood group antigen expression.

Optimal Management

In abetalipoproteinemia, treatment involves dietary restriction of triglycerides and supplementation of lipid soluble vitamins A, D, E, and K. Vitamin E supplementation may stabilize or improve the retinal and neuromuscular abnormalities. Because the hematologic manifestations are minimal in the chorea–acanthocytosis and McLeod syndromes, no specific therapy has been described.

Stomatocytosis

Definition

Stomatocytes contain a wide transverse slit or stoma. On three-dimensional views, these cells have the shape of a cup or bowl. The slitlike appearance on blood films is an artifact, resulting from folding of the cells during blood smear preparation. Few stomatocytes (3% to 5%) commonly are found on blood films of normal persons. Several inherited and acquired disorders are associated with stomatocytosis; these include *hereditary stomatocytosis*, *hereditary xerocytosis*, and *Rh deficiency syndrome*.

Etiologic Factors and Pathogenesis

Inherited disorders are associated with abnormalities in erythrocyte cation permeability and volume, which is increased (hence the designation hydrocytosis), decreased (desiccocytosis or xerocytosis), or near normal. Although the mechanism behind this morphologic abnormality is unknown, stomatocytosis can be produced in vitro by certain drugs that intercalate into the inner half of the asymmetrical lipid bilayer, resulting in surface area expansion relative to that of the outer half of the bilayer.

In hereditary stomatocytosis, overhydration and swelling of cells occurs as a result of a membrane permeability defect, which leads to marked sodium influx into the cells, producing an increase in intracellular sodium and water content. The underlying molecular lesion is unknown.

Hereditary xerocytosis is characterized by erythrocyte dehydration and decreased osmotic fragility. The underlying defect in hereditary xerocytosis is complex and involves a net loss of potassium from the erythrocytes that is not accompanied by a proportional gain of sodium, resulting in a reduced net intracellular cation and cell water content. Except for an increase in membrane-associated glyceraldehyde-3-phosphate dehydrogenase, which binds to band 3, no other abnormalities have been detected.

The term *Rh deficiency syndrome* is used to designate those rare individuals who have absent (Rh_{null}) or markedly reduced (Rh_{mod}) expression of the Rh antigen in association with hemolytic anemia and the presence of stomatocytes and occasional spherocytes on the blood film. The erythrocytes of this disorder are also dehydrated as evidenced by decreased cell cation and water content and increased cell density. However, the relation between the absence of the Rh antigen and erythrocyte alterations leading to hemolysis is unknown.

Clinical/Laboratory Findings and Disease Management

Hereditary stomatocytosis is an uncommon dominantly inherited hemolytic anemia that also has been designated hereditary hydrocytosis to indicate an overhydration and swelling of cells. The disorder manifests as moderate to severe hemolysis with 10% to 30% stomatocytes on the blood film, an increased mean corpuscular volume, and a reduced mean corpuscular hemoglobin concentration. Osmotic fragility is markedly increased. The hemolytic anemia is improved, although often not fully corrected, by splenectomy.

Hereditary xerocytosis presents as an autosomal dominant hemolytic anemia. Sporadic cases have been described that share features of hereditary stomatocytosis and xerocytosis. Both stomatocytes and some target cells are seen on the blood film. Splenectomy may ameliorate hemolysis in some, whereas in others it is ineffective.

Osmotic fragility is increased in Rh deficiency syndrome, reflecting a marked reduction of the membrane surface area. Splenectomy results in a marked improvement of hemolytic anemia.

Acquired Abnormalities of the Erythrocyte Membrane

Numerous acquired hemolytic states are caused primarily by alteration of the balance among the membrane lipid moieties. Increased membrane cholesterol causes the membrane surface to expand, producing *target cells*. Substances that localize in the outer membrane lamina cause *echinocytic* (burr cell) shape change; those that bind to the inner lamina produce *stomatocytic* (slitlike or bowl-shaped) alterations.

Acquired Acanthocytosis, Target Cells, Stomatocytosis, and Echinocytosis

Definition, Etiologic Factors, and Pathogenesis

Acquired acanthocytosis is found most commonly in patients with severe alcoholic hepatocellular disease. It may be associated with a rapidly progressive hemolytic anemia, termed *spur cell anemia*, which is a rare but ominous complication of severe liver disease. In the usual state, plasma free cholesterol readily equilibrates with the erythrocyte membrane cholesterol pool, in contrast to esterified cholesterol, which cannot be transferred from plasma to the erythrocyte membrane. Patients with severe liver disease have abnormal lipoproteins that contain a high free (unesterified) cholesterol/phospholipid ratio. The excess free cholesterol preferentially partitions into the outer hemileaflet of the erythrocyte membrane, which normally contains equal amounts of free cholesterol and phospholipids, and leads to an expansion of its surface relative to the inner hemileaflet. This increase in free cholesterol together with remodeling in the spleen results in acanthocyte formation. Phospholipid biosynthesis and repair may also be impaired, thus contributing to this process. These cells enter the circulation but are readily trapped in the spleen and destroyed. A similar clinical syndrome has been described in advanced metastatic liver disease, cardiac cirrhosis, Wilson's disease, and fulminant hepatitis. A few acanthocytes are seen in malnutrition, hypothyroidism, post-splenectomy states, and AIDS, possibly because of a superimposed nutritional deficiency.

Acanthocytes should be differentiated from echinocytes (see later).

Target cells (codocytes) seen in patients with cirrhosis, hepatitis, acute (alcoholic) fatty liver, or obstructive jaundice have expanded membrane surface area because of symmetrically increased membrane cholesterol and phospholipid. In contrast, target cells occurring in hemoglobinopathies and iron deficiency have a high membrane surface area relative to the decreased hemoglobin content.

Acquired stomatocytosis is associated most commonly with ethanol abuse and obstructive hepatocellular liver diseases in which asymmetrical expansion of the inner lipid layer of the erythrocyte membrane occurs. Stomatocytosis can also be produced *in vitro* by procaine, phenothiazines, and calcium channel blockers, and may be seen in malignant neoplasms.

Echinocytes (burr cells) differ from acanthocytes in that they have uniform, fine surface spicules. The most common cause of echinocytosis is a laboratory artifact related to blood storage, contact with glass, or increased pH. Echinocytes are also seen in uremia, in pyruvate kinase deficiency, and following red cell transfusion. The mechanism of echinocytosis in uremia is unknown, but in pyruvate kinase and post-transfusional states, it may be associated with depletion of adenosine triphosphate (ATP), a state known to produce echinocytes *in vitro*. Hemolytic anemia with echinocytosis has been described in athletes after strenuous physical exertion, and in patients with hypomagnesemia and hypophosphatemia, presumably due to decreased intracellular ATP stores.

Clinical and Laboratory Findings

The anemia of chronic liver disease is multifactorial (gastrointestinal blood loss, iron and folic acid deficiencies, hemodilution, and alcohol effects on erythrocyte precursors). In patients with end-stage liver disease, development of spur cell anemia is associated with a grim prognosis.

Optimal Management

In patients with end-stage liver disease, treatment is largely supportive, with nutritional replacement and transfusions as needed. Although the spleen plays a major role in the remodeling and sequestration of acanthocytes, its removal is not advisable.

Paroxysmal Nocturnal Hemoglobinuria

Definition

In its classic form, paroxysmal nocturnal hemoglobinuria (PNH) is characterized by hemolysis accompanied by nocturnal hemoglobinuria. It is unique among hemolytic anemias in being an acquired intrinsic abnormality of the erythrocyte, but it is also a clonal hematopoietic disorder affecting all hematopoietic elements.

Etiologic Factors and Pathogenesis

PNH appears to be caused by the acquisition of a mutation in the *pig-A* gene in a totipotent hematopoietic stem cell. This results in the inability of the affected stem cell and its progeny to synthesize the glycosylphosphatidylinositol (GPI) anchor that is used to attach numerous integral membrane proteins to the cell surface. One such protein, membrane inhibitor of reactive lysis (MIRL; CD59), protects cells from lysis by the complement membrane attack complex. Decay-accelerating factor (DAF; CD55) controls C3 convertase. The combined deficiency of DAF and MIRL accounts for the increased susceptibility to lysis by complement. Lack of these proteins may be responsible for the underlying hypercoagulability and may also account for the increased incidence of infections and deficient hematopoiesis.

Clinical Findings

Patients with PNH manifest all of the clinical and laboratory signs of chronic hemolytic anemia. Nocturnal hemoglobinuria occurs in a minority of patients. More commonly, hemoglobinuria is irregular in its occurrence and may be infrequent or even absent. Other symptoms are recurrent abdominal pain, vomiting, severe headaches, and ocular pain. Iron loss occurs in the urine, and hemosiderinuria is a constant feature of the disease, frequently leading to iron deficiency.

One of the most serious manifestations of PNH is the formation of venous thromboses at several unusual sites. Budd–Chiari syndrome, resulting from hepatic vein thrombosis, is a particularly common development that has an ominous prognosis. Clots in the cerebral veins, the splenic vein, and the veins of the dermis have occurred, the last resulting in necrotic skin lesions.

Laboratory Findings

Anemia is accompanied by reticulocytosis. If iron deficiency is present, the red cells may be microcytic and hypochromic. The bone marrow usually is hypercellular as a result of increased erythropoiesis, and the myeloid-to-erythroid ratio may be reversed. Hypoplasia of the marrow is not unusual. PNH commonly is associated with aplastic anemia. Aplasia may be the presenting disorder or, less commonly, develop during the course of PNH. Both erythrocyte membrane acetylcholinesterase and leukocyte alkaline phosphatase activities are decreased.

The most convenient screening test for PNH is the sucrose hemolysis test. If the results of this test are positive, the diagnosis may be confirmed using the acidified serum lysis test (Ham test) in which the red cells have an increased susceptibility to lysis by complement. Hemosiderin is usually found in the urine. Flow cytometry is used to demonstrate the lack of CD59 and CD55.

Optimal Management

The course of PNH is highly variable, with some patients dying within months of the onset of symptoms and others surviving for decades. Although the long-term outlook is good for many patients, the disease can be fatal, particularly as a result of the thrombotic manifestations or complications of pancytopenia.

Acute hemolysis may be treated with glucocorticoids, which inhibit the activation of complement. Iron deficiency due to chronic urinary loss is corrected with supplementation. If iron is given, the apparent rate of hemolysis rises as a result of increased marrow production of complement-sensitive red cells. To maintain an adequate hematocrit, transfusion may be necessary.

Acute thrombotic events are managed with anticoagulation. In some instances, such as hepatic vein thrombosis, thrombolytic therapy has been recommended. Bone marrow aplasia has responded to infusions of antithymocyte globulin. PNH may be cured by allogeneic or syngeneic bone marrow transplantation.

HEMOLYTIC ANEMIAS RESULTING FROM METABOLIC DEFICIENCIES

The metabolism of the mature erythrocyte depends on glucose catabolism by the glycolytic pathway and the hexose monophosphate (HMP) shunt. These metabolic pathways depend on the function of more than 20 enzymes and the availability of five major substrates: glucose, glutathione, nicotinamide adenine dinucleotide (NAD), nicotinamide adenine dinucleotide phosphate (NADP), and adenosine diphosphate (ADP). Glucose catabolism maintains the integrity of protein constituents, cell shape, and deformability; maintains hemoglobin iron in the ferrous form; and modulates the oxygen affinity of hemoglobin. These functions are achieved by the generation of sufficient levels of ATP, reduced glutathione, reduced NAD, reduced NADP, and 2,3-bisphosphoglycerate (2,3-BPG; formerly known as 2,3-diphosphoglycerate, or 2,3-DPG).

The principal role of the glycolytic pathway is the generation of ATP, which is required for ATP-linked sodium–potassium and calcium membrane pumps and is essential for cation homeostasis and erythrocyte deformability. The production of 2,3-BPG is regulated by the Rapoport–Luebering shunt. 2,3-BPG lowers hemoglobin–oxygen affinity and facilitates oxygen unloading at the partial pressure of oxygen levels found in the tissues. The major function of the HMP shunt is the production of reduced glutathione for the protection of hemoglobin and other cellular and membrane proteins against oxidant damage.

Hemolytic Anemias Resulting from Erythrocyte Glycolytic Enzyme Defects

Pyruvate Kinase Deficiency and Related Disorders

Definition and Pathogenesis

The principal consequences of glycolytic pathway defects are a decrease in the production of ATP and a decrease or increase in the level of 2,3-BPG. Deficiencies of erythrocyte hexokinase (HK), glucose phosphate isomerase, phosphofructokinase (PFK), and pyruvate kinase (PK) all lead to a decrease in the ATP concentration. Although inherited deficiencies of nearly all of the glycolytic enzymes have been described, PK deficiency accounts for more than 95% of the hemolytic anemias resulting from glycolytic abnormalities. Glucose phosphate isomerase, HK, and PFK deficiencies are rare but next most common. All glycolytic enzyme defects are autosomal recessive in inheritance except for phosphoglycerate kinase, which is X-linked.

Clinical/Laboratory Findings and Optimal Management

Glucose phosphate isomerase and HK deficiencies are rare nonspherocytic hemolytic anemias that result in decreased ATP and 2,3-BPG concentrations with reduced exercise tolerance; these anemias show improvement after splenectomy. A form of acquired HK deficiency occurs in Wilson's disease, in which hypercupricemia inhibits the enzyme and may lead to episodes of brisk hemolytic anemia. PFK deficiency (Tarui's disease) combines hemolytic anemia with muscle glycogen storage disease. A low red cell ATP level leads to low-grade hemolysis, but muscle pain and weakness on exertion usually are the limiting symptoms. PK deficiency usually is manifested in early childhood as moderate hemolytic anemia with jaundice, splenomegaly, and failure to thrive. Echinocytes, spherocytes, and acanthocytes are observed in the peripheral blood. These cells (called xerocytes) are markedly dehydrated because of low levels of ATP resulting in potassium and water loss and have an increased mean corpuscular hemoglobin concentration. They are poorly deformable, which results in splenic entrapment and destruction. Splenectomy in PK-deficient patients results in significant improvement in the hemolytic anemia, but usually is reserved for patients with poor quality of life, chronic transfusion requirements, and persistent anemia.

Hemolytic Anemia Caused by Disorders of the Hexose Monophosphate Shunt

Glucose-6-Phosphate Dehydrogenase Deficiency

Definition

Glucose-6-phosphate dehydrogenase (G6PD) deficiency is the most common inherited abnormality of erythrocyte metabolism and by far the most clinically important defect of the HMP shunt. Defects of other HMP shunt enzymes are rare but should be considered in cases of oxidant-induced hemolysis when G6PD levels are normal.

Incidence and Epidemiology

In blacks, the predominant form of the enzyme is designated GdA, the faster migrating isozyme; GdA⁻ is the designation for the usual African type of deficiency, which is estimated to occur in about 12% of African American males. In regions of West Africa, its gene frequency is even higher, perhaps because it confers a survival advantage against *Plasmodium falciparum* malaria. The gene is carried on the X chromosome and exhibits extensive polymorphism. Heterozygous carrier females have two erythrocyte populations, one normal (GdA or GdB) and one deficient (GdA⁻). Female carriers possess varying degrees of erythrocyte enzyme deficiency depending on the extent of inactivation ("lyonization") of the affected X chromosome bearing the abnormal gene.

A second form of G6PD deficiency, seen in 3% to 5% of persons of Mediterranean ancestry, Ashkenazi Jews, and Asians, is exemplified by the deficient variant G6PD⁻Mediterranean, designated GdB⁻.

Etiologic Factors and Pathogenesis

Nearly 300 genetic variants of G6PD have been described and are grouped into categories depending on whether they possess normal, moderately deficient, or severely deficient activity, or are associated with chronic hemolytic anemia. GdA⁻ is a moderately deficient variant that is unstable and has a shortened duration of activity; enzyme levels are normal in young red cells and deficient in older cells, which are susceptible to oxidant-induced hemolysis. GdB⁻ is extremely unstable and remains active in the red cell for only a few hours; therefore, both reticulocytes and older cells are extremely susceptible to oxidant hemolysis.

The hemolytic mechanism in G6PD deficiency results from a failure to produce sufficient quantities of reduced NADP to maintain adequate levels of reduced glutathione. Oxidant drugs generate hydrogen peroxide and other peroxides on interaction with oxyhemoglobin. These and other oxidant radicals oxidize reduced glutathione, which complexes with hemoglobin to form a mixed disulfide, resulting in alteration of globin chain configuration, loss of heme, and further mixed disulfide formation. The resultant denatured hemoglobin aggregates into *Heinz bodies*, which bind to membrane cytoskeletal proteins. Cells containing Heinz bodies have decreased deformability and are entrapped primarily in the spleen, where membrane is lost by "pitting" of Heinz bodies. The severity of hemolysis in G6PD-deficient persons depends on the level of enzyme in the erythrocytes and the severity of the oxidative stress.

Clinical and Laboratory Findings

Patients with GdA⁻ do not manifest anemia until an oxidant challenge, in the form of an oxidant drug, diabetic ketoacidosis, severe liver injury, or bacteremia, provokes brisk hemolysis with hemoglobinemia, hemoglobinuria, and a fall in the hematocrit. The oxidant drugs that most commonly cause hemolysis in G6PD-deficient persons are listed in [Table 244.4](#), and those drugs that are probably safe in therapeutic dosages are listed in [Table 244.5](#).

Acetanilid	Phenylhydrazine
Dapsone	Primaquine
Furazolidone (Furoxone)	Sulfacetamide
Isobutyl nitrite	Sulfamethoxazole
Methylene blue	Sulfanilamide
Nalidixic acid	Sulfapyridine
Naphthalene	Thiazolesulfone
Nitridazole	Toluidine blue
Nitrofurantoin (Furadantin)	Trinitrotoluene (TNT)
Phenazopyridine (Pyridium)	Urate oxidase

TABLE 244.4. DRUGS AND CHEMICALS THAT CAUSES CLINICALLY SIGNIFICANT HEMOLYTIC ANEMIA IN PERSONS WITH GLUCOSE-6-PHOSPHATE DEHYDROGENASE DEFICIENCY

Acetaminophen	Phenytoin
Aspirin (acetylsalicylic acid)	Phytomenadione (vitamin K)
p-Aminobenzoic acid	Probenecid
Aminoglycoside	Procainamide hydrochloride
Antiazoline	Pyrimethamine
Antipyrine	Quinine
Ascorbic acid (vitamin C)	Quinine
Chloramphenicol	Streptomycin
Chloroquine	Sulfacycline
Chloroquine	Sulfadiazine
Colchicine	Sulfaguanidine
Diphenhydramine	Sulfamerazine
Isoniazid	Sulfamethoxygyridazine
Levodopa	Sulfisoxazole
Menadione (menaphthone)	Trihexyphenidyl (benzhexol)
Menadione sodium bisulfite	Trimethoprim
Phenacetin (acetophenetidin)	Triptennamine
Phenylbutazone	

(From Beutler E. Glucose-6-phosphate dehydrogenase deficiency. In Stanbury JB, Wyngaarden JB, Fredrickson DS, et al., eds. The metabolic basis of inherited disease, 11th ed. New York: McGraw-Hill, 1983:29, with permission.)

TABLE 244.5. DRUGS THAT ARE PROBABLY SAFE WHEN GIVEN IN NORMAL THERAPEUTIC DOSES TO PERSONS WITH GLUCOSE-6-PHOSPHATE DEHYDROGENASE DEFICIENCY

Drug-induced hemolysis in G6PD-deficient persons usually is mild and self-limited. Between 1 and 3 days after the ingestion of an oxidant compound, hemolysis becomes evident, with a fall in the hematocrit and, possibly, hemoglobinuria. The peripheral blood film shows bite cells, spherocytes, and polychromatophilia. Heinz bodies can be demonstrated on incubation of red cells with supravital dyes such as cresyl violet. The hematocrit reaches its nadir at 7 to 10 days, and the reticulocyte response, which begins at about day 3, peaks at 7 to 14 days. Because young cells are resistant to hemolysis, recovery of the hematocrit occurs despite continuation of the offending agent. Hemolysis may occur in women but is milder because G6PD levels are higher.

Patients with GdB– may have chronic nonspherocytic hemolytic anemia, with persistent splenomegaly. They manifest favism (hemolysis after the ingestion of fava beans), which can be severe or fatal, particularly in children. Newborns often have hemolytic anemia with neonatal icterus.

The clinical findings should make the diagnosis highly suspect. In the presence of increased reticulocytes, which possess normal enzyme levels, screening tests may fail to detect G6PD deficiency. Establishment of the diagnosis in a patient with hemolytic anemia requires the use of quantitative spectrophotometric measurement of G6PD enzyme activity, with adjustment for the reticulocyte count.

Optimal Management

Treatment involves patient education and the avoidance of oxidant drugs and chemicals. Patients deemed at risk, such as those about to start an oxidant drug, should be screened for the defect and the information clearly documented in the medical record. If an implicated drug is continued, hemolysis may be self-limited, chronic, and low grade.

In other forms of G6PD deficiency, erythrocytes of all ages are deficient, producing chronic hemolysis and more severe hemolytic reactions on exposure to an oxidant stress.

Hemolytic Anemia Due to Disorders of Erythrocyte Purine and Pyrimidine Metabolism

Adenylate Kinase Deficiency and Related Disorders

Definition and Pathogenesis

Adenylate kinase deficiency is the most common of the rare hemolytic disorders of erythrocyte purine and pyrimidine metabolism that produce hemolytic anemia, and leads to decreased adenosine production by the normal salvage pathway. Lack of ATP within the red cell leads to the same metabolic consequences described for glycolytic defects.

In another rare disorder, hemolysis is caused by *adenosine deaminase hyperactivity*, which precludes normal salvage of adenosine from plasma and its subsequent phosphorylation of ATP. Decreased red cell ATP is believed to be the cause of hemolysis.

Pyrimidine 5'-nucleotidase deficiency is a defect in pyrimidine metabolism associated with hemolysis.

Clinical/Laboratory Findings and Optimal Management

Person with adenylate kinase deficiency have a chronic nonspherocytic hemolytic anemia and splenomegaly. Splenectomy is of questionable value.

In its congenital form, the hemolytic anemia of pyrimidine 5'-nucleotidase deficiency is often associated with mental retardation. Hemolysis is associated with prominent coarse basophilic stippling identical to that seen in the anemia of lead intoxication, in which the same enzyme deficiency is induced.

IMMUNE-MEDIATED HEMOLYTIC ANEMIAS

Autoimmune hemolytic anemias (AIHAs) are a diverse group of disorders in which red cell destruction is caused by an autoantibody. A classification of AIHAs is given in [Table 244.6](#).

Warm-antibody autoimmune hemolytic anemia
Idiopathic
Secondary (e.g., chronic lymphocytic leukemia, lymphomas, systemic lupus erythematosus)
Cold-agglutinin syndrome
Idiopathic
Secondary: Mycoplasma pneumoniae infection or infectious mononucleosis (polyclonal cold agglutinin); malignancies, such as chronic lymphocytic leukemia or lymphoma (monoclonal cold agglutinin)
Combined cold- and warm-antibody autoimmune hemolytic anemia
Paroxysmal cold hemoglobinuria
Idiopathic
Secondary to viral infection (common) or syphilis (rare)
Hemolytic anemia with a negative direct antiglobulin test
Drug-induced autoimmune hemolytic anemia
Caused by methylidopa, procainamide, levodopa, phenacetin, chlorpromazine, mefenamic acid*

* Other nonsteroidal anti-inflammatory drugs (e.g., ibuprofen, naproxen, tolmetin, sulindac, tenoxicam) have caused hemolysis, but the mechanism is not clearly attributable to red blood cell autoantibodies.

TABLE 244.6. CLASSIFICATION OF AUTOIMMUNE HEMOLYTIC ANEMIAS

Warm Antibody Autoimmune Hemolytic Anemias

Definition

About 70% of AIHAs are associated with warm autoantibodies (i.e., antibodies that are optimally reactive at 37°C).

Etiologic Factors

Nearly 50% of warm antibody AIHAs are associated with autoimmune, infectious, or neoplastic diseases (chronic lymphocytic leukemia, systemic lupus erythematosus, ovarian tumors, ulcerative colitis), whereas others are related to drug-induced phenomenon or are idiopathic.

Pathogenesis

In warm antibody AIHA, the patient's erythrocytes almost always are coated with IgG, complement (C3d), or both. Macrophages in the reticuloendothelial system recognize either the Fc portion of the immunoglobulin or the complement component coating the erythrocyte and then phagocytize these cells. Partial phagocytosis results in loss of erythrocyte membrane, with a decrease in surface area/volume ratio, and is the pathogenic mechanism for the formation of the spherocyte (a common finding in the blood film).

Clinical Findings

In some patients, the onset of AIHA is insidious, with the gradual emergence of symptoms of anemia, often associated with fever and jaundice. In others, the onset is sudden, with pain in the abdomen and back, malaise, and manifestations of rapidly increasing anemia. The anemia may be severe and progress before therapy becomes effective. A history of dark urine results from the presence of bile pigments or hemoglobinuria. The latter is a prominent finding in the most seriously ill patients. Jaundice is present in about 40% of patients. In idiopathic AIHA, splenomegaly occurs in 50% to 60%, hepatomegaly in 30%, and lymphadenopathy in about 25%. Splenomegaly, hepatomegaly, and lymphadenopathy are absent in about 25% of patients.

Laboratory Findings

The cardinal feature of AIHA is a positive DAT. Antiglobulin serum contains antibodies to IgG or C3d, and, when reacted with erythrocytes coated with the appropriate globulin, causes their agglutination. Warm antibodies are found in the serum or can be eluted from the red cells. They typically are of the IgG class and react with normal red cells. Platelet and leukocyte counts usually are normal but are elevated in some patients, often with the presence of occasional metamyelocytes and myelocytes. However, platelet and leukocyte antibodies have been documented, resulting in thrombocytopenia or leukopenia. As in other types of hemolytic anemia, a persistently raised reticulocyte count is a characteristic, although not invariable, finding. The peripheral blood film often reveals spherocytosis and mild to moderate poikilocytosis. Polychromatophilia is present except in patients with reticulocytopenia. Erythroid hyperplasia or, less commonly, hyperplasia of all cell lines is seen in the bone marrow.

Optimal Management

Warm reactive IgG autoimmune antibodies produce hemolytic anemia predominantly through the interaction of antibody-coated red cells with macrophage Fc receptors. In most patients, this process can be altered rapidly with corticosteroids. Initial treatment with prednisone, 1 to 1.5 mg per kilogram per day orally, usually decreases the rate of hemolysis in 3 to 7 days and produces stable erythrocyte counts in 4 to 6 weeks. The initial effect of corticosteroids is to reduce the destruction of antibody-coated red cells, without changing antibody production or the strength of antiglobulin testing. Long-term corticosteroid therapy for several weeks to several months usually leads to a reduction in autoantibody concentration.

After the hematocrit has stabilized, prednisone is gradually tapered by 10 to 20 mg per day increments each week. As the dosage is reduced below 20 mg per day to 10 mg per day, slower tapering is required. Hematocrit and reticulocyte counts should be obtained frequently during this tapering process. Alternate-day therapy with prednisone may be used with dosages below 30 mg per day. Some patients can be treated successfully by reducing the prednisone dosage below 10 to 15 mg per day, but many patients experience relapse as the dosage is decreased. Warm reactive IgG AIHA is a chronic relapsing disease, and repeated courses of treatment may be necessary. If the prednisone dosage cannot be reduced to an acceptable level, alternative forms of treatment should be used. A prednisone dosage above 20 mg per day for more than 3 to 6 months produces iatrogenic Cushing's syndrome, which increases the perioperative morbidity and mortality of splenectomy.

Splenectomy is the next appropriate therapeutic procedure for most patients with warm reactive IgG AIHA who do not respond adequately to prednisone. The major effect of splenectomy is to reduce the destruction of antibody-coated red cells, but some patients also benefit by a reduction in antibody production. Unfortunately, isotopic red cell survival or sequestration studies do not predict the response to this therapy. Patients who are to undergo splenectomy should receive pneumococcal *H. influenzae* type b and meningococcal vaccines and be warned of the susceptibility to acute overwhelming sepsis. About two-thirds of patients have sustained hematologic improvement after splenectomy, and most maintain hematologic remission after corticosteroid therapy has been discontinued. In a smaller subset of post-splenectomy patients, lower dosages of corticosteroids may be necessary to control hemolysis. Because of the chronic relapsing nature of this disease, patients need long-term follow-up.

Other types of immunosuppressive therapy are useful in patients who cannot be treated by or do not respond to splenectomy. Cyclophosphamide or azathioprine may be useful at initial dosages of 50 to 100 mg per day and 50 to 150 mg per day, respectively, with subsequent maintenance dosages designed to prevent the absolute granulocyte count from falling below 1,000 per microliter or the platelet count from falling below 100,000 per microliter. At least 3 to 6 months of such therapy usually is necessary to decrease antibody production. Because long-term cytotoxic therapy carries an increased risk of secondary malignancy, such as acute leukemia, it should be considered only in older patients. Patients with refractory AIHA also have been treated successfully with high doses of intravenous d-globulin, plasmapheresis, or the androgen danazol. However, experience is limited and reports of favorable responses are anecdotal.

Transfusion is indicated in patients with hemodynamic compromise. Antierythrocyte autoantibodies may make compatibility testing difficult to perform by masking the presence of erythrocyte alloantibodies. In these cases, the autoantibody from the serum should be adsorbed using autologous erythrocytes or carefully selected allogeneic erythrocytes to detect the presence of alloantibodies. Even though the autoantibody may react with all normal erythrocytes, so that it is impossible to find compatible blood, transfusion must never be regarded as contraindicated. In such patients, transfusion with the "least incompatible" blood is warranted and necessary.

Cold Agglutinin Disease

Definition

Cold agglutinin disorders are caused by autoantibodies that react at cooler temperatures (4°C to 18°C). Depending on the underlying disease process, cold agglutinins can be either monoclonal or polyclonal.

Incidence and Epidemiology

About 15% of patients with AIHA have cold agglutinin syndrome. This syndrome typically affects the middle-aged or elderly, with a peak incidence of onset from 51 to 60 years of age.

Etiologic Factors

Typically, cold agglutinin syndrome is idiopathic, but it may be associated with several infectious diseases, particularly *Mycoplasma pneumoniae* pneumonia and infectious mononucleosis. Although unusual, some patients have cold agglutinin syndrome in association with hematologic malignancies, particularly chronic lymphocytic leukemia, Hodgkin's disease, and the lymphocytic lymphomas.

Pathogenesis

The pathogenic antibody in the cold agglutinin diseases is IgM, which is highly effective in activating the complement cascade on the erythrocyte membrane. These antibodies are active in the peripheral circulation and dissociate from the erythrocyte as it enters the warmer visceral circulation. However, this time is sufficient to activate the complement cascade to the stage of C3b, which remains on the surface of the erythrocyte. Those erythrocytes that are not cleared by the C3b receptor,

expressing hepatic macrophages, enter the circulation where C3b is degraded to C3dg or C3d, or both. Since opsonization with C3d is even less effective than that with C3b, these cells usually escape destruction and are responsible for the findings on the DAT.

Clinical Findings

Symptoms often are those of a chronic anemia. Some patients experience hemoglobinuria, particularly in cold temperatures, and many complain of acrocyanosis of the ears, tip of the nose, fingers, and toes—a condition that vanishes quickly with warming. Physical findings include pallor, jaundice, and, in most cases, splenomegaly. Hepatomegaly and lymphadenopathy are not prominent findings.

Laboratory Findings

In classic cases, the degree of anemia varies with the degree of cold exposure. However, a fairly stable anemia that is mild or moderate in severity is much more common. Autoagglutination of blood samples is characteristic and creates problems in making satisfactory blood films and performing blood counts. Erythrocyte morphology is less abnormal than in warm antibody AIHA, with lesser degrees of spherocytosis, anisocytosis, and poikilocytosis. Reticulocytopenia is rare, as are abnormalities of leukocytes and platelets.

The DAT is positive in cold agglutinin syndrome as a result of C3d on the red cells. The causative IgM antibody usually is not demonstrated on the erythrocytes in vitro by the DAT because antiglobulin serum does not readily detect IgM antibodies. The autoantibodies in the patient's serum cause the agglutination of normal erythrocytes to a higher titer than normal (greater than 1:50) at 4°C and react to a lesser titer up to a temperature of at least 30°C. In classic cases, the cold agglutinin titer at 4°C is greater than 1,000, and it may be as high as 256,000. In about 40% of cases, however, the cold agglutinin titer is less than 1,000. The antibody usually has specificity within the Ii blood group system, most commonly anti-I.

Optimal Management

Most patients with cold reactive IgM antibodies do not have severe hemolysis, and those with overt intravascular hemolysis may respond to cold avoidance. Patients must be educated about the importance of maintaining skin temperature at or as close to body temperature as possible. They may experience overt hemolysis with reduction in temperature of exposed skin that is not perceived as unacceptably cold.

For the unusual patient with severe cold agglutinin immune hemolytic anemia who does not respond to cold avoidance, immune manipulations may be attempted. Prednisone is usually not helpful but has been used in doses similar to those for warm reactive hemolytic anemias. It may benefit a subset of patients by decreasing antibody production or the interaction of complement-coated red cells with phagocytic cells. Splenectomy usually is not helpful since most red cell destruction occurs in the liver. Other immune manipulations, such as cytotoxic chemotherapy, have been used. Plasmapheresis, although theoretically effective in removing an IgM antibody, must be undertaken with extreme caution because inadvertent cooling of blood in the tubing or the pheresis apparatus can lead to severe hemolysis.

Most cold agglutinin diseases are chronic, with intermittent exacerbations. Simply avoiding exposure to cold temperatures may suffice to ameliorate the hemolysis and avoid exacerbations. In patients with secondary causes, treatment of the underlying process is indicated.

The prognosis of patients with idiopathic cold agglutinin syndrome is significantly better than that of patients with warm antibody AIHA. Many patients have a chronic course and tolerate their mild or moderate anemia well. Death may result from complications of slowly progressive anemia or long-term blood transfusion therapy.

Paroxysmal Cold Hemoglobinuria

Definition, Etiologic Factors, and Pathogenesis

Paroxysmal cold hemoglobinuria (PCH) is a rare disorder that composes about 1% of AIHAs. Historically, PCH occurred after cold exposure in patients who had congenital syphilis or who were in the quiescent stage of late syphilis. The causative agent is an IgG antibody, usually with anti-P specificity, which fixes to normal red cells in the cold and subsequently causes hemolysis of the cells when they are warmed to 37°C in the presence of complement (the Donath–Landsteiner test).

Clinical and Laboratory Findings

Paroxysmal cold hemoglobinuria is most common in children, and most patients have histories of a recent viral disorder or flulike illness. However, a history of cold exposure may not be elicited. Hemolysis is acute in onset and causes severe and rapidly progressive anemia. Patients may have symptoms of chills, fever, malaise, abdominal distress, aching in the back or legs, and nausea. Manifestations of intravascular hemolysis are present, such as hemoglobinemia and hemoglobinuria. The blood film may reveal spherocytosis, anisocytosis, poikilocytosis, erythrophagocytosis, and nucleated erythrocytes.

The diagnosis of PCH is established by demonstrating the presence of the erythrocyte autoantibody. The so-called Donath–Landsteiner antibody fixes the first two components of complement in the cold and completes the cascade on warming to 37°C. The DAT is usually negative but occasionally complement can be demonstrated. Since the Donath–Landsteiner test is not routinely available, diagnosis of the disorder rests on recognition of the clinical manifestations.

Optimal Management

Since the acute illness characteristically resolves spontaneously after several weeks, usually no specific treatment is indicated, save for transfusional support as needed. Corticosteroids are not effective.

Combined Cold and Warm Antibody Autoimmune Hemolytic Anemias

Definition, Etiologic Factors, and Pathogenesis

About 8% of patients with AIHA have serologic findings that satisfy the criteria for both warm antibody AIHA and cold agglutinin syndrome. The cold antibody in such cases is normal or only modestly elevated in titer at 4°C but reacts up to at least 30°C. There appears to be an association between combined cold and warm antibody AIHA and systemic lupus erythematosus because this disorder is present in more than 25% of patients.

Clinical Course

Most patients have severe hemolysis and, although the initial response to therapy (see above) usually is excellent, many have a chronic course.

Autoimmune Hemolytic Anemias With Negative Direct Antiglobulin Tests

Definition and Clinical/Laboratory Findings

Some patients who ultimately are diagnosed as having AIHA have negative DAT results. These patients have findings suggestive of AIHA; that is, they have an acquired hemolytic anemia, spherocytes are present on the peripheral smear, no other diagnosis is apparent after exhaustive evaluation, and the response to therapy is similar to that in patients with AIHA who have characteristic immunohematologic findings. Small concentrations of autoantibodies usually can be demonstrated on red cells or in an eluate from the red cells using techniques that are more sensitive than the routine DAT, such as tests using radiolabeled antiglobulin sera or agglutinating potentiators.

Drug-Induced Immune Hemolytic Anemias

Definition and Etiologic Factors

Drugs have been identified as the cause of acquired immune hemolytic anemia in about 10% of cases. In most instances, a drug-specific antibody can be shown in vitro to react with erythrocytes in the presence of the drug or one of its metabolites. In other cases, the antibody has specificity for intrinsic red cell antigens and is similar to autoantibodies found in warm antibody AIHA.

Pathogenesis

Because drugs have relatively low molecular weight, they may function as haptens by combining with red cell membrane proteins to become immunogenic. The resulting antibody may react with drug absorbed to the cell surface or with a compound antigen consisting of the drug and erythrocyte membrane proteins. Because the binding of most drugs to cellular proteins seems too labile to be immunogenic, however, an alternative proposal suggests that a more probable immunogen might be a drug–plasma protein compound. The resulting antibody may react with the drug to form an immune complex that in turn reacts with erythrocytes by an unknown mechanism. Some drugs, such as penicillins, do bind tightly to red cells, and hemolysis may result from the reaction of antidrug antibody with the cell-bound drug. In some patients, the antibodies responsible for immune hemolysis cannot be shown to react with drug-specific antigens but instead have specificity for intrinsic red cell antigens, and the resultant disorder is classified as drug-induced AIHA. The causative drugs may alter erythrocyte antigens, causing them to be recognized by the immune system as nonself. Alternatively, the primary effect of the drugs may be on cells of the immune system, causing unregulated production of erythrocyte autoantibodies.

Clinical and Laboratory Findings

More than 75 drugs have caused the development of drug-specific antibodies and immune hemolytic anemia. These include acetaminophen, cephalosporins, chlorpromazine, chlorpropamide, erythromycin, hydralazine, hydrochlorothiazide, penicillins, phenacetin, quinidine, quinine, rifampicin, tetracycline, tolbutamide, and triamterene. The DAT result is usually positive with polyspecific antiserum, an anticomplement reagent, or both. The causative antibody is detected by the incubation of drug-coated red cells with the patient's serum or by the incubation of a mixture of the patient's serum, a solution of the drug, and erythrocytes, followed by observation for in vitro hemolysis, agglutination, or the development of a positive indirect antiglobulin test.

Prototype drugs responsible for causing AIHA are methyldopa and procainamide, with rare cases also associated with levodopa, mefenamic acid, phenacetin, and chlorpromazine. Therapy with methyldopa for at least 3 months is required before hemolysis develops; anemia usually develops gradually. The DAT is strongly positive using anti-IgG antiserum and is negative using anticomplement. The antibodies in the serum and in a red cell eluate react with normal red cells and have serologic characteristics similar to those found in idiopathic warm antibody AIHA. Because no serologic evidence of a relation between the antibodies and the drug has been demonstrated, proof that methyldopa causes AIHA has come from clinical observations.

Optimal Management

When clinical findings lend strong support to a diagnosis of drug-induced immune hemolytic anemia, the possible offending drug should be discontinued while confirmatory laboratory tests are carried out. This is particularly important because many drug-induced immune hemolytic anemias lead to the development of renal failure, especially when signs of intravascular hemolysis, such as hemoglobinemia and hemoglobinuria, are present. Such brisk hemolysis commonly occurs when drug-specific antibodies are present against drugs that are loosely bound to the erythrocyte. Hemolysis usually resolves within a matter of days after cessation of the causative drug. Drug-induced AIHA usually is less acute in onset but can become life threatening if the diagnosis is not recognized. A short course of corticosteroids may be indicated when the hemolysis is severe. Blood transfusion may be necessary and, in patients with drug-specific antibodies, compatibility testing is not affected.

HEMOLYTIC ANEMIAS DUE TO TRAUMATIC RED CELL FRAGMENTATION

Erythrocyte fragmentation is caused by the interaction of red cells with altered intravascular surfaces or by direct physical trauma to the cells resulting from excessive shear forces within the circulation. The resultant fragmentation hemolytic anemia is characterized by intravascular hemolysis with elevated plasma hemoglobin levels, decreased haptoglobin levels, hemoglobinuria, hemosiderinuria (becomes evident after a week or more), and the diagnostic fragmented erythrocyte known as a *schistocyte*. [Table 244.7](#) lists the laboratory findings in fragmentation hemolysis, and [Table 244.8](#) indicates the disorders associated with this condition.

Normocytic or microcytic anemia with elevated absolute reticulocyte count and increased red blood cell distribution width
Schistocytes and polychromatophilla
Elevated indirect bilirubin value
Elevated serum lactic dehydrogenase value
Elevated plasma hemoglobin value
Decreased serum haptoglobin value
Hemoglobinuria
Hemosiderinuria

TABLE 244.7. LABORATORY FINDINGS IN FRAGMENTATION HEMOLYSIS

Microangiopathic Disorders
Vasculitis, collagen vascular disorders
Disseminated intravascular coagulation
Disseminated malignancy
Thrombohemolytic microangiopathy
Thrombotic thrombocytopenic purpura
Hemolytic-uremic syndrome
Cavernous hemangiomas
Homograft rejection (renal, hepatic, cardiac)
Footstrike hemolysis (and related disorders)
Cardiac and Large-Vessel Diseases
Cardiac valvular disease: aortic stenosis, calcific mitral stenosis
Defective cardiac valvular prostheses
Patch repairs of intracardiac defects
Aortic and large-vessel prostheses and grafts

TABLE 244.8. DISORDERS ASSOCIATED WITH FRAGMENTATION HEMOLYTIC ANEMIA

Microangiopathic Disease

Definition and Etiologic Factors

Intrinsic microvascular disease is the most common cause of fragmentation hemolytic anemia and has led to the term *microangiopathic hemolytic anemia* (MAHA). This type of hemolysis may accompany acute vasculitides such as occur in polyarteritis nodosa, lupus, rheumatoid arthritis, and allergic vasculitis, which primarily involve small arteries and arterioles. Fragmentation hemolysis has also been observed in diabetic microvascular disease, although the association has not been proved, and disseminated intravascular coagulation (DIC). DIC is associated most commonly with sepsis, shock, placental abruption, intrauterine fetal death, and

malignancy. Evidence for fragmentation hemolysis is found in about 40% of cases of DIC, regardless of cause, and correlates with the severity of the coagulopathy. Disseminated malignancy usually leads to fragmentation hemolysis through associated DIC, which often is of low grade. Local intravascular coagulation leading to fragmentation hemolysis can occur in giant cavernous hemangiomas (Kasabach–Merritt syndrome) and during organ homograft rejection reactions, particularly of the kidney, but also of the liver and heart.

Pathogenesis

In the acute vasculitides, endothelial injury by immune complexes is accompanied by perivascular inflammation and fibrin deposition in the vessel lumen. In syndromes associated with DIC, coagulation is activated and leads to the generation of excessive thrombin, which results in deposition of fibrin strands and thrombi in arterioles and capillaries. In tumor-associated hemolysis, abnormal tortuous tumor vessels and tumor-released thromboplastins contribute to the associated DIC. Mucin-producing adenocarcinomatosis has a particular association with DIC and fragmentation hemolysis, often presenting before treatment and temporarily worsening with effective chemotherapy of the tumor as more mucin thromboplastin is released into the circulation. A similar phenomenon may be seen with acute promyelocytic leukemia and other acute leukemias.

Optimal Management

The clinical and laboratory findings of vasculitis can be found elsewhere in this book. Successful therapy results in resolution of the hemolytic process, although an element of anemia of chronic disease may persist. In DIC, treatment of the underlying disorder, if possible, is the key to controlling the hemolytic process. The fragmentation hemolysis seen in organ rejection will abate when rejection is abrogated.

Thrombohemolytic Microangiopathy

Definition

Thrombohemolytic microangiopathy includes TTP and hemolytic-uremic syndrome (HUS).

Etiologic Factors

Thrombotic thrombocytopenic purpura has been associated with drugs, hypersensitivity reactions, bone marrow and solid organ transplantation, viral and bacterial infections, pregnancy, and other causes. However, no clear etiologic process has emerged. Most cases of HUS are preceded by viral or bacterial infections, particularly of the gastrointestinal tract. The rare adult form of HUS is observed in peripartum women with complications of pregnancy and delivery, and in untreated patients with disseminated cancer. Both HUS and TTP have been caused by numerous chemotherapeutic agents. Mitomycin C is the most commonly implicated drug, but others include bleomycin, cisplatin, vinca alkaloids, the combination of mitomycin and 5-fluorouracil, cyclosporine, and FK-506. Quinine sensitivity is a relatively newly recognized cause of HUS where an immune mechanism has been well documented.

Pathogenesis

Intravascular fibrin and platelet thrombus formation characterizes the arteriolar lesion. Fibrin thrombi entrap erythrocytes during flow. The increased shear forces within these pathologic microvessels physically disrupt the red cells by tearing them away from points of attachment or fracturing them across fibrin strands. This direct physical hemolysis leads to the production of schistocytes with markedly reduced circulatory survival. Inhibitory antibodies against von Willebrand's factor–cleaving protease have also recently been described in patients with acute TTP and may have a role in the pathogenesis of this disorder.

Clinical Findings

Thrombotic thrombocytopenic purpura is a clinical syndrome comprising the pentad of fragmentation hemolysis, thrombocytopenia, fluctuating neurologic signs, renal dysfunction, and fever. It occurs primarily in young and middle-aged adults and is more common in women. TTP manifests as two clinical forms: (a) a chronic relapsing variety that extends from weeks to years and (b) the more common acute fulminant type that represents a medical emergency. Although formerly associated with an 80% mortality rate, TTP can be cured in most cases if it is recognized and treated before irreversible neurologic and renal injury has occurred.

HUS is primarily a disease of infants and children that presents as renal failure, fragmentation hemolytic anemia, thrombocytopenia (less marked than in TTP), and fever. In its less common adult form it is difficult to distinguish from TTP, except that the central nervous system is spared and renal dysfunction is more severe.

Laboratory Findings

Laboratory findings of DIC are absent. The peripheral blood film shows striking erythrocyte fragmentation with thrombocytopenia accompanied by polychromasia, and elevation of the LDH (more than 500 IU per deciliter) and indirect bilirubin. Varying degrees of renal dysfunction are present, the severity of which depends on whether TTP or HUS is present.

Optimal Management

High-volume plasma exchange is the treatment of choice in TTP. Plasma infusions may be given until plasma exchange can be arranged. Recovery is marked by a fall in serum LDH, as well as improvement of anemia, thrombocytopenia, and the neurologic and renal parameters of the disease. Adjuncts to treatment include corticosteroids, antiplatelet agents, and vincristine. Platelet transfusions are contraindicated, except in suspected or documented central nervous system or other severe bleeds, as they can exacerbate the underlying process. Splenectomy may have some efficacy in prevention of relapses in the chronic form of the disease, although this is based on anecdotal data.

Management of both the childhood and adult forms of HUS relies on the combination of plasma exchange and, with severe renal dysfunction, dialysis. Additional measures have included vincristine, high-dose intravenous immunoglobulin, and splenectomy. Corticosteroids and antiplatelet drugs have been of limited value. With effective therapy, more than 85% of children recover, but a subset have persistent impairment of renal function and are subject to relapse. Adult HUS has higher mortality and propensity for residual renal dysfunction.

Footstrike Hemolysis

Definition, Etiologic Factors, and Pathogenesis

Footstrike hemolysis originally was recognized as *march hemoglobinuria* in German soldiers subjected to strenuous marches. Related forms of hemolysis caused by physical injury to the feet and hands have been recognized in long-distance runners, conga drummers, and pneumatic hammer operators.

Optimal Management

Cessation of the cause of injury always leads to resolution of the anemia.

Heart Valve Hemolysis

Definition

Heart valve hemolysis is the term applied to fragmentation states caused by pathologic heart valves or defective cardiac valvular prostheses. The most common associated valvular abnormality is severe aortic stenosis, with calcific mitral stenosis or septal defects implicated less often.

Etiologic Factors and Pathogenesis

Surgically implanted prosthetic valves, especially artificial aortic valve prostheses, tend to cause frequent and severe heart valve hemolysis. Several intracardiac or vascular surface and flow alterations contribute to hemolysis. Increased turbulence and jet effects produce high shear forces that may disrupt red cells directly or tear them across fibrin strands. Prosthetic valvular, vascular, or patch surfaces that are not endothelialized may become covered with a fibrin–platelet meshwork that entraps and fragments the erythrocytes.

Clinical and Laboratory Findings

Hemolytic anemia usually is mild, characterized by red cell fragmentation and hemoglobinuria that worsens with increased cardiac output, tachycardia, and heart failure. Hemolysis often is greater during activity in the daytime and decreases during rest at night. Chronic hemoglobinuria and hemosiderin loss in the urine lead to iron deficiency. Iron-deficient red cells have greater mechanical fragility. Worsening anemia leads to further hemodynamic deterioration, which increases the hemolytic rate.

Optimal Management

Successful therapy for this disorder requires breaking the cycle by correcting the iron deficiency and optimizing the patient's hemodynamic state. When severe hemolysis is present, it often is necessary to replace the defective valve or prosthesis.

HEMOLYTIC ANEMIAS RESULTING FROM PARASITISM OF RED BLOOD CELLS

Malaria

Definition

Malaria is the most common cause of hemolytic anemia worldwide. The following description is confined to changes that occur with *Plasmodium falciparum* infections, since the consequences of *P. malariae*, *P. ovale*, and *P. vivax* infections usually are much milder.

Etiologic Factors and Pathogenesis

Merozoites emerging at first from the tissues and later from previously parasitized red cells enter the erythrocyte and grow intracellularly. The intracellular development of the parasites leads to intravascular rupture of the red cells, but the degree of hemolysis and anemia always is in excess of what could be accounted for by this one mechanism. An immune mechanism may also be present since a positive DAT is present in some patients, the erythrocytes being sensitized by IgG with or without complement. The antibody eluted from the red cells has been shown to have activity against *P. falciparum* schizont antigen. The destruction of parasitized red cells appears to be a largely splenic phenomenon whereby pitting of the parasites from the red cells occurs (i.e., the parasite surrounded by a small ring of red cell and membrane is retained in the pulp and phagocytosed, whereas the remaining unparasitized part of the red cell emerges into the splenic sinus and returns to the circulation). The circulating fragment is spherocytic, has increased osmotic fragility (as do cells containing plasmodium), is more rigid, and is prone to sequestration when it next reaches the spleen.

Clinical and Laboratory Findings

Splenomegaly is usually present in chronic infections. *P. falciparum* malaria occasionally is associated with particularly severe hemolysis that may result in dark, almost black, urine, known as *blackwater fever*. It was common among Europeans in Africa and India, usually after treatment with quinine. Free and intraerythrocytic malarial parasites can be seen on thick-film preparations of the peripheral blood.

Optimal Management

When acute and unusually severe hemolysis occurs in the course of *P. falciparum* malaria, the physician should be certain that a hemolytic drug is not being administered to a G6PD-deficient person. Transfusions may be needed in blackwater fever; if renal failure occurs, extracorporeal dialysis may be required.

Bartonellosis

Definition

Human bartonellosis is transmitted by the sandfly, and the red cells become infected with *Bartonella bacilliformis*.

Pathogenesis and Clinical Findings

The organism does not appear to grow within the red cell but adheres to its exterior surface. During the first stage of the disease, most patients manifest no clinical symptoms whereas some have an acute, severe hemolytic anemia known as *Oroya fever*. The second stage of *Bartonella* infection, *verruca peruviana*, is a nonhematologic disorder characterized by an eruption of warty, bleeding tumors over the face and extremities.

Optimal Management

The mortality rate among untreated patients is high, but Oroya fever responds well to antibiotics and supportive care.

Babesiosis

Definition

Babesiosis is an intraerythrocytic protozoan infection that is transmitted by ticks and is characterized by malaria-like symptoms and hemolytic anemia.

Etiologic Factors and Pathogenesis

Most cases in the United States have been attributed to infection with *Babesia microti*, a rodent parasite maintained by *Ixodes dammini* ticks, the primary vector of the agent of Lyme disease (*Borrelia burgdorferi*). The parasite also may be transmitted by blood transfusion.

Clinical and Laboratory Findings

Asplenic, immunocompromised, and elderly persons are at greatest risk for severe illness, whereas other infected persons commonly are asymptomatic or mildly symptomatic. The disease usually has a gradual onset, with malaise, anorexia, fatigue, fever, sweats, and muscle and joint pains. Intraerythrocytic parasites can be seen on thin blood films, and serologic tests for antibodies to *Babesia* have been described.

Optimal Management

The disorder has responded well to treatment with clindamycin and quinine.

CHAPTER 245: SICKLE CELL ANEMIA

BERTRAM H. LUBIN

[Incidence and Epidemiology](#)
[Etiologic Factors](#)
[Pathogenesis and Pathophysiologic Factors](#)
[Clinical Findings](#)
[Laboratory Evaluation](#)
[Optimal Management](#)

Sickle cell disease is a hereditary hemoglobin disorder that results in sickling of the red cell, leading to chronic hemolytic anemia, vascular occlusion, and progressive organ damage. Sickle cell anemia (SS disease), sickle hemoglobin C disease (SC disease), and sickle b-thalassemia are the most common forms of the disease. For detailed information concerning each of these diseases, the reader is referred to several recent books listed in the bibliography.

INCIDENCE AND EPIDEMIOLOGY

The estimated incidence of sickle cell anemia in newborn African Americans is 1 in 600, for SC disease 1 per 800, and for sickle b-thalassemia 1 per 1,700. About 8% of African Americans have sickle cell trait. The distribution of the sickle cell gene throughout the world parallels that of *Plasmodium falciparum*. Persons with sickle cell trait who are infected with this parasite have a selective advantage over those who do not have sickle cell trait. Given this fact, it is not surprising that newborn screening programs for hemoglobinopathies have identified sickle cell hemoglobin in a substantial number of nonblacks.

ETIOLOGIC FACTORS

Sickle cell disease is a hereditary hemoglobin disorder due to a mutation in the b-globin gene. It is inherited in an autosomal codominant manner. In sickle cell anemia, both of the b-globin chains have a substitution of valine for glutamic acid in their sixth position, and all b-globin in the red cell is sickle. In SC disease, one b-globin gene codes for sickle globin and the other for hemoglobin C, which has lysine substituted for glutamic acid, also in the sixth position of the b-globin chain. In sickle b-thalassemia, one b-globin gene has the sickle cell mutation and the other has a thalassemia mutation. Depending on the type of thalassemia mutation, the synthesis of the normal b-globin chain is completely (b^0) or partially (b^+) suppressed. Sickle cell trait occurs when one b-globin gene codes for sickle hemoglobin and the other for hemoglobin A.

PATHOGENESIS AND PATHOPHYSIOLOGIC FACTORS

Adult hemoglobin (hemoglobin A) is a tetrameric protein containing two a-globin and two b-globin chains. Sickle hemoglobin (hemoglobin S) contains two normal a-globin chains and two sickle b-globin chains. The substitution of the neutral amino acid valine for an acidic amino acid (glutamic acid) changes the charge on the surface of the deoxygenated hemoglobin molecule and causes it to polymerize into a 14-stranded structure. Polymerized sickle hemoglobin is relatively insoluble, rigid, and unstable, and it causes the abnormal red cell properties resulting in sickle cell disease. Hemoglobin C can form polymers with hemoglobin S, resulting in SC disease. Hemoglobin A (a_2b_2) and hemoglobin F (fetal hemoglobin, a_2g_2) prevent polymer formation, explaining the lack of clinical symptoms in persons with sickle cell trait, the mild clinical course of sickle b⁺-thalassemia, and the therapeutic benefit of elevated fetal hemoglobin.

The generation of hemoglobin polymers within the cell depends on several factors. Hypoxia and acidosis promote sickling by lowering the oxygen saturation of hemoglobin. In the arterial circulation, where the P_{O_2} is about 95 mm Hg and hemoglobin is at least 90% saturated with oxygen, about 10% of the cells are sickled. In mixed venous blood, where the P_{O_2} is about 40 mm Hg, hemoglobin is approximately 60% saturated with oxygen, and as many as 70% of the cells may be sickled. Systemic hypoxemia secondary to pulmonary insufficiency is likely to increase the number of sickled cells in the peripheral blood. Conditions within the kidney, spleen, retina, and bone marrow are sufficiently hypoxic and acidotic to induce polymer formation and sickling, and are likely to explain why these organs are often affected.

Studies of the kinetics of polymerization of sickle hemoglobin have demonstrated that after complete deoxygenation of the molecule, a delay time of about 11 milliseconds occurs before polymer formation. This delay time is dramatically shortened when the mean corpuscular hemoglobin concentration (MCHC) is increased. Under normal circumstances, where the transit time of blood through capillaries is about 1 second, hemoglobin is reoxygenated before sufficient numbers of polymers can form inside the cell to cause it to sickle. However, if the transit time is prolonged (an event that could occur as a consequence of adhesive interactions between the red cell and the endothelial cell, abnormal deformability of the red cell, or increased plasma viscosity) or if the MCHC is elevated, polymer formation is favored. When significant amounts of polymer are formed within a red cell, the morphology of the cell transforms from a biconcave disk into a sickle shape. This process is reversible in most red cells by reoxygenation. In a subpopulation of red cells, called irreversibly sickled cells, abnormal morphology persists in the completely oxygenated state.

Although the hemoglobin defect is the primary cause of sickle cell disease, several acquired red cell membrane alterations occur as a consequence of sickling. These include increased calcium permeability and elevated intracellular calcium, decreased intracellular potassium and water, oxidation of membrane proteins and lipids, membrane phospholipid abnormalities, and abnormal expression of adhesive receptors, particularly in reticulocytes. These secondary membrane effects probably contribute to the hemolytic anemia and vaso-occlusive events characteristic of sickle cell disease, and they may be important factors in determining clinical severity.

In addition to the red cell, a number of other factors may contribute to the clinical severity of sickle cell disease. These include an elevated white blood cell count, a hypercoagulable coagulation profile, and upregulation of endothelial cell receptors in the large and small microvascular system. The search for genetic polymorphisms in addition to the sickle cell gene is likely to uncover multiple genes that contribute to clinical severity and help to explain the extreme variability in clinical manifestations that characterize this disease.

CLINICAL FINDINGS

The clinical manifestations of sickle cell disease can be classified into two categories: anemic and vaso-occlusive. The anemic category includes chronic hemolytic anemia, aplastic crisis, splenic sequestration, and hyperhemolysis. The vaso-occlusive category includes painful crisis and organ impairment, such as splenic infarction, stroke, aseptic necrosis of the hip, and acute chest syndrome. Although the term "crisis" is used in sickle cell disease to indicate a change in the patient's clinical course, it has no particular medical significance. Almost every organ system in the body can be significantly affected by sickle cell disease ([Table 245.1](#)).

Ocular: Proliferative retinopathy, tortuous conjunctival vessels
Cardiac: Cardiomegaly, high-output failure, transfusion-related hemosiderosis, hypertension
Pulmonary: Acute chest syndrome, infection (pneumococcal, mycoplasma), chronic hypoxic lung disease
Gastrointestinal and Hepatic: Gallbladder disease, splenic sequestration, splenic infarction, hepatic crisis
Musculoskeletal: Infarction (painful crises), aseptic necrosis, pain, infection (Salmonella osteomyelitis), arthritis (collagen vascular, gout)
Genitourinary: Renal concentration defects, hematuria, nephrosis, chronic renal failure, priapism
Immune: Susceptibility to infection, defect in the alternative complement pathway, functional asplenia, phagocytic defects
Skin: Leg ulcers
Hematopoietic: Chronic hemolytic anemia, aplastic crises, hyperhemolysis
Neurologic: Stroke, transient ischemic attacks, silent infarctions

TABLE 245.1. CLINICAL MANIFESTATIONS OF SICKLE CELL DISEASE

ANEMIC COMPLICATIONS

The life span of the red cell in sickle cell anemia may be only 15 to 20 days, compared to the normal 120 days. Increased production of bilirubin due to hemoglobin catabolism is reflected by the frequent occurrence of bilirubin-containing gallstones and, in patients with compromised liver function, an elevated serum bilirubin level. Gilbert's disease should be ruled out in patients who have persistent or extreme elevations in bilirubin. This can now be accomplished using molecular diagnostic techniques. The spleen may be enlarged in young children but is rarely palpable in adults. If dietary folic acid intake is limited, megaloblastic changes can occur. Low dietary folate can also affect the hypercoagulable profile due to its effects on homocysteine metabolism. Factors that lower intracellular polymer formation, such as α -thalassemia trait (low MCHC), elevated fetal hemoglobin (β -globin haplotype), small amounts of hemoglobin A (sickle β^+ -thalassemia), and hemoglobin C (SC disease), decrease the rate of hemolysis and cause an increase in the hemoglobin. Variations among patients exist, but a given patient's hemoglobin value and reticulocyte count are relatively stable.

Patients with sickle cell anemia are very susceptible to infectious or inflammatory processes that suppress erythropoiesis. A common infection is due to parvovirus B19. This virus, previously thought to be restricted to veterinary medicine, is a common cause of red cell hypoplasia or aplasia in sickle cell anemia. Specific receptors for the virus are found on erythroid progenitors. Infected patients have a rapid fall in the reticulocyte count and hemoglobin level, called an aplastic crisis. If not promptly treated, congestive heart failure can result. Within 7 to 10 days, bone marrow recovery is heralded by an increase in the reticulocyte count, followed by a rise in hemoglobin. Currently, trials of a vaccine to prevent parvoviral infections are in progress. A hyperhemolytic crisis has been reported in patients with sickle cell anemia that is characterized by anemia and a marked increase in the reticulocyte count over baseline values. This event may be secondary to glucose-6-phosphate dehydrogenase (G6PD) deficiency or Gilbert's disease, or it may be a sign of recovery after an aplastic crisis.

Acute splenic sequestration is a hematologic complication that primarily occurs in infants and young children. Within hours, the spleen rapidly enlarges and sequesters most of the circulating red cells. Although rarely documented, it is thought that a splenic sequestration crisis is preceded by a viral infection. Massive splenomegaly and a fall in the hemoglobin concentration to as low as 1 g per deciliter can rapidly occur and cause death. Parents should be taught to palpate the spleen and to bring the child to the physician if they feel the spleen is enlarged. In some children, chronic splenic sequestration associated with pancytopenia occurs.

VASO-OCCLUSIVE COMPLICATIONS

Vaso-occlusive and pain crises are the clinical manifestations that distinguish sickle cell disease from other hemolytic anemias. Pain crises occur sporadically and are unpredictable. They may last for a few days or up to several weeks. The frequency of painful crises varies over time and between patients, with an average of one to one and a half crises per year. Although a few patients appear to be particularly prone to these complications, the mechanisms responsible for this unique susceptibility are unknown. An inverse correlation exists between the fetal hemoglobin level and the frequency of painful crises. Patients with frequent vaso-occlusive crises have a shorter life span than those with infrequent ones.

Almost every organ system in the body can be affected by sickle cell disease. A proliferative retinopathy, similar to that in diabetes, can result in loss of vision if not treated promptly. Several cardiovascular abnormalities can occur. Cardiomegaly may result as a consequence of the chronic high-output state due to anemia, or cardiac dysfunction may occur secondary to transfusion-related hemosiderosis. Hypertension has been observed in association with painful crises, after an exchange transfusion, or in patients with progressive renal disease.

Acute pulmonary disease is responsible for 20% of deaths in sickle cell disease. Although patients can develop focal pulmonary infections with limited severity, in others a rapidly progressive disease, acute chest syndrome, is noted. The clinical manifestations are similar to those noted in adult respiratory distress syndrome. Patients typically present with symptoms consistent with a vaso-occlusive crisis, but within hours pulmonary disease develops and spreads to both lungs, resulting in pulmonary failure. The cause of acute chest syndrome is often not established since bronchoscopy, although safe in sickle cell patients, is rarely used to obtain the tissue required for a diagnosis. Infection or bone marrow fat embolism should be considered in the differential diagnosis. Elevated plasma levels of phospholipase A₂ predict embolism derived from bone marrow fat as a cause of acute chest syndrome. Changes in nitric oxide levels may also be predictive. Chronic restrictive pulmonary disease resulting in persistent hypoxemia may occur after recurrent episodes of acute chest syndrome.

The most common gastrointestinal complication in sickle cell anemia is gallbladder disease. Ultrasonograms have detected bilirubin stones as early as the first decade of life. Biliary problems can include common duct stones, biliary sludge, cholelithiasis, and cholestasis. The decision to perform a cholecystectomy should be based on the patient's symptoms, not the presence of stones. Intense hyperbilirubinemia (up to 60 to 80 mg per deciliter) can occur when the common bile duct is obstructed. This hepatic crisis is associated with hepatic enlargement and abnormal liver function. Liver biopsy shows bile stasis, hepatitis, hemosiderin, and sickled cells. The course of this complication may be as long as 14 days. In rare cases, hepatic failure occurs.

Musculoskeletal manifestations of sickle cell anemia include bone and muscle pain, aseptic necrosis of the bone, and osteomyelitis. Bone pain occurs in the hands and feet in young children. In adults, it usually involves the long bones and lower back. The hip and shoulder joints are often sites of aseptic necrosis. The microcirculatory blood flow in the head of the femur or humerus lends itself to permanent vascular obstruction by sickled cells. Although aseptic necrosis in the humerus has limited morbidity, aseptic necrosis of the head of the femur, due to the weight-bearing role of this bone, can result in permanent disability. When clinical symptoms suggest a hip problem, conventional radiography or magnetic resonance imaging should be used to establish a diagnosis. Conservative management should initially be attempted, but if necrosis progresses, a decompression coring procedure or total hip replacement should be considered. Although osteomyelitis can occur secondary to infection with *Staphylococcus aureus*, it is not unusual to find *Salmonella* in aspirates obtained from inflammatory bone sites. The mechanisms responsible for the susceptibility to *Salmonella* osteomyelitis are unknown, but biliary disease and bone infarction probably contribute.

The kidney is particularly prone to complications in sickle cell anemia due to its hypoxic, acidotic, and hypertonic environment. Renal concentration defects, silent hematuria, nephrosis, and chronic renal failure occur. Even in people with sickle cell trait, renal infarction, hematuria, and hyposthenuria occur. Urinary specific gravity cannot be used as an index of hydration in sickle cell anemia. In adults with hematuria, causes in addition to sickle cell anemia, such as malignancy, must be considered in the differential diagnosis. Hyperuricemia resulting in gouty arthritis is usually related to renal pathologic processes. Chronic renal failure is common in older patients. Since it can be associated with a fall in the baseline hemoglobin value, patients may have fewer vaso-occlusive crises due to decreased blood viscosity. Renal transplantation has been successful in patients with renal failure.

Acute priapism may occur during or shortly after a penile erection due to sluggish blood flow and sickling within the glans of the penis. It is associated with significant pain. Although transfusions may help, surgical intervention is often required. Intermittent episodes of priapism can also occur; these may be remedied by chronic transfusion therapy. Clinical trials using nitric oxide are currently being considered for this complication.

Patients with sickle cell anemia have a marked increase in susceptibility to bacterial infections, including *Streptococcus pneumoniae*, *Haemophilus influenzae*, and, less commonly, *Staphylococcus aureus* and *Mycoplasma pneumoniae*. The absence of splenic function is a primary factor in regard to infections due to polysaccharide-encapsulated organisms. Other immune defects may be secondary to transfusion-related hemosiderosis, defects in the alternate complement pathway, and phagocytic defects.

Skin ulcerations result from sluggish blood flow in superficial capillaries. These ulcerations, which often occur over the lateral malleoli of the tibia, often become infected and require systemic and local therapy. Transfusion therapy should be considered for patients who are severely disabled by skin ulcers.

Neurologic events occur in 15% to 25% of patients with sickle cell anemia. Stroke, convulsions, transient ischemic attacks, and behavioral disturbances have been reported. Hemorrhagic strokes are more common in adults, infarctive strokes more common in children. After transfusion to lower the percentage of hemoglobin S, dramatic clinical improvement is often observed. Early identification of cerebrovascular changes, followed by transfusion therapy, may prevent major central nervous system complications. Noninvasive techniques such as transcutaneous Doppler ultrasonography may be a useful way to detect patients at risk. Computed tomography scans have shown evidence of infarction in children who do not have overt strokes. Transfusion therapy for at least 5 years is recommended for patients who have had a stroke, but the appropriate treatment for "silent" cerebral infarcts remains to be established. Hydroxyurea administration and bone marrow transplantation are alternative therapies that are now being evaluated in patients who require long-term intervention for stroke.

The frequency and severity of anemic and vaso-occlusive complications among patients with sickle cell disease are highest in patients with sickle cell anemia, followed by sickle β^0 -thalassemia, sickle β^+ -thalassemia, and sickle hemoglobin C disease. However, the individual complications may be as severe in any type of

sickle cell disease.

LABORATORY EVALUATION

Laboratory evaluation of a patient with suspected sickle cell disease should include examination of the peripheral blood smear; a complete blood count with red cell indexes; a reticulocyte count; hemoglobin electrophoresis on cellulose acetate (pH 8.6) and citrate agar (pH 6.2); and quantitative determinations of hemoglobins A, S, A₂, and F, or other variant hemoglobins. A solubility test (SickleDEX) can be performed to confirm that a hemoglobin migrating in the S position on electrophoresis is S and not D or G. In many programs, molecular techniques are being used to confirm the hemoglobin diagnosis.

The peripheral blood smear in sickle cell anemia may show irreversibly sickled cells, polychromatophilic macrocytes, and occasional cell fragments. The mean corpuscular volume is high due to the presence of young red cells. Granulocytes are increased in number and a slight shift to the left may occur. Platelets are increased in number and size. The presence of nuclear remnants (Howell–Jolly bodies) within the red cell indicates functional asplenia. In sickle b⁺-thalassemia or sickle b⁰-thalassemia, hypochromic microcytic cells, target cells, and occasional sickle cells are noted. The hemoglobin A₂ level is increased as a consequence of the b-thalassemia gene. Iron deficiency must also be excluded if sickle b⁺-thalassemia is being considered. The mean cell volume is below normal for age. Although patients with sickle b⁺-thalassemia have both hemoglobin A and S, like people with sickle cell trait, the quantitative measurement of hemoglobins S and A can distinguish these two. Patients with sickle cell trait have more hemoglobin A than S; patients with sickle b⁺-thalassemia have more hemoglobin S than A. In sickle hemoglobin C, target cells and rare sickle forms are seen. The mean cell volume is normal or slightly decreased and the reticulocyte count is slightly elevated. Molecular techniques can be used to definitively establish the diagnosis of sickle cell trait versus sickle cell–thalassemia.

[Table 245.2](#) lists the clinical and laboratory findings characteristic of these common forms of sickle cell disease.

Disease	Clinical Severity	Hemoglobin Electrophoresis				Hematologic				MHC	Morphology
		S (%)	F (%)	A ₂ (%)	A (%)	Hb g/dL	Retic (%)	MCV (fL)	MCHC (g/dL)		
SC	Severe	>60	<10	<3.5	0	6-10	5-10	<30	<30	>35	Sickle cells HbS Hemoglobinuria Hematuria Pulmonary infarction Target cells Hemolytic anemia
S ⁺ Thal	Mild to moderate	>60	<10	<3.5	0	6-10	5-10	<30	<30	>35	Sickle cells HbS Hemoglobinuria Hematuria Pulmonary infarction Target cells Hemolytic anemia
S ⁰ Thal	Mild to moderate	>60	<10	<3.5	20-30	6-10	5-10	<30	<30	>35	Sickle cells HbS Hemoglobinuria Hematuria Pulmonary infarction Target cells Hemolytic anemia
SC	Mild to moderate	0	<5	—	80-90	10-15	5-10	30-40	30-40	>35	Target cells HbC Hemoglobinuria Pulmonary infarction Target cells

TABLE 245.2. CLINICAL AND HEMATOLOGIC FINDINGS IN SICKLE CELL DISEASE

Several laboratory parameters have been evaluated in an attempt to predict clinical severity. Among these, the coinheritance of a-thalassemia trait (which lowers the mean corpuscular volume and MCHC) and an increase in fetal hemoglobin are two that have shown beneficial effects. Analysis of the b-globin haplotype is a good predictor of the fetal hemoglobin level and as such has some predictive value. However, there are no specific measurements for predicting clinical severity that can be used to direct experimental therapy in newly diagnosed patients.

Cord blood screening, which is mandatory in an increasing number of states, can identify all forms of sickle cell disease during the newborn period. Detection of sickle cell disease by analysis of fetal DNA makes prenatal diagnosis by amniocentesis or chorionic villus sampling safe and reliable for couples at risk. Collection of cord blood for potential use in transplantation should be encouraged in families that have a child with sickle cell disease. Discussions regarding this should be initiated during consultation for prenatal diagnosis.

OPTIMAL MANAGEMENT

Although bone marrow transplantation offers the only cure for sickle cell disease at the present time, comprehensive care can minimize many of the associated complications. Data from the National Cooperative Study of Sickle Cell Disease demonstrate that among patients with sickle cell anemia receiving care in designated sickle cell programs, 50% are alive at age 45 years. A comprehensive manual distributed by the Sickle Cell Program at the U.S. National Institutes of Health (NIH) provides detailed information on current management and treatment guidelines.

There is an unfortunate tendency among health care providers to emphasize episodic treatment and to underestimate the importance of comprehensive health care. In addition to providing health care maintenance, the patient's primary physician, psychosocial services, and nursing and rehabilitation personnel are responsible for helping patients to cope with the chronicity of their illness, to deal with pain, to continue their education, to adjust to adolescence, and to plan for the future. Clinical examination should focus on early identification of problems by establishing standardized evaluations of various organ systems. Therapy should be directed at prevention, eliminating factors such as hypertonicity, acidosis, or hypoxia. Even mild dehydration must be corrected by the oral or intravenous route, recognizing that the inability to concentrate urine requires one and a half to two times the usual volume of fluids. Also, limited cardiac function may predispose the patient who is aggressively treated with intravenous fluids to pulmonary edema. Acidemia and hypoxia should be corrected, but routine oxygen therapy should be avoided, as it can suppress erythropoiesis. Managed care organizations must be educated as to the importance of comprehensive care and the data that demonstrate its cost-effectiveness.

Painful crises should be treated with adequate analgesia once surgical causes of pain have been excluded. Physicians should be familiar with the pharmacology of narcotic analgesics and should use doses sufficient to block painful symptoms quickly. Severe pain requires the parenteral administration of morphine, preferably by patient-controlled methods. Patients may benefit from the addition of nonsteroidal anti-inflammatory agents, provided the effects on renal function are considered. Pulmonary exercises should be added to the treatment plan to prevent atelectasis and hypoxia. As pain abates, the dose of analgesic can be reduced, but the dosing interval should not be changed. With continued improvement, a switch to oral analgesics can be considered. Although addiction is a concern in any patient who requires narcotic analgesics, the factors that predispose to addiction are usually based on social rather than medical issues.

Because of the frequency and serious consequences of septicemia, the sudden appearance of unexplained fever should be considered a medical emergency. A careful medical history should be taken and a complete physical examination performed. Blood and urine cultures and prompt therapy with intravenous antibiotics are required. Signs of neurologic involvement should determine if a lumbar puncture is required. The white cell count and differential should be compared to baseline values. Chest x-ray should be considered to exclude pneumonia. If an infiltrate is noted, the choice of antibiotics should include coverage for *M. pneumoniae*. Although most patients have been immunized with polyvalent purified pneumococcal polysaccharide antigen, this vaccine has not provided sufficient protection against the most virulent forms of *S. pneumoniae*, and newer vaccines are under development. Because all therapy must cover *S. pneumoniae*, the possibility of penicillin resistance must be considered. Improved vaccines, such as the new conjugated pneumococcal vaccines, may be of benefit in patients with sickle cell anemia.

Early recognition of an aplastic crisis is facilitated by obtaining a reticulocyte count during the initial evaluation of an acutely ill patient and comparing it to baseline values. Identification of a splenic sequestration crisis can be facilitated by teaching the caregivers how to palpate the spleen. In both of these complications, transfusion therapy is often required.

Red cell transfusions are the mainstay of interventional therapy in sickle cell anemia. [Table 245.3](#) lists the indications for transfusion, according to the recent NIH guidelines. As a consequence of transfusion requirements, iron overload has now become a problem for many patients and iron chelation therapy is often required. Use of techniques such as erythropheresis may decrease the extent of iron overload in the patient who requires a chronic transfusion program.

Definite:
 Cardiac decompensation
 Severe acute anemia during an acute splenic sequestration or hepatic crisis
 Erythroid hypoplasia or aplasia with a hemoglobin ≤ 5.0 g/dl
 Cardiovascular accidents and transient ischemic attacks
 Multiorgan failure syndrome
 Acute chest syndrome
 Acute pruritus unresponsive to fluid and analgesic therapy
 Preoperative preparation for major surgery
Equivocal:
 Intractable or frequent painful events
 Before injection of hypertonic contrast material
 Leg ulcers
 Complicated pregnancy
 Chronic organ failure
 Extreme diminution in performance status due to recurrent complications of sickle cell disease
 Growth failure
Indications and Contraindications:
 Chronic steady-state anemia
 Acute painful episodes
 Infections
 Minor surgery not requiring prolonged general anesthesia
 Aseptic necrosis of the hip or shoulder (except when surgery is required)
 Uncomplicated pregnancy

TABLE 245.3. TRANSFUSIONS IN SICKLE CELL DISEASE

For aplastic crisis, splenic sequestration crisis, acute stroke, or acute chest syndrome, partial exchange transfusion may be indicated. Preoperative transfusions minimize the risk of major surgery and should be administered to provide a hemoglobin level of 10 g per deciliter. Chronic blood replacement therapy in patients who have had a stroke or who are being treated for organ failure can be given at 3- to 4-week intervals. The posttransfusion hemoglobin level should never exceed 13 g per deciliter; at this level, the whole-blood viscosity approaches a range likely to cause vascular obstruction. Alloimmunization is a common problem in transfused patients due to the lack of African American blood donors. Providing phenotypically matched blood (especially for C, E, and Kell antigens) decreases this risk. Transfusion reactions can be confused with painful crises, and such reactions might be life threatening.

During the past decade, new therapeutic agents have been evaluated in patients with sickle cell anemia. Treatment with hydroxyurea, although not curative, can increase the red cell volume, increase the fetal hemoglobin level, decrease the frequency of painful crises, and increase the hemoglobin level. The incidence of acute chest syndrome is lower in patients treated with hydroxyurea. This drug must be carefully titrated to prevent toxicity. Its use during pregnancy has not been associated with toxicity. Patients with hemoglobin SC disease have also benefited from treatment with hydroxyurea. Short-chain fatty acids also reportedly elevate fetal hemoglobin levels but not to the extent noted with hydroxyurea. Among these, butyric acid appears to be the most promising. Treatment with clotrimazole and with magnesium has been shown to hydrate red cells by preventing potassium loss during sickling. Clinical trials with magnesium salts are currently under way. Allogeneic bone marrow transplantation has effected a cure in more than 80 patients with sickle cell anemia. A 10% risk of death following this procedure was reported. Alterations in pretransplantation conditioning regimes and use of cord blood as a source of stem cells are being evaluated. Criteria for consideration of transplantation are stringent and may be modified due to its success. Identification of risk factors for clinical severity should assist in the early selection of patients who should be considered for transplantation. Other therapies likely to be developed in the future are those that modify the adhesive receptors on red cells and endothelial cells. Progress in gene therapy has been slow, although use of improved vectors to deliver genes to hematopoietic stem cells has increased the chance that this approach will be successful.

CHAPTER 246: ANEMIA OF CHRONIC DISEASE

ROBERT T. MEANS, JR.

[Incidence](#)
[Pathogenesis](#)
[Clinical and Laboratory Findings](#)
[Treatment](#)

The anemia of chronic disease (ACD) is the anemia associated with chronic infectious, inflammatory, and neoplastic diseases. It is defined by the demonstration of a hypoproliferative anemia with low serum iron but adequate marrow iron stores. The syndrome does not include anemias associated with chronic renal or liver failure, with endocrine deficiencies, or with chronic bleeding. Many authors also include anemia associated with acute infections in the category of ACD. For these reasons, the term "anemia of chronic disease" is often criticized, and alternatives, such as "anemia of inflammation" or "anemia of defective iron reutilization," have been proposed. However, the disorders associated with ACD are united by the involvement of cytokines in their pathogenesis; these cytokines, in turn, are responsible for the resultant anemia (discussed below).

INCIDENCE

Anemia of chronic disease is generally considered to be the second most common anemia syndrome encountered in clinical practice. Blood loss, with consequent iron deficiency, is usually the cause of anemia. ACD can be identified in up to 27% of outpatients with rheumatoid arthritis and in 58% of patients admitted to the hospital with new rheumatologic diagnoses. In 1985/86, Cash and Sears performed iron studies on all anemic persons admitted to the medical service of a busy metropolitan public hospital during two 2-month periods. After patients with bleeding, hemolysis, or known hematologic malignancies were excluded, 52% of the remaining anemic patients met clinical laboratory criteria for ACD.

PATHOGENESIS

Three processes contribute to the development of ACD ([Table 246.1](#)). There is first a modest shortening of red cell survival creating an increased demand for red cell production. The marrow cannot fully respond to this increased red cell requirement, and anemia develops. The marrow cannot increase red cell production because of abnormalities in the mobilization and utilization of reticuloendothelial iron stores and because of impaired erythroid progenitor response. The impaired erythroid progenitor response, in turn, results from two processes.

Shortened red cell survival in vivo
Impaired marrow erythropoietic response to increased red cell requirements
Blunted erythropoietin response to anemia
Inhibited marrow progenitor response to erythropoietin
Impaired mobilization and utilization of reticuloendothelial iron stores

TABLE 246.1. PATHOGENETIC MECHANISMS IN THE ANEMIA OF CHRONIC DISEASE

The production of erythropoietin (EPO), the renal hormone that is the principal regulator of erythropoiesis in vivo, is blunted in ACD; that is, at any given hemoglobin or hematocrit, an ACD patient has a lower EPO level than does a patient with iron deficiency anemia. However, this blunting of the EPO response to anemia cannot fully explain the poor erythropoietic response of these patients. The EPO level in an ACD patient is still higher than the level found in a normal person who is not anemic, indicating that erythroid progenitors are also defective in their ability to respond to EPO.

The observation that the severity of anemia was correlated with the activity of the associated infectious or inflammatory disease led investigators to consider the possibility that the cytokines that mediate inflammation and the response to infection or to tumor invasion, such as tumor necrosis factor (TNF), interleukin-1 (IL-1), and the interferons (IFN), may be responsible for ACD. Evidence accumulated over the last several years indicates that the three pathogenetic mechanisms implicated in the development of ACD ([Table 246.1](#)) can be attributed to the actions of these cytokines. The shortened red cell survival observed in anemic patients with rheumatoid arthritis (a model for ACD) correlates with plasma IL-1 levels. Production of EPO in vitro by hepatoma cell lines is inhibited by TNF and IL-1, mimicking the blunted EPO response observed in ACD. The impaired response of erythroid progenitors to EPO can be produced in vitro by IL-1 and TNF acting through IFN- γ and IFN- β , respectively.

Interleukin-1 increases translation of ferritin messenger RNA, implying a shift of transferrin-bound iron immediately available for erythropoiesis to the storage form, ferritin. Acute-phase reactants such as α_1 -antitrypsin also impair the binding of iron-bearing transferrin to erythroid precursors and the internalization of occupied transferrin receptors. Thus, cytokines and other mediators of the acute-phase reaction impair mobilization of iron and its use by erythroid precursors.

CLINICAL AND LABORATORY FINDINGS

Anemia of chronic disease is typically a moderate anemia, although 20% to 30% of patients have a hemoglobin level of 8 g per deciliter or less. Clinical findings are essentially those of the associated disease and of anemia. Early studies described ACD as a microcytic anemia; in more recent series, 70% to 80% of patients with ACD are normocytic. The reticulocyte response is typically low for the degree of anemia.

The hallmark of ACD is the demonstration of a low serum iron level with adequate reticuloendothelial iron stores. The major syndrome with which ACD is confused is iron deficiency anemia. This is an important distinction: a diagnosis of iron deficiency typically implies the need to identify a site of blood loss, usually by endoscopic investigation of the gastrointestinal tract. Typical laboratory results for ACD and iron deficiency are compared in [Table 246.2](#).

Factor	Iron Deficiency	Anemia of Chronic Disease
Serum iron	Low	Low
Serum TIBC	Typically increased	Decreased
TIBC saturation	<10%	>16%
Serum ferritin	Low	Normal or elevated
Mean corpuscular volume	Decreased	Typically normal
Serum transferrin receptor concentration	Increased	Normal
Marrow iron stores	Absent	Present

* These are typical findings; exceptions are discussed in text.
TIBC, total iron-binding capacity.

TABLE 246.2. IRON DEFICIENCY VS. ANEMIA OF CHRONIC DISEASE^a

Evaluation of suspected ACD begins with the determination of the serum iron level, serum total iron-binding capacity (TIBC), and the serum ferritin level. In ACD, the serum iron level is low, with a low serum TIBC, a TIBC saturation greater than 16%, and a normal or elevated serum ferritin level. Iron deficiency is typically associated with a low serum iron level, an elevated TIBC, a TIBC saturation less than 10%, and a low serum ferritin level. However, in some circumstances these observations may not hold true. A patient with concomitant inflammation may fail to show an increase in serum TIBC in response to iron deficiency. Conversely, if the serum TIBC is less than 200 µg per deciliter, a TIBC saturation of less than 16% may be observed in ACD. A low serum ferritin level always indicates iron deficiency; however, the serum ferritin may be elevated to as high as 200 ng per milliliter by inflammation in the absence of marrow iron stores.

Other tests may help distinguish iron deficiency from ACD. The mean corpuscular volume is low in iron deficiency anemia and normal in most cases of ACD. The red cell distribution width is elevated in iron deficiency and typically (but not always) normal in ACD. The serum soluble transferrin receptor level (sTfR) was initially reported to be elevated in iron deficiency and normal in ACD. In other studies, the distinction is less absolute, but it appears that an elevated serum sTfR identifies iron deficient patients with increased serum ferritin concentrations due to inflammation.

If iron deficiency cannot be ruled out, bone marrow examination should be performed. The evaluation of a Prussian blue–stained marrow aspirate or particle section should provide a definitive determination of the presence or absence of marrow iron stores. The evaluation of iron status is the principal indication for marrow examination in suspected ACD. The morphologic features of the bone marrow in ACD are nonspecific, and the diagnosis remains a clinical one.

TREATMENT

There is no specific treatment for ACD; therapy should be directed at the associated disease. The use of iron supplementation and of recombinant human (rh) EPO deserve special mention.

There is no role for iron therapy in the treatment of ACD. Reports in which iron therapy has partially corrected this anemia probably represent cases in which patients with ACD subsequently developed iron deficiency, as when patients with ACD due to rheumatoid arthritis have gastrointestinal blood loss provoked by nonsteroidal anti-inflammatory drugs. In these cases, only the component of anemia due to iron deficiency is corrected; the ACD component of the anemia is not corrected.

Recombinant human EPO can correct the anemia of patients with ACD. Results from the study of erythroid progenitors in vitro and in animal models suggest that this effect results from the ability of high rhEPO concentrations to oppose the inhibitory effects of cytokines. However, most patients with ACD are only moderately anemic and lack symptoms attributable to anemia. rhEPO therapy would not be indicated in these patients, but it should be considered in patients sufficiently anemic on a chronic basis to be symptomatic or to require transfusion, in patients who wish to donate blood to be stored for autologous transfusion at elective surgery, in patients who are anemic from cancer chemotherapy, and in significantly anemic patients with HIV infection. Patients who have anemia due to cancer chemotherapy or who have severe ACD requiring transfusions may be treated with subcutaneous rhEPO 150 units per kilogram 3 times weekly or 50 units per kilogram 5 times weekly. The practice of using a once-weekly rhEPO dose at 40,000 units, shown to be effective in cancer patients, is also likely to be effective in ACD. HIV patients may be treated with subcutaneous rhEPO 100 to 150 units per kilogram 3 times weekly or 4000 units 6 times weekly.

Responses are typically seen by 6 weeks. Failure to respond suggests iron deficiency (which may develop in association with the response to rhEPO in a patient not previously iron-deficient), blood loss, or active inflammation suppressing erythropoiesis. It is generally good practice to treat a patient with ferrous sulfate 325 mg 3 times a day during rhEPO therapy; the alternative, monitoring the serum ferritin every other week to ensure that it is 100 ng per milliliter or more, is much more costly. Patients with clinically significant iron overload would be an exception to this practice. If iron deficiency, blood loss, or active inflammation is not present, a dose increment (usually 50% to 100%) can be tried. Failure to respond to the increased dose after an additional 6 weeks indicates that the patient is unlikely to respond to further therapy with rhEPO. The rhEPO doses of responding patients should be adjusted to maintain a hematocrit of 36% or a hemoglobin level of 12 g per deciliter. Patients donating blood for autologous transfusion may be treated with subcutaneous rhEPO 150 units per kilogram 3 times weekly or 300 units per kilogram twice weekly (and ferrous sulfate 325 mg 3 times a day) during the 3 to 4 weeks before surgery. Autologous blood for storage can then be collected according to the local blood center's protocol.

CHAPTER 247: PARANEOPLASTIC SYNDROMES

GREGORY P. KALEMKERIAN

[Definition and Incidence](#)
[Pathogenesis](#)
[Clinical Findings](#)
[Disease Management](#)

DEFINITION AND INCIDENCE

The paraneoplastic syndromes are a heterogeneous group of clinical disorders with signs and symptoms affecting sites distant from both the primary tumor and metastatic foci. Although paraneoplastic syndromes occur, by definition, in patients with cancer, nearly all of them have also been reported in the absence of underlying malignancy. Indeed, many of these syndromes occur more frequently in patients without cancer, whereas only a few have been reported solely in the paraneoplastic setting. For instance, less than 10% of patients with dermatomyositis are found to have cancer, whereas necrolytic migratory erythema is considered pathognomonic for glucagonoma. Paraneoplastic syndromes are most frequently associated with carcinomas of the lung, stomach, and breast, or with hematologic malignancies, especially Hodgkin's disease and non-Hodgkin's lymphoma. A few paraneoplastic syndromes, such as cancer-related anemia and anorexia–cachexia, occur frequently in patients with a variety of malignancies, while most others are associated with specific histologic types of cancer. Despite the high frequency of nonspecific symptoms in cancer patients, most of the organ-specific paraneoplastic syndromes are rare, with an estimated overall incidence of 5% to 10%. As an example, although many patients with lung cancer exhibit gross neuromuscular or autonomic deficits, less than 2% of them are found to have definable neurologic syndromes. However, the high incidence of constitutional symptoms and laboratory abnormalities in cancer patients has recently led investigators to suggest that paraneoplastic syndromes may affect over 50% of these patients. It is important for the primary care physician to be familiar with the myriad manifestations of paraneoplastic syndromes because these disorders are frequently the earliest indication of cancer and their prompt recognition may allow for the diagnosis of the disease at an earlier, more treatable stage. In addition, the timely initiation of appropriate treatment for a specific paraneoplastic syndrome can have a tremendous impact on quality of life, even in the setting of advanced disease.

PATHOGENESIS

Although the cause of most paraneoplastic syndromes remains unknown, several mechanisms by which tumors can induce these syndromes have been described, including (a) ectopic production and secretion of peptide hormones or hormone precursors; (b) metabolic conversion of steroid hormones; (c) production and secretion of cytokines; and (d) stimulation of autoimmune antibody production. The endocrine syndromes, such as humoral hypercalcemia and the syndrome of inappropriate secretion of antidiuretic hormone (SIADH), are generally caused by the ectopic production of peptide hormones by tumor cells. Many normal and malignant nonendocrine cells produce small quantities of protein hormones that serve autocrine or paracrine functions. However, some cancers produce large quantities of these hormones or have greater potential for converting precursor molecules to the active form, resulting in a clinically apparent systemic syndrome. Paraneoplastic syndromes caused by the overproduction of steroid hormones are exceedingly rare due to the complexity of the steroid synthetic pathways. However, sarcomas and hepatocellular carcinomas can express increased aromatase activity that enhances the conversion of androgens to estradiol, resulting in gynecomastia. In addition, some hematologic malignancies express increased vitamin D hydrolase activity leading to elevated levels of calcitriol and systemic hypercalcemia. Although the production of a wide variety of cytokines by tumor cells has been well documented, the direct causal relationship between these substances and specific syndromes remains unproven. Nevertheless, available data suggest that the secretion of cytokines may be responsible for some of the more common paraneoplastic syndromes, including leukocytosis, tumor fever, and anorexia–cachexia. A variety of paraneoplastic syndromes, especially those with neurologic manifestations, are associated with the generation of autoantibodies directed against tumor-expressed antigens that are not normally accessible for immune recognition. These autoantibodies can cross-react with antigens on normal cells, such as neurons, resulting in tissue-specific cytotoxicity, or they can form complexes with circulating antigen to induce end-organ damage through immune complex deposition. In a few syndromes with an apparent autoimmune mechanism, specific causative antibodies have been identified, such as the anti-Yo and anti-Hu antibodies in subacute cerebellar degeneration, but in most the etiologic antigen and antibody remain unknown. The ability to establish a causal link between specific antibody production and a clinical syndrome has been confounded by the findings that many cancer patients without neurologic symptoms express low levels of autoantibodies and that some afflicted patients lack expression of the putative anti-body.

CLINICAL FINDINGS

The signs and symptoms of paraneoplastic syndromes can precede the diagnosis of cancer by months or years, or can arise at any time during the course of known malignant disease. Paraneoplastic syndromes are usually associated with a relatively rapid onset of symptoms, which should heighten the clinician's suspicion of an underlying malignancy. The constellation of symptoms can also be affected by this rapid course and can help establish a cancer-associated etiology. For instance, paraneoplastic Cushing's syndrome differs from Cushing's disease in that it is rarely associated with truncal obesity, cutaneous striae, and hyperpigmentation. Although the clinical course of a paraneoplastic syndrome can be notoriously unpredictable, in most cases it closely parallels that of the underlying malignancy.

As noted in [Table 247.1](#), nearly every organ system and anatomical site can be affected by paraneoplastic syndromes. Patients with neurologic syndromes typically display worsening of symptoms over weeks to months prior to stabilization of disease at a level of moderate to severe disability. The dermatologic syndromes can cause significant cosmetic and functional morbidity that is usually underestimated by health care providers; in rare cases, severe desquamation, such as that associated with paraneoplastic pemphigus, can be fatal. Among the endocrine syndromes, SIADH and humoral hypercalcemia can induce severe, even lethal, metabolic disturbances. Similarly, anemia is a major contributing factor in cancer-related fatigue and cardiopulmonary morbidity, while thromboembolic phenomena are not an uncommon cause of death in patients with advanced cancer.

TABLE 247.1. SELECTED PARANEOPLASTIC SYNDROMES

DISEASE MANAGEMENT

The appropriate management of paraneoplastic syndromes is dependent on the specific nature of the syndrome, the severity of symptoms, the therapeutic responsiveness of the underlying malignancy, and the overall prognosis of the patient. Usually, the dual goals of treatment are to alleviate the symptoms of the paraneoplastic syndrome and to control the associated cancer. In patients with mild paraneoplastic symptoms and surgically resectable or chemosensitive tumors, such as small-cell lung cancer or lymphomas, anticancer treatment alone may be sufficient. However, specific therapy directed at the paraneoplastic syndrome is usually required in patients with significant symptoms and/or advanced or poorly responsive tumors. Frequently, it is appropriate to forego specific therapy in favor of comfort measures in patients in the terminal phases of disease.

Paraneoplastic syndromes resulting from hormone or cytokine overproduction usually improve with successful anticancer therapy and recur upon relapse of disease. Ancillary therapies, such as the inhibition of cortisol production with aminoglutethimide or ketoconazole in Cushing's syndrome, hydration and bisphosphonates in humoral hypercalcemia, fluid restriction and demeclocycline in SIADH, and phosphate and vitamin D replacement in oncogenic osteomalacia, are frequently useful for symptom palliation. In contrast, the symptoms associated with autoimmune neurologic syndromes are often due to specific neuronal damage that is usually irreversible at diagnosis. Although clinical improvement is noted in less than 10% of these patients after cytotoxic or immunosuppressive therapy, such as plasmapheresis and corticosteroid administration, these measures frequently prevent further neurologic deterioration. Topical and systemic immunosuppressive approaches have also been tried with varying degrees of success in a wide variety of the dermatologic syndromes. Recent advances have led to substantial improvements in the quality of life of patients with some of the most common paraneoplastic syndromes. For example, appetite stimulants, such as medroxyprogesterone acetate, can reverse weight loss in up to 50% of patients with cancer-associated anorexia–cachexia, and erythropoietin can alleviate fatigue in a significant subset of patients with cancer-related anemia.

CHAPTER 248: IMAGING IN ONCOLOGY

STEPHEN I. MARGLIN AND RONALD A. CASTELLINO

[Principles of Oncologic Imaging](#)
[Evaluating Diagnostic Modalities](#)
[Specific Modalities](#)
[Conclusion](#)

Perhaps more so than for the majority of other medical specialties, oncology relies on the quality of information uniquely provided by radiologic imaging. Because of the rapidity with which radiology has evolved and the consequent increase in the number of examinations from which to choose, selecting the most appropriate examination has become an increasingly difficult and daunting challenge. As a result, and in the belief that technologic advances are likely to continue, this chapter emphasizes what we believe to be the principles of oncologic imaging rather than the specific examinations that should be used in a given clinical setting. The indications for oncologic imaging and the manner in which one might attempt to evaluate these modalities are also emphasized. The technologies currently most applicable to oncology are also reviewed.

PRINCIPLES OF ONCOLOGIC IMAGING

The choice of an examination for a patient with a known or suspected malignancy depends primarily on the questions being posed. Put somewhat differently, the decision depends on the reason the information is being sought and on how the information will be used. Unless “the question” is carefully considered, an inappropriate test might be chosen—one that would waste valuable time, unnecessarily burden the patient, and produce little if any useful information. [Table 248.1](#) lists some common reasons for obtaining an imaging examination.

To aid in establishing a diagnosis (i.e., establishing how best to obtain tissue)
 Staging
 Evaluating extent of disease
 Establishing a baseline
 Formulating prognosis
 Planning treatment
 Assessing response to therapy
 Detecting relapse
 Evaluating possible complications of disease or therapy
 Detecting infections
 Detecting second neoplasms
 Evaluating cardiac dysfunction
 Clinical research

TABLE 248.1. COMMON INDICATIONS FOR IMAGING IN ONCOLOGY

Imaging is often used, before a diagnosis of cancer has been established, as a way to elucidate the etiology of symptoms or to better understand a palpable or biochemical abnormality. During these examinations, it is not uncommon to encounter unexpected abnormalities. However, these aberrations do not invariably represent cancer. An important contribution that radiologists can render is the ability and experience to discriminate between benign and malignant lesions (i.e., between abnormalities that require histologic confirmation and those that do not). As an example, a lung nodule should, as a rule, be considered potentially malignant, particularly in a smoker or in someone over age 50. However, if the nodule is homogeneously or concentrically calcified, the lesion is almost certainly benign (i.e., it represents the residuum of an earlier granulomatous infection). Similarly, a hypodense liver lesion discovered on a contrast-enhanced computed tomography (CT) examination also should be viewed with concern. However, if scans obtained after the administration of intravenous contrast demonstrate that the lesion equilibrates in attenuation or “fills in,” and particularly if the lesion avidly accumulates radiotracer on a tagged red cell scan, a radiologist can provide a high degree of reassurance that the abnormality is a benign hemangioma.

Although the radiographic appearance of an abnormality is an important component in the decision as to whether to perform additional tests, rarely can the appearance be relied on to provide a histologically specific diagnosis. Few findings are sufficiently pathognomonic (e.g., the CT appearance of a meningioma) to permit an unequivocal pronouncement regarding treatment or prognosis. This limitation must be borne in mind. Major decisions, especially those relating to the choice of initial therapy, generally require pathologic verification of the nature of the abnormality.

Having said this, accurate depiction of a lesion, especially when presented in cross-sectional format, is often exceedingly helpful in deciding how best to obtain tissue. Sometimes a conventional (open surgical) biopsy may be necessary. On other occasions, an image-guided, percutaneous aspiration or biopsy may provide the information needed to guide management.

Because most forms of imaging provide anatomical rather than histologic or metabolic information, the test's specificity must be well understood. It is essential that the predictive accuracy of a positive diagnosis not be overstated or misinterpreted. This is particularly important when staging a newly diagnosed cancer (i.e., when decisions regarding initial therapy are being made). CT or magnetic resonance imaging (MRI) examinations of patients with newly diagnosed lung cancer commonly reveal enlarged mediastinal lymph nodes. It might be tempting to declare such patients inoperable. However, extensive experience has shown that an appreciable number of these enlarged nodes are reactive (i.e., do not contain tumor). Excessive reliance on the size and appearance of such nodes might therefore contribute inadvertently to the loss of a unique opportunity to treat, and possibly to cure, such patients.

Staging and defining the anatomical extent of disease are not necessarily synonymous, nor do these tasks necessarily require the same type or intensity of imaging. As an example, in non-Hodgkin's lymphoma, a bone marrow biopsy may be all that is required to categorize a patient as having advanced (stage IV) disease. This is quite different from the information that would be necessary to describe the degree of involvement in all nodal and extranodal sites. Thus, for certain diseases, if all that is required is “staging,” little or no imaging may be required. To visualize the actual extent of disease, however, multiple examinations (e.g., CT or MRI) may be necessary. As always, the decision about which imaging tests to use depends on understanding what information is required and how that information is going to be used.

If appropriate management requires identification of all major sites of disease, the selection of examinations requires substantial knowledge of the anticipated biologic behavior of the tumor. Sites that are suggested by the results of biochemical tests or symptoms should of course be evaluated. But what about sites that are clinically silent? If a tumor is known to have a low propensity to metastasize to a given location, radiologic interrogation of that site is probably not warranted. For instance, in Hodgkin's disease, neither bone scans nor contrast examinations of the gastrointestinal (GI) tract are routinely performed in newly diagnosed patients because the yield is low to nonexistent, respectively.

There is one important caveat to this approach. If the consequences of missing metastatic disease in a particular location are serious enough (i.e., if they pose an unacceptable risk to the patient), a given test may still be warranted, even when the yield from that examination is known to be low.

Earlier we noted that the selection of a radiologic examination depends in part on a tumor's anticipated biologic behavior. This information is also essential for the accurate interpretation of a radiologic examination. In Hodgkin's disease, clinical research has demonstrated that the tumor spreads in a remarkably predictable manner. Thus, disease in the neck or mediastinum is known to place the upper abdominal lymph nodes and the spleen at risk. If CT or lymphography fails to demonstrate abnormalities in these sites but instead reveals enlargement of pelvic lymph nodes, radiologists and clinicians should interpret these findings with

caution; something other than Hodgkin's is more likely responsible for the pelvic adenopathy.

When treatment is to consist of or include irradiation, the precision and accuracy of the information needed may be extraordinarily high. However, if the patient is going to receive chemotherapy, much can be accomplished without this same degree of anatomical precision; chemotherapeutic agents can accomplish their task without precise road maps.

If imaging is being performed to evaluate response to treatment or to detect relapse, it is useful to ask whether it is necessary to visualize all known sites of disease. Many tumors behave in a synchronous fashion; sites of disease wax or wane synchronously as they respond to variations in therapy. For these tumors, it may be possible to limit examinations to so-called index sites (sites of original bulk disease). Other sites, barring evidence to the contrary, can be assumed to behave in concert with the sites being imaged.

In reviewing the literature, it is sometimes difficult to decipher the significance of reports describing new therapeutic interventions, largely because of differences in the way in which the patients were evaluated. If the results of a patient's treatment are likely to be of interest to others, and particularly if the patient has been enrolled in an investigation that compares the efficacy of differing forms of therapy, some thought should be given to using the same imaging studies, in the same way, as other investigators.

EVALUATING DIAGNOSTIC MODALITIES

Having decided that some form of imaging is indicated, the clinician must then decide which examinations to obtain. Other things, such as cost and invasiveness, being equal, it might appear that the choice would come down to a straightforward comparison of the accuracy of the competing tests. Unfortunately, the task is not nearly so simple.

For any test, the term *accuracy* means the number of correct diagnoses divided by the number of examinations performed. Although this definition describes one facet of a test's performance, it provides no explicit information concerning its actual ability to detect disease. Consider the example of a tumor with a low likelihood of distant spread. If we assume that the tumor metastasizes between 1% and 10% of the time, and if the test in question were to be uniformly reported as "negative," the overall accuracy would be 99% and 90%, respectively. This test might therefore be considered respectable despite the fact that not a single incident of disease spreading beyond the confines of the original site was detected. Although the overall accuracy of this test is high, such a test is unlikely to be particularly helpful.

Thus, because the "accuracy" of a test provides limited information, it has become customary to report the results of tests in terms of their sensitivity and specificity (Fig. 248.1). These parameters provide much more information concerning the test's ability to detect disease. Useful information is also provided concerning the test's propensity to produce false-positive diagnoses. If the prevalence of the abnormality being studied is known, knowledge of a test's sensitivity and specificity permits one to calculate the probability of a false-positive or a false-negative diagnosis.

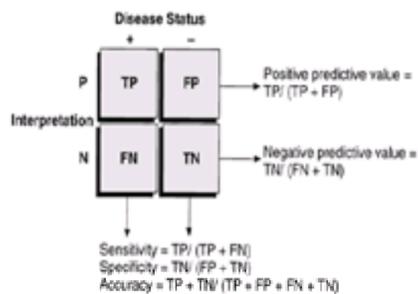

FIGURE 248.1. A classification table of test results compared with a gold standard. D, disease status; FN, false-negative; FP, false-positive; N, negative interpretation; P, positive interpretation; TN, true negative; TP, true positive.

Although these amplifications and modifications represent significant improvements, they are still not entirely satisfactory. First, published results often represent the best that can be achieved by dedicated specialists under the best possible circumstances. Other well-trained, highly motivated physicians may not be able to replicate these results. More importantly, the results are significantly influenced by the prevalence of disease in the population originally studied. If that population differs greatly from the population in the "real world," results such as the "accuracy of positive diagnoses" or the "accuracy of negative diagnoses" will not be the same. If, however, the prevalence (the pretest probability of disease in the real world) is known, it is possible to recalculate the new and locally applicable values.

It is perhaps of greatest importance that simply providing a list of the relevant parameters of accuracy (sensitivity, specificity, predictive accuracy of positive and negative diagnoses, and overall accuracy) does not easily or inexorably lead to the selection of one examination over another. Which is better: a test with high sensitivity (one that can detect more cancers) or one with high specificity (one that has fewer false-positive diagnoses)? Even the conventional five parameters of accuracy only serve to describe a single point on a continuous curve, a curve that plots the sensitivity of the test against its false-positive fraction (the inverse of specificity). This curve, known as a receiver operating characteristics (ROC) curve (Fig. 248.2), is a better descriptor of the performance of a given examination and of the people who use it. If all other things are equal, comparing the areas under the ROC curves of different tests permits one to identify the test that is theoretically the best.

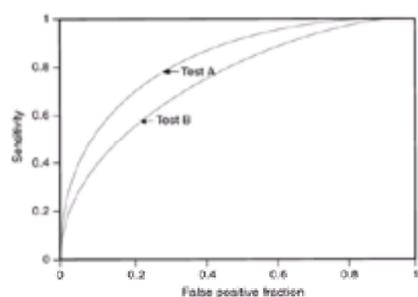

FIGURE 248.2. Receiver operating characteristic (ROC) curves of two hypothetical imaging examinations. Test A is theoretically the more accurate; that is, for each sensitivity or true-positive fraction, it has a lower false-positive fraction.

However, the generation of an ROC curve is an artificial and somewhat labored process. The curve describes what *might* occur, given certain conditions—not all of which are likely. The single point described by the parameters of accuracy actually describes how the test performed in a given clinical setting. In other words, although the area under test A's ROC curve may exceed that for test B, the single point of practice for test B may still be judged as producing better results than the site that users have adopted for test A.

Finally, published reports of the prowess and accuracy of a given modality often describe what specialists under optimal conditions can achieve. It is unrealistic to assume that similar results will be obtained in every hospital and in every clinic. Thus, the preferences, skills, and talents of the radiologists performing the

examinations must be considered and integrated into the decision.

SPECIFIC MODALITIES

Plain radiographs are usually the first imaging examinations that are obtained. Although they are less sensitive and less specific than the more sophisticated and expensive examinations, they are probably a reasonable compromise. If an abnormality is detected (which is certainly not uncommon) and/or if the signs and symptoms are sufficiently compelling, further evaluation invariably proceeds. Because plain radiographs, particularly those that examine the chest, are readily available and low in cost, they are also important in the periodic surveillance of patients with cancer.

Plain radiographs are produced when x-rays pass through the human body, interact with structures in their path, and contact and become recorded by a detector such as film or a luminescent screen. The x-rays originate when an accelerated stream of electrons is abruptly decelerated in the target of an x-ray tube. The resultant packets of energy, or photons, are used in the formation of most medical images, including plain films, contrast examinations of the GI tract, excretory urograms, angiography, and CT. In these examinations, a detector (e.g., film, a fluoroscopic screen, or the detectors used in image intensifiers and CT gantries) records the x-rays.

For imaging studies that do not involve x-rays, other forms of radiant energy, emitted from the patient, are detected and analyzed. Examples of these forms of energy include the reflected sound waves in ultrasonography, the radiofrequency waves in MRI, and the g-rays (photons) in nuclear medicine.

As x-rays traverse the body, they are attenuated, or scattered, in proportion to the atomic number of the tissues they contact. Structures of high attenuation (e.g., bone, metal-containing contrast media) absorb more x-rays than "water-density" tissues (e.g., organs, blood), which absorb more than fat-containing and finally air-containing structures. The packets of energy that emanate from the body represent the summation of the atomic composition of the objects in the path of the beam. In most plain film examinations, the x-rays interact with a luminescent screen that produces light in direct proportion to the number of x-rays that reach it. The light exposes a film, which when developed results in the formation of an image. This projection image (e.g., a chest or abdominal radiograph) superimposes or compresses the patient's three-dimensional anatomy onto a two-dimensional sheet of film.

In addition to plain radiographs obtained without contrast, examinations performed after contrast administration (e.g., upper GI series, barium enemas, and intravenous urograms) are important means of interrogating specific organ systems. These examinations permit excellent definition of anatomical abnormalities that arise from the mucosa, as well as from the walls of a hollow viscus. A limitation of these examinations is their relative insensitivity to the presence of enlarged lymph nodes and/or nearby masses, even when such masses are quite large.

Angiography is a unique form of plain film radiography. In this increasingly important and technically demanding subspecialty, a contrast agent is injected into a vessel, enabling visualization of segments of anatomy that would otherwise be hidden from view. Angiography actually embraces a number of different examinations (e.g., arteriograms, venograms, and lymphangiograms). When the task involves establishing a diagnosis of cancer, CT and MRI have largely supplanted arteriography. However, if resection of part of the liver is being considered (e.g., for a hepatoma or for a small number of apparently localized metastases), performing a hepatic or superior mesenteric arteriogram can significantly increase CT's sensitivity to the presence of lesions.

In many radiology departments, angiography is combined with interventional radiology, reflecting the fact that what was formerly a purely diagnostic specialty has evolved into one that has become increasingly therapeutic. In addition to depicting normal and abnormal vascular anatomy, angiograms are now used to deliver cytotoxic agents and to embolize a tumor's blood supply. Sometimes this is done for palliation; on other occasions, it may be used as an adjunct to surgery (e.g., to diminish blood loss). Interventional radiology has proved particularly effective as a means of obtaining diagnostic material and as a way of percutaneously draining infected fluid collections.

Lymphography is a form of imaging in which an oily, iodinated contrast agent is directly infused into tiny lymphatic channels that course beneath the skin on the dorsum of the feet. Part of the contrast becomes trapped in the sinusoids of abdominal and pelvic lymph nodes, thereby permitting remarkably detailed visualization of the nodes' internal architecture. Lymphography was once a mainstay in the armamentarium of diagnostic oncology. Today CT has largely supplanted it. However, in certain diseases, such as Hodgkin's disease, lymphography has a small statistical advantage over CT. Despite this, the technical demands of the procedure, combined with the relatively infrequency with which it is performed, have led many radiologists to abandon it. In centers that specialize in cancer and in many large urban hospitals, lymphography is still performed. If the information provided by lymphography is considered important and if expertise in performing and interpreting lymphograms is unavailable locally, consideration should be given to referring the patient to a center that specializes in this examination.

Unlike conventional radiography, in which x-rays traverse a patient and directly produce a transmission image on film, in CT the images are actually rendered by a computer. The fundamental principle of CT is that an object's structure can be elicited and depicted on the basis of information obtained from sequentially passing x-rays through the object from multiple, different directions. In practice, a narrow slice of anatomy is interrogated with a series of thin, tightly collimated x-ray beams. The transmitted radiation is measured with several sensitive radiation detectors. In contrast to conventional radiography, the detectors in CT do not actually capture or form the image; rather, they tally or record the energy of the transmitted photons. The numerical data are then computer-processed to reconstruct the image.

Plain radiography transcends virtually all other forms of medical imaging in the ability to distinguish two or more closely positioned objects, a property known as *spatial resolution*. CT's spatial resolution is far below that of plain films. However, CT has a remarkable capacity to distinguish the densities of objects, or regions within an object, that differ only minimally in their electron density. This prowess enables CT to graphically depict normal and abnormal anatomy in ways that far exceed the capabilities of plain radiography. Two important attributes of CT, as they relate to oncology, are its ready availability and the fact that clinicians and radiologists have become comfortable with the way in which the information is presented. The reproducibility of the cross-sectional display makes it ideal for measuring lesions and for assessing their response to treatment.

In contrast to other forms of medical imaging, in ultrasound high-frequency sound waves are used to produce images. These waves are created when an electrical field is applied rapidly to a piezoelectric crystal. Such crystals are characterized by their ability to change dimensions, albeit minimally, in response to a change in electrical voltage. The deformation of the crystal and its subsequent return to normal produce sound waves that are directed to, and focused on, segments of a patient's anatomy. These waves travel at speeds determined by the densities and elasticities of the tissues. When sound waves encounter a tissue of different acoustic impedance, a sound wave (echo) is reflected back in the direction of the transducer. These returning echoes are processed by ultrasound computers to generate images. The location of various interfaces, deep within the body, are determined from the length of time it takes for the echoes to return; the longer the time, the farther an interface is from the transducer.

Ultrasound is an appealing examination, in part because it is less expensive than CT or MRI, but also because it is portable, and because it does not use ionizing radiation. Since images are obtained in real time, ultrasound is extremely valuable for guiding biopsies and other interventional procedures, such as drainage. The quality of an ultrasound image, somewhat analogously to the images obtained at GI fluoroscopy, depends very much on the skills of the person who performs the examination. This relative lack of reproducibility, coupled with the vagaries in visualization that occur as a result of changes in the position and amount of bowel gas, make ultrasonography less successful than CT for periodic surveys. Ultrasonography, however, is a very helpful adjunct to other examinations and an exceptional tool for solving specific problems.

Magnetic resonance imaging uses perturbations in the energy states of objects within a strong, externally applied magnetic field to create two- and three-dimensional images that are notable for their clarity and detail. The strength of the magnetic field can vary both within and between the products of different manufacturers, usually between 0.5 and 2.0 tesla (1 tesla is about 10,000 times the strength of the earth's magnetic field, measured at the surface). In CT, image contrast is related to differences in the electron density of tissues. In MRI, however, contrast is determined by differences in the concentration of mobile hydrogen protons. Without embarking on a treatise in physics, the single most important virtue of MRI, compared to CT and other forms of imaging, is its extraordinary contrast resolution.

The examinations that have been discussed above, as excellent as they are, all suffer from one common limitation. The information that they provide is primarily morphologic. While they are generally excellent at delineating both normal and abnormal anatomy, they sporadically fail to resolve clinically important questions. As an example, when a mass is seen, particularly in a patient who has previously been treated, it can be difficult to know whether the mass represents viable tumor or merely the extinct residuum of earlier disease. It is nuclear medicine's unique ability to provide physiologic information that has resulted in its recent resurgence as an oncologic imaging tool.

In nuclear medicine, radioisotopes are used to interrogate the function or biologic activity of a particular organ or a region of the body. Areas of increased activity are

produced by tissues that concentrate the administered isotope (e.g., when a lymphoma concentrates gallium 67). Areas of diminished activity occur when a tumor displaces cells that are normally imaged, e.g., when hepatocytes are displaced by liver metastasis on a technetium Tc-99m sulfur colloid liver scan. Photopenic areas can also arise when a biologic activity such as bone repair is impaired. In the past, nuclear medicine examinations were occasionally derided because of their perceived poor image quality. Today, improvements in detection, recording electronics, and imaging processing have greatly improved the clarity of the images and the sensitivity of the examinations.

Of the radionuclide examinations currently employed, bone scanning is the most common. This test is based on the observation that bone metastases tend to elicit the formation of new bone. Consequently, when a bone-seeking agent (e.g., a ^{99m}Tc -phosphonate compound) is administered, the radionuclide is incorporated into hydroxyapatite crystal near the site of metastasis. Regrettably, however, bone scanning cannot distinguish between tumors, arthritis, or the residuum of prior trauma. Because of this, unless the results are viewed as unequivocally positive, i.e., related to a malignancy, consideration should be given to obtaining corroborative plain films. Like all tests, bone scans are not perfect; sometimes they fail to detect metastases. If a patient's pain is severe and if a planar bone scan is normal or equivocal, consideration should be given to further evaluation with a tomographic scan (e.g., CT, MRI, or single photon emission CT).

The most recent addition to nuclear medicine's arsenal is positron emission tomography (PET). In contradistinction to other nuclear medicine examinations that primarily provide semiquantitative physiologic information, PET provides truly quantitative metabolic information. As such, PET has shown remarkable proficiency in tumor detection and in characterizing potentially abnormal areas depicted on other examinations. Of similar significance, PET offers the potential to rapidly assess a tumor's response to therapy. Without question, PET promises to be one of the most powerful and important modalities for cancer imaging.

CONCLUSION

Given the high cost of health care and the public's skepticism over whether all of the health care services being purchased are worth their cost, the practice of oncology has come under considerable scrutiny. Because imaging is an important component of the costs associated with treating cancer, these costs and their associated benefits will continue to be carefully analyzed.

With this in mind, it is important to carefully consider whether the information obtained from a given examination is worth the cost, defined in both physical and economic terms. If the information being sought is not likely to alter a patient's stage or treatment, the examination probably should not be performed. A second tenet, only a little less axiomatic than the first, is that a test of limited accuracy probably should not be obtained, even if the prevalence of disease in a given location is high. Third, although the "accuracy" of a test may be high, if the prevalence of disease in the location interrogated is low, the test should probably not be performed. An important caveat concerning the second and third recommendations concerns situations in which the discovery of an abnormality would greatly influence therapy. If the "cost" of missing the presence of disease in a given location is regarded as sufficiently high, the test may still be warranted.

CHAPTER 249: PATHOLOGY AND CYTOLOGY

VIRGINIA A. LIVOLSI AND JOHN E. TOMASZEWSKI

[Cytology](#)
[Biopsy](#)
[Frozen Section](#)
[Gross Examination of Tissue](#)
[Tissue Preparation](#)
[Tissue Processing, Embedding, and Sectioning](#)
[Ancillary Tests](#)
[Utility of Immunohistochemistry and in Situ Hybridization](#)

The morphologic examination of tissue is a powerful diagnostic modality. Human disease is highly polymorphic in its biology and clinical characteristics. Imaging at the light microscopic and ultrastructural levels captures data-dense packages of information that are efficient representations of illness in the majority of circumstances. In each image there is an enormous wealth of integrated information. The pictures created in the morphologic examination of tissue are really summary statements as to which genes are present and active and how they are related to one another. For a particular disease process the entire interplay of genetics, biochemistry, and physiology is often retold in microscopic imaging studies, if only the observer is astute enough to deduce the tale!

Because of this robust nature, microscopic imaging can be an efficient and cost-effective means of arriving at a diagnosis. Biopsy early in the course of a patient's workup can significantly accelerate the establishment of a diagnosis and the design of a therapeutic program. Modern biopsy techniques offer the opportunity of obtaining image-based data at the microscopic level with a minimal risk of morbidity. Biopsy material may also be used for antigenic phenotyping, flow cytometry, and molecular diagnosis. Clinicians should see the biopsy as a powerful tool to be considered early in many diagnostic algorithms and not as a procedure of last resort.

CYTOLOGY

The specialty of cytopathology (the evaluation of cellular changes) has developed over the past 50 years. Sampling for cytology can be viewed in two discrete manners, one as a screening technique and the other as a diagnostic modality.

SCREENING

The origin of cytopathology as a subspecialty of anatomical pathology began in the late 1940s with the work of Dr. Papanicolaou who discovered, while screening vaginal pool aspirates for hormonal abnormalities, cases of dysplastic and malignant cells. Doctor Papanicolaou recognized the possible use of this technique as a screening test for cervical carcinoma. Hence, the "Pap" smear was born. Since then, by the wide application of this screening test, pathologists have been able to define and diagnose preclinical, pre-invasive lesions of both the squamous epithelium and glandular epithelium of the cervix. This has led to a decrease in the incidence of the mortality from invasive cervical squamous carcinoma.

Other areas in which cytologic screening of high-risk groups have been shown to be of use include screening for urothelial abnormalities in individuals who are exposed to work-related chemicals that are known transitional cell carcinogens. Individuals working in the aniline dye industry are an example. The screening of sputa for pre-clinical and dysplastic bronchial lesions in individuals who are heavy smokers or who have associated with asbestos is another example. However, the cost-effectiveness of these screening programs has not yet been proven.

DIAGNOSTIC CYTOPATHOLOGY

The screening tests described above are noninvasive or minimally invasive procedures. Diagnostic cytopathology usually involves evaluation of specimens obtained by at least minimally invasive procedures. Hence, cytologic evaluation of effusions (pleural, pericardial or peritoneal) can be very useful in diagnosing the spread of carcinomas to these sites. It has been shown by numerous studies that adenocarcinomas are much more commonly identified in fluids than are squamous cell carcinomas. When one assesses the likelihood of a primary site based on the cytologic findings, the following "clinical pearl" is of use regarding adenocarcinoma:

In pleural fluid in a woman, the primary site is usually breast.

In peritoneal fluid in a woman, the primary site is usually ovary.

In pleural fluid in a man, the primary site is usually lung.

In pericardial fluid, the primary sites are: lung in a man, and breast in a woman.

In addition to effusion cytology, assessment of endoscopically obtained samples, such as from the bronchus (bronchial washings and bronchial brushings), gastrointestinal tract (esophageal and gastric brushings), and other sites, has proven useful. If one uses biopsy techniques, the sampling from these various endoscopically available sites is relatively limited, whereas if one uses washings and brushings, one can obtain cells from a broader area allowing for a greater chance of obtaining diagnostic material.

The statistics of success rates in the evaluation of such specimens obtained by minimally invasive procedures are excellent with specificities of 95% to 97%. During evaluation of effusions, the chance of a diagnostic sampling obviously increases when there is a history of a known carcinoma in the patient; the diagnostic accuracy increases in endoscopically obtained samples when an endoscopically visible lesion is present.

FINE-NEEDLE ASPIRATION CYTOLOGY

In the past 10 to 15 years, the technique of fine-needle aspiration (FNA) cytology has been utilized in virtually every organ. This involves placing a small-bore needle, usually 23 to 25 gauge, into a clinically visible, palpable, or radiologically accessible lesion and obtaining a small aspirate sample. In the latter case, direct visualization under ultrasonographic or computed tomographic guidance can be most helpful in actually obtaining an adequate and diagnostic sample.

The successes with FNA cytology have been most notable in the thyroid gland, the breast, and superficial nodules including lymph nodes (in the latter instance especially for the diagnosis of metastatic carcinoma). For deep-seated lesions, especially those evaluated and sampled under radiologic control, the diagnostic sensitivity is about 90% ([Table 249.1](#)). A variety of special techniques can be applied to these samples including immunohistochemistry, in situ hybridization, special stains, flow cytometry, and molecular diagnosis methods.

When the FNA sample contains adequate material, a histologic preparation of residual material not used for smears can be obtained. This is known as a *cell block*. This is a histologic preparation of tissue fragments and can be a diagnostic supplement to the smeared aspiration slides.

Site	Specificity (%)
Thyroid	90
Breast	77-99
Lymph nodes	
Metastases	90-96
Lymphoma	80
Salivary glands	96-98
Kidney	89
Liver, pancreas	61-91

TABLE 249.1. UTILITY OF FINE-NEEDLE ASPIRATION

BIOPSY

Biopsy pathology, as opposed to cytopathology, involves the evaluation of tissue. The advantage of biopsy sampling over cytologic examination is that the pathologist can identify structures, as well as the relationships between cells and between cells and stroma. This is extremely useful in making diagnoses, especially in the realm of oncologic specimens. In certain areas, biopsy samples have replaced cytology sampling and FNA. These include prostatic biopsies with the utilization of the small biopsy needle, leading to histologic preparations and breast core biopsies (especially under stereotactic radiologic control).

Biopsies may be excisional or incisional. The latter is more commonly encountered in the modern surgical pathology practice. The biopsy should be handled properly with all pieces of the biopsy sent to the pathology laboratory for analysis. Care should be taken especially in endoscopically obtained samples not to crush the tissue since this can interfere with diagnostic interpretation. The tissue should be placed in fixative immediately because drying artifact will also hamper correct interpretation.

Another problem with biopsies involves sampling error. Since the biopsy surveys an area that is less broad than the endoscopic brush technique, the possibility of false-negative results due to sampling error must be recognized. One must be careful in evaluating specimens that are excessively inflamed or contain extensive areas of necrosis. In very large lesions, biopsies may encounter only the superficial aspects of the lesion and therefore may not be representative. For example, a superficial biopsy of an ulcerated gastric mass may show only granulation tissue and necrotic debris, whereas the neoplasm is present beneath the ulcer.

It is important to recognize that the biopsy of a visualized lesion is usually more productive than a random biopsy of an organ in which no lesion is identified. Biopsies obtained under direct visualization such as endoscopic procedures have excellent diagnostic yields (greater than 95%).

FROZEN SECTION

The utilization of frozen sections as an intraoperative technique for diagnosis has declined over the past decade for several reasons. Many patients now have preoperative testing, biopsies under endoscopic control, FNA cytology sampling, and so forth, at which time the diagnosis is made and surgery is the definitive procedure.

Frozen section should be utilized for three purposes only: (a) to define the nature of the pathologic process (often this has already been done preoperatively); (b) to determine adequacy of margins of resection; and (c) to ascertain if appropriate and sufficient diagnostic tissue has been obtained. Hence, frozen section should be performed only to guide the surgeon in the immediately subsequent surgical procedure being performed on the patient. In many institutions, intraoperative cytology is used to offer a diagnosis using a minimal amount of the lesion and avoiding compromise of the sample.

As lesions are detected by more effective radiologic techniques, they are identified when very small and therefore not clinically palpable. Frozen sections are inappropriate on such samples. This has become a problem most recently in breast biopsies that are directed by mammographic abnormalities without palpable lesions. Often there is no gross lesion and many of the lesions that are malignant are in situ, noninvasive cancers. It is inappropriate to ask for frozen sections on these lesions because with the availability of techniques to perform flow cytometric ploidy analysis and immunohistochemistry for steroid receptor and oncogenes on paraffin-embedded material, the most important function that a pathologist can serve in these cases is to ensure adequate material for diagnosis. Frozen section, by the nature of the technique, wastes precious diagnostic material. This can impede diagnostic accuracy and may so distort the tissue as to make definitive diagnosis impossible.

The technique of frozen section in experienced hands can be diagnostically accurate. Depending on the organ or system sampled, accuracy rates of 99% should be expected. False-positive results are very unusual. In some organs, however (e.g., thyroid, lymph nodes, spleen for lymphoproliferative diseases), a high deferral rate should be expected.

GROSS EXAMINATION OF TISSUE

The gross examination of tissue is a simple and cost-effective way to obtain important data. Resected specimens are best examined in the fresh state after rapid transport from the operating rooms to the anatomical pathology laboratories. In our institution, a pneumatic tube device is used to facilitate this delivery. Specimen orientation is critical so that a tumor's relationship to the margins of resection or other vital structures can be determined. Orientation can be communicated by marker sutures or direct consultation between the surgeon and the pathologist. The latter method is preferable since areas of particular concern can be immediately chosen for sampling. Multicolored inks can be used by the pathology staff to maintain orientation and allow microscopic visualization of the margins throughout the entire sectioning and embedding process.

Standardized approaches to gross description are fast becoming the norm in anatomical pathology. The most progressive labs embed gross description templates into their laboratory information systems. Tumor size, shape, color, texture, scarring pattern, anatomical location, and relationship to margins are all generic features that should be mentioned with each neoplasm.

TISSUE PREPARATION

The way in which tissue is prepared determines which types of tests can be performed on the sample. Certain methodologies are better suited for the evaluation of selected tissue types and require special handling. If the clinician is uncertain as to the best method of tissue handling, a prebiopsy consultation with the pathologist is encouraged. Following are discussed several preparative methods and their utility.

10% NEUTRAL BUFFERED FORMALIN FIXATION

Immediate fixation in 10% formalin is the standard protocol for the majority of tissues in most labs. Neutral buffered formalin (NBF) penetrates tissue slowly. Small biopsies may fix in a few hours, whereas large specimens with a high lipid content may take days for adequate penetration and thorough fixation. Partially fixed tissue will not process adequately and this can jeopardize a diagnosis. A 20:1 ratio of fixative to specimen volume is recommended. Immunohistochemistry, in situ hybridization, flow cytometry, and molecular diagnosis can all be performed on NBF-fixed tissue, although the sensitivity of these studies may be affected by time of fixation.

BOUIN'S FIXATIVE

Bouin's fixative is a combination of formalin, acetic acid, and picric acid that imparts a yellow color. Bouin's has the advantage of penetrating tissue relatively rapidly. It is an excellent nuclear fixative, and for this reason it is well suited for small biopsies where nuclear detail may be critical. Immunohistochemistry works well in

Bouin's-fixed tissue. Nucleic acids are more rapidly degraded and molecular diagnosis in situ hybridization is problematic. Bouin's is contraindicated for flow cytometry.

MERCURY-BASED FIXATIVES

Fixatives containing heavy metals such as mercury may also produce superior nuclear cytology. This is particularly advantageous in certain material such as hematopoietic tissue. Zenker's fixative and Helly's fluid are examples of mercury-based fixatives. Hazardous waste disposal issues may limit the use of these fixatives.

NON-CROSS-LINKING AND WEAKLY CROSS-LINKING FIXATIVES

Alcohols and proprietary fixatives such as Omnifix or Histochoice are non-cross-linking, whereas paraformaldehyde is a weakly cross-linking fixative. Non-cross-linking fixatives denature by precipitation. Antigens and nucleic acids in tissue section are more easily recognized by antibodies and probes, and most immunohistochemical and in situ hybridization studies can be performed with these fixatives. The disadvantage is the poorer morphologic preservation.

DECALCIFICATION

Decalcification is best performed using a strong acid such as nitric or sulfuric acid. Decalcification of small biopsy specimens can be accomplished in 24 hours. Larger specimens or specimens with very dense bone may take several days. Residual acid must be neutralized after decalcification and before processing to allow nuclear visualization with basophilic dyes. Nucleic acids are fragmented by decalcification, making in situ hybridization and flow cytometry problematic. Tissue antigens are variable in their resistance to acid fixation.

FRESH TISSUE

Fresh tissue is the most flexible form with which to conduct analysis. It can be divided in the pathology laboratory to provide specimens that are optimally preserved for a variety of studies. Certain studies, such as cryostat sections for intraoperative consultation or classic karyotypic analysis, can only be performed on fresh tissue. The interval between harvest and processing is critical. Certain labile antigens may degrade within minutes. Morphologic preservation varies depending on the tissue type. Rapid delivery to the laboratory for immediate processing is recommended.

TISSUE PROCESSING, EMBEDDING, AND SECTIONING

Fixed tissue must be cleared with a series of organic solvents, impregnated with paraffin, embedded in a wax block, sectioned on a rotary microtome, and stained before slides are available for review. Even with discrete-mode processing this procedure takes a minimum of 6 hours. Cost-efficient labs must utilize batch processing with next-day turnaround.

ANCILLARY TESTS

SPECIAL HISTOCHEMISTRY

These tests represent the classic "special stains." Various dyes and reagents will bind to cell and matrix components in a differential manner. The advantages of these tests are that there is a large body of knowledge as to their operating characteristics, most labs are conversant with the methodologies, and many tests can be done in a rapid fashion. Enzyme histochemistry tests tissues for the presence of endogenous enzymes by providing the appropriate substrates coupled to a visual reporter system. [Table 249.2](#) is a small partial listing of biologic components that can be highlighted with special histochemistry tests.

Basement membranes	Silver stains, PAS
Cell wall	PAS, Gram, silver stains
Collagen	Trichrome
Amyloid	Congo red, crystal violet
Mucins	Mucicarmine, PAS, Alcian blue
Myeloid granules	Giemsa
Lipids	Oil red O, Sudan black

PAS, periodic acid-Schiff.

TABLE 249.2. COMMON HISTOCHEMICAL TESTS

IMMUNOHISTOCHEMISTRY

Immunohistochemistry has been used heavily in the practice of diagnostic pathology for the past dozen years. Testing relies on the binding of preserved antigenic epitopes to an antibody reagent and the visualization of this reaction by some reporter signal that allows localization to a tissue substructure. Antibodies may be either polyclonal or monoclonal. Monoclonal antibodies offer the advantage of reproducibility; however, their sensitivity may be limited by the narrowness of their antigen target. Polyclonal antibodies see a broader range of specificities and in general are more sensitive. The problem of reagent standardization for polyclonal antibodies has been addressed with the newer methods of peptide immunization.

The original immunohistochemical methodologies employed antibodies directly labeled with fluorochromes. This "immunofluorescence" technique has been used to great advantage in nephropathology to stratify the glomerulonephritides. The disadvantage of direct immunofluorescence is the relatively poor sensitivity of the method and thus the requirement for large amounts of target before useful visualization. Over the years a number of multistep procedures have been linked with histochemical amplification systems to markedly enhance the sensitivity of immunohistochemistry. Current methodologies often employ variations of the avidin-biotin complex technique of Hsu wherein the primary antibody is reacted with a biotin-conjugated secondary antibody and then the signal is amplified using enzyme-linked avidin-biotin complexes. The sensitivity of modern multilayer techniques exceeds that of direct immunofluorescence by several logs.

Since differential diagnostic questions are most often raised after review of the standard light microscopic sections, formalin-fixed, paraffin-embedded tissue is often the starting point for any special studies. Immunohistochemistry has been hampered by the limited availability of antibody reagents that see formalin-resistant epitopes. An alternative approach has been to "unmask" antigens that are hidden by the cross-linking process. "Antigen retrieval" refers to the use of enzymes, microwave irradiation, or steam heat to break some of the steric hindrance that prevents antigen-antibody recognition in tissue section. The diagnostic effect of antigen retrieval methods has been to improve the sensitivity of immunohistochemical testing.

IN SITU HYBRIDIZATION

Nucleic acid probes may be applied to tissue sections for the localization of either genomic elements or transcripts. In situ hybridization offers the opportunity for the pathologist to (a) distinguish antigen uptake from cellular production by the simultaneous localization of transcripts and antigen in the same cell; (b) identify infectious genomic elements; and (c) perform interphase cytogenetics on tissue. The first and second uses are established in the literature and their application is rapidly expanding in many diagnostic labs. To date, interphase cytogenetics on smears or tissue section has mostly been confined to the analysis of microsatellite distribution and the evaluation of chromosomal deletions, translocations, or amplifications. The sensitivity of in situ hybridization as performed in our diagnostic labs is about ten copies. Point mutations cannot be seen with this method. New amplification techniques such as in situ polymerase chain reaction may allow the tissue localization of

known mutations as this technology matures.

UTILITY OF IMMUNOHISTOCHEMISTRY AND IN SITU HYBRIDIZATION

Immunohistochemical analysis may be used in tumors for the assignment of histogenetic origin, as a prognostic marker, or in the identification of infectious elements. [Table 249.3](#) lists some of the tests which can be performed in each of these three categories. The exact classification of poorly differentiated tumors can be quite difficult based only on standard light microscopic examination. Since the determination of histogenetic origin may significantly impact on therapy, employing immunohistochemistry can be very helpful. [Table 249.4](#) shows a short panel of five antibodies that can help in the separation of poorly differentiated carcinoma, sarcoma, high-grade lymphoma, and melanoma.

Marker	Utility
Prognostic	
Estrogen receptor protein	Certain
Progesterone receptor protein	Certain
Chromogen (Hb, Hm, Hly, etc.)	Investigational
Tumor suppressor genes (p53, VpF, Rb)	Investigational
Proliferation markers (PCNA, Ki-67, Cyclin)	Investigational
Histogenetic Assignments	
Prostatic (PSA)	Certain
Thyroid (Thyroglobulin)	Certain
Immunoglobulin markers (IgA, T-cell, B-cell, myeloid)	Certain
Epithelial differentiation (cytokeratins, EMA)	Certain
Neural and Melanocytic (S-100, HMB45)	Certain
Muscle (smooth muscle actin, SMA, CD113)	Certain
Muscle differentiation (Desmin, HMF35, myoglobin)	Certain
Neuroendocrine differentiation (Chromogranin, neuron-specific enolase, cell-specific hormones)	Certain
Infectious Agents (Hepatitis B, Herpes, EBV, HPV, Chlamydia, and many others)	Certain

TABLE 249.3. TISSUE MARKERS IN IMMUNOHISTOCHEMISTRY AND/OR IN SITU HYBRIDIZATION

Antibody	Carcinoma	Lymphoma	Sarcoma	Melanoma
LCA (CD45)	-	+	-	-
Cytokeratin	+	-	-	-
EMA	+	-	-	-
S-100	+/-	-	-	+
HMB45	-	-	-	+

LCA, leukocyte common antigen; EMA, epithelial membrane antigen; HMB45, melanoma marker.

TABLE 249.4. IMMUNOHISTOCHEMISTRY IN THE EVALUATION OF ANAPLASTIC TUMORS

FLOW CYTOMETRY

Flow cytometry can be used either as a tool for ploidy analysis or as a method for immunophenotyping. In the former instance, nuclei are stained with a fluorochrome (propidium iodide or acridine orange) that stoichiometrically binds to nucleic acid and provides a quantitative measure of DNA content. Aneuploid populations can be identified and S phase calculated. The DNA Consensus Conference has reviewed the literature on the clinical utility of flow cytometry in several settings. The Conference recommends ploidy analysis as a significant prognostic feature in transitional cell carcinoma of the bladder, with less defined roles for breast and prostate cancer. S-phase analysis is recommended as a prognostic variable in breast cancer and non-Hodgkin's lymphoma.

MOLECULAR DIAGNOSIS

The reader is referred to Dr. Sklar's excellent chapter on molecular diagnosis in oncology ([Chapter 251](#)). Expert selection of the target tissue is critical for obtaining informative results. Fresh tissue that is to be used for molecular diagnosis should be collected rapidly, snap-frozen in liquid nitrogen, and a scout frozen section of the block performed. Areas of tumor should be subdivided as directed by the pathologist's review of the frozen section. Microdissection techniques can be performed if finer discrimination of the target is required. RNAase protection should be used if Northern analysis or reverse transcriptase polymerase chain reaction is considered, although we have not found RNAase protection necessary for in situ hybridization in paraffin-embedded tissue.

CHAPTER 250: TUMOR MARKERS

DANIEL F. HAYES

[Determination of Risk and Screening](#)
[Differential Diagnosis](#)
[Prognosis](#)
[Evaluation and Monitoring for Recurrent Disease](#)
[Summary](#)

Tumor markers provide an indication of the risk, presence, status, or future behavior of malignancy; they are genetic or biochemical changes that can be identified in association with one of these states. Detection or monitoring of these changes is useful in several clinical situations ([Table 250.1](#)): to identify otherwise healthy persons who are predisposed to develop cancer (i.e., are at higher risk than persons without the marker), to detect cancer at a very early stage, to determine a differential diagnosis, to predict the future behavior of an established malignancy, to monitor a patient who is free of clinically detectable disease for signs of early relapse, and to follow a patient with widespread disease to determine the effects of therapy.

Determine risk
Screen for early diagnosis
Determine differential diagnosis
Predict prognosis or response to therapy
Detect early relapse
Monitor course of metastatic disease

TABLE 250.1. POTENTIAL UTILITIES OF TUMOR MARKERS

Tumor markers can be detected using various assay technologies. Two fields of technological progress have revolutionized the ability to detect biochemical and genetic molecular changes. The development of tumor immunology—in particular, the emergence of hybridoma/monoclonal antibody technology—has permitted the detection of specific tumor-associated antigens and the capacity to map individual epitopic sites present on distinct molecular structures. The second advance is the ability to identify specific genetic changes at the DNA or RNA level, or both. Indeed, before the 1980s tumor markers were limited to visual observations of histopathology and crude assays using polyclonal antisera. With the development of these technologies, there are examples of clinically useful markers in nearly all, if not all, of the clinical categories listed above.

Identifiable genetic or biochemical changes that represent markers of malignancy may be detected in various tissues. In this regard, germ line genetic markers in all cells of the body might predict an inherited susceptibility to the development of cancer. Markers of early malignant transformation, tumor burden, or tumor biology might be assayed within the target organ tissue itself, either through biopsy or needle aspirate, or by collection of excreted/secreted contents, either directly (in aspirates, urine, stool, sputum, effusions) or indirectly (circulating in blood, serum, or plasma).

Circulating tumor markers are of particular interest because blood, plasma, and serum can be so easily obtained for assay with only minor inconvenience and cost to the patient. Circulating tumor markers have been most widely applied with respect to carcinomas (in contrast to malignancies of hematologic or mesenchymal origin). Examples of these markers include carcinoembryonic antigen (CEA), prostate-specific antigen (PSA), a-fetoprotein (AFP), and beta human chorionic gonadotropin (hCG). A series of newer markers identified using monoclonal antibody-based assays include CA 125, CA 15-3, CA 549, CA 27.29, CA 19-9, and squamous cell antigen (SCA). Although each of these was originally purported to be associated with a specific malignancy, subsequent studies have usually demonstrated that elevated levels can be detected in patients with carcinomas originating from other sites.

Appropriate use of tumor markers requires an understanding of the biology underlying the premise that the marker might be useful and of the technology used for the assay. For example, several different monoclonal antibodies might be used to assay a single molecular structure, such as an oncogene product. These might detect different epitopes that might be differentially expressed on the oncogene under different circumstances, and they might have varying affinities and avidities for that epitope. Furthermore, distinct changes in the expression of the oncogene might be related to various alterations, such as mutations, deletions, or amplifications of the gene, or over- or underexpression of the product. Therefore, seemingly similar assays for the same marker, such as an assay for “HER-2/neu,” might result in very different correlations with clinical outcome. Moreover, simply identifying a possible future outcome does not imply clinical utility. Therefore, clinicians should not automatically alter therapeutic decisions based on marker data if it has not been proven that such a change results in a more favorable clinical outcome, such as cure, improved survival, or enhanced quality of life. For example, a marker may reliably predict a poorer prognosis and therefore the clinician may be inclined to treat the patient more aggressively. However, if the application of more aggressive therapy is not beneficial, the patient may actually suffer from inappropriate interpretation of the marker results.

Finally, marker results may duplicate information already known. The clinician may not need or want marker results if they will repeat the information already ascertained by an equally reliable but less expensive or more easily performed test, such as the history and physical examination.

In summary, tumor markers are valuable only if they provide information that cannot be obtained by other means, or if they are either less expensive (in terms of financial or morbidity factors) or more reliable than other sources of information. The clinician must take into account the available biologic, technological, and clinical data to use tumor markers wisely.

DETERMINATION OF RISK AND SCREENING

DETERMINATION OF SUSCEPTIBILITY TO CANCER

Identifying patients who are at a higher risk to develop cancer might permit more efficient application of prevention or screening strategies, if they exist. Recently, several candidate “cancer” genes have been identified and cloned. In their normal state, these “tumor suppressor” genes appear to be responsible for maintaining the nonmalignant state. If a person inherits one abnormal copy of one of these genes (a germ line mutation), he or she is at an extraordinarily high risk of developing one or more malignancies in his or her lifetime. Although the abnormal gene is carried in every cell in the person's body (and can therefore be identified in DNA that is easily obtained from circulating white blood cells or scraped buccal smears), most of these genes appear to be associated with malignancies of specific organ types. These scientific discoveries are very exciting. However, screening of the normal population for genetic susceptibility to cancer is fraught with ethical, social, economic, cultural, and medical problems that have not been resolved. At present, routine screening for genetic susceptibility is recommended only in the context of a well-designed genetic counseling program. The patient can then obtain the pros and cons of being tested as well as appropriate support and advice once the results are available.

SCREENING FOR EARLY MALIGNANCY

Screening for signs of malignancy might provide an opportunity for early treatment. Indeed, screening and early treatment reduce the mortality rate for several malignancies, including breast, colon, cervical, and perhaps prostate carcinomas. Genetic or biochemical markers of early malignancy might be an inexpensive,

cells can be detected in the bone marrow by polymerase chain reaction (PCR) assays that detect genetic changes such as translocations or mutations specific to the malignancy (see [Chapter 251](#)). Patients who harbor these clones may have a significantly worse outcome than those who have been rendered completely disease-free. Patients with such findings might be candidates for more aggressive or alternative treatment approaches, but these findings are not absolute. For example, t(8;21) translocations have been detected in bone marrow from patients who are otherwise free of any evidence of recurrent leukemia for as long as 14 years after treatment.

Most patients with newly diagnosed solid tumors present without evidence of distant disease and can be rendered disease-free by local treatment (surgical excision, radiation therapy). Carcinoma tissue-associated prognostic markers may be used to estimate the presence of distant micrometastatic disease. Indeed, as discussed previously, histopathologic identification of regional lymph node metastasis is essentially an *in vivo* assay for tumor metastatic potential. Other ways of detecting occult metastasis in regional lymph nodes could indicate a long-term risk of recurrence in patients who have histopathologically negative lymph nodes. However, it is unclear that the long-term prognosis of patients with occult regional lymph node metastases, detectable only by immunologic or genetic assays, is substantially different from that of patients who do not have such detectable lymph node metastases.

In addition to the evaluation of regional lymph nodes, immunocytochemical staining for tumor-associated antigens can demonstrate whether micrometastases are present in distant organs as well. Up to 25% of patients with stage I and II breast cancer have bone marrow metastases at the time of their primary surgery. Similarly, for patients who receive high-dose chemotherapy and subsequent autologous hematopoietic progenitor cell support (bone marrow or peripheral progenitor cells), these techniques may be used to identify microscopic contamination by tumor cells. In small studies with short follow-up, occult bone marrow micrometastases have been associated with a significantly worse disease-free and overall survival. Other investigators have urged caution regarding these methods, as the specificity of these assays is not absolute and the treatment implications are uncertain.

EVALUATION AND MONITORING FOR RECURRENT DISEASE

MONITORING PATIENTS WHO ARE FREE OF DETECTABLE DISEASE FOR EARLY RELAPSE

Patients with a history of invasive cancers are at risk for relapse for variable time periods after initial therapy. Therefore, patients with a history of malignancy might be screened for impending relapse throughout their course. Such screening would require time-dependent marker changes, as opposed to static marker changes such as those measured in primary tissue. For patients with a history of leukemia, serial bone marrow evaluations are easily performed, which are reasonably reliable predictors of recurrence. However, with routine histopathology, leukemic cells can be detected only at a sensitivity of 1 per 20 normal cells. Using even more sensitive techniques, the detection limit may only be as high as 1 per 50 for cytogenetics and 1 per 100,000 for PCR assays. When these relatively poor sensitivities are coupled with the ambiguity over the clinical significance of such findings, the value of routine serial bone marrow monitoring over a prolonged time is limited.

For solid malignancies (including lymphomas, sarcomas, and carcinomas), soluble/circulating tumor markers found in serum (or plasma) and urine would be ideal for such monitoring. The best example of this strategy is the use of serial bhCG and AFP to detect impending relapse in men with a history of germ cell malignancy. Rising marker levels after treatment (surgery or chemotherapy) in these patients are an absolute indication to begin "salvage" chemotherapy, which can be curative. Several circulating tumor markers associated with epithelial cancers, such as CEA (colon and other gastrointestinal, lung, breast, and ovarian cancers), CA 125 (ovarian cancer), PSA (prostate cancer), CA 15-3, CA 27.29, CA 549, breast cancer mucin, mammary serum antigen, and mucinous carcinoma antigen (breast cancer), and AFP (hepatocellular carcinoma), may permit detection of occult recurrence. However, these markers usually provide lead times of only a few months before the metastases would have been made evident by symptoms. As for any screening test, the positive and negative predictive values (i.e., that a positive test accurately predicts subsequent relapse and that a negative test reliably predicts that the patient will remain disease-free) depend on the likelihood of relapse in the first place and the sensitivity and specificity of the test (which require careful delineation of cutoff levels).

Detecting impending relapse may not be associated with any clinical benefit. In many malignancies, the treatment of asymptomatic metastases with potentially toxic systemic therapy has not been demonstrated to result in either increased cure or survival rate, and treatment of patients with asymptomatic metastasis is unlikely to provide improved palliation. However, for certain types of leukemias and lymphomas, detection of early relapse might provide an increased opportunity to establish higher cure rates through the use of high-dose chemotherapy and bone marrow transplantation. The advantage of early detection of recurrence for germ cell malignancies is established, and these patients should be routinely followed with periodic bhCG and AFP levels.

Resection of isolated colorectal carcinoma liver metastases renders a small percentage of patients disease-free for prolonged periods of time. Although it has never been tested in a randomized trial, monitoring patients after initial colectomy with serial CEA levels provides an indication of early and occasionally isolated hepatic relapse, and a few such patients may be cured as a result of this approach. Likewise, monitoring ovarian cancer patients after initial treatment with serial CA 125 levels may provide an indication of microscopic peritoneal recurrence. In this case, rising CA 125 levels are an indication for further evaluation, and early treatment with chemotherapy may result in modest prolongation of survival and even cure. Such advantages have not been demonstrated for patients with other malignancies, including breast or lung cancer.

MONITORING PATIENTS WITH METASTATIC DISEASE

Palliation of patients with recurrent or metastatic malignancy may be accomplished with a series of treatment modalities, including surgery, radiation, hormone therapy, and chemotherapy, depending on the tumor type. Although each may provide benefit, the risks and toxicities of the separate therapies differ widely. Therefore, accurate knowledge of the status of a patient's disease is essential in deciding whether to continue the current therapy or proceed to an alternate regimen.

Circulating and bone marrow levels of leukemic blasts provide rough estimates of the effects of chemotherapy during induction and consolidation. For most leukemias, patients who do not clear their marrows of blasts have a very poor prognosis. In patients with myeloma, quantitative analysis of serum globulin levels provides an indication of the relative success or failure of treatment. For lymphomas, serial LDH is a reliable indicator of clinical course, although usually the tumor itself is relatively easily followed by physical or radiographic examination. In patients with germ cell malignancies, bhCG and AFP are exquisite indicators of the response to chemotherapy, and they should be monitored with each treatment cycle. For epithelial malignancies, serial levels of CEA (gastrointestinal, breast, lung, and others), CA 125 (ovarian, lung, breast), and CA 15-3 or CA 27.29 (breast, ovarian) can supplement clinical estimates of the disease course. In general, rising levels suggest progression, decreasing levels suggest response to therapy, and stable levels suggest stable disease. These marker trends are not always perfectly associated with the expected clinical changes; for example, all three may transiently rise and then decrease (so-called tumor spikes) in relation to early tumor response, presumably a result of the release of stored marker protein during tumor lysis. Moreover, the production of CEA levels is related to tumor differentiation in colon cancer, and serial levels may decrease during a time of tumor dedifferentiation and progression. Finally, several benign conditions, especially benign inflammatory diseases of the bowel, lung, and especially liver, can elevate levels of these glycoproteins.

SUMMARY

Many tumor-associated antigenic and genetic markers have been proposed for identification, screening, prognosis, detection, or monitoring of patients with suspected or established malignancies. The precise clinical utilities of these markers must be carefully evaluated to avoid inappropriate changes in clinical care based on false-positive or false-negative results. Even if the marker results correlate reliably with the underlying biologic process or status of the disease, the clinician must decide on a therapeutic change only if such a change is known to provide clinical benefit. The relative independence of the marker in relation to other available markers must be determined to avoid the unnecessary cost and expense of redundancy. With these caveats in mind, judicious application of germ line, tissue, and soluble tumor markers can improve the clinical care of patients at risk for and with cancer.

CHAPTER 251: MOLECULAR DIAGNOSIS OF CANCER

JEFFREY SKLAR AND NEAL LINDEMAN

[Basic Principles](#)
[Technology of Cancer Diagnosis](#)
[Molecular Markers of Cancer Diagnosis](#)

The field of molecular diagnosis can be defined as the detection of diseases and conditions by the analysis of specific nucleotide sequences within DNA and RNA. Application of molecular diagnosis to cancer grew out of two major developments of the late 1970s: the demonstration that certain inherited diseases, such as hemoglobinopathies, could be diagnosed by the direct detection of mutations in DNA for specific genes, and the understanding that cancers arise from clonal proliferations of cells derived from single progenitor cells that acquire critical mutations that render those cells neoplastic. Inspired by these developments, researchers shortly thereafter set out to devise methods for diagnosing and monitoring cancer through the identification of changes in nucleic acids that distinguish malignant from normal tissues.

Interest in the molecular diagnosis of cancer has increased over the ensuing years because this approach to diagnosis has several advantages over conventional histopathology. These advantages include the relative objectivity of the results of molecular tests compared to the more subjective, morphologic criteria on which histopathologic diagnosis is based. Molecular diagnosis also is potentially far more sensitive for detecting small numbers of cancer cells, a feature that is particularly relevant to monitoring the effects of therapy. Additionally, molecular methods can be used for the presymptomatic determination of inherited predispositions to various types of cancer—a form of diagnosis not generally possible by other means. Finally, certain molecular methods lend themselves to efficient, simultaneous screening of numerous diagnostic markers—a feature that has generated enormous recent enthusiasm, especially for improved systems of tumor subclassification and for the determination of prognosis.

BASIC PRINCIPLES

At their core, all methods currently utilized in the molecular diagnosis of cancer rely on the principle of molecular hybridization, i.e., the ability of two strands of DNA or RNA to bind to each other through formation of hydrogen bonds between adenosine (A) and thymidine (T) or guanosine (G) and cytosine (C) nucleotides in the two strands. Strands of nucleic acid that are capable of forming high numbers of consecutive A:T and G:C nucleotide pairs over their lengths are said to be complementary. The presence of greater numbers of such A:T and G:C nucleotide pairs between the strands leads to tighter binding and higher stability with respect to factors such as increased temperature, high pH, low ionic strength, and elevated concentrations of various chemicals, all of which tend to disrupt hydrogen bonds and separate, or denature, nucleic acid duplexes. DNA in most situations is made up of complementary strands of nucleotides, so that two fragments of DNA containing identical or similar nucleotide sequences may exchange strands if first denatured and renatured together. Based on this property, the hybridization of strands from a labeled or tagged DNA fragment, often referred to as a *probe*, with strands of an unlabeled DNA is a common step in many procedures used in molecular diagnosis. DNA may be labeled with radioactivity, fluorescent adducts, or antigenic substituents that can be detected by the subsequent binding of an antibody tagged in one of a variety of ways. Probe fragments of DNA are routinely prepared by molecular cloning procedures in bacterial hosts. Relatively short, single-stranded DNA fragments, termed *oligonucleotides*, can also be synthesized in the test tube by chemical methods to contain specific nucleotide sequences complementary to defined regions of DNA.

RNA usually exists as single strands of ribonucleotides rather than the deoxyribonucleotides found in DNA; however, the small structural difference between ribonucleotides and deoxynucleotides (the substitution of a hydroxyl group for a hydrogen in the pentose sugar moiety of the nucleotide) does not appreciably affect hybridization, and complementary strands of DNA and RNA will pair with each other, as will two complementary strands of RNA. The RNA normally transcribed from the DNA of a gene as the first step in protein synthesis is complementary in nucleotide sequence to the template strand of the DNA and can therefore be detected by hybridization with a probe derived from the DNA of that gene.

TECHNOLOGY OF CANCER DIAGNOSIS

SOUTHERN BLOT HYBRIDIZATION

Four techniques have played prominently in the molecular diagnosis of cancer. The first of these is Southern blot hybridization. In this technique, DNA extracted from tissue is digested by one or more bacterial restriction enzymes, which cleave DNA at specific short sequences (usually six nucleotides long) recognized by the particular restriction enzyme or mixture of restriction enzymes used. The resulting collection of fragments are separated according to size by electrophoresis through an agarose gel. The DNA within the gel is denatured to single strands by soaking in alkali and then is transferred to a nylon membrane, where the DNA fragments bind irreversibly, forming an invisible ladder of bands on the membrane with each band containing fragments of different size. DNA of interest is identified by hybridization with a radiolabeled probe containing complementary nucleotide sequence. After sufficient time has elapsed for binding of complementary sequences within the probe to target sequences of the membrane, the membrane is dried and placed in the dark against x-ray film for autoradiography. Following exposure of the membrane to the film (usually lasting hours to days), the film is developed and the position of the DNA on the membrane complementary to the probe sequence is revealed as a band or bands in the film, or autoradiogram. From start to finish, Southern blot analysis of DNA requires at least 4 or 5 days.

POLYMERASE CHAIN REACTION

The second technique, which is an integral part of methods that have largely superseded Southern blot hybridization for many purposes, is the polymerase chain reaction (PCR). This technique permits enormous amplification of any nucleotide sequences contained in DNA or RNA through repetitive cycles of brief in vitro DNA synthesis, provided the sequences of the nucleic acid flanking the region to be amplified are known. In the past, the size of the region amplified could not exceed 1 or 2 kb; more recently, methods have been described for amplifying regions up to 20 kb or greater. To perform PCR, short, single-stranded oligonucleotides (usually 15 or more nucleotides long and termed *primers*) are constructed to be complementary to these known sequences on both sides of the region to be amplified. A small amount of DNA template, such as total tissue DNA, is added to a reaction tube containing a great molar excess of the two primers, along with nucleoside triphosphates (the form of nucleotide monomers that are joined together by DNA synthetic enzymes referred to as DNA polymerases) and heat-resistant DNA polymerase purified from thermophilic species of bacteria. The reaction mixture is heated to denature the template DNA to single strands, cooled to allow primers to hybridize to their complementary sequences, and brought to the proper temperature for polymerization of nucleotides. The DNA polymerase then processively adds nucleotides to the 3' end of the primers according to the sequence specified by the template strand downstream of the two primers (heat-resistant DNA polymerases used in this reaction, like most DNA polymerases, cannot begin synthesis de novo but can only extend preexisting 3' ends within DNA).

The steps of template denaturation, primer hybridization, and primer extension are repeated about 20 to 60 times during a standard PCR amplification. In each cycle, DNA synthesized in the previous cycle becomes a template for the subsequent cycle, thereby doubling the amount of template DNA and leading in theory to the accumulation, after 20 cycles, of about one million copies of the target sequence for each copy of the template provided at the beginning of the reaction. The products of PCR consist of fragments containing the amplified sequences and having a length precisely determined by the distance between the two sequences complementary to the primers in the template DNA. The success and specificity of the reaction is usually assessed by formation of a discrete band within a gel after electrophoresis. Sufficient product is often generated so that a band representing the product fragments can be viewed directly in the gel by staining with the fluorescent dye ethidium bromide and illuminating the gel with an ultraviolet lamp. PCR analysis can easily be completed in 1 or 2 days. Unlike Southern blot analysis, PCR can be performed on the short fragments of DNA that are recoverable from formalin-fixed and paraffin-embedded tissue (still the predominant form in which tissue is preserved in most pathology departments).

To detect sequences in RNA, the usual PCR procedure has been modified by the addition of an initial step in which a complementary copy, or cDNA, of the RNA is generated in vitro by a reverse transcription reaction using an RNA-dependent RNA polymerase, termed *reverse transcriptase*, which is produced by one of several retroviruses. Thereafter, the sequences within the cDNA are amplified by standard PCR. PCR carried out in this manner is commonly referred to as RT-PCR.

Two major problems are associated with PCR used for diagnostic purposes. One problem concerns false-positive results arising from spurious amplification of sequences due to contamination of the initial reaction mixture with small amounts of product from previous reactions. Another problem is that PCR generally does not

provide quantitative information regarding the number of template molecules present at the start of the reaction. This deficiency is related to the fact that the accumulation of product in PCR plateaus after some number of cycles, so that the amount of product that results from the amplification of only one template can be almost as great as that amplified from abundant template. Several solutions have been employed to counteract this problem. For example, the template present in a sample may be calculated by assuming that a single template molecule will give rise to product and performing multiple amplification reactions on successively higher dilutions of the template material until no further product is generated. As an alternative to numerous reactions required in this method of limiting dilution, quantitation of PCR has been attempted by adding known concentrations of an internal standard in the form of template that gives a product distinct from that produced from the real template but can also be amplified using the same primers. However, this approach presupposes that the sequences in the standard template will be amplified with same kinetics as those in the real template, and this assumption is not always justified. The most effective solution for quantitating PCR is real-time measurement of amplification as the reaction progresses. This is achieved by using fluorescent oligonucleotide probes that bind to adjacent sequences within the template and are released as DNA synthesis moves through that portion of the template, thereby disrupting the transfer of energy between the probes and quenching a fluorescent signal. The amount of template in the reaction can be accurately determined by comparing the results with template standards containing the same sequence. The procedure has additional advantages, such as completion of the entire process within a sealed tube (reducing the chances of contamination in subsequent reactions) and elimination of gel electrophoresis in many cases to check the specificity of the reaction. Unfortunately, the instruments that have the capability for real-time PCR measurement are expensive.

ANALYSIS OF NUCLEOTIDE SEQUENCE

The third technique fundamental to molecular diagnosis is direct analysis of nucleotide sequence. As most widely practiced, sequence analysis is performed using single-stranded DNA to be sequenced as a template for *in vitro* DNA synthesis directed by a bacterial or bacteriophage DNA polymerase. Four separate synthetic reactions are carried out, each beginning at the same oligonucleotide primer complementary to DNA immediately flanking the region to be sequenced. The reactions are performed in the presence of the four nucleoside triphosphates, one of which is labeled with sulfur 35 to permit detection of the products. The four reactions differ from each other by the inclusion of a chain-terminating nucleotide analogue (2',3'-dideoxynucleoside triphosphate) for one or the other of the four bases in DNA, so that some portion of the primer-extension reaction stops whenever the nucleotide complementary to the dideoxy analogue appears in the template. The result of each reaction is a series of radioactive, single-stranded products having the same 5' end but varying in length by the distance between the positions of the nucleotides in the template complementary to the nucleotide analogue in the reaction. The products of the four reactions are analyzed by electrophoresis in adjacent lanes of a polyacrylamide gel, followed by autoradiography of the gel. The sequence for the template is deduced by reading up the autoradiogram, moving back and forth from lane to lane, noting which lane contains the next band nearest the bottom. A nucleotide corresponding to the nucleotide analogue used in the reaction to generate the lane is added to the sequence for each band that appears in that lane. Up to about 700 nucleotides can be ascertained by performing sequence analysis with a single primer. Sequence analysis in recent years has increasingly relied on nucleoside triphosphates tagged with fluorescent chromophores rather than radioactivity. Using this modification, each of the primer extension reactions can be separately labeled with a different chromophore, run together in one lane of the electrophoretic gel, and analyzed with gel readers that scan the same lane at the four different wavelengths corresponding to the various chromophores that distinguish the products of the four reactions.

FLUORESCENCE IN SITU HYBRIDIZATION

The fourth important technique in molecular diagnosis of cancer is fluorescence in situ hybridization (FISH). In this procedure, DNA probes usually containing many thousands of nucleotide pairs of DNA are hybridized to metaphase chromosomes or interphase nuclei deposited on glass microscope slides. The probe is labeled either directly with a fluorescent chromophore or with an antigenic tag that can be detected immunochemically, and the hybridized material is viewed through a fluorescence microscope. The hybridized probes appear as dots within the nuclei or on the metaphase chromosomes at the site of the DNA contained in the probe.

MOLECULAR MARKERS OF CANCER DIAGNOSIS

A wide variety of different nucleic acid markers have been applied in some form of cancer diagnosis, at least on an experimental basis. Among the purposes for which these markers have been applied are primary determination of malignancy in biopsy specimens, tumor classification, staging of disease extent, assessment of prognosis, detection of residual disease, screening of patients for cancer in body fluids, and evaluation of patients for hereditary predisposition to cancer. [Table 251.1](#) lists the more commonly used markers, along with the cancers, methods, and diagnostic purpose associated with their use.

TABLE 251.1. EXAMPLES OF MORE COMMONLY USED MOLECULAR MARKERS IN CANCER DIAGNOSIS

ANTIGEN RECEPTOR GENE REARRANGEMENTS

Among those markers that have most clearly already established a role for themselves in cancer diagnosis are rearrangements of antigen receptor genes (i.e., genes that direct synthesis of the polypeptide subunits that make up immunoglobulins and T-cell receptors). Rearrangements of these genes are not markers for cancer per se but rather for clonality of lymphocytes in non-Hodgkin's lymphoma and lymphocytic leukemias. These rearrangements are created by a series of genetic recombination events that occur normally in the process of assembling functional antigen receptor genes during early stages of lymphocyte development. As inherited in the germ line and retained in all nonhematopoietic cells, each of these genes is encoded over relatively large stretches of DNA as discontinuous segments belonging to three or four multimer sets, termed V, D, J, and C. During gene rearrangement, one D segment becomes joined to one J, and one V segment becomes joined to the previously linked DJ segments. Some antigen receptor genes lack D segments, in which case a V segment is joined directly to a J segment. The joined VDJ or VJ segments are transcribed into RNA along with a downstream C segment, and the resulting transcript is spliced to produce a mature V(D)JC transcript that can then be translated into an antigen receptor polypeptide. In normal B-cell precursors, this process takes place in two or three immunoglobulin genes (the heavy-chain gene and one or both of the light-chain genes, κ and λ), and rearrangement may occur in one or both alleles for each gene. In normal T-cell precursors, two of the four T-cell receptor genes (a and b or g and d) are rearranged. In general, once rearrangement is completed within a gene, that configuration of V, D, and J segments is fixed in the cell and any descendants that it may produce.

From a biologic perspective, the joining of various V, D, and J segments serves as a mechanism to generate structural diversity that is the basis of the specificity of immunoglobulins and T-cell receptors for binding individual antigens; from a diagnostic perspective, joining of V, D, and J segments provides a marker for a given cell or any clone derived from that cell. These rearrangements of segments in antigen receptor genes among cells within a lymphocytic population can be assessed by Southern blot analysis using a probe containing genomic DNA sequences lying downstream of the last J segment. To be visible as a band in the autoradiogram, the same rearrangement must be present within at least 5,000 to 10,000 cells (or about 1% of the 5 to 10×10^5 total cells routinely assayed in one analysis). In non-neoplastic processes in lymphoid tissues, such as inflammatory lesions, or in normal blood or bone marrow, clonal populations constituting as many as 1% of the cells within a tissue are very rare; consequently, non-germ line bands are not seen in Southern blot autoradiograms prepared from such tissues. In contrast, in analyses of tissues containing lymphocytic cancers, one or two non-germ line bands (depending on whether one or both alleles are rearranged within the tumor) are usually detected, provided the clonal population of neoplastic lymphocytes exceeds the 1% threshold.

In most cases, when sufficient material is available, several antigen receptor genes are ordinarily screened, often by analyzing two or three separate restriction enzyme digests of DNA with the same probe. This procedure yields a rearranged band in one or more immunoglobulin genes in B-cell tumors or T-cell receptor genes

in T-cell tumors. A small fraction of lymphoid tumors show no detectable bands in the Southern blot autoradiogram, probably due in some cases to technical reasons that are not fully understood or to the origin of these tumors from natural killer cells or other lymphoid cells that do not normally rearrange their antigen receptor genes. In other cases, tumors may arise from lymphocyte precursors that have not yet rearranged their antigen receptor genes. A version of this situation is seen among acute lymphoblastic leukemias, in which many rearranged bands may be detected, presumably because malignant transformation occurs in a pre-pre-B cell precursor that generates descendants capable of rearranging their antigen receptor genes in diverse ways. The converse problem—detection of antigen receptor gene rearrangements in certain disorders traditionally regarded as clinically benign—is also encountered. Such disorders, which include lymphomatoid papulosis, lymphoepithelial lesions of the salivary gland, and so-called pseudolymphomas, tend to be chronic and are associated with relatively high risk of subsequent lymphoma or leukemia. Increasingly, these disorders are considered to be either benign neoplasms with a propensity for progression to malignancy, or very low-grade cancers.

Rearrangements of antigen receptor genes can also be analyzed as clonal markers using PCR. Whereas Southern blot analysis of antigen receptor gene rearrangements examines the configuration of specific rearranged V, D, and J gene segments, PCR focuses on the nucleotide sequences at the junctions between rearranged segments. During the rearrangement process, prior to fusion of the segments, novel sequences are created at these sites by the combined effects of two events: deletion of variable numbers of nucleotide pairs at the ends of the gene segments and insertion of variably sized short stretches of random nucleotide pairs between the segments. The sequences at the VDJ and VJ junctions can be amplified using primers complementary to sequences in the V and J segments flanking these junctions. Uniform junctional sequences indicative of clonal populations of lymphocytes can be identified as discrete bands in electrophoretic gels. Resolution of these bands may be based solely on the size of the PCR products (using standard agarose or polyacrylamide gels) or on the size plus the sequence of the products (using gradient denaturing gels). Either approach has about the same sensitivity for detecting clonal populations of lymphocytes as Southern blot analysis. However, as a practical prerequisite for PCR amplification of a given antigen receptor gene, sufficiently similar sequences must exist in the various V and J segments to permit amplification with a limited set of primers complementary to these sequences. For this reason, immunoglobulin heavy-chain and γ T-cell receptor genes are the only genes routinely analyzed for rearrangements by PCR. Furthermore, clonal rearrangements in only about 75% to 80% of B-cell neoplasms can be detected by PCR with multiple sets of primers for immunoglobulin heavy-chain genes. Nevertheless, the speed and convenience of PCR analysis (significantly, the avoidance of radioactive chemicals) relative to Southern blot analysis makes PCR a useful technique to assess gene rearrangements, at least as a preliminary screen before having to resort to Southern blot analysis. Additionally, because of the power of PCR to amplify very small amounts of DNA, it can be the only means to evaluate the clonality specimens having few lymphocytes, such as in skin biopsy specimens containing possible early cutaneous T-cell lymphoma.

Junctional sequences between segments of rearranged antigen receptor genes have also been utilized to search for residual disease after therapy. In this application, the V(D)J junction is amplified by PCR from the DNA of a diagnostic biopsy sample. Nucleotide sequence analysis is performed on the amplified fragment, and the tumor-specific junctional sequence is used to prepare an oligonucleotide primer or probe. Specimens obtained after administration of therapy can be then analyzed for residual disease by attempting amplification of DNA with the tumor-specific primer and a second nonspecific primer complementary to V or J sequences. Alternatively, V(D)J sequences can be amplified in aggregate from the DNA of a posttherapy specimen and the products tested for the tumor-specific junctional sequence by hybridization with an oligonucleotide probe constructed from the sequence determined from the original diagnostic specimen. These strategies have the ability to detect one malignant cell from a total of about 10^5 total cells.

The greatest interest in applying PCR of antigen receptor genes for monitoring of residual disease has centered on acute lymphoblastic leukemia because of the potential curability of the disease and the theoretical option of intensifying therapy or performing bone marrow transplantation if leukemic cells are found to persist in patients undergoing treatment. Studies attempting to correlate residual disease detected by these techniques with clinical outcomes have yielded somewhat contradictory results. Overall, a rapid decline in the detection of a clonal junctional sequence and continued absence of this sequence throughout the course of therapy predicts a better chance of survival. However, large fluctuations in the level of the clonotypic sequence can be found during therapy, and some patients lacking detectable clonotypic sequences at the end of therapy will ultimately relapse. Relapses among these patients are likely due to residual disease below the threshold detectable by testing for junctional sequences and in some cases to origin of the leukemia from pre-pre-B cells, which can give rise to subclones having different V(D)J sequences. Perhaps most surprising is evidence that some patients in clinical remission for years following cessation of all therapy continue to harbor viable cells bearing the junctional sequence found in their leukemic clone at diagnosis.

CHROMOSOMAL REARRANGEMENTS

Chromosomal rearrangements represent a large category of marker for the molecular diagnosis of certain cancers, especially hematopoietic neoplasms and sarcomas. Many of these rearrangements can also be detected by conventional cytogenetic analysis of metaphase chromosomes obtained from cancer cells. However, when molecular methods are applicable, they usually provide test results faster than cytogenetics and with much greater sensitivity for detecting small numbers of abnormal cells. Interpretation of these results does not require the degree of technical expertise needed for cytogenetics. Furthermore, biopsy specimens that fail to yield adequate metaphases for standard cytogenetic analysis or produce overgrowth of normal fibroblasts in culture do not affect molecular analysis. Molecular analysis can also detect diagnostically relevant submicroscopic chromosomal alterations that cannot be resolved by standard cytogenetics and disease-specific chromosomal rearrangements that are obscured in cytogenetic preparations by complex nonspecific karyotypic changes.

Chromosomal translocations have received particular attention as diagnostic markers, compared to other chromosomal abnormalities such as deletions or inversions, both because translocations are relatively common in cancer and because they are especially favorable markers for detection by molecular means. The most important technical consideration in detecting translocations within biopsy specimens is the variability of the positions of breakpoints in the DNA. Usually these breakpoints on the two participating chromosomes join portions of two genes, creating a chimeric gene with novel functions or properties that contribute to the malignant transformation of the cells that contain them. Sometimes the positions of the breakpoints for a specific translocation cluster closely over short lengths of DNA, in which case the translocation can be detected by Southern blot analysis using a probe complementary to DNA near one of the breakpoints, or by PCR using two primers that flank the point of fusion between the two chromosomes. Detection of a translocation is indicated by the presence of a band in a non-germ line position in the Southern blot autoradiogram or by a band produced by gel electrophoresis of the PCR products. The threshold for detecting neoplastic cells by these methods is about 1% (Southern blot analysis) and $1/10^5$ (PCR).

Rather than being tightly clustered within DNA, the positions of the chromosomal breakpoints more often vary considerably among cases with a specific translocation, particularly over the sizable stretches of DNA that constitute introns within the affected genes. Detection of translocations in this situation requires the use of multiple probes for Southern blot analysis and frequently precludes PCR of DNA for most practical purposes. To circumvent this problem, RT-PCR of RNA from biopsy tissues is commonly performed. Primers are constructed to complement sequences within exons lying on both sides of the site of breakpoint fusion. For most translocations, this approach permits detection of neoplastic cells using a few sets of primers and with a sensitivity at least as high as that obtained by PCR of DNA.

Because of the great sensitivity of PCR-based detection of chromosomal translocations, amplification across sites of chromosomal fusion has been extensively employed for monitoring residual disease after therapy or for identifying small numbers of neoplastic cells in autologous bone marrow transplantation. To date, most experience with these methods has been obtained in chronic granulocytic leukemia using the t(9;22)(q34;q11), the Philadelphia chromosome (Ph), as a marker. In general, the findings have paralleled those described above with PCR of V(D)J junctional sequences in acute lymphoblastic leukemias; levels of Ph may vary widely over the course of therapy and detectable numbers of it may persist for years in patients who remain in complete clinical remission. Even longer disease-free intervals have been seen in patients with M2 acute myelogenous leukemia carrying numbers of the t(8;21)(q22;q22) detectable by RT-PCR. On the other hand, early treatment of patients in whom detectable levels of the t(15;17)(q21;q11) have reappeared after therapy seems to prolong survival in M3 acute myelogenous leukemia.

In addition to Southern blot analysis and PCR, FISH has been applied for detecting translocations and other forms of chromosomal rearrangement. To test for chromosomal translocations, two probes are utilized, each distinguished by a different color of fluorescence and each complementary to DNA near one or the other breakpoints on the two participating chromosomes. If the appropriate translocation is present, three dots are seen—one with the color of the labeled probe for each of the normal chromosomal homologues and one with the combined colors corresponding to a product of the translocation. The principal virtue of FISH for diagnostic testing is its speed; analysis can be completed within hours when interphase cells are used. Furthermore, it can be used to detect chromosomal translocations, such as those involving the *MYC* gene in Burkitt's lymphoma, in which the breakpoints are so widely scattered in the DNA of chromosome 8 that neither Southern blot analysis, PCR, nor RT-PCR is applicable. A drawback to FISH is that cells must be examined individually, and therefore the method does not lend itself to the monitoring of residual disease. The sensitivity of FISH is further reduced by the fact that in any individual cell there is a significant risk of missing a dot because of failure of hybridization to DNA within the largely intact nuclei on the slide. Inconsistent hybridization within intact nuclei also complicates the use of FISH to detection of small deletions by probes to the deleted region; consequently, the method has not been widely employed for this purpose beyond experimental situations. On the other hand, detection of additions or deletions of whole chromosomes is generally less problematic in this way since strongly hybridizing probes to highly repetitive sequences surrounding chromosomal centromeres can be used.

Amplification of genes is another type of chromosomal rearrangement that has a potential role in the molecular diagnosis of certain cancers, particularly for

assessment of prognosis. In one cancer, neuroblastoma, both the presence and degree of amplification of the *N-myc* oncogene is a well-recognized prognostic indicator. For other genes and cancers, such as the *her2/neu/c-erbB-2* oncogene in breast cancer, the significance of amplification as an independent prognostic variable is more controversial (although *HER2* amplification appears to be a valuable indicator of responsiveness to the therapy with recombinant monoclonal antibodies directed against the HER2 protein). In the past, increased copy number of these genes has been detected by Southern blot, but FISH on interphase nuclei has lately been increasingly used for this purpose. However, in some instances immunohistochemistry for the protein product of these genes may be more convenient than molecular diagnostic methods or may provide results more directly correlated with subsequent tumor behavior than copy number of the gene.

Efforts have also been made to exploit amplifications and deletions of much smaller regions of DNA for cancer diagnosis. These regions of DNA contain so-called microsatellite sequences made up of short stretches of tandem di- or trinucleotide repeats (most commonly CA dinucleotides) located at thousands of sites throughout the genome, predominantly outside of coding sequences. Microsatellite sequences are prone to replicative errors that occasionally add or subtract repeat units as cells proliferate, making most normal body tissues cellular mosaics with respect to the number of microsatellite repeats at certain loci. Additionally, mechanisms of mismatch DNA repair that work to prevent errors in DNA replication that occur in microsatellite sequences may be relaxed in cells early during tumorigenesis. The nonrepeated sequences surrounding many microsatellite repeats are known, and primers complementary to these sequences can be used to amplify individual microsatellite regions to search for changes in the number of repeats by noting alterations in the size of the resulting PCR product. The frequency of variation at any one microsatellite site is usually very low, so that a change in the size of the microsatellite region cannot be detected by amplification of total DNA from normal tissue. However, if clonal expansion has occurred, as happens during tumor development, alterations in size of the microsatellite region may become apparent. This type of clonal analysis has been used to assay for tumor cells in body fluids and even for free DNA released from tumors into blood. Unfortunately, many microsatellite regions may have to be examined before a polymorphism in repeat number can be identified, greatly reducing the utility of this approach to diagnosis.

VIRUS-DERIVED GENES

Viruses have been implicated as an etiologic factor in several forms of cancer, and the nucleic acids of these pathogens may serve as diagnostic markers in certain settings. Included within this group of viruses are Epstein-Barr virus (EBV), human T-cell leukemia/lymphoma virus type 1 (HTLV-1), human papillomavirus (mostly types 16 and 18), and human herpesvirus 8 (HHV-8). Detection of viral DNA in tissue biopsies can be carried out either by PCR or by Southern blot hybridization using primers or probes specific for the viral genome. However, both PCR and Southern blot analysis (although to a lesser extent with Southern blot analysis because of its lower sensitivity) run the risk of detecting infections by the above viruses unassociated with neoplasia. For example, neither method discriminates between the EBV DNA found in EBV-associated lymphomas and the EBV DNA in acute infections of patients with mononucleosis or in latently infected lymphoblasts found in most normal individuals. In the example of EBV, this problem has been overcome by performing Southern blot hybridization for the region of the DNA spanning the site where the termini of the linear genome present in the viral capsids are fused to form the circular episome found in infected cells. The termini differ from virion to virion due to varying numbers of tandemly repeated sequences 500 nucleotides long at the ends of the linear genome. Additionally, some repeat units may be discarded as the termini become joined through a process of homologous recombination. Consequently, the length of the restriction fragment containing the fused termini of the genome is likely to vary from one infected cell to another. The presence of an infected clone of lymphocytes, each member of which carries a uniform EBV episome with identical fused termini, is indicated by a predominant band in the Southern blot autoradiogram, in contrast to the ladder of bands that appear in autoradiograms produced from polyclonal cells infected by EBV.

ECTOPIC RNA

Structurally normal RNA molecules transcribed from cellular genes have been utilized as markers for cancer diagnosis in two contexts. One context involves the detection of metastatic tumor cells from non-hematopoietic tumors using as markers RNA transcribed from genes expressed primarily in the normal tissue from which that tumor arose. This approach to diagnosis takes advantage of the sensitivity of RT-PCR to detect specific RNA sequences and is based on the rationale that the finding of RNA at an inappropriate site must be due to metastasis. RT-PCR of such ectopic RNAs has the attractive feature of requiring no preliminary characterization of the primary tumor (e.g., identification of a specific chromosomal translocation or mutation). The chief limitation of the method has so far been the difficulty in discovering usable RNAs due to the phenomenon of so-called illegitimate transcription (the physiologically insignificant transcription of low levels of many or most genes in a wide variety of tissues). Low levels of nonspecific transcription in large numbers of normal cells at a site of possible metastasis is indistinguishable by RT-PCR from high levels of transcription in small numbers of metastatic cells at that site.

The original paradigm for application of RT-PCR of ectopic RNA for detecting metastatic cells was in testing for bloodborne tumor cells in melanoma patients using tyrosinase RNA as a marker for circulating malignant melanocytes. More recently, extensive study has been directed at the detection of metastatic tumor cells in blood, bone marrow, or pelvic lymph nodes of patients with prostate cancer by RT-PCR of RNA for prostate-specific antigen (PSA). Preliminary studies suggesting that detection of PSA RNA at ectopic sites predicts a shortened course await confirmation in larger prospective studies now underway.

TRANSCRIPTIONAL PROFILING

A second context in which RNA has been regarded as having great potential in cancer diagnosis is in the characterization of tumors through comprehensive surveys of gene transcription in cancer cells. These surveys are often called *transcriptional profiles* and have become feasible as a result of international efforts, now in progress, to determine the nucleotide sequence of all human genes. Another development critical for this work has been the creation of instruments and technologies that permit the construction on glass slides, often referred to as "chips" in this field, of microarrays composed of thousands of very small spots, each containing a different specific gene sequence. Two technologies have been used to construct microarrays: the deposition by robots of DNA fragments onto the chip and the photochemical synthesis of oligonucleotides directly on the chip surface. Additionally, chip-reading devices have been produced to rapidly collect signals generated from each individual spot.

The general procedure in transcriptional profiling is that pools of fluorescently labeled complementary DNAs (cDNAs) are synthesized from total-gene RNA in a tissue and hybridized to the chip. Hybridization of the test cDNA pool is usually performed together with a differently labeled cDNA pool prepared from a second source, and the chip reader compares the relative hybridization of the two cDNA pools at each spot. For example, cDNAs of an individual tumor can be compared in this way to the cDNAs of its normal tissue counterpart to determine those genes that are more or less active in the malignant versus the normal cells, or transcription in individual tumors can be compared pairwise to identify differences in the activities of certain genes. The diagnostic value of transcriptional profiling in cancer diagnosis rests on the concept that the clinical behavior of a tumor is largely determined by the activity of genes within it and that differences in gene activity will better define subclasses of tumors, predict responses to therapies, and dictate overall prognosis.

At present, transcriptional profiling of tumors is only beginning and there are difficulties to be overcome in the analysis and management of data from arrays containing as many as 10^5 spots (corresponding to the 10^5 unique genes in the human cell) and in problems posed by the cellular heterogeneity of many tumors. However, the latter difficulty may be mitigated by laser microdissection apparatuses that have been devised to excise homogeneous regions of pure tumor from tissue sections. It also remains to be seen as to whether transcriptional profiling will become a diagnostic method in itself or, perhaps more likely, a vehicle for the discovery of a set of critical markers that may be assessed by other methods, such as RT-PCR or immunohistochemistry.

POINT MUTATIONS

Point mutations—the substitution of one nucleotide pair for another within the DNA of genes—are a type of diagnostic marker with ramifications for many types of diagnostic applications in cancer. Such mutations are responsible for the conversion of some proto-oncogenes to oncogenes and often for the inactivation of tumor suppressor genes. In aggregate, these alterations probably represent the most common type of acquired genetic lesion present in human cancers. Furthermore, point mutations passed through the germ line, frequently in one allele of a tumor suppressor gene, account for most hereditary cancer syndromes. It is also widely anticipated that differences in single nucleotide pairs may affect gene products that interact with drugs and therefore could influence the response to therapy. Some of these differences will probably be acquired somatically, in the tumor itself. Other differences may be inherited, in which case they are usually referred to as polymorphisms rather than mutations because they are more common in the population than mutations and do not inactivate a gene or its product, although they may alter its function. The search for such genetic variations and their correlation with toxicities or therapeutic efficacy of drugs has engendered a new field of pharmacogenomics, which may significantly affect the practice of oncology in coming years.

Two considerations qualify the use of point mutations as diagnostic markers in cancer. One consideration relates to the essential multistep process of tumor development. Mutations in individual genes appear to be insufficient for full transformation to malignancy. Most cancers derive from progenitor cells that have accumulated a series of mutations, which may include nucleotide substitutions, deletions, amplifications, and chromosomal rearrangements, in addition to possible epigenetic changes (such as altered methylation of particular regions of DNA) that govern the activities of various genes. Therefore, mutations in a given oncogene or tumor suppressor gene may be present in dysplasias, in other premalignant conditions, or even in benign conditions, and these changes by themselves cannot be

regarded as absolutely diagnostic of cancer. For example, mutations of the *K-ras* oncogene, found in about 90% of pancreatic adenocarcinomas, have also been detected in epithelial cells from the pancreatic ducts of a minority of patients with chronic pancreatitis. Moreover, point mutations present in the cells of primary tumors may also occasionally disappear in recurrences, underscoring the need for caution in applying these changes as markers for detection residual disease.

Nevertheless, if found in follow-up samples, point mutations that match those detected in an earlier specimen diagnosed by conventional morphologic and other criteria may be useful for staging of tumors or for monitoring of recurrent disease. For purposes of monitoring cancer, there are effective and relatively straightforward methods for "redetecting" such mutations. These methods usually depend on PCR of DNA for a particular gene, followed by molecular hybridization with oligonucleotides complementary to a sequence containing the specific mutation previously determined in the reference sample. Examples of these types of studies have been carried out using mutations of the *P53* tumor suppressor gene to screen for recurrences of bladder carcinoma in urinary sediments and to stage the extent of local spread in squamous carcinoma of the oropharynx. The maximal sensitivity of this method is on the order of detecting one malignant cell in 10^4 or 10^5 total cells, but working out the precise conditions for this level of detection can be challenging.

The second consideration in the attempt to use point mutations as diagnostic markers pertains to technical difficulties in their de novo detection in primary diagnostic samples, as opposed to redetection in follow-up samples. Although mutations tend to occur repeatedly in certain positions of some cancer-related genes (notably genes of the *RAS* family, in which mutations occur predominantly in codons 12, 13, and 61), the sites of mutations are generally widely scattered throughout the sequence of most tumor suppressor genes among different cases and within those genes involved in hereditary cancers among different pedigrees. These mutations can be definitively determined by nucleotide sequence analysis of PCR products, but this process is generally considered to be too labor-intensive to be employed as a routine diagnostic procedure. In addition, nucleotide sequence analysis for cancer diagnosis is frequently complicated by the need to identify nucleotide changes in heterozygous tissues or in impure samples in which the malignant cells represent a minor component. Various methods have been devised to expedite detection of mutations. Most of these methods depend on the altered mobility of mutant DNA fragments in electrophoretic gels [single-strand conformational polymorphism analysis (SSCP) and denaturing gradient gel electrophoresis (DGGE)] or on the enzymatic cleavage at the position of mismatched bases within heteroduplexes of nucleic acids containing one normal strand and one mutant strand (enzyme mismatch scanning). These methods also have their disadvantages, including significant effort required to optimize the procedure in a given case and frequent false-negative results. Another potential solution to the problem of detecting point mutations is hybridization of DNA probes generated from tissue DNA to commercially prepared oligonucleotide microarrays containing all possible nucleotide substitutions for a given region of sequence. Although currently these microarrays are expensive, this approach has succeeded for detecting many mutations in certain genes and greatly reduces the labor needed to screen large segments of DNA for mutations at many possible sites.

CHAPTER 252: PRINCIPLES OF SURGICAL ONCOLOGY

JOHN M. DALY AND MICHAEL D. LIEBERMAN

[Preoperative Assessment: Clinical Diagnosis and Staging](#)
[Pathologic Diagnosis and Staging](#)
[Preoperative Preparation](#)
[Goals in Surgical Intervention](#)

The surgical oncologist occupies a unique position in the management of the patient with cancer. Most cancer patients undergo some form of operative therapy for the diagnosis, primary treatment, or management of complications during the course of treatment for their neoplastic disease. Survival statistics of patients with cancer treated surgically have reached a plateau; earlier detection through selective screening and multimodal therapy should further improve cure rates. Inclusion of radiation therapy or chemotherapy or both may also preserve a comparable survival rate while permitting less extensive operative resection, thus enhancing cosmesis and function.

The surgical oncologist is responsible for the initial diagnosis and management of many types of cancer. Knowledge of tumor staging and the natural history of the disease should be integrated into a multimodal approach to treatment in concert with the medical oncologist and the radiation therapist. The guiding principles of the surgical oncologist should be the accurate diagnosis and staging of the cancer with adequate operative removal of locoregional disease.

The surgical oncologist's role varies with the type of cancer. For example, curative operations may be performed on patients with primary breast, head and neck, gastrointestinal, gynecologic, lung, skin, and urinary tract malignancies. In other forms of cancer, such as lymphoma, the surgeon may provide diagnostic and staging information. In patients with hematologic malignancies, the surgeon may provide vascular access or manage complications related to chemotherapy or radiation therapy.

PREOPERATIVE ASSESSMENT: CLINICAL DIAGNOSIS AND STAGING

On the first examination of the patient with cancer, a complete history and physical examination are indispensable before further judgments can be made regarding laboratory testing and treatment. Common symptoms range from anorexia, nausea, vomiting, hematemesis, abdominal pain, melena, and hematochezia in patients with gastrointestinal cancer to anorexia, productive cough, and hemoptysis in lung cancer, to an enlarging mass in breast and soft-tissue tumors. Symptoms generally correspond to the sites involved, but nonspecific symptoms such as night sweats and weight loss may be the initial manifestations of an underlying neoplastic tumor. The duration of symptoms may indicate the aggressiveness of the cancer. The degree of impairment should be noted, as this will influence treatment decisions regarding palliation.

The patient's past medical history often provides clues to the diagnosis. The medical history also reveals environmental factors such as smoking, alcohol ingestion, or exposure to asbestos or aniline dyes that can be related to organ-specific sites of tumor development. Finally, a thorough medical history provides an important index of operative risk for the patient.

Physical examination should begin with an overall assessment, proceed through a systemic examination, and then focus on the specific sites suggested by the medical history. Simple screening examinations, such as a complete pelvic examination with uterine cervical Pap smear and fecal occult blood testing, should be performed routinely.

In addition to routine laboratory tests such as complete blood count, coagulation profile, multichannel serum biochemistry profile, and chest roentgenography, other studies are useful in determining the primary tumor site and extent of disease. The oncologist frequently requires assays for tumor markers in the blood or urine as well as radiologic studies.

Serum tumor markers have been most useful in following the patient's response to therapy (see [Chapter 250](#)). Serum markers such as carcinoembryonic antigen (CEA), b-human chorionic gonadotropin, CA 125, thyroglobulin, and a-fetoprotein (AFP) are useful in the management of patients with specific tumors.

The surgical oncologist relies heavily on preoperative imaging for diagnosis, staging, and planning the operation. Most commonly, a dynamic helical computed tomography (CT) scan is the first and only radiologic test required to assess an intra-abdominal process. Magnetic resonance imaging (MRI) is helpful for extremity sarcomas, retroperitoneal tumors, and the assessment of bowel wall penetration of rectal tumors. Endoscopic ultrasonography has a major role in the preoperative assessment of esophageal, gastric, and some pancreatic tumors. External ultrasonography is user-dependent but in experienced centers is a superb modality for evaluating tumors involving the hepatobiliary system. The use of preoperative angiography has been drastically reduced with the advent of Duplex ultrasound, magnetic resonance angiography, and contrast-enhanced helical CT scanning. However, preoperative arteriography can be useful in patients under consideration for hepatic artery infusional therapy. Mammography is useful for detecting occult breast masses and areas of suspicious microcalcifications, for stereotactic needle biopsies, and for providing needle localization of occult mammographic abnormalities for excisional biopsy. Radionuclide scans are useful for evaluating the presence of bone metastases in patients with symptomatic musculoskeletal complaints. Radiolabeled octreotide, cholesterol, and CEA scans have utility in staging patients with carcinoid, adrenal, and colorectal tumors, respectively. Positron emission tomography (PET) scanning complements other diagnostic modalities for lung, melanoma, and gastrointestinal cancers and may prove to be more cost-effective. Diagnostic sensitivity, specificity, and accuracy are 85% to 90% or better when assessing for primaries, metastases, or recurrence. The use of PET scanning altered patient management in 15% to 44% of patients with recurrent colorectal cancer, lung cancer, lymphoma, and melanoma ([Table 252.1](#)).

Disease	No. of Patients	Change in Treatment (%)
Recurrent colorectal cancer	93	38
Lung cancer	159	41
Lymphoma	74	15
Melanoma	50	44

TABLE 252.1. ALTERED PATIENT TREATMENT WITH PET SCANNING

PATHOLOGIC DIAGNOSIS AND STAGING

The importance of accurate pathologic diagnosis in the proper surgical treatment of cancer patients cannot be overstated. The determinations of histologic grade, primary site, and surgical resection margins provide critical information.

Diagnosis can frequently be made by the use of fine-needle aspiration cytology (FNA). Diagnosis using FNA (22- to 25-gauge needle) techniques concurs with the surgical pathologic diagnosis in 97% of tested lymph nodes in patients with metastatic solid tumors and 77% of primary breast tumors examined. This technique is rapid, minimally traumatic, and highly accurate for diagnosis of a clearly palpable mass or a radiographically visible lesion. False-positive results are rare; false-negative results may occur because of the small sample size and the site of the lesion. With the use of FNA techniques in combination with helical CT scans

and ultrasonography, deep nonpalpable lesions have become amenable to diagnosis with minimal morbidity. Tumor cell implantation of the aspiration site is rare. FNA cytology is particularly useful in diagnosing palpable masses in the breast or thyroid or palpable suspected nodes in the neck, axilla, or groin. However, aspiration cytology cannot be relied on for grading solid tumors, for subdividing types of lymphoma, or for making an accurate diagnosis after radiation treatment, but a positive diagnosis of malignancy greatly facilitates diagnostic and treatment planning.

When an accurate diagnosis of tumor type and grade is necessary and cannot be accomplished by FNA, an incisional or excisional biopsy is required. Care should be taken in the planning of a surgical biopsy so as not to jeopardize later surgical extirpation or the use of skin flaps. In general, large soft-tissue lesions (5 to 7 cm) that are deeper than the superficial fascia are best sampled by incisional biopsy to provide a diagnosis and allow planning for a definitive procedure. Small (less than 2 cm) superficial lesions should be managed by excisional biopsy with a view to further treatment depending on tumor type, grade, and depth of invasion. Frozen section diagnosis should not be relied on to provide accurate histologic grade and information about invasion depth. Surgical margins of resection should be evaluated by frozen section or permanent section examination of a properly marked and oriented specimen.

The surgical staging of intra-abdominal tumors with a concomitant decrease in morbidity has improved with minimal access surgery. Utilizing small incisions and ports with one-way valves, surgical instruments, and cameras can be introduced into the gas, CO₂, distended abdomen for exploration, direct organ ultrasonography, tissue biopsy, peritoneal cytology, and, sometimes, curative resection. Many surgical oncologists utilize laparoscopic techniques to rule out carcinomatosis prior to laparotomy for pancreatic, gastric, and hepatic malignancies. Limiting laparotomy to patients who may benefit from resection reduces patient morbidity, time to definitive therapy, duration of hospitalization, and cost.

PREOPERATIVE PREPARATION

Appropriate preoperative preparation includes knowledge of the natural history of the disease, evaluation of operative risk, decisions relevant to the need for and timing of operative intervention, estimation of the physiologic stress potentially imposed by the operation, and quantitative assessment of the patient's physiologic status. Comprehensive preparation of a patient for operative therapy requires physiologic and psychological support. The physician should consider potential abnormalities such as acid-base disorders, malnutrition, infection, respiratory insufficiency, hepatic and renal dysfunction, anemia, and clotting abnormalities.

The two aims of all treatment during the preoperative period should be to prepare the patient to withstand the stresses of operative therapy and to minimize the risks of the surgical procedure. The appropriate duration of the preoperative period depends on the urgency of the operative procedure. Determining this urgency requires knowledge of the operative risk and the natural history of the disease without immediate operative intervention. Included in this evaluation are factors such as age (chronologic and physiologic), degree of physiologic derangements and nutritional deficits, presence of organ system failure or insufficiency, and stage of the primary disease. Although the urgency of operative intervention may limit both the length of preoperative preparation and the methods available for correcting preexisting abnormalities, partial repair of deficiencies should be initiated promptly, with plans made for more complete correction during and after operative therapy. Months of chronic undernutrition cannot be corrected in a matter of hours, but anemia, dehydration, and electrolyte abnormalities can be ameliorated by early initiation of intensive intravenous support, guided by appropriate laboratory monitoring. Preoperative assessment of high-risk patients, in particular looking at reversible factors such as malnutrition, is essential for optimal outcome. Nutritional assessment techniques include a detailed history, noting the degree of weight change as well as dietary and alcohol intake, and physical examination. Other parameters studied are serum albumin and transferrin levels.

The feeding regimen selected depends on the patient's nutritional status, the integrity of gastrointestinal function, and the type and magnitude of proposed treatment. If the patient cannot meet his or her daily nutritional requirements by voluntary oral ingestion of food, the first step in nutritional support should be oral nutrient supplementation and intensive dietary counseling. The patient who exhibits a moderate to severe degree of protein-calorie malnutrition by definition has failed to maintain himself or herself with spontaneous oral nutrient intake and must receive supplementation by an additional route and regimen of nutrition. A functional gastrointestinal tract is the best means to ensure normal digestion and assimilation of food, but the enteral route may be contraindicated by malabsorption, intestinal obstruction, upper gastrointestinal bleeding, or intractable vomiting or diarrhea. If the gastrointestinal tract is unavailable for use, intravenous nutritional support should be initiated. However, routine preoperative nutritional intervention has not been shown to diminish postoperative complications and may increase infectious complications. Thus, it should be reserved for the severely malnourished patient ([Table 252.2](#)).

Author	No. Patients	Preoperative TPN Duration (Days)	Nutrition Criteria (Defined)	Complication Rate (%) TPN vs. Control	Mortality Rate (%) TPN vs. Control
Notter	16	2	< 60 kcal (10-15)	12 vs. 19	7 vs. 8

TABLE 252.2. PROSPECTIVE RANDOMIZED TRIALS OF PREOPERATIVE TOTAL PARENTERAL NUTRITION IN SURGICAL PATIENTS

After major elective operations, wound infection rates have varied from 0.5% to 40%, depending on whether the procedure was clean or contaminated ([Table 252.3](#)). Besides the added morbidity and potential mortality, surgical infection increases the average duration of hospitalization, resulting in a large increase in hospital costs. Resistance to infection (immune function), the quantity and virulence of invading bacteria, obesity, steroid usage, and the duration of the operation are major factors determining the probability of wound infection. Local wound resistance is aided by good surgical technique: gentle tissue handling, adequate hemostasis, debridement of dead tissue, good blood supply, avoidance of hematoma, and closure of the wound without tension.

Operation	Incidence (%)	Type of Infection	Major Pathogens
Intradural craniotomy	4-8	Wound	<i>Staphylococcus aureus</i>
	0.5-1	Meningitis/abscess	Gram-negative
Head and neck	15-40	Wound	<i>S. aureus</i> , gram-negative anaerobes
Pulmonary	0.5-6	Wound	<i>S. aureus</i>
	1-2	Empyema	Gram-negative aerobes
Laparotomy	2-4	Wound	Anaerobes, gram-negative
Gastric resection	5-10	Wound	<i>Streptococcus</i> , anaerobes
Biliary tract	3-10	Wound	Gram-negative enterococci, clostridia
Colon resection	8-40	Wound	Anaerobes
	2-10	Abdominal abscess	Gram-negative aerobes
Mastectomy	1-3	Wound	<i>S. aureus</i> , gram-negative aerobes

TABLE 252.3. OPERATIVE SITES: INCIDENCE OF POSTOPERATIVE INFECTIONS AT THE OPERATIVE AREAS

The use of perioperative antibiotics to reduce infectious complications after surgery requires an understanding of the potential for encountering a contaminated viscus, the bacteriology of the contaminant, and the patient's immunity. When antibiotics are selected, the following guidelines are applied: antibiotics should be administered to allow adequate antibiotic levels in the wound before contamination; they should be administered for only a short time during the perioperative period; they should be specific for the most likely infecting organism; and they should be safe ([Table 252.3](#)).

GOALS IN SURGICAL INTERVENTION

The intent of operative intervention is to resect the tumor, to provide tissue for diagnosis and complete staging, or to palliate symptoms. A decision for curative operation presupposes that the tumor is localized or confined regionally, that the area of the tumor can be encompassed by regional excision, that distant metastases cannot be documented, and that the tumor is appropriately treated by operation. If a curative operation is selected, the extent of the surgical procedure must then be defined. In principle, an en bloc resection should be performed, encompassing the primary tumor, regional lymph nodes, and intervening lymphatic channels. Perhaps this principle is best illustrated by operations for large bowel cancer, in which the regional lymphatics of the intra-abdominal colon course in one direction with the major arteries and veins.

Surgical resectability is determined by the tumor's relation to vital anatomical structures. Preoperative radiologic assessment is essential in defining the anatomy to guide the operative approach. For example, preoperative duplex ultrasonography and helical CT scanning have been invaluable in accurately defining the anatomical location, the number of tumors, and the relation of the tumor to the major vessels for resection of hepatic malignancies. Helical CT and endoscopic ultrasonography are highly accurate in defining the anatomy of pancreatic cancers. Intraoperative ultrasonography is now widely used to determine the resectability of hepatic and pancreatic tumors. PET scanning is quite sensitive for whole-body evaluation of the presence or absence of metastatic disease for many solid tumors. Laparoscopy has emerged as a powerful diagnostic as well as a therapeutic technique for the assessment of intra-abdominal solid tumors. These imaging techniques are extremely helpful in determining resectability or guiding resection, but often resectability is determined by careful surgical exploration.

The extent of resection is determined by the biology of the tumor, anatomy, and the patient's overall medical condition. Improved survival has been described for tumors of the esophagus, lung, and stomach with the addition of radical lymphadenectomy. Diminished local recurrence has been reported for rectal cancer after total mesorectal excision. However, a trend toward less radical surgical procedures is emerging. For example, wide local excision is preferred over limb amputation for extremity sarcomas. The technique of transanal excision or low anterior resection with coloanal anastomosis with or without chemoradiation for rectal cancer has increased sphincter preservation. Survival after segmental breast resection (lumpectomy) with axillary dissection and radiation therapy is comparable to that for modified radical mastectomy for stage I and II breast cancers. A recent prospective randomized trial from Denmark failed to demonstrate improved survival following extended lymphadenectomy for stomach cancer. These results are in contrast to those reported in Japan.

Further attempts to limit patient morbidity by less radical surgical procedures have been incorporated in techniques to identify sentinel lymph nodes, the immediate draining nodes, with intraoperative radionuclide and dye lymphatic mapping. In 1990, Morton and colleagues first introduced the concept of lymphatic mapping and sentinel lymph node identification to select patients for radical lymphadenectomy for stage I malignant melanoma. Utilizing both dye and radionuclide, Morton was able to identify the sentinel lymph node in most patients (98%) with melanoma. Only patients with occult lymph node metastasis underwent complete lymph node dissection. Recent data from other investigators suggest that only patients with a positive sentinel lymph node or clinically palpable lymphadenopathy will benefit from a complete lymphadenectomy for malignant melanoma. The National Adjuvant Surgical Breast Project (NSABP) has recently initiated a large study evaluating the role of sentinel node sampling for patients with breast cancer (NSABP-B32). Other investigators are studying intraoperative lymph node mapping for squamous cell cancers of the head and neck, thyroid cancer, gastrointestinal and gynecologic malignancies. The role of intraoperative lymph node mapping for these diseases has not been defined.

The therapeutic value of regional node dissection has been questioned by some, but performed properly it may establish the data base for precise staging, which may require other adjuvant treatments. The extent of an operation may relate to the presence of additional precancerous lesions and genetics. For example, in a patient with familial polyposis coli or chronic and active ulcerative colitis (after 10 years), total proctocolectomy is recommended to prevent cancer of the colon. Finally, operability and treatment decisions must take into account the patient's medical status and ability to tolerate the proposed operation. Assessment of cardiopulmonary status, hepatic and renal function, and nutritional status is vital to proper determination of operative risk.

In various settings, operative intervention is used for palliative treatment. Bypasses are performed around obstructed viscera, e.g., gastrojejunostomy for obstructing carcinomas of the stomach, choledochoduodenostomy or choledochojejunostomy for a carcinoma of the pancreas obstructing the common bile duct, or nephrostomy for an obstructed ureter. Plastic Celestin tubes may be inserted through an obstructing esophageal carcinoma; colon diversion may be performed for obstructing large-bowel cancer. Transanal fulguration of an obstructing rectal tumor may provide adequate palliation for a debilitated patient.

The surgical oncologist must also be prepared to treat complications of radiation therapy or chemotherapy. Complications of radiation therapy, which occur infrequently, may include skin breakdown, intestinal fistulas, intestinal obstruction, and perforation. Radiation therapy as an adjunct in the management of gynecologic and urologic cancer may result in bladder and rectal injuries weeks to years after treatment. Anslin and associates reported 104 patients with radiation injury of the rectum; 50 patients required surgery for proctitis unresponsive to conservative measures ($n = 14$), rectal stricture or fistula ($n = 32$), or rectosigmoid perforation ($n = 4$). Diversion was considered the safest form of treatment for rectovaginal fistulas, rectal strictures, and proctitis; intestinal resection resulted in increased morbidity and mortality. Intestinal bypass or diversion is the safest approach to bowel obstruction or intestinal fistulas secondary to the late effects of pelvic irradiation. Diabetes mellitus, hypertension, and previous abdominal surgery predispose the bowel to radiation injury.

The surgeon is often called on to perform surgery on a patient who has been treated with radiation therapy or chemotherapy. Relatively small amounts of radiation therapy have no impact on the nature or extent of operation. More extensive amounts, such as 40 to 50 Gy over 5 weeks in the preoperative treatment of sarcomas or breast or rectal cancer, may require a delay of 4 to 6 weeks to allow resolution of skin erythema and tissue edema, and to obtain maximal tumoricidal effect. At the same time, operative risk is greater. Radiation may diminish local blood flow and tissue perfusion affecting subsequent wound healing. The risk of an anastomotic disruption may be sufficiently high in the setting of extensive preoperative radiation therapy to require a temporary proximal colostomy. It may also be necessary to apply reinforcement to a wound closure. The concurrent application of radiomimetic drugs, such as doxorubicin and actinomycin D, will augment the adverse side effects of radiation therapy to multiple tissues.

The surgeon may have to deal with the complications of chemotherapy. Patients with gastrointestinal lymphomas may perforate during radiation therapy or chemotherapy and thus require operative intervention. Patients undergoing chemotherapy may develop gastroenteritis or discrete ulcers leading to bowel perforation or bleeding, thus requiring surgical intervention. In the presence of perforation in a hematopoietically depressed patient, exclusion of the perforated intestine may provide a better chance for survival than resection and anastomosis.

Chemotherapy may inhibit wound healing, resulting in increased complications. Devereux and colleagues found significant impairment in wound healing when doxorubicin was given in the perioperative period (day 7 before surgery to day 3 after surgery). Corticosteroids, vincristine, methotrexate, actinomycin D, bleomycin, carmustine, and cyclophosphamide have also been shown to be deleterious in animal studies on wound healing.

The surgeon and the medical oncologist collaborate in regional chemotherapy in several areas. Cannulation of the gastroduodenal artery can be performed for chronic infusion of the hepatic artery with chemotherapeutic drugs for patients with hepatic metastases, particularly from large-bowel cancer. Hyperthermic limb perfusion in patients with melanoma or soft-tissue sarcoma has excellent results for patients with extensive tumors using combinations of cytokines (e.g., tumor necrosis factor) and chemotherapy.

Direct surgical interaction with radiation therapists includes the application of interstitial therapy (brachytherapy) by implanting radioactive isotopes or afterloading catheters in patients with lung and rectal cancer or after dissection for large, high-grade, soft-tissue sarcoma. Another area of growing interest is the application of intraoperative radiation therapy through the exposure of sites at operation, permitting direct contact of radiation at the desired tumor sites without the need for penetration of intervening skin, soft tissue, and viscera. Neuropathy remains the greatest morbidity factor associated with this method.

The surgical oncologist is responsible for the initial diagnosis and management of patients with various neoplasms. Accurate diagnosis and complete staging are coupled with adequate en bloc operative removal of localized disease. The surgical oncologist's role varies with the type of cancer (curative, palliative, staging) and should be integrated into a multimodal approach.

CHAPTER 253: PRINCIPLES OF RADIATION ONCOLOGY

ALLEN S. LICHTER

[Physical Basis of Radiation Therapy](#)
[Biologic Basis of Radiation Therapy](#)
[Clinical Application of Radiation Therapy](#)
[Summary](#)

Radiation treatment is one of the most widely used forms of antineoplastic therapy. Radiation can be used as a sole modality to cure many types of malignant disease, such as Hodgkin's disease or carcinoma of the cervix. It is often used in combination with organ-preserving surgery to allow curative therapy without removing an important structure; examples include lumpectomy plus radiation instead of mastectomy for breast cancer, and wide local excision plus radiation instead of amputation for soft-tissue sarcomas of the extremities. Another important use of radiation is to provide increased local/regional control after definitive surgery. This therapy is frequently applied if positive regional lymph nodes are found at surgery, such as in most head and neck cancer sites or in node-positive lung cancer. Finally, radiation is probably the most important palliative therapy for malignant disease. Patients with metastasis to bone or to brain often achieve symptomatic relief for significant periods of time after a short course of radiation.

Since the discovery of the x-ray a century ago, there has been substantial progress in our understanding of the biologic and physical basis of radiation therapy and in the sophistication with which radiation can be applied in the treatment of malignant disease. This chapter will briefly summarize these areas.

PHYSICAL BASIS OF RADIATION THERAPY

X-rays are a short-wavelength, deeply penetrating form of energy. They are part of a continuum of waveform energy called the electromagnetic spectrum, which spans an extremely broad area from long-wavelength, low-energy waves, such as radio waves, to deeply penetrating, extremely short-wavelength energy such as cosmic rays. Therapeutic radiation can be derived from two sources: the decay of radioactive elements, called radionuclides, which can be naturally occurring or synthesized in nuclear reactors (these rays are often referred to as gamma rays); and x-ray generating equipment.

Radionuclides have played an important role in the treatment of cancer with radiation. Among the first therapeutic uses of radiation therapy was the direct application of the radioactive element radium directly onto superficial skin and lip cancers. Most of these radioactive materials are formed into small pellets or seeds that can be inserted directly into the tumor as part of an operative procedure. However, two radioactive materials are used in a somewhat different fashion.

Iodine 131 is commonly administered orally to patients with functioning thyroid malignancies. The malignant cells (as well as the normal cells) take up the radioactive iodine and are destroyed. This renders the patient hypothyroid and necessitates permanent thyroid replacement, but it is extremely effective and relatively nontoxic in its ability to control thyroid malignancies permanently.

Cobalt 60 is a radionuclide that produces a very energetic g-ray. Cobalt has been used since the mid-1950s in machines designed to treat the patient with externally administered radiation. Due to the high energy of the cobalt g-ray, deep-seated tumors could be safely treated, a distinct advantage over the low-energy x-ray generators of the time. Cobalt machines became the dominant form of external radiation treatment in the 1960s and continue to play a role in radiation therapy today.

However, the cobalt machine has largely been replaced by a synthetic x-ray generating device, the linear accelerator. From the initial discovery of the x-ray, production of these rays has involved accelerating an electron to high speed and allowing it to strike a target. There it is rapidly stopped and its kinetic energy is rapidly dissipated, mostly as heat but partially as the waveform we call an x-ray. Linear accelerators produce very high-energy x-rays but are small enough to be housed in a limited space ([Fig. 253.1](#)).

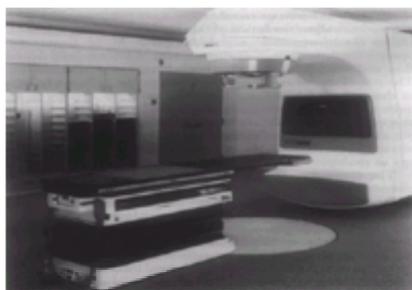

FIGURE 253.1. A modern linear accelerator. The patient lies on the rigid couch and the beam is directed precisely to treat the region of interest. The machine is capable of rotating 360 degrees around the patient so that treatment can be delivered from numerous cross-firing directions. (Photo courtesy of Varian Associates.)

A cobalt machine produces a g-ray of about 1.25 MeV (1 eV is the energy acquired by an electron as it passes from a negatively charged to a positively charged plate across a potential of 1 V). Low-energy linear accelerators produce x-rays in the range of 4 to 6 MeV, and high-energy accelerators produce 10- to 25-MeV x-rays. Other advantages that linear accelerators have over the older cobalt machines include the following:

1. The edges of the beam are much sharper than in a cobalt machine. This allows improved treatment precision, which is especially important when tumors lie very close to sensitive structures.
2. The target of a linear accelerator can be removed and the energetic electrons can be allowed to emerge from the machine directly. These charged particles can be used very effectively to treat superficial tumors, where a deeply penetrating beam is not necessary or desirable.
3. The amount of radiation emerging from the machine per unit of time can be varied, and extremely high dose rates can be produced. This allows effective treatment of large fields, such as those required for total body irradiation as part of bone marrow transplantation, where the patient must be a substantial distance from the machine to achieve the field size necessary. The dose rate of a cobalt machine is determined by the rate of nuclear decay of cobalt 60 (a fixed rate) and the physical amount of cobalt in the machine; there is no practical way to vary this dose rate.

For radiation to be useful in medical treatment, it must be measurable so that known amounts of radiation can be delivered from day to day, and so that one treatment center can communicate its treatment schema with another. The first unit of radiation measurement was the roentgen, abbreviated as "r." This was a unit of radiation exposure and was measured by quantifying the amount of ionization in the air produced by the radiation. The roentgen was a useful measurement unit several decades ago, but it had several major defects. It did not measure what was absorbed in the patient's tissues, only the amount of radiation present in the environment of the patient. For technical reasons, the roentgen can be measured only for relatively low energies, up to about 3 MeV. With the advent of high-energy linear accelerators, the roentgen became impractical. Finally, the roentgen is defined only for x-rays, not for particle irradiation. With the advent of electron beams and, later, many other particulate forms of radiation such as protons and neutrons, the roentgen could not be used.

In the early 1960s, a new unit that actually reflected the amount of radiation absorbed by tissue (the radiation absorbed dose) was defined and became known by its acronym, "rad." More recently, the rad has been replaced by the gray (named in honor of L. H. Gray, a British radiation biologist), which represents 100 rads. More commonly today, rads are converted to centigrays (cGy). A former prescription of 6,000 rad would now be written as 6,000 cGy, or 60 Gy.

BIOLOGIC BASIS OF RADIATION THERAPY

X-rays are ionizing radiation; that is, they interact with atoms by striking an orbital electron and displacing it from the atom. The resulting atom lacks an electron for a short time and has thus been ionized. When radiation strikes biologic material, ionizations can occur anywhere within the cell, but it appears that the ionization and subsequent damage of DNA is the event that produces the biologic consequences of radiation that lead to cell death. DNA can be damaged directly by having an x-ray interact with atoms inside the DNA molecule itself. However, most of the damage to DNA appears to be indirectly mediated from the ionization of water. When a water molecule is irradiated, several highly reactive species, such as oxygen radicals, hydroxyl radicals, and aqueous electrons, are formed; these short-lived, highly reactive species can interact with the DNA molecule, damaging it.

Although DNA can be damaged in various ways (e.g., DNA/DNA cross-links, DNA-protein cross-links, base damage, single-strand DNA break), circumstantial evidence supports a specific lesion, the DNA double-strand break, as the biologically important lesion. For example, patients with ataxia telangiectasia have a very enhanced sensitivity to radiation and also have a defect in their ability to repair double-strand breaks. Radiation precisely near the nucleus of a cell results in cell death, whereas radiation to the cytoplasm has relatively little effect. The amount of DNA double-strand breaks appears to correlate very closely with cell lethality.

After DNA is damaged (by radiation or any other DNA-damaging agent, or simply by faulty replication of a DNA strand), repair enzymes in the nucleus repair the damage. Cells can efficiently, if not always faithfully, repair radiation damage. The rejoining of single-strand and double-strand breaks in DNA can be measured and appears to have a half-life of about 6 hours. If the cell has not sustained too much damage, and if the damage is repaired with acceptable fidelity, an irradiated cell can go on to function and divide, with relatively few effects from the radiation exposure. However, if the radiation damage is great and the repair is not sufficient to allow the cell to function normally, the cell generally dies. This cell death does not occur immediately but rather after one or more cell divisions (mitotic death); however, some cells die before mitosis, secondary to radiation-triggered apoptosis or programmed cell death. This latter form of radiation-induced cell death is gaining increasing attention: as the factors that influence the cells to die an apoptotic death are elucidated, experimental techniques to manipulate these factors to enhance cell death in target tissue and reduce cell death in normal structures will be applied.

When a dose of radiation is administered, both normal and malignant tissues are affected. There are few data to suggest that malignant tissue is preferentially more sensitive to radiation damage than normal tissue. The fact that radiation works to eradicate malignant populations while leaving normal tissues without permanent damage is well known but poorly understood. There may be subtle differences in the efficiency of radiation repair between normal and malignant cells that would be difficult to measure in the laboratory but clinically important over 25 or 30 daily treatment sessions. Clinically and experimentally, there are differences in radiation sensitivity among different types of malignancies. For example, melanoma and glioma cell lines appear to be much more radiation-tolerant than cell lines derived from breast or cervical cancers. The reasons for these differences are under intense radiobiologic investigation. Unraveling the factors that account for radiation resistance or sensitivity would open new avenues to improve the therapeutic gains from radiation. On the basis of our clinical experience, we have classified some tumors as relatively radiation-sensitive and others as much more difficult to cure with radiation ([Table 253.1](#)).

Sensitivity	Tumor Type
Very high	Lymphomas
	Small-cell cancers
	Seminoma
	Neuroblastoma
	Retinoblastoma
Medium	Head and neck cancer
	Breast cancer
	Lung cancer
	Gastrointestinal malignancy
	Gynecologic malignancy
	Prostate cancer
	Glioblastoma
Low	Sarcoma
	Renal cell cancer
	Melanoma

TABLE 253.1. RELATIVE SENSITIVITY OF CANCERS TO RADIATION TREATMENT

Along with histology, several other factors influence the effect of radiation on malignant cells. Tumor size is one of the most important factors. Microscopic disease, such as might be left behind in a surgical bed after gross total removal of a malignancy, can be controlled in 80% to 90% of cases with modest doses of radiation, typically 5,000 to 6,000 cGy. Small primary tumors can often be controlled with 6,500 to 7,000 cGy of radiation, whereas larger primary tumors are more difficult to control with doses in the 7,000-cGy region. For example, 80% to 90% of small lesions involving the true vocal cord can be cured with radiation, whereas large laryngeal cancers have only a 40% rate of local control with radiation. After wide excision of a soft-tissue sarcoma, local control can be obtained in 80% to 90% of patients with 6,000 cGy of radiation, but treating a bulky sarcoma of the same histology rarely produces local control. Thus, when possible, radiation treatment should be used with the smallest number of residual malignant cells. This can be done after surgical excision and more often is being done in combination with the cytotoxic effects of chemotherapy.

There are important effects on all normal tissues subjected to radiation exposure. Radiation effects are divided into acute effects (those occurring within 1 to 3 months after treatment) and late effects (which occur thereafter). In general, early effects are the direct result of parenchymal cell damage (e.g., loss of intestinal crypt cells in the small bowel, damage to type II pneumocytes in the lung); late effects are due to a combination of damage to parenchymal cells and longer term damage to the microvasculature, leading to late cell death and fibrosis.

Several important clinical observations can be explained by these facts. The first concerns the time course of clinical radiation effects. Because most cells die a mitotic death and many radiation effects are due to direct parenchymal cell damage, the speed at which tissues manifest clinical radiation damage should be in direct proportion to their rate of cell turnover; in fact, this is the case. Rapidly dividing tissues, such as the small intestine, oral mucosa, and skin, show clinical radiation effects 2 to 3 weeks after the beginning of a course of radiation. Slowly dividing tissues, such as bone or brain, exhibit few if any acute effects and manifest their radiation damage months to years after a radiation exposure.

Another important clinical correlate is the potential dissociation between acute and late effects. Because parenchymal cell damage dominates the acute effects and vascular damage is a key component of late effects, there may be little correlation between early and late damage. Thus, a patient who has a very easy time getting through the treatment course may end up with severe radiation damage later, whereas a patient who has a very difficult time with acute symptoms may heal those injuries and never manifest further toxicity. The acute radiation effects to organs are listed in [Table 253.2](#), and the long-term radiation tolerance of normal tissues is summarized in [Table 253.3](#).

Site	Symptom	Typical Onset ^a
Bladder	Dysuria frequency	2-4 wk
Bone marrow	Various cytopenias predominantly thrombocytopenia and leukopenia	1-3 wk
Esophagus	Dysphagia	2-3 wk
Heart	Acute pericarditis	3-6 mo
Liver	Radiation hepatitis	3-6 mo
Lung	Radiation pneumonitis	3-6 mo
Oral mucosa	Mucositis	2-3 wk
Rectum	Tenesmus	2-4 wk
Skin	Erythema-desquamation	2-4 wk
Small intestine and stomach	Diarrhea	2-3 wk
Systemic effects	Nausea, vomiting	Hours/days
	Fatigue, lethargy	2-4 wk

^a Effects are volume dependent; the greater the volume of an organ treated, the greater the chance that symptoms will be seen.
^b After start of radiation.

TABLE 253.2. ACUTE EFFECTS OF RADIATION^a

Organ	Dose-Limiting Toxicity	Radiation Dose (cGy)
Bladder	Contracture	6,500
Brain	Necrosis	4,000
Eye	Cataract	1,000
	Retinal injury	5,000
Esophagus	Stricture	6,000-6,500
Heart	Peri pericarditis	4,500
Kidney	Nephritis	2,000
Liver	Hepatitis	3,000
Lung	Pneumonitis	2,000 (one lung)
Ovary	Menopause	500-1,000
Pituitary	Hypopituitarism	4,500
Rectum	Bleeding	4,500
Salivary gland	Xerostomia	3,000-4,000
Skin	Necrosis	6,000-6,500 (10 × 10 cm)
Stomach	Bleeding/ulceration	5,000
Spinal cord	Paralysis	5,000 (5-cm segment)
Testes	Azoospermia	200-400
Thyroid	Hypothyroidism	4,500

^a Approximately 5% chance of complication; treatment at 200-cGy/d dose.

TABLE 253.3. TOLERANCE OF NORMAL TISSUES TO RADIATION^a (TREATMENT OF ENTIRE ORGAN)

It would be ideal to manipulate the sensitivity of malignant and normal tissue to enhance the therapeutic benefit of radiation. Thus, over the past two decades, physical or chemical agents that purport to have radiation-sensitizing or protecting properties have been tested. Among these are radiation-sensitizing agents such as hypoxic cell sensitizers, DNA incorporation agents, and hyperthermia; the protective agent ethiofos has also been the subject of clinical trials. In general, these agents work extremely well in the laboratory, and the biologic basis for classifying them as radiation-sensitizing or protecting agents is incontrovertible. However, it has been extremely difficult to show that these agents improve the clinical outcome of a course of radiation. It is unknown as to whether the type of resistance or sensitivity that these cells overcome is not terribly important in the clinical environment, or whether these agents simply have not been applied in the proper dose or scheduling sequence with radiation. Much clinical research continues using these compounds, and further results can be expected in the next few years.

The cytotoxic chemotherapeutic agents have been successfully used to modify a course of radiation. Many of the commonly used drugs, especially cisplatin, 5-fluorouracil, and gemcitabine, are clearly radiation sensitizers in the laboratory, and when applied along with radiation, the curability of various neoplasms has been enhanced. For example, radiation plus chemotherapy is much more effective in the curative treatment of esophageal carcinoma than radiation alone. Bladder cancers can be controlled more often with combined chemotherapy and radiation than with radiation alone. Anal carcinoma has effectively been cured with combinations of chemotherapy and radiation without the need for abdominoperineal resection. In randomized clinical trials, unresectable lung cancer and advanced cervical cancer have been more effectively treated with combined chemotherapy and radiation than with radiation alone.

The reason for the enhanced effectiveness of combined chemotherapy and radiation remains speculative. It could be simply a case of additive cell killing, with radiation destroying some of the cells and chemotherapy destroying others. There could be some measure of radiation sensitization involved; in other words, the chemotherapy could enhance the cytotoxicity of the radiation. Whatever the mechanism, it is increasingly common for radiation therapy to be combined with chemotherapy in the curative treatment of malignant disease.

CLINICAL APPLICATION OF RADIATION THERAPY

Radiation treatment for malignant disease begins with treatment planning. Once the decision to treat with radiation therapy is made, the patient usually begins the treatment planning process on a machine called a simulator. This machine has the exact geometry of a high-energy linear accelerator but produces diagnostic intensity x-rays and usually has fluoroscopy capabilities as well. The patient is positioned on the simulator table and the area that requires radiation is aligned in a simulated radiation field. One can then confirm immediately by fluoroscopy and ultimately by simulator x-rays that the intended target region is within the radiation volume. Once the films of the treatment fields are taken, the radiation oncologist can further shape the field by indicating which areas of normal tissue should be further protected; these marks are then translated into custom-shaped lead blocks that can create the desired radiation aperture. Once the patient is on the treatment machine, films are exposed before the radiation treatment with the field-shaping blocks in place. This allows direct confirmation that the intended radiation plan is being delivered on the linear accelerator with appropriate precision ([Fig. 253.2](#)).

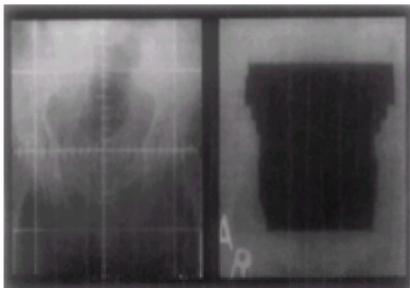

FIGURE 253.2. A simulation and port film for the treatment of a pelvic malignancy. The simulator film (*left*) shows the bony anatomy in detail. The small hash marks are a 1-cm scale. The hash marks cross at the center of the radiation field. The port film (*right*) shows less bony detail because it is taken with high-energy photons while the patient is on the linear accelerator table. However, the location of the field center (*dots*) and the field borders can be seen easily. The two films can be compared to ensure that the treatment is being carried out as desired.

More sophisticated treatment planning is done with the aid of computed tomography (CT) and three-dimensional reconstruction of the patient's anatomy. The process once again begins on the simulator, and the region to be treated is again marked out. The patient is then taken to the CT scanner, where multiple cross-sectional images are taken from several centimeters above to several centimeters below the intended region of treatment. These CT scans are then loaded into the treatment planning computer, and various normal tissues (e.g., external skin, lung, spinal cord, kidneys, liver) are outlined on a slice-by-slice basis. The area to be targeted with radiation is also indicated on each slice. Using relatively straightforward graphics techniques, three-dimensional renderings of the anatomical structures stacked one on another can be quickly made and viewed from any angle ([Fig. 253.3](#)). While the patient is comfortably at home, the appropriate beams can be placed onto the patient's anatomy and numerous combinations of fields can be tried until the appropriate plan has been created. In some respects, this is a simulation based on computer data rather than directly on the patient, and some have called it "virtual simulation." The fields to be treated are then verified on the simulator, and the accuracy of delivery is confirmed with films taken on the linear accelerator itself.

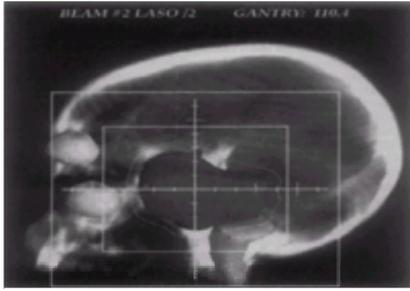

FIGURE 253.3. Computed tomographic scan information can be reformatted into useful three-dimensional images. In this case, a brain tumor is visualized lying directly superior to the brain stem. The eyes are on the left side of the figure. The target volume is represented by the large structure in the center of the cross-hairs. A shielding block has been drawn around the target to help protect the eyes and the brain stem from excessive radiation while exposing the target to full dose.

A typical course of radiation lasts 5 to 7 weeks, with treatment given daily, Monday through Friday. This fractionation of daily treatment is designed so that the normal tissues within the radiated volume can repair from one day to the next, allowing high doses of radiation to be safely administered with as few complications as possible. In some sites, especially in the head and neck, hyperfractionation (two fractions per day, ten fractions per week) has been used to spare normal tissue further, to allow higher doses of radiation to be given, and to shorten the overall time of treatment in some cases.

Radiation is used in the clinical treatment of virtually every type of tumor in the body. [Table 253.4](#) summarizes the common types of malignancy treated with radiation.

Treatment	Malignancy
Definitive radiation	Hodgkin's, early-stage non-Hodgkin's lymphoma, gliomas, cervix, head and neck, lung, bladder, anal, esophagus, prostate, pancreas, skin, pituitary
Radiation follows organ-sparing (conservative) surgery	Breast, sarcoma, rectum
Radiation may follow radical surgery (to improve local control in selected cases)	Breast, rectum, lung, head and neck, endometrium, most margin-positive resections at many tumor sites (e.g., cervix, low-grade OIG tumors)
Palliation	All tumor types

TABLE 253.4. CLINICAL USES OF RADIATION IN CANCER MANAGEMENT

SUMMARY

Radiation therapy plays a major role in the management of most malignant tumors. New insights into the biology and physics of radiation are making treatment more effective and less toxic, and hold promise for further advances. Used alone or in combination with local surgery or chemotherapy, radiation has allowed more patients to survive their malignancy without the need for radical surgery and the removal of important structures. Progress in the use of combined-modality therapy in oncologic treatment can be anticipated.

[Mechanisms of Drug Resistance](#)
[Chemotherapeutics](#)
[Principles of Combination Chemotherapy](#)
[Principles of Hormonal Therapy](#)
[Future Advances in Cancer Therapeutics](#)

Although it has been recognized as a disease entity for almost 200 years, cancer was not appreciated as a systemic illness until the last century, when careful pathologic examination of patients who had died of the disease disclosed the locally invasive and ultimately metastatic potential of a once-localized process. From this knowledge, surgical strategies evolved that attempted to encompass primary disease and regional lymph nodes, which were recognized as the initial site of spread. Radical surgery for colon, breast, genitourinary tumors, and soft-tissue tumors proved successful in establishing local control in most patients and cure in a smaller percentage of patients. Radiation therapy proved able to add to the cure rate for lymphomas and tumors of the head and neck and uterus. By the 1960s, about one-third of cancer patients could be rendered free of disease by these local treatment modalities. However, for the remaining two-thirds of patients with cancer, local therapies were unable to prevent or cure metastatic disease, and not until the first testing of chemotherapy in lymphomas at Yale in 1944 and in human leukemia at Harvard in 1948 did a truly systemic approach to cancer become a reality. Treatment for cancer was changed forever by these early experiments with drugs, as clinicians readily appreciated the logic of seeking systemic therapy for what is in most patients a disseminated process. At present, with these advances in treatment and with earlier diagnosis, 60% of newly diagnosed cancer patients live at least 5 years after initial disease recognition, mortality is decreasing for most solid tumors, and many more patients are cured.

This chapter describes the general process by which oncologists, including surgeons, radiation therapists, and medical oncologists, develop a treatment plan for the cancer patient. It considers in greater detail the role of drugs in cancer treatment. The reader should consult more specialized texts for an in-depth discussion of the pharmacology of cancer drugs and specific regimens used.

INITIAL EVALUATION OF THE PATIENT WITH CANCER

The optimum care of the patient with cancer requires a multidisciplinary approach, including physicians of multiple specialties as well as nurses and social workers. This team approach helps ensure the close coordination of evaluation and treatment among the pertinent specialties of surgery, radiation therapy, and medical oncology and also aims to minimize treatment-related morbidity and the physical and emotional pain and suffering associated with malignancy.

The initial evaluation must be comprehensive, logical, expeditious, and ideally cost-effective. Obviously, development of a specific evaluation plan requires in-depth knowledge of the malignancy under consideration, in particular its typical presentation and patterns of dissemination. Nevertheless, general principles are applicable to all patients under evaluation and are reviewed in [Table 254.1](#). Once in progress, evaluations should be thorough but rapid, because they often generate considerable anxiety for the patient and family, who want to know the extent of disease and the chances for cure, and anxiously anticipate the initiation of treatment.

Unambiguous tissue diagnosis
Appropriate staging studies
Complete evaluation for significant comorbid diseases
Social and psychological history
Assessment of performance status
Design of appropriate treatment
Assessment of eligibility for clinical trial
Rehabilitation
Pain management, psychosocial support, end-of-life care

TABLE 254.1. EVALUATION OF THE PATIENT WITH A SUSPECTED MALIGNANCY

The most important initial step is to establish an unambiguous tissue diagnosis. Essentially, every organ of the body may give rise to either benign or malignant tumors, and the treatment and prognosis of these tumors vary dramatically. Even patients with clinical findings suggestive of metastatic disease should have appropriate biopsies to establish the primary diagnosis and confirm suspicions of dissemination. Diseases such as sarcoidosis, histiocytosis, amyloid, multifocal osteomyelitis, neurofibromatosis, mononucleosis, vitamin deficiency, osteomalacia, Paget's disease, tuberculosis, and many others can mimic the presentation of metastatic malignant diseases.

Advances in minimally invasive techniques, including fine-needle aspiration, core biopsy, endoscope-guided biopsy, CT-guided stereotactic biopsy, laparoscopy, and thoracoscopy are available to diagnose and often stage most epithelial malignancies and can be performed safely and without significant risk of tumor dissemination. In some organs, such as the kidney and testis, most solid tumors are malignant, and tumor contamination through the biopsy site is a real concern. In these situations, primary surgical excision of the affected organ may be part of the appropriate initial evaluation. Patients with suspected lymphoma should have lymph node excision for a more complete histologic evaluation, including detailed evaluation of the pattern of lymph node replacement. Patients with suspected sarcomas of either soft tissue or bone should have biopsy sites carefully planned in conjunction with a surgeon so as not to cross and contaminate future resection planes.

Once tissue is available, standard histologic techniques usually generate an unambiguous diagnosis. Inability to make a diagnosis may result from tissue sampling errors, excessive tissue necrosis, crush artifact, or the presence of inflammatory cells with only rare malignant cells. In these cases, re-biopsy is indicated. Ideally, a second biopsy may collect a larger specimen or a specimen from a second lesion or may sample a more peripheral site in the primary tumor, where there is often less necrosis. Alternatively, some tumors are so poorly differentiated that identifiable histologic structures do not allow classification of the site or cell of origin. The differential diagnosis for these tumors often includes poorly differentiated carcinoma, lymphoma, melanoma, germ cell tumors, and rarely sarcoma. Because the drug sensitivities and potential curability of these various tumors are different, further evaluation should be undertaken. In these cases, immunohistochemistry, electron microscopy, tumor cytogenetics, serum tumor markers (such as human chorionic gonadotropin [HCG] or α -fetoprotein [AFP]), or molecular analysis of tumor DNA or RNA often allows unambiguous classification ([Chapter 249](#), [Chapter 250](#) and [Chapter 251](#)).

Typically, tumor staging (TNM staging) is undertaken after the initial tumor biopsy. Staging of the neoplasm serves three important functions. First, it identifies the local and regional extension of tumor as well as the presence or absence of distant metastatic disease. Treatment plans for most cancers are based on clinical stage, which is determined by the size and local extension of the primary tumor, the involvement of regional lymph nodes, and the presence of distant metastasis. Second, staging often provides critical prognostic information for both the clinical care team and the patient. An understanding of the overall risk of disease progression and the impact of specific therapy provides information for clinical decision making by the physician and patient. Finally, staging is important in clinical research, because it allows accurate comparison of the outcome of different treatment modalities.

Appropriate staging requires knowledge of typical patterns of spread for a particular malignancy. In general, most carcinomas can spread hematogenously to organs such as bone, brain, liver, and lung as well as to regional lymph nodes via lymphatics. In contrast, some lymphomas (particularly Hodgkin's disease) often remain confined to lymphatic tissue, whereas others have a predilection for bone marrow spread (follicular lymphomas) and for organ invasion (large-cell lymphomas).

It is not mandatory or appropriate to perform whole-body radiologic evaluation in all patients with cancer. Techniques such as screening mammography and serum prostate-specific antigen have allowed early diagnosis of breast cancer and prostate cancer. Very few of these patients with small-volume primary carcinomas have evidence of metastatic disease. In breast cancer patients, assessment of regional lymph node involvement by surgical sampling is usually indicated, as is a chest x-ray and bone scan. But extensive evaluation for more distant disease by CT scans, bone marrow biopsies, or other invasive procedures is usually not rewarding when no symptoms are present. Alternatively, when very aggressive local therapies are considered, such as pelvic exenteration, pancreatoduodenectomy, partial hepatectomy, or extremity amputation, the presence of distant disease outside the operative field must be carefully excluded, because this finding may nullify the benefit of radical surgery.

After the histology and staging have been completed, a specific treatment plan should be established. Developing a treatment plan requires a careful review of the patient's medical history and current non-neoplastic illness. Significant cardiac, renal, pulmonary, neurologic, or hepatic dysfunction may absolutely preclude certain types of chemotherapy or immunotherapy, may predispose to toxicity, or may necessitate dose reductions. For example, patients with ventricular dysfunction are poor candidates for treatment with anthracyclines such as doxorubicin, daunorubicin, idarubicin, or mitoxantrone. Patients with renal dysfunction should not receive full doses of nephrotoxic chemotherapy drugs, such as cisplatin, or drugs that require extensive renal excretion, such as methotrexate. Patients with pulmonary dysfunction should not be treated with bleomycin because of the possibility of enhanced pulmonary damage. Neurologic impairment, particularly significant peripheral neuropathies, can be exacerbated by treatment with paclitaxel, vinca alkaloids (e.g., vincristine, navelbine), or cisplatin.

All patients with malignancy should have a careful evaluation of areas of pain, discomfort, and decreased mobility. Such symptoms may herald threatened fracture, skeletal instability, spinal cord compression, or visceral organ compromise. Early diagnosis of these complications may permit local therapeutic intervention that will minimize future complications and maximize symptom control. Multiple techniques and medications are available to improve and often control pain from advanced malignancy ([Chapter 260](#)).

A patient's performance status is also important in the appropriate planning of cancer therapy and correlates directly with tolerance to therapy and outcome. Assessment of performance status is based on the patient's level of function and absence of symptoms. Patients who can care for their daily needs independently, have few or no symptoms, and carry on normal work and home activity are considered to have normal performance status. Patients who cannot care for themselves, have significant symptoms related to their malignancy, or spend part of the day in bed owing to fatigue, pain, or inanition have a poorer performance status, less tolerance for surgery, irradiation, or drugs, and a poorer prognosis. Several standardized but somewhat subjective scales of performance status are available ([Table 254.2](#)). More objective criteria such as the serum albumin level may be a better measure of prognosis.

Functional Capability	Level of Activity
Able to carry on normal activity, no special care needed	100%—normal, no complaints, no evidence of disease 90%—able to carry on normal activity; minor signs or symptoms of disease 80%—normal activity with effort; some signs or symptoms of disease 70%—needs for self-care in carrying on normal activity or to do active work 60%—requires occasional assistance but is able to care for most of own needs 50%—requires considerable assistance and frequent medical care 40%—disabled, requires special medical care and assistance 30%—severely disabled; hospitalization indicated, although death not imminent 20%—nearly all hospital care; remaining active requires treatment intensive 10%—nearly total person progressing rapidly 0%—dead
EASTERN COOPERATIVE ONCOLOGY GROUP PERFORMANCE STATUS SCALE	
Grade	Level of Activity
0	Fully active, able to carry on all professional/business/academic/social (as usual) (100%)
1	Restricted in physically strenuous activity but ambulatory and able to carry out work of a light or sedentary nature, e.g., light housework, office work (80%)
2	Ambulatory and capable of all self-care but unable to carry out work activities; up and about more than 50% of waking hours (50-80%)
3	Capable of only limited self-care; confined to bed or chair more than 50% of waking hours (30-50%)
4	Completely disabled; cannot carry on any self-care; confined to bed or chair (10-20%)

TABLE 254.2. KARNOFSKY PERFORMANCE STATUS SCALE

Some cancer therapies are complex, requiring significant cooperation and participation by patients, and can be challenging or impossible in the mentally or physically impaired patient. Equally important is the patient's social and psychological background. Cancer therapy can be associated with significant morbidity, symptoms that can provoke anxiety and fear of loss of control. Patients with extensive social support systems generally cope better with the morbidity and fatigue associated with cancer therapy. Other patients can benefit from referral for psychosocial evaluation and support by professional staff.

Finally, cancer care can be very expensive, especially with some of the dose-intensive chemotherapy protocols in use, and financial costs should be considered, particularly when the chance of benefit is minimal.

GENERAL THERAPEUTIC APPROACHES

After the diagnosis of cancer has been established and the staging completed, a specific plan of treatment must be established. The plan for a patient with newly diagnosed cancer usually requires the participation of more than a single specialist, in that both local control and systemic therapy must be addressed. In recent years, there has been increasing evidence for the early, up-front use of sequences or combinations of surgery, chemotherapy, and radiation to improve local disease control and to prevent distant recurrence, even in patients with apparently localized disease. The details of optimal sequence and optimal combination differ with each type and stage of cancer, but intelligent decision making requires participation of all three specialties in the planning stage. A number of factors influence the components of the plan of treatment. The most obvious of these is the stage, which is usually based on the size and extent of local, regional, and distant spread of the tumor. However, stage is not the only determinant of therapy. The histopathologic and molecular features of the tumor may provide information on likelihood of systemic spread and responsiveness to specific forms of therapy. Thus, apparently localized breast cancers that display lymphatic or blood vessel invasion, that lack hormone receptors, or that carry an amplified *HER2/neu* oncogene have a greater propensity for systemic spread and require aggressive adjuvant chemotherapy, usually with an anthracycline-containing regimen. In contrast, an elderly patient with a small tumor that is positive for estrogen receptor may best be treated with surgical excision and the estrogen antagonist, tamoxifen. Other tumors, such as well-differentiated prostate cancers may require only local therapy or, in older patients, observation, in that they have a minimal tendency to spread to distant sites and may not affect the patient's expected life span. For some malignancies, systemic therapy is required, regardless of stage, because of their aggressive pattern of growth and dissemination. These include large-cell lymphomas, small-cell lung cancers, and most cases of ovarian cancer.

When distant spread is detected, the treatment plan may have to accommodate special measures to prevent disability and restore function. Thus, brain metastases or spinal cord compression demand immediate treatment, and skeletal metastases that threaten to lead to fracture also require aggressive local therapy, usually radiation and possibly fixation. Superior vena cava obstruction by lymphoma or small-cell carcinoma may require immediate irradiation, with concomitant chemotherapy. Endobronchial, biliary, or ureteral obstruction similarly require restoration of flow, either through stenting, irradiation, or diversion by surgical intervention. Only in the case of a highly drug-responsive tumor such as a non-Hodgkin's lymphoma will drug therapy alone relieve obstruction in most cases.

Cancer treatments should be designed to accomplish specific goals beneficial to the patient. Optimally, therapy should be directed at the complete eradication of tumor cells both at the primary site, including the contiguous regional structures, and at systemic sites. Treatments should maximize effectiveness while minimizing morbidity, including disfigurement, pain, loss of function, and short- and long-term toxicity associated with the therapy. Local control is often best achieved through either complete surgical resection of the local (primary) tumor or a combination of surgery and irradiation. Very small breast cancers are often cured with lumpectomy alone, whereas larger tumors are often more difficult to resect completely, have a higher chance for microscopic dissemination, and require lumpectomy and chest wall irradiation. Such patients also have a higher risk of progressive metastatic disease. Locally advanced tumors not amenable to initial surgical resection may be resectable after radiation therapy, chemotherapy, or both. Such combined-modality approaches are often used in large locally advanced malignancies, such as cancers of the breast, lung, head and neck, rectum, esophagus, and bladder. Reducing the size of the primary tumor through the initial use of chemotherapy and radiation therapy shows promise of allowing preservation of the larynx, bladder, and anus in patients who formerly might have been treated by organ removal.

Adjuvant chemotherapy after a definitive local procedure reduces the burden of occult metastatic disease and thereby minimizes the risk of recurrence. The actual mechanisms whereby adjuvant therapy increases the cure rate of breast and colon cancer tumors is still uncertain. Reducing the amount of microscopic metastatic disease may permit normal host defenses to eradicate the residual disease. Even when complete eradication of the microscopic disease is not feasible, reducing the burden of microscopic metastatic disease may significantly prolong the period of time that the patient is clinically asymptomatic and may extend overall survival. Over

the last several decades, randomized, controlled studies of adjuvant chemotherapy have demonstrated prolongation of survival in patients with apparently localized cancer of the breast, colon, or rectum. Adjuvant therapy also has a role in a number of solid tumors in children and young adults, including Ewing's sarcoma, Wilms' tumor, osteosarcoma, and neuroblastoma.

In patients with metastatic disease, local control remains an important goal, particularly if the primary tumor causes significant morbidity or loss of function (e.g., pain, obstruction). Even if curative therapy is unavailable, palliation is appropriate if the therapy prolongs survival, reduces pain or suffering, or delays a catastrophic complication of advancing malignancy (e.g., spinal cord compression, tracheoesophageal fistula, bowel obstruction).

Once a realistic goal is selected, the cancer care team must select the modalities most likely to achieve the desired outcome. When cure is impossible, the physician must weigh the likely benefit of therapy against its anticipated toxicity. For instance, very aggressive and toxic therapies may not be appropriate unless these measures are likely to provide symptomatic relief and alter the progression of disease in a positive manner.

Patients should be given the appropriate information to allow them to make an informed decision regarding their treatment options. This discussion should include information on prognosis and the benefits and toxicity associated with the recommended therapy. If other reasonable treatments are available, these should be discussed, too.

Special attention should be given to participation in clinical trials. Patients participating in studies designed to compare the relative efficacy of two therapies (phase III trials), the efficacy of new therapy (phase II trial), or the toxicity and efficacy of a new drug or biologic agent (phase I trial) should have a clear understanding of the purpose of the trial and the anticipated benefit and potential hazards of the proposed treatment.

PRINCIPLES OF CANCER CHEMOTHERAPY

Fundamental to the treatment of cancer is the understanding that qualitative and quantitative changes in the regulation of tumor growth cause malignancy. These changes occur as the result of genetic changes either inherited or resulting from environmental exposures, viruses, or more rarely chronic inflammation. Genetic damage may cause a loss of cell-cycle controls (*p53* mutation), a decreased ability to repair DNA damage (*BRCA-1* mutation), or a decreased ability to undergo apoptosis or programmed cell death (*bcl-2* activation). Cancer cells are distinguished by their ability for unrestrained growth, invasiveness, and metastasis. Initial attempts to treat cancer have been primarily directed at unrestrained growth and more specifically at the synthesis of DNA. However in recent years the biotechnology industry has targeted its efforts at the various factors that regulate proliferation, including growth factors and their receptors, and signal transduction pathways, as well as properties such as invasiveness, metastasis, and angiogenesis.

Cell growth and division in both normal and malignant cells are accomplished by progression through the cell cycle. Cells in mature organs such as liver, brain, and pancreas spend most of their life cycle in the interphase or resting phase (also termed the G₀ and G₁ portions) of the cell cycle, which precedes DNA synthesis (S phase) and cell division (M phase). The precise signals that initiate cell division differ among different cells types, but both autocrine and paracrine growth factors are believed to initiate the transition from the resting phase into a phase of DNA synthesis and cell division. A cascade of biochemical changes is associated with progression through the cell cycle. These signals for proliferation may include autocrine growth factors, growth factors produced by neighboring cells (paracrine factors such as fibroblast growth factor or interleukins secreted by stromal cells or immune cells), or signals transmitted by cell-to-cell contact (adhesion molecules). Central to this progression is a collection of proteins named cell cycle–dependent kinases and their activators and inhibitors. Specific activators of these kinases, called cyclins, initiate cell movement through critical checkpoints at the G₁/S and G₂/M interface.

The best-known checkpoint is the p53 protein, which monitors the integrity of DNA and directs the process of DNA repair and, if DNA damage is too severe, promotes apoptosis or cell death. In normal cells, DNA synthesis is allowed to proceed only if the genome is intact and undamaged. Proteins that monitor DNA integrity and prevent the replication of damaged cells have been identified, and mutations of proteins such as p53 have been implicated as leading to genetic instability and cancer. Likewise, increased synthesis of cyclins and loss of the CDK4 inhibitor, p16, are common mutations associated with cancer.

Initial attempts to treat cancer have focused on the property of unrestrained proliferation. Through animal tumor screening, drugs capable of selectively killing tumor cells have been identified, although the basis for selectivity is incompletely understood. Drugs targeting DNA synthesis in general prove most effective against rapidly growing tumors, which logically spend more of their time in DNA synthesis. For many of these drugs, tumor cell kill is a function of the concentration of drug in plasma (C) and the duration of that cytotoxic concentration (T). For many DNA-interactive drugs, such as the anthracyclines, etoposide, antimetabolites, and carboplatin, C × T, the integral of the drug concentration versus time curve, correlates well with cytotoxicity, probably because for most cancer drugs the longer a cytotoxic concentration can be maintained, the greater the number of cells exposed to drug during their most vulnerable phase (S phase) of the cell cycle (Fig. 254.1). For others, including taxanes, toxicity is a direct function of duration of exposure above the threshold for cytotoxicity. For alkylating agents, which interact chemically with sites on DNA, drug dose and peak plasma concentration, and not duration of exposure, determine cell kill.

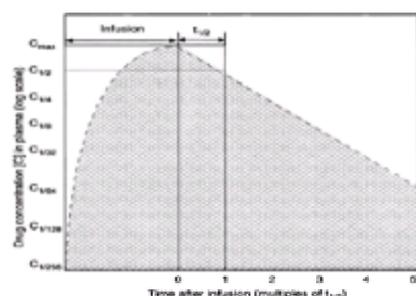

FIGURE 254.1. Hypothetical curve of logarithm of drug concentration versus time, where units of time are equal to the half-time ($t_{1/2}$) for drug disappearance from plasma. Overall drug exposure, often expressed as the area under the C × T curve (AUC), equals the integral or space of the hatched area. C_{max} , the maximum concentration in plasma, is directly related to the infusion rate and inversely related to the $t_{1/2}$ or rate of elimination of drug from plasma.

For drugs that cause DNA breaks or miscoding, cytotoxicity may result from either the initiation of the apoptotic pathway (programmed cell death) or, with more extensive cell damage, necrosis. Laboratory and clinical studies indicate that the presence of a functional p53 checkpoint is critical to the initiation of apoptosis in response to DNA damage due to irradiation, alkylating agents, and antimetabolites. Unfortunately, p53 is deleted or mutated in many human tumors, particularly during their late stages of growth, possibly contributing to treatment failure.

The growth characteristics of solid tumors change during tumor expansion. The most rapid growth occurs when tumors are relatively small and when the blood supply and nutrients are adequate. With further expansion, tumors must stimulate new blood vessel growth and often outgrow their existing blood supply, leading to a slowing of cell growth, tumor hypoxia, and even necrosis. Thus, the tumor cell growth characteristics vary with time and, at any instant in time, vary in different locations. In addition, tumors become increasingly heterogeneous as mutations occur over time; each metastasis, for example, represents a new clone of tumor cells, with altered growth characteristics, potential for survival, and drug sensitivity. Thus, it seems logical to initiate therapy as early as possible in the natural history of tumor development, as in the adjuvant setting to lessen the chance of encountering drug-resistant disease.

MECHANISMS OF DRUG RESISTANCE

The mutability of tumor cells, a central property of cancer, allows for diversity of phenotype and leads to the unique properties of these cells: invasiveness, metastasis, production of autocrine and paracrine growth factors, and the emergence of drug resistance. Indeed, the same biologic features that allow unrestrained growth and inhibit apoptosis—namely, loss of cell cycle checkpoints—also lead to drug resistance. Thus, biologic resistance to drug therapy in many solid tumors and leukemias, is associated with mutation of the *p53* suppressor gene and with the overexpression of *bcl-2*, an antiapoptotic gene translocated in follicular cell lymphomas. In

addition to these biologic resistance factors, other features of the tumor cell environment, such as increased interstitial fluid pressure, hypoxia, and poor perfusion, limit drug access and decrease response.

The high rate of spontaneous mutations also results in genetic changes that alter the specific target proteins against which cancer drugs act, thus providing a survival advantage for a particular tumor cell (Table 254.3). For example, methotrexate inhibits the enzyme dihydrofolate reductase, which is responsible for maintaining intracellular folic acid in its active and fully reduced form. If sensitive tumor cells are incubated with methotrexate over several generations, resistant sublines grow out, which contain alterations in the structure or levels of expression of dihydrofolate reductase. Resistant cells may also arise as the result of mutations that decrease the transmembrane uptake of the drug or its conversion to its long-lived polyglutamate form. Examples of these defects have been found in methotrexate-resistant tumor cells from patients treated with this drug.

Drug	Mechanism of Action	Mechanism of Resistance
Methotrexate (MTX)	Inhibits dihydrofolate reductase (DHFR)	Amplification of DHFR Mutation of DHFR Decreased transport of reduced folates Decreased polyglutamation (PGC)
Cytosine arabinoside 5-Fluorouracil	Inhibits DNA elongation Inhibits thymidylate synthase (TS)	Decreased activation by deoxycytidine kinase Decreased drug activation Increased TS activity
Docetaxel	Inhibits topoisomerase I (Topo I)	Decreased or mutated Topo I Increased export due to <i>mdr</i> or <i>mpr</i> gene products
Topotecan Irinotecan	Inhibits topoisomerase I (Topo I) Promotes polymerization of tubulin	Decreased mutated Topo I Tubulin mutation decreases drug binding Increased repair due to <i>mdr</i> gene product
Cytosine phosphamide	Alkylates DNA	Increased DNA repair of alkylations Decreased apoptosis (p53 mutation)
Cisplatin	Forms covalent adduct with DNA	Increased repair of adduct Inactivation of drug by glutathione Increased apoptosis (p53 mutation)

TABLE 254.3. MECHANISMS OF RESISTANCE TO REPRESENTATIVE ANTICANCER DRUGS

Although the above alterations in methotrexate-resistant tumor cells have no impact on response to other agents, mutations induced by other drugs may confer broad patterns of drug resistance. For example, the multidrug-resistance gene (*mdr-1*) encodes a membrane glycoprotein, p170, which exports complex molecules across the cell membrane and increases resistance to various natural product drugs, including the vinca alkaloids, anthracyclines, and etoposide. Increased p170 expression is characteristic of many epithelial tumors, including lung, kidney, and colon cancers, and is also found in many patients with refractory forms of leukemia or lymphoma. Similar drug-exporting proteins encoded by the *mpr* gene and *bcrp* gene have been identified in human tumors and confer resistance to natural products such as anthracyclines. Patterns of drug cross-resistance and the likelihood of p170 expression in specific tumors are critical factors in selecting new drugs for clinical development and in the design of combination chemotherapy regimens.

CHEMOTHERAPEUTICS

The drugs in use for cancer treatment, except for hormonal agents, have a narrow therapeutic index. The maximally effective conventional doses produce toxicity (primarily to gastrointestinal epithelium and bone marrow but also to other organs) and in some patients produce late toxic effects, such as secondary neoplasia, pulmonary fibrosis, peripheral neuropathy, and infertility. Despite the risks of toxicity, most clinical oncologists believe that the best results are obtained by regimens that use maximally tolerated doses. Results in drug treatment of breast cancer, ovarian cancer, lymphoma, and leukemia all support the notion that more intensive treatment, up to the limits of tolerance of normal tissues, increases the response rates and improves survival. Thus, the drugs should be used in a fashion that produces definite but readily controllable toxicity. In particular, regular monitoring of peripheral blood counts is essential after drug administration to detect periods of severe neutropenia and thrombocytopenia and to allow adjustments of subsequent doses of drug. The discovery of stimulating factors for granulocyte production (granulocyte colony-stimulating factor [G-CSF] and granulocyte-macrophage CSF [GM-CSF]) and more recently for platelet production (thrombopoietin) will undoubtedly allow further dose escalations, earlier recovery of blood counts, and fewer infectious complications and bleeding episodes from high-dose chemotherapy. Whether these products should be used as part of routine treatment has not been proved. Typically, drugs are delivered to maximal antitumor response as determined by physical examination, radiologic evaluation, and tumor marker measurement.

More than 50 chemotherapeutic drugs are currently available for the treatment of patients with malignancies (Table 254.4). Physicians who use these drugs or who care for patients receiving such treatment must know the pharmacology and potential side effects of these toxic agents. However, treatment should not be individualized for each patient; protocol-based therapy is mandatory for the safe use of these drugs. The physician must consider whether the efficient elimination of the drug or drugs will be altered by abnormal renal or hepatic function; whether intercurrent neurologic, cardiac, or pulmonary disease presents special problems in drug tolerance; and whether past exposure to other drugs or radiation might predispose the patient to toxicity. The accompanying tables provide information on the mechanism of drug elimination for commonly used cancer drugs and suggest circumstances in which drug doses need to be altered. In general, doses of paclitaxel, docetaxel, and the vinca alkaloids must be reduced by at least 50% in patients with significant hepatic dysfunction (bilirubin higher than 3 mg per deciliter). Similarly, the doses of methotrexate, hydroxyurea, bleomycin, etoposide, carboplatin, fludarabine, cladribine, and deoxycoformycin should be reduced in proportion to decreases in creatinine clearance. The dose of carboplatin, a drug eliminated by renal excretion, should be calculated for the individual patient based on measurement of creatinine clearance.

TABLE 254.4. PROPERTIES OF ANTICANCER DRUGS

Pharmacokinetic monitoring and dose adjustment is used infrequently in the routine practice of medical oncology, the only common example being the measurement of methotrexate levels 24 to 48 hours after high-dose administration. In this situation, abnormal drug levels in plasma prompt the institution of prolonged rescue with the antidote leucovorin (5-formyltetrahydrofolate).

Even when abnormal renal or hepatic function is taken into account in adjusting drug dosage, significant interindividual variability in drug clearance and tolerance remains among patients. In some cases, genetic defects in drug elimination or activation account for these findings. Examples include the absence of dihydropyrimidine dehydrogenase, the enzyme responsible for degradation of 5-fluorouracil. Persons lacking this enzyme have extreme sensitivity to 5-fluorouracil, even to topically administered drug for treatment of basal cell carcinomas, and may experience fatal toxicity from small doses. Low activity of thiopurine methyltransferase, the enzyme responsible for inactivating 6-mercaptopurine, is also associated with extreme drug toxicity. Both of these defects are found infrequently (less than 1 in 100 patients), but extreme toxic reactions should prompt testing for the mutation in question and caution in continuing drug treatment.

High-dose chemotherapy with rescue by bone marrow or peripheral blood stem cells allows dose escalation and curative responses in patients with leukemia or lymphoma refractory to standard chemotherapy, but introduces a unique set of toxicities. These include profound immunosuppression and opportunistic infection; vascular endothelial damage; severe damage to pulmonary and gastrointestinal epithelium; hepatocellular injury; myocardial necrosis; and secondary leukemia. The

specific pattern of toxicity depends on the agents used, but alkylating agents remain the mainstay of high-dose therapy and are capable of producing any or all of the latter toxicities. In allogeneic marrow transplants, the immune response of the donor lymphocytes to the tumor (graft-versus-leukemia effect, for example) adds further benefit to the therapeutic response, but at the cost of graft-versus-host disease. Because of their linear dose-response relation extending into the high-dose range, alkylating agents are unlikely to be replaced in these regimens, although carboplatin, etoposide, and total body irradiation are often used in combination with the conventional alkylators.

Despite the disadvantages, high-dose chemotherapy with stem cell rescue has proved successful in producing long-term disease-free survival in acute and chronic myelocytic leukemia and other hematologic malignancies. However, the value of high-dose chemotherapy with bone marrow rescue remains unproven in most solid tumors, either for metastatic disease or in the adjuvant setting, and should be undertaken only in the context of a clinical trial.

Cancer drugs can also cause late side effects ([Table 254.4](#)). The risk of secondary leukemias may reach 5% to 10% for regimens that use high doses of DNA-modifying agents, such as alkylating agents, procarbazine, and even certain natural products such as teniposide or etoposide. Often, these cases of leukemia occur 2 to 5 years after drug exposure, and most are refractory to treatment. Equally troublesome are the cardiac toxicity of anthracyclines; the pulmonary fibrosis that follows bleomycin, the nitrosoureas, and other high-dose alkylating agents; and the peripheral neurotoxicity of vincristine, paclitaxel, and cisplatin. Neurotoxicity usually develops within days or weeks of drug administration, but evidence of pulmonary fibrosis or cardiac failure may appear many months after drug treatment. The total dose limits for anthracyclines (550 mg per square meter for doxorubicin) should be respected to avoid cardiac failure.

PRINCIPLES OF COMBINATION CHEMOTHERAPY

In the treatment of malignant disease, as in the treatment of relatively resistant microbial infection, combinations of individually active agents can cure diseases that respond incompletely to single agents. This principle was first demonstrated in the successful treatment of acute lymphoblastic leukemia in children and later in the lymphomas and testicular cancer. With few exceptions, maximum benefit from chemotherapy requires the use of multiple drugs. The selection of the individual components of a regimen, as well as their scheduling and sequencing in combination, is usually based on pharmacologic and toxicologic considerations.

The basic principles of combination chemotherapy are reviewed in [Table 254.5](#). These principles are useful but not rigid guidelines. Thus, although alkylating agents and anthracyclines are strongly myelosuppressive, their potent activity against lymphomas becomes the overriding factor in their common use in combination against Hodgkin's disease and non-Hodgkin's lymphoma. In addition to the general consideration of toxicity and individual activity, drug interaction at the level of pharmacokinetics may lead to problems in regimen design ([Table 254.6](#)). Drugs may have organ toxicity that may affect the elimination of a second agent—for example, the renal toxicity of cisplatin can prolong the plasma half-life of methotrexate or bleomycin. Drug interactions at the biochemical level have guided the construction of many commonly used regimens (e.g., the use of leucovorin to enhance the binding of 5-fluorouracil nucleotide to its target enzyme [thymidylate synthase]). A thorough understanding of the pharmacology of the individual components of such regimens forms the underpinning of safe and effective combination chemotherapy.

Individual drugs should have antitumor activity
 Toxicity of individual drugs should have minimal overlap
 Combination regimens should avoid unfavorable drug interactions
 Each drug should have different mechanism of action
 Each drug should have different mechanism of drug resistance

TABLE 254.5. PRINCIPLES OF COMBINATION CHEMOTHERAPY

Inhibition of Drug Elimination (Altered Pharmacokinetics)
 Allopurinol blocks metabolism of 6-mercaptopurine by xanthine oxidase
 Nonsteroidal analgesics block methotrexate excretion by kidneys
 Cisplatin inhibits taxol metabolism by P-450 in liver

Biochemical Synergy
 Leucovorin (5-formyltetrahydrofolate) enhances binding of 5-fluorouracil monophosphate to its target, thymidylate synthase.
 Methotrexate enhances metabolic activation of 5-fluorouracil and 6-mercaptopurine through effects on phosphoribosylpyrophosphate pools.
 L-asparaginase blocks protein synthesis and cell cycle progression, protects cells against methotrexate toxicity.
 Repair of cisplatin/DNA crosslinks inhibited by antimetabolites (cytosine arabinoside, 5-fluorouracil).
 Sulfhydryl compounds (ethyol) protect kidney and bone marrow from cisplatin toxicity by intracellular inactivation of active platinum species and alkylating agents.

TABLE 254.6. DRUG INTERACTIONS IN CANCER CHEMOTHERAPY

PRINCIPLES OF HORMONAL THERAPY

Many neoplasms of the breast, prostatic, and uterine epithelium require corticosteroid hormones for rapid growth. Synthesis of these steroid hormones, namely estrogens, androgens, and progestins, depends on the action of hypothalamic hormones, such as luteinizing hormone-releasing hormone (LHRH) and pituitary hormones: follicle-stimulating hormone (FSH), luteinizing hormone (LH), and adrenocorticotrophic hormone (ACTH). The latter hormones stimulate end organs such as the ovaries, testes, and adrenals to synthesize the appropriate steroid hormones that enter the circulation and bind to the intracellular receptors in tumor cells ([Fig. 254.2](#)). The ability of these hormones to stimulate growth is due to a complex interaction of these lipid-soluble hormones with their cytoplasmic receptors and the subsequent activation of gene transcription by the hormone-hormone receptor (ligand-receptor) complex. Structure and function studies of both the estrogen and androgen receptor demonstrate that these proteins contain hormone-binding, DNA-binding, and transactivating domains. Binding of the hormone to the receptor leads to a conformational change in the receptor, allowing the receptor-ligand complex to enter the nucleus and bind specific sites on DNA (estrogen- or androgen-responsive elements) through the DNA-binding portion of the receptor. Protein-protein interactions between the transactivating portion of the steroid receptor and other receptor-modulating proteins lead to unique patterns of expression of corticosteroid-dependent genes that determine the specific pattern of response in normal tissues and in tumors.

CHAPTER 255: PRINCIPLES OF BIOLOGIC THERAPY

JOHN W. SMITH II AND WALTER J. URBA

[Nonspecific Immune Stimulants](#)
[Cytokines](#)
[Adoptive Cellular Therapy](#)
[Active Immunization](#)
[Monoclonal Antibodies](#)
[Alteration of Tumor Cell Biology](#)
[Gene Therapy](#)

Biologic therapy for the patient with cancer has changed substantially in recent years. These advances cross conventional treatment boundaries and provide a fourth treatment modality, in addition to surgery, radiation, and chemotherapy, which will increasingly influence the practice of medicine. The goal of biologic therapy is to achieve tumor regression through agents or approaches that modify the relation between tumor and host. Most biologic agents are found naturally in the body and have roles in the normal function of the immune system or another physiologic process. They may act directly on the tumor to inhibit growth, to induce differentiation or death, or to block metastasis. Or, they may act indirectly on the host to augment an immune response or restore the activity of host defense mechanisms inhibited by the tumor itself or damaged by other cancer treatments.

Historically, biologic therapy has been synonymous with immunotherapy, but, despite some overlap, biologic therapy includes many strategies that do not necessarily have an immunologic rationale (e.g., differentiation and apoptosis-inducing agents). Furthermore, an historical classification of biologic approaches to cancer treatment (“active” for agents that stimulate the host, “passive” for agents that act directly against the tumor, and tumor-specific or tumor-nonspecific) has persisted but is inadequate for understanding biologic therapy. Many agents have several actions that defy such categorization. For example, tumor necrosis factor (TNF) has both active, or direct, cytotoxic effects on tumor cells and passive actions. It can kill tumor-associated vascular endothelial cells and activate monocytes that can kill tumor cells. Likewise, interferon can inhibit the growth of tumor cells, induce differentiation, and augment the activity of natural killer (NK) cells, and anti-CD20 antibodies can induce apoptosis or mediate tumor cell killing by complement fixation or antibody-dependent cellular cytotoxicity (ADCC).

Our limited understanding of in vivo tumor biology and tumor–host interactions and our inability to deliver agents to sites of tumors have presented significant barriers to the development of effective biologic therapy. A single cytokine, when isolated from the other mediators of a local inflammatory response and administered systemically at pharmacologic doses, probably does not act as it would as part of the finely orchestrated multicomponent physiologic process. Nevertheless, some significant clinical advances have emerged over the last decade. This chapter reviews the major biologic molecules of current use in clinical oncology.

NONSPECIFIC IMMUNE STIMULANTS

Bacteria and bacterial products are potent activators of the immune system. Some bacteria contain “superantigens,” peptides capable of activating large populations of T cells. Bacteria and their products have been tested for their ability to act as immune “adjuvants” to stimulate the immune system in a nonspecific fashion in the hope that specific antitumor immunity would result. *Bacillus Calmette–Guérin* (BCG) is a strain of *Mycobacterium bovis* that has been used to elicit immune responses to vaccines. BCG has been tested in cancer patients, and the most impressive results have been observed when the inflammatory response was elicited at the site of tumor and the tumor cells were destroyed as bystanders of the inflammation. Direct injection of BCG causes regression of cutaneous melanoma and intravesical delivery is an approved, effective treatment for superficial bladder cancer.

CYTOKINES

Cytokines are polypeptides that control the function, growth, and differentiation of cells. Cytokines act by engaging a specific receptor on the surface of the target cell and transducing signals intracellularly that activate or repress particular genes. Several cytokines are approved for use in humans with cancer, and many more are undergoing clinical development.

INTERFERONS

Interferon- α (IFN- α) and IFN- β are class I interferons that share the same receptor, whereas interferon- γ is a class II interferon that binds to its own receptor and exhibits distinct biologic effects. Although IFN- β and IFN- γ are used in the treatment of multiple sclerosis and chronic granulomatous disease, respectively, neither is used in cancer therapy at this time. Two forms of recombinant IFN- α are available for clinical use: $\alpha 2a$ and $\alpha 2b$. There are no important differences between them. The mechanism of action of IFN- α against tumor cells is unclear. It has the following diverse effects on tumor cells: induction of growth arrest or differentiation, inhibition of protein synthesis, up-regulation of major histocompatibility complex (MHC) class I expression and activation of NK cells. In addition, IFN- α can inhibit ornithine decarboxylase and thus block polyamine synthesis, an action that leads to growth arrest. Most of the clinical activity of interferon appears to be a direct antitumor effect.

IFN- α is active against chronic myelogenous leukemia (CML), cutaneous T-cell lymphoma, functional endocrine tumors, and AIDS-associated Kaposi's sarcoma. In patients with myeloma and follicular B-cell lymphoma, IFN- α appears to prolong the duration of a response to combination chemotherapy, and although active in hairy cell leukemia, it has been supplanted by the nucleoside, 2-chlorodeoxyadenosine, which produces more durable complete responses. IFN- α also induces tumor regression in patients with metastatic renal cell cancer and melanoma and may improve disease-free and overall survival of patients with high-risk melanoma (greater than 4-mm skin lesions or lymph node involvement) when given after surgery.

The dose of IFN- α required for antitumor activity varies (3 to 50 mU), and the usual route of administration is subcutaneous. The responses are usually partial and short-lived if treatment is discontinued, but they can be maintained, at times, for prolonged periods if therapy is continued. Dose-limiting toxicities are fatigue, muscle aches, headache, and anorexia (a flulike syndrome). Nausea, myelosuppression, proteinuria, elevated transaminase levels, and cardiac ischemia and dysrhythmias occur rarely. Resistance to IFN- α can be mediated by neutralizing antibodies. Alternate forms of IFN (e.g., lymphoblastoid IFN, a mixture of type I interferons) can be used to maintain the response. The antibodies are generally short-lived (median 8 months); when they disappear, IFN α can be reinstated with restoration of efficacy.

INTERLEUKIN-2

Interleukin-2 (IL-2), originally named T-cell growth factor, is a 133-amino acid, 15-kD glycoprotein that plays a critical role in the activation and maintenance of an immune response to antigens. It is produced mainly by CD4 T cells after they encounter an immunogenic peptide presented by the human leukocyte antigen (HLA) class II molecule in combination with a second costimulatory signal. IL-2 promotes the proliferation, expansion, and activation to cytotoxicity of T cells, NK cells, and monocytes.

Early studies of recombinant human IL-2 (aldesleukin) also included the administration of peripheral blood leukocytes that had been cultured ex vivo with IL-2 for 3 to 5 days to generate lymphokine-activated killer (LAK) cells. The demonstration of dramatic tumor regressions (including complete regressions) in some patients with renal cell carcinoma and melanoma led to many confirmatory clinical trials. A randomized trial demonstrated that the LAK cells did not add to the benefit of IL-2 administered alone. IL-2 is the best example of a treatment for cancer that works purely by activating the immune system rather than by directly killing tumor cells. IL-2 is usually administered intravenously over 5 days by bolus or continuous infusion, but it can also be given subcutaneously at a much lower dose for a more protracted length of time. IL-2 toxicity is dose-related and can be substantial. In high doses, it induces a cytokine cascade that includes several other biologic mediators, such as IL-1, IFN, TNF, IL-6, and nitric oxide.

The clinical sequelae of IL-2 treatment are similar to that of septic shock except that the severity of symptoms may be controlled by skipping doses or discontinuing treatment. Patients experience chills, rigors, fever, decreased peripheral vascular resistance, hypotension, tachycardia, vascular leak of fluid into the tissues, fluid retention, prerenal azotemia, intrahepatic cholestasis, diarrhea, pruritic rash, and sometimes severe compromise of organ function such as pulmonary edema, cardiac arrhythmias, confusion, hallucinations, or seizures. Fatal complications occurred in up to 4% of patients in early studies, but have declined to less than 1%, because more experience with the agent was gained and patients were screened for underlying heart and lung disease. Despite their severity, most toxicities resolve within 3

to 5 days of discontinuing IL-2. Some IL-2–treated patients develop hypothyroidism, and some with melanoma develop patchy vitiligo, findings that have been reported to correlate with response rates.

The Food and Drug Administration (FDA) has approved IL-2 at high doses for the treatment of metastatic melanoma and renal cell carcinoma with which 15% to 20% of patients experience more than a 50% shrinkage of their tumor. The truly remarkable aspect of IL-2 treatment is that 7% to 8% of patients experience complete responses, 75% of whom continue without additional treatment in follow-up that ranges from 5 to 12 years. Similar response rates, including complete responses in patients with renal cell cancer treated with lower doses of IL-2, have been reported. Because the optimal regimen has not been determined, a variety of IL-2 doses are used in practice. The dose depends on the treating physician and on individual patient characteristics. IL-2 may represent the first curative systemic treatment for patients with metastatic melanoma or renal cell cancer. IL-2 has also been reported to improve remission duration for patients with acute myelogenous leukemia when given after allogeneic bone marrow transplantation and appears to produce sustained rises in the number of circulating CD4 cells in AIDS patients.

COLONY-STIMULATING FACTORS

Hematopoiesis is regulated by a complex network of cell interactions and positive and negative cytokine regulators of cell growth and differentiation. A single hematopoietic stem cell gives rise to all lymphocytes, erythrocytes, and myeloid cells (including granulocytes, eosinophils, basophils, mast cells, monocytes, macrophages, and platelets). Many of the factors that influence hematopoiesis have been cloned, and four (granulocyte colony-stimulating factor [G-CSF], granulocyte-macrophage colony-stimulating factor [GM-CSF], erythropoietin, and IL-11) are approved for clinical use in humans ([Chapter 256](#)).

OTHER CYTOKINES

TNF produced negligible antitumor effects when administered systemically to patients at its maximal tolerated dose, which was limited by toxicity to the cardiovascular system. However, when a tumor-bearing limb is isolated on the heart–lung machine and perfused with TNF, together with interferon, hyperthermia, and melphalan, dramatic antitumor effects have been observed in up to 90% of patients with sarcoma and melanoma.

IL-3, IL-4, IL-6, and IL-7 have been tested clinically for their hematopoietic, immunologic, and antitumor effects, but all have been abandoned because of their lack of efficacy or their toxicity. IL-12 demonstrated impressive antitumor activity in animal models of kidney cancer; however, phase II testing in patients with renal cell carcinoma failed to demonstrate significant responses. Its immunologic effects, the promotion of a Th1 T-cell response that promotes cytotoxic T-cell activity, are being investigated in many trials in which IL-12 is the adjuvant for a vaccine against an infectious disease or cancer.

ADOPTIVE CELLULAR THERAPY

Several different approaches have been used to activate cells *ex vivo* and administer them to cancer patients. LAK cell and IL-2 therapy was mentioned earlier. Macrophages cultured *ex vivo* with IFN- γ or lipopolysaccharide have also been used. Various routes of delivery have been used for both cell types: intravenous, intraperitoneal, intrapleural, and intra-arterial. Although occasional tumor regressions have been reported, neither cell type is used for the treatment of any malignancy.

In general, antigen-specific CD8⁺ T cells are thought to be the most potent killers of cancer cells. Accordingly, efforts have been made to activate T cells *ex vivo* for adoptive transfer. Rosenberg and colleagues have resected tumor masses, cultured the tumor-infiltrating lymphocytes with IL-2, and administered them back to patients along with intravenous IL-2. One-third of patients who received cells had regression of their tumors; however, the advantage of this approach, compared with IL-2 without cells, is unclear.

T-cell therapy has been used to treat viral diseases. After adoptive transfer, CD8⁺ T-cell clones specific for cytomegalovirus (CMV) and HIV have been shown to localize to sites of antigen and to lyse targets *in vivo*. These clones require CD4⁺ helper T cells to persist and replicate *in vivo*. In transplantation patients with a high risk of CMV, reconstitution of CMV-specific T-cell responses and protective immunity were observed after transfer of CD8⁺ CMV-specific cytotoxic T lymphocytes isolated from their HLA-matched sibling donor. In an important demonstration of the potency of the cellular immune response, adoptive transfer of Epstein–Barr virus (EBV)–specific, polyclonal, donor-derived CD4⁺ and CD8⁺ T cells prevented and also caused regression of established EBV-related lymphomas in allograft recipients. Thus, T-cell therapy may be useful against virus-associated malignancies, such as Hodgkin's disease, cervical carcinoma, and adult T-cell leukemia/lymphoma, which express EBV, human papillomavirus (HPV) and human T-cell leukemia/lymphoma virus (HTLV)-I–related antigens, respectively.

The most effective adoptive therapy is the graft-versus-tumor effect seen in patients undergoing allogeneic bone marrow transplantation. T cells from the donor graft mediate significant antitumor effects in acute leukemia, lymphoma, and Hodgkin's disease. Several strategies are being tested to exploit the graft-versus-tumor effect, including infusing recipients with donor lymphocytes, which induces sustained remissions in up to 80% of patients with relapsed CML. Unfortunately, the infusions are often accompanied by graft-versus-host disease (GVHD), which has led investigators to introduce suicide genes into donor lymphocytes, which can be eliminated if severe GVHD ensues.

ACTIVE IMMUNIZATION

The “Holy Grail” of tumor immunology is to prevent or treat cancer by active immunization (vaccination). An example of successful prevention is the reduction in hepatocellular cancer after vaccination for hepatitis B. This strategy is most easily understood in the context of viral-associated tumors, which may be eradicated by immune responses to viral-specific antigens. However, the molecular identification of nonviral antigens on cancer cells has provided the tools to develop strategies to immunize patients against other cancers as well. In some instances, true tumor-specific antigens have been described. For example, the immunoglobulin idiotype on a B-cell lymphoma, a mutated oncogene (*p53*, *Ras*) or a new hybrid protein created by the chromosomal translocation in promyelocytic leukemia (PML)(PML-RAR α) or CML (*bcr-abl*). Under certain conditions, normal proteins may serve as tumor antigens. These antigens, often called *differentiation antigens*, are expressed by cancer cells and their normal counterparts. Examples include HER2/*neu* in breast cancer, and MAGE, MART-1, and gp100, among others, in malignant melanoma. These proteins may serve as tumor rejection antigens.

Experiments in mice and clinical trials in patients have demonstrated that immunity to a tissue autoantigen can induce antitumor effects without inducing evidence of autoimmune disease. A variety of clinical trials have been performed in which patients have been immunized with modified or unmodified whole tumor cells, DNA coding for the tumor antigen, viruses (adenovirus or vaccinia) carrying the tumor antigen, or peptide fragments of the tumor antigen. Major tumor responses have been observed in patients with metastatic melanoma vaccinated with whole cells (autologous or allogeneic) and with peptides given alone or with dendritic cells as antigen-presenting cells.

Similar results have been reported for patients with low-grade lymphoma vaccinated against the immunoglobulin idiotype. As vaccination strategies are demonstrated to be safe and effective in patients with advanced cancer, they are being used earlier in the course of disease. For example, a trial of melacine (a lysate of two allogeneic melanoma cell lines) versus observation has been completed in patients with completely resected melanoma. The results are pending. A recent European trial compared an autologous tumor cell vaccine given with BCG to observation in patients with stage II and III colon cancer. Researchers reported a 44% reduction in recurrence in vaccinated patients, but no significant differences in overall survival. These promising results indicate that vaccine strategies are likely to play a major role in the management of patients with cancer in the near future.

MONOCLONAL ANTIBODIES

The concept of generating antitumor antibodies to treat cancer has been around for many years but has been hampered by a number of largely technical difficulties. The ability to humanize murine antibodies has enhanced their circulating half-life and allowed repeated administration without the induction of anti-antibody immune responses. Antibodies have the theoretical attribute of tumor specificity and therefore reduced toxicity. Several mechanisms of action have been postulated for antitumor antibodies: Fc-mediated immune activation (complement fixation, antibody-dependent cellular toxicity [ADCC]), blockade or activation of a critical receptor molecule (e.g., growth factor receptor), induction of apoptosis after engagement of a cell surface receptor, and the delivery of lethal drugs, toxins, or radionuclides.

A variety of antibodies have been approved for use in patients with cancer. Arcitumomab and capromab, monoclonal antibodies to carcinoembryonic antigen (CEA) and prostate-specific membrane antigen, respectively, are approved as radiolabeled agents for diagnostic imaging; two humanized monoclonal antibodies, rituximab

(Rituxan) and trastuzumab (Herceptin) have been approved for treatment of non-Hodgkin's lymphoma and breast cancer, respectively.

Rituximab, which binds to the B-cell marker, CD20, causes tumor regression in approximately 50% of patients with previously treated low-grade lymphomas. Recent studies show that it is also effective in patients with aggressive non-Hodgkin's lymphomas and is particularly effective if administered in combination with chemotherapy. Rituximab may mediate antitumor effects by traditional antibody mechanisms, such as complement fixation and ADCC, or by inhibiting B-cell proliferation directly and inducing apoptosis. Radionuclide-conjugated anti-CD20 antibody has had significant antitumor effects at doses that ablate bone marrow and even at moderate doses (not requiring stem cell support).

In September 1998, the FDA approved the first antibody for the treatment of breast cancer, trastuzumab, an antibody to HER2/ *neu*, a cell surface protein of the epidermal growth factor receptor family that is overexpressed in 25% to 30% of breast cancer patients. Approval was based on its activity by itself in heavily pretreated women and in combination with paclitaxel chemotherapy as first-line treatment in women with metastatic breast cancer whose tumors overexpress HER2/*neu*. Weekly therapy with trastuzumab was well tolerated, and only one of 903 women developed an antibody response to trastuzumab. When given in combination with paclitaxel as first-line treatment of metastatic breast cancer, trastuzumab more than doubled the time to progression, the overall response rate, and the duration of response. The percentage of patients alive at 1 year increased from 61% to 73%. The mechanism of action of this antibody when used alone is thought to be due to the resultant down-regulation of HER2/ *neu* expression and the disruption of HER2/HER3 and HER2/HER4 heterodimers, with both events leading to a decrease in cell proliferation. Upcoming clinical trials will test the value of trastuzumab in the adjuvant setting.

ALTERATION OF TUMOR CELL BIOLOGY

Agents have been identified that physically interfere with the interaction of a growth factor with its receptor (e.g., antibodies or peptides that block the receptor, and suramin, which binds to basic growth factors) or with one or more steps in the receptor's signal transduction pathway (e.g., antagonists of protein kinase C, phospholipase C, tyrosine kinase, and phosphoinositol-3 kinase). A protein kinase C antagonist, bryostatin, is in clinical development, as are various inhibitors of tyrosine kinases. Prospects for the development of agents to target the expression of particular genes include antisense oligonucleotides, which block gene expression, and ribozymes, which cleave specific RNAs. Although there are many barriers to overcome before these molecules become drugs, clinical testing of some of these agents has begun ([Table 255.1](#)). Tumor growth beyond a small avascular solid tumor requires the induction of new blood vessels (angiogenesis) to meet the growing tumor's need for oxygen and nutrients. For tumor cells to become invasive and metastatic, they must penetrate the epithelial basement membrane and migrate through the extracellular matrix (ECM) to the lymphatics and blood vessels and adhere to stromal proteins through specific attachment sites (integrins and laminin). The metastatic process may be blocked by interfering with several steps: the inhibition of laminin binding to its receptor, the inhibition of metalloprotease activity to prevent digestion of basement membrane and interstitial matrix, the inhibition of angiogenesis and the blockade of factors that promote tumor motility.

Type	Strategy	Comments/Tumor Types
Antibody	Block EGF receptor Selective toxicity with 40-42-antibody Selective toxicity with anti-CD20 Selective toxicity to CD44-positive cells	Head and neck, breast B-cell lymphoma B-cell lymphoma K-562 + refractory T-cell lymphoma
Receptor protein	Block EGF receptor Block CD20 receptor Block CD44 receptor	Small molecules act inside cell to block EGF binding site and prevent signal transduction; genetics, CD44
Tyrosine kinase inhibitor	Block EGF receptor Block CD20 receptor Block CD44 receptor	Small molecules act inside cell to block EGF binding site and prevent signal transduction; genetics, CD44
Phosphatidylinositol 3-kinase inhibitor	Block PI3K activity	Small molecules act inside cell to block PI3K activity; genetics, CD44
CD44 inhibition (epithelial basement invasion)	Block cell cycle	Small molecules act inside cell to block PI3K activity; genetics, CD44
Antisense	Block cell cycle	Small molecules act inside cell to block PI3K activity; genetics, CD44
Gene therapy	Block cell cycle	Small molecules act inside cell to block PI3K activity; genetics, CD44
VEGF inhibition	Block VEGF activity	Small molecules act inside cell to block VEGF activity; genetics, CD44
MMP inhibition	Block MMP activity	Small molecules act inside cell to block MMP activity; genetics, CD44

TABLE 255.1. NEW BIOLOGIC AGENTS IN CLINICAL TRIALS

Matrix metalloproteases (MMPs) are a family of enzymes that are responsible for the turnover and remodeling of extracellular matrix proteins. The ECM consists of a network of fibrous proteins including collagens, laminin, fibronectin, proteoglycans, and gelatins. MMPs are zinc and calcium-dependent enzymes that are subclassified according to their substrate specificity. Inhibitors of MMPs have the potential of slowing or preventing tumor growth, local invasion, and metastasis. Because MMPs are involved in angiogenesis, MMP inhibitors also have antiangiogenic effects. Clinical trials of several MMP inhibitors are underway and some have reached phase III testing.

The discovery of positive and negative regulators of angiogenesis has led to the development of exciting new strategies to inhibit angiogenesis in cancer. There are more than ten compounds in clinical trial that attempt to target angiogenesis. Approaches include antagonizing angiogenesis factors, such as vascular endothelial growth factor (VEGF) or angiopoietin 1 with antibodies or soluble receptors, or developing agents that act directly on endothelial cells to block their migration or proliferation or induce apoptosis. Angiostatin and endostatin belong to the latter group of compounds. The MMP inhibitors and antiangiogenic agents offer a different paradigm of treating cancer; instead of killing cancer cells, these agents prevent growth and metastasis—a strategy that may complement surgery, radiation, and chemotherapy.

Differentiating agents may alter the malignant phenotype. Retinoids already have a useful role in cancer prevention and treatment. Retinoids bind to specific nuclear receptors that influence gene expression. Isotretinoin (13- *cis*-retinoic acid) is therapeutic for the premalignant condition, oral leukoplakia, and prevents second cancers of the aerodigestive tract in patients with head and neck cancer. Toxic effects include dry skin, phlebitis, hypertriglyceridemia, and conjunctivitis; dose reductions are required in many patients. Tretinoin (all- *trans*-retinoic acid—ATRA) induces remission in most patients with acute promyelocytic leukemia (APL), which contains a t(15:17) translocation that causes abnormal distribution of the retinoic acid receptor. With tretinoin, the chimeric receptor localizes normally and the malignant cells undergo terminal differentiation. Tretinoin works best when used together with chemotherapy. In addition to the usual retinoid toxicities, tretinoin-treated APL patients may experience the “retinoic acid syndrome” (fever and respiratory distress related to hyperleukocytosis).

GENE THERAPY

Human gene therapy has progressed from the bench to the bedside in a very short time. In 1990, a 4-year-old girl with severe combined immunodeficiency received an infusion of her own gene-modified T cells, which helped correct her underlying adenosine deaminase deficiency. Gene-marked tumor-infiltrating lymphocytes and bone marrow cells have been used to monitor the trafficking of lymphocytes and to determine the origin of relapsed leukemia or neuroblastoma, respectively. Gene therapy has many applications for cancer, and clinical trials are already in progress. Inactivation of oncogenes and gene replacement for lost or mutated tumor suppressor genes have been attempted. In vivo delivery of normal p53 to “correct” p53-deficient tumor cells using retroviral or adenoviral vectors has been attempted with occasional tumor regressions observed. In a particularly novel approach, investigators removed the gene in a normal adenovirus that disables the cellular p53 gene. This creates an adenovirus that can only grow in and kill p53-deficient (i.e., cancer) cells only after infection. Intratumoral injection of virus kills tumors in mice and has elicited significant tumor regressions in patients with head and neck cancer. Gene transfer has been used to deliver drug sensitivity genes (e.g., the herpes simplex thymidine kinase gene, HSV-TK) to tumor cells or normal T cells. Gene-modified cells can be exposed to gancyclovir, and only those cells expressing TK metabolize the drug and die. This cellular suicide strategy has been used against brain tumors and is being used to eliminate T cells causing GVHD after infusion of donor lymphocytes in patients with CML. The transfer of drug resistance genes to bone marrow cells has been performed to increase the dose of chemotherapy that can be administered safely. The most common application of gene therapy at present is to enhance the immune response to tumor antigens. Specific tumor antigens have been cloned into viral vectors for immunization. Tumor immunogenicity has been enhanced by in vitro or in vivo insertion of foreign HLA antigens, cytokines, and costimulatory molecules, alone or in combination.

Despite an occasional promising response, many challenges to the successful application of gene therapy remain. Many obstacles associated with vector design, gene delivery, and tissue-specific expression, as well as immunogenicity of many of the components must be overcome. However, as technology and our understanding of the basic physiologic processes improve, gene therapy approaches will become part and parcel of our daily treatment plans for patients with cancer.

[Granulocyte-Macrophage Colony-Stimulating Factor](#)
[Erythropoietin](#)
[Platelet-Stimulating Factors](#)

Hematopoietic growth factors (HGFs) make up a family of cytokines with pleiotropic and frequently overlapping activities that regulate steady-state lymphohematopoiesis and also mediate acute responses involving specific cell lineages. HGFs are named (a) after the lineage they regulate (e.g., erythropoietin [EPO], thrombopoietin [TPO]), (b) after an assay that permitted their detection (e.g., colony-stimulating factors [CSFs]), (c) by the cell populations from which they are produced and with which they interact (e.g., interleukins), or (d) by the receptors with which they interact (e.g., c-*kit* and Flk-2/Flt-3 ligands). There are currently 18 interleukins (IL-1–18), and three CSF species (granulocyte, macrophage, and granulocyte-macrophage [G-, M-, GM-CSF]). The factors are not thought to be instructive but rather to act permissively to support the expression of a differentiation program that may, in large part, be stochastically determined. In certain cases, biologic activity is observed only when an HGF is combined with another factor or factors, resulting in synergy or antagonism.

GROWTH FACTOR RECEPTORS

HGFs signal through either of two large classes of receptor: the family of type III tyrosine kinase receptors (c-*kit*, Flk-2/Flt-3, fms/M-CSF, ab PDGFR [platelet-derived growth factor receptor]) or a large family of structurally related hematopoietin receptors. The conserved extracellular motifs of this latter family are derived from the fibronectin type III module. Different family members contain one to three chains. All such receptors are associated with one or more members of a family of Janus kinases (JAKs). These kinases couple ligand binding to tyrosine phosphorylation, both of known signaling proteins and of a unique family of transcription factors termed the signal transducers and activators of transcription (STATs).

The receptors for IL-3, IL-5, and GM-CSF each consist of a ligand-binding α chain associated with a common β chain whose membrane proximal domain associates with JAK2, leading to signal transduction. The receptors for a number of cytokines, including IL-6, IL-11, and leukemia inhibitory factor (LIF), all use ligand-specific binding chains that associate with gp130, which, in turn, associates with and activates JAK1 and JAK2. A third category is that of receptors consisting of single chains, which associate with JAK2 through a receptor membrane-proximal domain (EPO, TPO, G-CSF, growth hormone, prolactin). The IL-2 receptor family (IL-2, IL-4, IL-7, IL-9, IL-15) and the interferon receptor family (IFN- α /IFN- β , IFN- γ , IL-10) represent an association pattern in which two chains are required for signaling. The IL-2 receptor contains α , β , and γ_c chains, the cytoplasmic domains of the latter two being required for signal transduction. The receptors for IL-4, -7, -9, and -15 each contain a ligand-specific α chain and a γ_c chain. The sharing of receptor subunits among different cytokine receptors accounts partly for the redundancy that is characteristic of the cytokine family.

GRANULOCYTE COLONY-STIMULATING FACTOR

The purification and molecular cloning of G-CSF were performed between 1984 and 1986, and clinical development commenced in 1986 with approval for clinical use in cancer patients treated with chemotherapy. Human G-CSF is a glycoprotein of 19,600 D, encoded by a single gene on chromosome 17q21-22. It is produced constitutively by many tissues, particularly by monocytes and macrophages, endothelial cells, and fibroblasts, and high serum levels are induced by a variety of inflammatory stimuli, including bacterial lipopolysaccharides. G-CSF receptors are expressed on mature neutrophils (500 to 3,000 per cell) as well as on the myeloblast-promyelocytes and pluripotent stem cells. In vitro, G-CSF stimulates committed progenitors to form neutrophil granulocyte colonies, but in synergy with other factors such as Kit ligand (KL), it enhances proliferation of pluripotent progenitors, including stem cells.

In vivo administration of G-CSF causes an increase in neutrophil granulocyte production, owing to a ~threefold increase in amplification divisions and a 3- to 4-day reduction in transit time to mature granulocyte. Unlike with GM-CSF, there is no effect on leukocyte half-life or margination. G-CSF is a potent activator of neutrophils (PMN), mobilizing secretory vesicles (leukocyte alkaline phosphatase, CD11b) and inducing the release of specific granules (lactoferrin, CD11b, and CD66b) and azurophil granules (elastase, α_1 -antitrypsin complexes). G-CSF enhances PMN superoxide release, and this enhances respiratory burst metabolism. Administration of G-CSF causes a significant increase in circulating CD34⁺ cells, including primitive subsets (CD34⁺Thy-1⁺, CD38⁻), with levels of circulating CD34⁺ progenitors of up to 35 times what is usually normally achieved by the fifth day. Extensive clinical application of G-CSF–mobilized, peripheral blood stem cells in autologous and, recently, allogeneic transplantation has resulted because of the ease with which large numbers of CD34⁺ cells can be obtained by apheresis and the more rapid platelet and neutrophil recovery observed, compared with results obtained with conventional marrow transplantation.

G-CSF (Filgrastim) was initially used as an adjunct to chemotherapy for ameliorating neutropenia, one of the major side effects of cancer chemotherapy. Its use led to reduced infections and hospital admissions. G-CSF has been approved for treatment of myelosuppression after bone marrow transplantation and for treatment of aplastic anemia and severe chronic neutropenia (idiopathic and congenital). Patients with Kostmann's syndrome are characterized by severe neutropenia, maturation arrest of the neutrophil lineage, and onset of severe, recurrent bacterial infections in early childhood. Most of these patients show sustained neutrophil recovery upon continuous G-CSF treatment (5 to 20 μ g per kilogram per day).

The use of G-CSF for treatment of acute myeloid leukemia (AML) and myelodysplastic syndrome (MDS) was initially contraindicated because of concern that it might lead to stimulation of leukemic clones. However, in several large randomized trials, G-CSF has proved effective in stimulating neutrophil recovery and reducing infectious episodes without promoting leukemic growth. It has also proved effective for reversing the neutropenia associated with AIDS. G-CSF also prevents progression of systemic nonresponsiveness in systemic inflammatory response syndrome and sepsis. It has been shown to stimulate host immunity by increasing leukocyte numbers and up-regulating neutrophil function in postoperative/post-traumatic patients at risk for sepsis.

MACROPHAGE COLONY-STIMULATING FACTOR

Over 30 years ago, a CSF was identified in serum, urine, and fibroblast cell line–conditioned medium that had a restricted ability to stimulate the development of colonies containing only macrophages. As a result of alternative splicing, three spliced variants of biologically active M-CSF are produced, a short or a form of 256 amino acids, a long or b form of 554 amino acids, and a g form of 438 amino acids. The COOH terminus anchors some forms of M-CSF in an active cell-associated form, with the native secreted form of M-CSFa being generated by proteolytic cleavage. M-CSF is present in normal plasma at levels of 100 to 200 units per milliliter. That M-CSF is ubiquitously expressed may reflect production by cells common to many organs, such as macrophages, endothelial cells, fibroblasts, and mesothelial cells. Fluctuations in levels of circulating M-CSF reflect a balance between production and excretion, with M-CSF receptors on tissue macrophages responsible for significant clearance by specific binding of M-CSF, with subsequent endocytosis and intracellular destruction. Adherence and bacterial lipopolysaccharides are potent inducing stimuli for monocyte and macrophage M-CSF production. High-affinity ($K_d = 10^{-13}$ M) M-CSF binding sites (cfms) are expressed at levels of 1×10^4 – 1×10^5 per cell on mature monocytes, macrophages, and osteoclasts. M-CSF is involved in survival, proliferation, and differentiation of monocyte-macrophage populations, and functions as a macrophage activator as part of an inflammatory host defense response. Acute events after M-CSF interaction with monocytes include increased cell spreading, membrane ruffling, receptor turnover, enhanced macrophage phagocytosis, enhanced bactericidal and amebicidal capacity, up-regulation of Fc receptor (FcR)g, antibody-dependent cell-mediated cytotoxicity (ADCC), and induction of a variety of cytokines (IL-1, G-CSF, tumor necrosis factor [TNF], IL-6). At the progenitor level, highly purified populations are stimulated by M-CSF alone, as well as by GM-CSF and IL-3, with a frequency indicating that many progenitors have receptors for all three growth factors. Osteopetrotic (op/op) mice have an autosomal recessive, inactivating mutation of the M-CSF gene, resulting in absence of M-CSF. They have quantitative macrophage defects, are toothless, and marrow cavities occluded by bone overgrowth due to an osteoclast deficit, thus indicating a critical role of M-CSF in osteoclast development or function. Clinical trials of recombinant human (rh)M-CSF revealed that treatment leads to expansion of circulating mononuclear phagocytes, enhanced macrophage ADCC and phagocytosis, reduced platelet levels, and reduction in serum cholesterol. The cholesterol-lowering effect may be attributed to enhanced macrophage activities of neutral and acidic cholesterol ester hydrolases, enhancing net hydrolysis of acidic cholesterol ester.

GRANULOCYTE-MACROPHAGE COLONY-STIMULATING FACTOR

GM-CSF has a molecular weight of 23 kD, with glycosylation at two N-linked glycosylation sites, and is encoded by a gene located on chromosome 5q23-31 in very close proximity to the IL-3 gene. The long arm of chromosome 5 contains a clustering of hematopoietic regulatory genes that includes GM-CSF, IL-3, IL-4, IL-5, M-CSF, and the receptors for PDGF and M-CSF (c-fms). GM-CSF is an inducible product of a variety of cell types, including activated T and B lymphocytes and activated macrophages.

The biologic effects of GM-CSF were initially related to its ability to stimulate proliferation and differentiation of myeloid-committed progenitors (colony-forming unit–granulocyte-macrophage [CFU-GM]) into neutrophilic granulocytes and monocyte-macrophages. GM-CSF can promote proliferation and differentiation of eosinophils, basophils, megakaryocytes, erythroid and dendritic cells, in synergy with other factors (e.g., with EPO for erythropoiesis, with TNF or IL-4 for dendritic differentiation). In synergy with KL or Flt-3 ligand (FL), it stimulates multipotent progenitors and stem cells. GM-CSF promotes survival of myeloid cells, including mature neutrophils, by suppressing apoptosis. The pleiotropic functions of GM-CSF extend to enhancement of innate as well as specific immune responses, which can be initiated alone or in synergy with other cytokines, such as TNF. GM-CSF enhances antibody-dependent cell killing and phagocytosis by neutrophils and macrophages and acts as a neutrophil migration (and adhesion-)–inhibitory factor. It also enhances Fc γ -receptor RII and class II major histocompatibility complex expression on monocytes and neutrophils and stimulates monocyte/macrophage cytokine, leukotriene, and prostaglandin release.

Excess levels of GM-CSF, achieved by intravenous or subcutaneous injections of glycosylated or nonglycosylated recombinant human GM-CSF, in primates and humans results in a leukocytosis involving elevation of neutrophils, eosinophils, monocytes, and, to a lesser extent, lymphocytes. The therapeutic applications of GM-CSF were initially restricted to amelioration of chemotherapy-induced myelotoxicity, allowing dose intensification. GM-CSF may also promote wound healing and has been used topically as a treatment for nonhealing wounds and ulcers. It has proved effective in radioprotection. Sustained administration of GM-CSF alone or in combination with cytoxan induces mobilization of CD34⁺ cells, including both stem and progenitor populations, into the circulation. The apheresis product can then be used for both autologous or allogeneic transplantation. GM-CSF has proved effective as adjuvant therapy for bacterial and fungal infections in cancer patients and for adjuvant treatment of opportunistic fungal infections in AIDS patients. GM-CSF has also been shown to be a potent stimulator of sustained, specific, antitumor immunity and is used in various cancer vaccine strategies.

ERYTHROPOIETIN

Human EPO is a glycoprotein of molecular weight 34,000 to 39,000 D, with a polypeptide backbone of 166 amino acids and N-linked carbohydrate side chains that are essential for full activity in vivo, owing to rapid clearance of the desialated hormone from the circulation. EPO is produced mainly in the kidney, with less than 10% produced by the liver. The cellular action of EPO begins at the erythroid progenitor (erythroid burst-forming unit [BFU-E]) stage, where, together with KL, IL-3, or GM-CSF, it promotes erythroid differentiation. EPO alone at low concentrations prevents apoptosis of CFU-E, and at higher concentrations, is mitogenic, stimulating the formation of colonies of 64 to 128 orthochromatic erythroblasts within 7 days. In vivo treatment with EPO induces polycythemia in healthy persons. Recombinant EPO has been approved for treatment of patients with anemia associated with renal failure and for treatment of anephric patients. It has also been shown to reduce blood transfusion requirements in cancer patients receiving myelosuppressive chemotherapy and to counteract the anemia frequently seen in AIDS patients treated with zidovudine (AZT).

PLATELET-STIMULATING FACTORS

INTERLEUKIN-11

IL-11 consists of 199 amino acids, including a 21–amino acid leader sequence, with a molecular weight of 19,154 D, encoded by a gene mapping to chromosome 19q13.3–19q13.4. The cytokine is expressed by a wide range of normal tissues, and expression is modulated by several proinflammatory cytokines (IL-1a, IL-1b, TGF β), and agonists. IL-11 has pleiotropic effects on hematopoietic cells, osteogenic cells, intestinal epithelium, and neural tissue. It is also a potent stimulator of acute-phase reactants, an inhibitor of adipogenesis, and an inducer of febrile response. It is a potent synergistic factor, acting with a variety of cytokines (IL-3, IL-4, IL-7, IL-12, IL-13, KL, FL, GM-CSF) to stimulate proliferation of primitive stem cells and progenitors. In vitro, IL-11 acts synergistically with IL-3 and TPO or KL to stimulate production, differentiation, and maturation of megakaryocytes, and in vivo it results in marked stimulation of megakaryopoiesis, with modest platelet elevation. A number of multicenter, randomized, placebo-controlled trials of IL-11 have been undertaken in cancer patients and have shown significant reduction in platelet transfusion requirements after high-dose chemotherapy, resulting in Food and Drug Administration approval of the cytokine for treatment of chemotherapy-associated thrombocytopenia.

THROMBOPOIETIN

The existence of a lineage-specific factor regulating platelet production was doubted until the discovery of an orphan cytokine receptor, c- *Mpl*, expressed on progenitor cells, megakaryocytes, and platelets, and the subsequent isolation of its ligand, TPO. Human TPO comprises an amino-terminal domain of 153 amino acids, showing 50% similarity to EPO, and a unique 181–amino acid C-terminal domain that is highly glycosylated. TPO is expressed constitutively in various tissues, and serum levels appear to be regulated by platelet and megakaryocyte mass, with TPO sequestered via high-affinity (kD ~100 to 400 pmol) binding to c- *Mpl* receptors. In vitro, TPO stimulates development of colonies of polyploid megakaryocytes from committed progenitors (CFU-Meg). TPO also acts synergistically (KL, FL) or additively (IL-6, IL-3) with other HGFs to stimulate megakaryocyte production.

Evidence for action of TPO on stem cells has been obtained in studies showing that TPO directly promotes survival and suppresses apoptosis of human primitive CD34⁺CD38⁻ bone marrow cells and by demonstration of c- *Mpl* on populations of highly enriched stem cells. In combination with the Flk-2/Flt-3 ligand, TPO produces prolonged (24 weeks) and extensive expansion of cord blood stem cells. Two forms of the protein have been clinically evaluated, one (recombinant hTPO) is a full-length polypeptide; the other is a recombinant, truncated form of TPO, consisting only of the EPO-like domain chemically modified by addition of polyethylene glycol (PEG-conjugated megakaryocyte growth and differentiation factor [PEG-MGDF]). Both are fully functional in vitro and have been evaluated in vivo in primates and in clinical trials.

In cancer patients, the platelet count begins to rise after 3 to 5 days, with up to a tenfold increase in platelets, using doses of 1.0 μ g per kilogram per day for 12 days, and no alteration in platelet activation status. TPO also mobilizes stem and progenitor cells into the circulation, an activity of value in peripheral blood stem cell transplantation. Platelet counts returned to baseline faster, and nadir counts were higher in cancer patients receiving myelosuppressive chemotherapy and PEG-MGDF.

The greatest potential for TPO in the near future may be in transfusion medicine, in collection and storage of platelets from healthy donors, or in autologous settings. A single dose of 3 μ g per kilogram of PEG-MGDF increased the yield of platelets by a factor of 4 and was associated with a quadrupling of platelet counts in recipients of the apheresed platelets. Clinical trials of MGDF have been terminated because some recipients developed thrombocytopenia due to development of cross-reacting antibodies to endogenous TPO. This serious side effect is not expected to be seen with full-length, glycosylated TPO.

INTERLEUKIN-3

IL-3 is a glycoprotein of 25 to 30 kD, with a core protein of 14.6 kD consisting of 152 amino acids with a 19–amino acid signal peptide. IL-3 is produced by activated T cells, natural killer (NK) cells, and mast cells after transient increase in gene transcription and messenger RNA (mRNA) stabilization. It is probably a locally acting factor, because it does not normally circulate at detectable levels in the blood.

IL-3 directly stimulates colony formation by a spectrum of progenitors, including pluripotent and neutrophil-, eosinophil-, basophil-, and macrophage-restricted progenitors. In synergy with other factors, it stimulates megakaryocyte and erythroid progenitors and pluripotent stem cells. In addition to growth stimulation and shortening of doubling time of early hematopoietic cells, IL-3 also has an antiapoptotic action on progenitor populations at concentrations lower than necessary to initiate proliferation. IL-3 alters the function of mature phagocytes, acting as a survival factor for monocytes and inducing macrophage secretion of TNF- α , IL-1b, and IL-6. In preclinical studies in primates, IL-3 administration after intensive myelosuppressive chemotherapy dramatically enhanced myeloid recovery and reduced the duration of neutropenia. Numerous clinical trials have shown the beneficial effect of IL-3 after cytotoxic therapy, in the post-transplantation period after bone marrow

transplantation, and in a variety of neutropenic settings.

KIT-LIGAND

Mutations at both the *Steel* and *white spotting* loci in mice cause macrocytic anemia, absence of mast cells, infertility, and depigmentation. The S1 and W loci encode a ligand–receptor pair—the kit receptor tyrosine kinase, the gene product of the protooncogene *c-Kit*, and its ligand. Mice bearing the S1 mutant have normal stem cells but a defective hematopoietic environment, due to absent or truncated ligand production, whereas W mutants have intrinsic stem cell defects due to *c-Kit* receptor mutations.

Two alternatively spliced KL RNA transcripts encode two cell-associated KL proteins, KL-1 and KL-2, of 248 and 220 amino acids, respectively. The presence of a major proteolytic cleavage site on KL-1 provides a mechanism for production of a biologically active, soluble form of KL, whereas KL-2 provides a differentially more stable, cell-associated form of the ligand. Soluble KL is a potent mast cell growth factor on its own and is a potent synergistic factor when combined with a variety of cytokines (IL-3, GM-CSF, G-CSF, EPO, TPO), stimulating both early and late progenitor populations of myeloid, erythroid, and megakaryocyte lineage. KL has an antiapoptotic action, promoting survival of primitive hematopoietic cells. KL also has important effects on cell–extracellular matrix and cell–cell interactions.

Potential clinical uses of KL have been limited by adverse events involving dermal mast cell activation, with pruritic wheal formation and 10% to 20% of patients developing allergy-like reactions characterized by urticaria and, in some cases, laryngeal edema. Lower doses of KL (stem cell factor) have been used in conjunction with G-CSF for mobilization of CD34⁺ cells, resulting in significant improvement in the quantity of CD34 cells harvested and in their quality, as measured by ex vivo expansion potential and stem cell content.

FLK-2/FLT-3 LIGAND

The Flk-2/Flt-3 receptor is activated by a cognate molecule termed the Flt-3 ligand (FL). The ligand exists in both a transmembrane and soluble form. FL promotes the survival and stimulates proliferation, differentiation, and mobilization of early hematopoietic progenitors, differing from KL in that it does not potentiate erythropoiesis nor stimulate mast cells, but it does potentiate the growth of pro-B cells in synergy with IL-6 and IL-7. It primarily acts as a synergistic factor, maximally stimulating CD34⁺ stem and progenitor cell proliferation when combined with IL-3, IL-6, KL, GM-GCF, or TPO. FL enhances the rate of growth of IL-3–dependent colonies by shortening the duration of the G1 phase. Of all the cytokines, FL appears to be the most effective synergistic factor in promoting stem cell self-renewal, resulting in expansion of stem cell numbers.

In vivo treatment of mice and primates with FL demonstrated that it is a potent mobilizer of hematopoietic progenitors and, when combined with G-CSF, gives much higher mobilization levels than does either cytokine alone. Dramatic increases in dendritic cells of both T-lymphocyte and myeloid derivation are seen, in blood and lymphohematopoietic tissues, after FL treatment, and this response can promote an antitumor effect.

CHAPTER 257: BLOOD TYPES, TISSUE TYPING, AND TRANSFUSION OF BLOOD PRODUCTS

FRANK T. HSIEH, STEVEN A. MECHANIC, EDWARD SNYDER AND ALBERT DEISSEROTH

[ABO Blood Types](#)
[Tissue Typing](#)
[Complications of Transfusion](#)

ABO BLOOD TYPES

Red blood cells (RBCs) contain numerous antigenic structures on their surfaces. The most important of these are the ABO antigens. The A and B genes of the ABO system code for glycosyl transferases that add *N*-acetyl galactosamine or galactose, respectively, to a common precursor H antigen. The O gene produces an enzyme with no activity, so only H antigen is present. These antigens form the basis for the ABO blood group system. ABO is the most important blood group system because most persons have naturally occurring IgM and IgG antibodies directed against non-self antigens of this system. These IgM antibodies can fix complement and cause rapid intravascular hemolysis. Major hemolytic transfusion reactions may cause hypotension, shock, disseminated intravascular coagulation (DIC), renal failure, and death. ABO antibodies directed against the antigens not present on an individual's own RBCs are normally present without prior exposure and are referred to as *naturally occurring antibodies*. Thus, in those with type A blood, anti-B antibodies are present, with type B blood, anti-A antibodies are present. Similarly, patients with type O blood recognize the A or B antigens as foreign and have naturally occurring anti-A and anti-B antibodies. Conversely, type O RBCs are not agglutinated by (do not react with) anti-A or anti-B antibodies. Therefore, transfused type O RBCs are compatible with any recipient blood type. Individuals of blood type AB, have neither anti-A or anti-B in their plasma.

The other major blood group system of clinical significance is the Rh system with five major antigens designated C, D, E, c, e (no "d" gene is expressed). Of the Rh antigens, the D antigen is the most important clinically. Fifteen percent of whites do not produce the D antigen; they are said to be Rh-negative. The D antigen is highly immunogenic. If an Rh-negative woman is transfused with Rh-positive RBCs, delivers an Rh-positive infant, or miscarries or aborts an Rh-positive fetus, resulting in fetomaternal hemorrhage with D antigen positive RBCs, she has a 70% chance of developing anti-D IgG antibodies. Because IgG can cross the placenta, any future Rh-positive infants will be at high risk for a potentially fatal intrauterine hemolytic anemia, also called *hemolytic disease of the newborn*, or erythroblastosis fetalis. For this reason, Rh-negative patients, particularly women with childbearing potential, should always be given Rh-negative blood. Furthermore, Rh-negative women who undergo abortion or delivery of an Rh-positive fetus are routinely treated with Rh Ig, a commercial hyperimmune globulin with anti-D specificity, which binds to the D antigen on the fetal Rh-positive blood cells that have entered the maternal circulation. Use of passive hyperimmune anti-D, Rh Ig prevents active D antibody formation in the mother by an as-yet undefined mechanism.

Because most fatal hemolytic transfusion reactions result from mistakes in patient identification made at the bedside rather than mistakes made in the laboratory, great care must be taken to draw the blood from the correct patient and to label the tube properly. When a physician orders a typing and cross-match, the blood bank requests a sample of blood from the recipient. The blood bank types the recipient's RBC using commercial reagent anti-A and anti-B antibodies. Then, the recipient's serum is tested for the presence of naturally occurring antibodies usually with commercial A and B reagent RBCs. An antibody screen is then routinely performed to reveal the presence of any "unexpected" RBC antibodies.

For the antibody screen, the recipient's serum is mixed with a set of two type O reagent RBCs that contain the antigens to which alloantibodies commonly develop. Agglutination in any reaction phase, that is, immediate spin, 37° C, or antihuman globulin, also known as *Coombs' phase*, would indicate the presence of an antibody. If a positive result is found with the antibody screening, then the recipient's serum is further studied by evaluating a panel of 10 or more type O reagent red cells whose antigen expressions are also known. Systematic elimination of nonreactive red cell antigens yields a pattern that can identify an antibody specificity. Antibodies that react with all panel cells are called panagglutinins; panagglutinins are seen in autoimmune hemolytic anemia. For transfusion, the recipient's serum is mixed in vitro (cross-matched) with an aliquot of RBCs from the units intended for transfusion. If compatible, the RBC unit is provided for transfusion.

TISSUE TYPING

Just as RBCs contain antigenic structures on their surface membranes, some of which are highly immunogenic and limit transfusion, so do other cells contain immunogenic antigen structures. One specific family of antigens present on almost all cells other than RBCs is the human leukocyte antigen (HLA) system. This is another system of genetic polymorphisms for which multiple alleles are present in the population. HLA antigens are encoded by a closely linked cluster of genes on the short arm of chromosome 6. From the point of view of tissue typing, two types of surface antigens are encoded by the genes of the HLA locus. Class I molecules, which are present on virtually all cell surfaces except RBCs and trophoblastic cells, are composed of two noncovalently linked polypeptide chains. The smaller chain is called b_2 -microglobulin, with a molecular weight of 11.5 kD. The larger 44-kD glycosylated heavy chain carries the antigenic specificity and is inserted into the cell membrane. The heavy chains of the class I molecules are encoded for by three loci on chromosome 6: HLA-A, HLA-B, and HLA-C. Each locus has several possible alleles, so a given person has a specific set of class I molecule heavy chains, depending on the HLA-ABC set or haplotype inherited from each parent.

b_2 -microglobulin is encoded for by a gene on chromosome 15, and the same structure is shared by all three class I molecules. Class II antigens are composed of a 34-kD a chain and a 29-kD b chain. Both are inserted into the cell membrane and are noncovalently linked. Class II antigens are present on B lymphocytes, monocytes, and activated T lymphocytes. They are encoded by several loci (HLA-DP, HLA-DQ, HLA-DR) within the D region of the HLA complex on chromosome 6.

The antigens HLA-A, HLA-B, HLA-C, and HLA-DR can be determined serologically with specific antibody testing, just as performed in RBC blood group testing. In addition, some of the HLA-D antigens, particularly the HLA-DR antigens, can be defined by mixed lymphocyte culture. In mixed lymphocyte culture, the patient's lymphocytes are incubated with a panel of irradiated or mitomycin-treated lymphocytes of known HLA-D type. The patient's lymphocytes transform when exposed to lymphocytes of a different D type. The irradiated or mitomycin-treated lymphocytes, however, cannot transform because of the damage to their DNA. Lymphocytes to which the patient does not respond are considered to be of the same HLA-D type. Transfusion of non-leukocyte-reduced random-donor platelets results in HLA alloimmunization in up to 80% of patients with aplastic anemia who have an intact immune system. Clinically significant HLA alloantibodies occur in a smaller percentage of transfused patients with acute leukemia and in transfused bone marrow transplantation recipients, presumably because of the immunosuppressive effects of the patient's disease and treatment.

There is increasing evidence that since platelets carry only HLA class I antigens, "pure" concentrations of platelets (i.e., those units of platelet concentrates that are leukocyte-reduced) are minimally immunogenic. The development of antibodies to platelet class I HLA antigens appears to require the concurrent presence of foreign HLA class II antigens, which are present on lymphocytes and monocytes. Exclusive use of leukocyte-depleted blood products using third-generation absorption filters markedly delays or totally prevents the development of platelet HLA alloimmunization. In addition, by markedly decreasing the number of white blood cells (WBCs) in RBC or platelet transfusions, these filters can reduce chills or fever related to blood product infusion and likely prevent the transmission of cytomegalovirus (CMV) as well.

COMPONENT THERAPY

The standard blood donation is up to 500 mL ($\pm 10\%$) of whole blood with addition of about 63 mL of an anticoagulant preservative solution containing citrate, phosphate, and dextrose (CPD), or CPD and adenine (CPDA-1). Citrate binds calcium, which is essential for the coagulation cascade, and thus serves as an in vitro anticoagulant. Dextrose is added to serve as a substrate for glycolysis. Phosphate serves as a buffer, and adenine can be added to promote the generation of adenosine triphosphate (ATP), necessary for normal RBC sodium-potassium pump function. In addition to CPD, an additive solution containing saline, dextrose, and adenine (Adsol) may be added to further extend the storage life of RBCs. Despite addition of these substrates and 1 to 6° C refrigeration of the blood unit to slow metabolism, progressive RBC glycolysis results in lactic acid accumulation. Because mature RBCs lack mitochondria, they do not have a Krebs cycle to remove pyruvate and prevent lactate accumulation. This slow lactic acid accumulation lowers the pH and eventually results in loss of viability of the stored cells.

The shelf life of RBCs stored in liquid phase at 1 to 6° C, is 21 days in CPD and 35 days in CPDA-1. With the addition of an additive solution, the shelf life extends to 42 days, because the additive solution contains more adenine and can produce more ATP. Blood may also be frozen at -80° C for a maximum of 10 years using glycerol as a cryoprotective agent to prevent freeze-thaw damage. This technique is generally reserved for rare blood types.

Most collected whole blood can be separated into blood components such as RBCs, platelets, plasma, and cryoprecipitate. The plasma may be further fractionated to produce albumin, immune globulin, or specific clotting factor preparations. The major advantages of component therapy are that a patient's specific needs can be met and that each element of the donated unit of blood is optimally used ([Table 257.1](#)).

Component	Indications	Complications
Whole blood (WB)	None	None
Red blood cells (RBCs)	Decreased oxygen-carrying capacity (hemoglobin < 8 g/dL or hematocrit < 24%)	Febrile transfusion reaction, allergic reaction, hemolytic transfusion reaction, bacterial contamination, infection, immunomodulation, immunosuppression, transmission of CMV, HIV, hepatitis, and other infections
Platelets	Thrombocytopenia (platelet count < 100,000/μL) or thrombocytopenic purpura	Febrile transfusion reaction, allergic reaction, hemolytic transfusion reaction, bacterial contamination, infection, immunomodulation, immunosuppression, transmission of CMV, HIV, hepatitis, and other infections
Plasma	Coagulopathy (prothrombin time > 1.5 times normal or partial thromboplastin time > 1.5 times normal)	Febrile transfusion reaction, allergic reaction, hemolytic transfusion reaction, bacterial contamination, infection, immunomodulation, immunosuppression, transmission of CMV, HIV, hepatitis, and other infections
Cryoprecipitate	Factor deficiencies (fibrinogen < 1.5 g/L or factor VIII < 0.5 IU/mL)	Febrile transfusion reaction, allergic reaction, hemolytic transfusion reaction, bacterial contamination, infection, immunomodulation, immunosuppression, transmission of CMV, HIV, hepatitis, and other infections
Factor VIII concentrate	Factor VIII deficiency	Febrile transfusion reaction, allergic reaction, hemolytic transfusion reaction, bacterial contamination, infection, immunomodulation, immunosuppression, transmission of CMV, HIV, hepatitis, and other infections
Factor IX concentrate	Factor IX deficiency	Febrile transfusion reaction, allergic reaction, hemolytic transfusion reaction, bacterial contamination, infection, immunomodulation, immunosuppression, transmission of CMV, HIV, hepatitis, and other infections
Factor VII concentrate	Factor VII deficiency	Febrile transfusion reaction, allergic reaction, hemolytic transfusion reaction, bacterial contamination, infection, immunomodulation, immunosuppression, transmission of CMV, HIV, hepatitis, and other infections
Factor X concentrate	Factor X deficiency	Febrile transfusion reaction, allergic reaction, hemolytic transfusion reaction, bacterial contamination, infection, immunomodulation, immunosuppression, transmission of CMV, HIV, hepatitis, and other infections
Factor XI concentrate	Factor XI deficiency	Febrile transfusion reaction, allergic reaction, hemolytic transfusion reaction, bacterial contamination, infection, immunomodulation, immunosuppression, transmission of CMV, HIV, hepatitis, and other infections
Factor XII concentrate	Factor XII deficiency	Febrile transfusion reaction, allergic reaction, hemolytic transfusion reaction, bacterial contamination, infection, immunomodulation, immunosuppression, transmission of CMV, HIV, hepatitis, and other infections
Factor XIII concentrate	Factor XIII deficiency	Febrile transfusion reaction, allergic reaction, hemolytic transfusion reaction, bacterial contamination, infection, immunomodulation, immunosuppression, transmission of CMV, HIV, hepatitis, and other infections
Factor VIII and IX concentrate	Factor VIII and IX deficiency	Febrile transfusion reaction, allergic reaction, hemolytic transfusion reaction, bacterial contamination, infection, immunomodulation, immunosuppression, transmission of CMV, HIV, hepatitis, and other infections
Factor VIII and XI concentrate	Factor VIII and XI deficiency	Febrile transfusion reaction, allergic reaction, hemolytic transfusion reaction, bacterial contamination, infection, immunomodulation, immunosuppression, transmission of CMV, HIV, hepatitis, and other infections
Factor IX and XI concentrate	Factor IX and XI deficiency	Febrile transfusion reaction, allergic reaction, hemolytic transfusion reaction, bacterial contamination, infection, immunomodulation, immunosuppression, transmission of CMV, HIV, hepatitis, and other infections
Factor VIII, IX, and XI concentrate	Factor VIII, IX, and XI deficiency	Febrile transfusion reaction, allergic reaction, hemolytic transfusion reaction, bacterial contamination, infection, immunomodulation, immunosuppression, transmission of CMV, HIV, hepatitis, and other infections
Factor VIII, IX, X, and XI concentrate	Factor VIII, IX, X, and XI deficiency	Febrile transfusion reaction, allergic reaction, hemolytic transfusion reaction, bacterial contamination, infection, immunomodulation, immunosuppression, transmission of CMV, HIV, hepatitis, and other infections
Factor VIII, IX, X, XI, and XII concentrate	Factor VIII, IX, X, XI, and XII deficiency	Febrile transfusion reaction, allergic reaction, hemolytic transfusion reaction, bacterial contamination, infection, immunomodulation, immunosuppression, transmission of CMV, HIV, hepatitis, and other infections
Factor VIII, IX, X, XI, XII, and XIII concentrate	Factor VIII, IX, X, XI, XII, and XIII deficiency	Febrile transfusion reaction, allergic reaction, hemolytic transfusion reaction, bacterial contamination, infection, immunomodulation, immunosuppression, transmission of CMV, HIV, hepatitis, and other infections
Factor VIII, IX, X, XI, XII, XIII, and XIV concentrate	Factor VIII, IX, X, XI, XII, XIII, and XIV deficiency	Febrile transfusion reaction, allergic reaction, hemolytic transfusion reaction, bacterial contamination, infection, immunomodulation, immunosuppression, transmission of CMV, HIV, hepatitis, and other infections
Factor VIII, IX, X, XI, XII, XIII, XIV, and XV concentrate	Factor VIII, IX, X, XI, XII, XIII, XIV, and XV deficiency	Febrile transfusion reaction, allergic reaction, hemolytic transfusion reaction, bacterial contamination, infection, immunomodulation, immunosuppression, transmission of CMV, HIV, hepatitis, and other infections
Factor VIII, IX, X, XI, XII, XIII, XIV, XV, and XVI concentrate	Factor VIII, IX, X, XI, XII, XIII, XIV, XV, and XVI deficiency	Febrile transfusion reaction, allergic reaction, hemolytic transfusion reaction, bacterial contamination, infection, immunomodulation, immunosuppression, transmission of CMV, HIV, hepatitis, and other infections
Factor VIII, IX, X, XI, XII, XIII, XIV, XV, XVI, and XVII concentrate	Factor VIII, IX, X, XI, XII, XIII, XIV, XV, XVI, and XVII deficiency	Febrile transfusion reaction, allergic reaction, hemolytic transfusion reaction, bacterial contamination, infection, immunomodulation, immunosuppression, transmission of CMV, HIV, hepatitis, and other infections
Factor VIII, IX, X, XI, XII, XIII, XIV, XV, XVI, XVII, and XVIII concentrate	Factor VIII, IX, X, XI, XII, XIII, XIV, XV, XVI, XVII, and XVIII deficiency	Febrile transfusion reaction, allergic reaction, hemolytic transfusion reaction, bacterial contamination, infection, immunomodulation, immunosuppression, transmission of CMV, HIV, hepatitis, and other infections
Factor VIII, IX, X, XI, XII, XIII, XIV, XV, XVI, XVII, XVIII, and XIX concentrate	Factor VIII, IX, X, XI, XII, XIII, XIV, XV, XVI, XVII, XVIII, and XIX deficiency	Febrile transfusion reaction, allergic reaction, hemolytic transfusion reaction, bacterial contamination, infection, immunomodulation, immunosuppression, transmission of CMV, HIV, hepatitis, and other infections
Factor VIII, IX, X, XI, XII, XIII, XIV, XV, XVI, XVII, XVIII, XIX, and XX concentrate	Factor VIII, IX, X, XI, XII, XIII, XIV, XV, XVI, XVII, XVIII, XIX, and XX deficiency	Febrile transfusion reaction, allergic reaction, hemolytic transfusion reaction, bacterial contamination, infection, immunomodulation, immunosuppression, transmission of CMV, HIV, hepatitis, and other infections
Factor VIII, IX, X, XI, XII, XIII, XIV, XV, XVI, XVII, XVIII, XIX, XX, and XXI concentrate	Factor VIII, IX, X, XI, XII, XIII, XIV, XV, XVI, XVII, XVIII, XIX, XX, and XXI deficiency	Febrile transfusion reaction, allergic reaction, hemolytic transfusion reaction, bacterial contamination, infection, immunomodulation, immunosuppression, transmission of CMV, HIV, hepatitis, and other infections
Factor VIII, IX, X, XI, XII, XIII, XIV, XV, XVI, XVII, XVIII, XIX, XX, XXI, and XXII concentrate	Factor VIII, IX, X, XI, XII, XIII, XIV, XV, XVI, XVII, XVIII, XIX, XX, XXI, and XXII deficiency	Febrile transfusion reaction, allergic reaction, hemolytic transfusion reaction, bacterial contamination, infection, immunomodulation, immunosuppression, transmission of CMV, HIV, hepatitis, and other infections
Factor VIII, IX, X, XI, XII, XIII, XIV, XV, XVI, XVII, XVIII, XIX, XX, XXI, XXII, and XXIII concentrate	Factor VIII, IX, X, XI, XII, XIII, XIV, XV, XVI, XVII, XVIII, XIX, XX, XXI, XXII, and XXIII deficiency	Febrile transfusion reaction, allergic reaction, hemolytic transfusion reaction, bacterial contamination, infection, immunomodulation, immunosuppression, transmission of CMV, HIV, hepatitis, and other infections
Factor VIII, IX, X, XI, XII, XIII, XIV, XV, XVI, XVII, XVIII, XIX, XX, XXI, XXII, XXIII, and XXIV concentrate	Factor VIII, IX, X, XI, XII, XIII, XIV, XV, XVI, XVII, XVIII, XIX, XX, XXI, XXII, XXIII, and XXIV deficiency	Febrile transfusion reaction, allergic reaction, hemolytic transfusion reaction, bacterial contamination, infection, immunomodulation, immunosuppression, transmission of CMV, HIV, hepatitis, and other infections
Factor VIII, IX, X, XI, XII, XIII, XIV, XV, XVI, XVII, XVIII, XIX, XX, XXI, XXII, XXIII, XXIV, and XXV concentrate	Factor VIII, IX, X, XI, XII, XIII, XIV, XV, XVI, XVII, XVIII, XIX, XX, XXI, XXII, XXIII, XXIV, and XXV deficiency	Febrile transfusion reaction, allergic reaction, hemolytic transfusion reaction, bacterial contamination, infection, immunomodulation, immunosuppression, transmission of CMV, HIV, hepatitis, and other infections
Factor VIII, IX, X, XI, XII, XIII, XIV, XV, XVI, XVII, XVIII, XIX, XX, XXI, XXII, XXIII, XXIV, XXV, and XXVI concentrate	Factor VIII, IX, X, XI, XII, XIII, XIV, XV, XVI, XVII, XVIII, XIX, XX, XXI, XXII, XXIII, XXIV, XXV, and XXVI deficiency	Febrile transfusion reaction, allergic reaction, hemolytic transfusion reaction, bacterial contamination, infection, immunomodulation, immunosuppression, transmission of CMV, HIV, hepatitis, and other infections
Factor VIII, IX, X, XI, XII, XIII, XIV, XV, XVI, XVII, XVIII, XIX, XX, XXI, XXII, XXIII, XXIV, XXV, XXVI, and XXVII concentrate	Factor VIII, IX, X, XI, XII, XIII, XIV, XV, XVI, XVII, XVIII, XIX, XX, XXI, XXII, XXIII, XXIV, XXV, XXVI, and XXVII deficiency	Febrile transfusion reaction, allergic reaction, hemolytic transfusion reaction, bacterial contamination, infection, immunomodulation, immunosuppression, transmission of CMV, HIV, hepatitis, and other infections
Factor VIII, IX, X, XI, XII, XIII, XIV, XV, XVI, XVII, XVIII, XIX, XX, XXI, XXII, XXIII, XXIV, XXV, XXVI, XXVII, and XXVIII concentrate	Factor VIII, IX, X, XI, XII, XIII, XIV, XV, XVI, XVII, XVIII, XIX, XX, XXI, XXII, XXIII, XXIV, XXV, XXVI, XXVII, and XXVIII deficiency	Febrile transfusion reaction, allergic reaction, hemolytic transfusion reaction, bacterial contamination, infection, immunomodulation, immunosuppression, transmission of CMV, HIV, hepatitis, and other infections
Factor VIII, IX, X, XI, XII, XIII, XIV, XV, XVI, XVII, XVIII, XIX, XX, XXI, XXII, XXIII, XXIV, XXV, XXVI, XXVII, XXVIII, and XXIX concentrate	Factor VIII, IX, X, XI, XII, XIII, XIV, XV, XVI, XVII, XVIII, XIX, XX, XXI, XXII, XXIII, XXIV, XXV, XXVI, XXVII, XXVIII, and XXIX deficiency	Febrile transfusion reaction, allergic reaction, hemolytic transfusion reaction, bacterial contamination, infection, immunomodulation, immunosuppression, transmission of CMV, HIV, hepatitis, and other infections
Factor VIII, IX, X, XI, XII, XIII, XIV, XV, XVI, XVII, XVIII, XIX, XX, XXI, XXII, XXIII, XXIV, XXV, XXVI, XXVII, XXVIII, XXIX, and XXX concentrate	Factor VIII, IX, X, XI, XII, XIII, XIV, XV, XVI, XVII, XVIII, XIX, XX, XXI, XXII, XXIII, XXIV, XXV, XXVI, XXVII, XXVIII, XXIX, and XXX deficiency	Febrile transfusion reaction, allergic reaction, hemolytic transfusion reaction, bacterial contamination, infection, immunomodulation, immunosuppression, transmission of CMV, HIV, hepatitis, and other infections

TABLE 257.1. BLOOD COMPONENT THERAPY: INDICATIONS AND COMPLICATIONS

RED BLOOD CELLS

The main goal of RBC transfusion is to increase oxygen carrying capacity. The life span of the RBC is 120 days. In general, anemia is fairly well tolerated down to a hemoglobin level of 8 g per deciliter. Below this level, cardiac output increases to compensate for the decreased oxygen carrying capacity. Young patients without cardiopulmonary, hepatic, renal, or cerebrovascular disease may tolerate a hemoglobin level as low as 6 to 7 g per deciliter. In most adult patients, each unit of transfused RBCs raises the hemoglobin level by 1 g per deciliter or the hematocrit by 3%. Cancer patients who are anemic due to chemotherapy often are transfused at a hemoglobin of 7 to 8 g per deciliter unless a condition such as angina exists that may require transfusion to a higher hemoglobin. Transfusion of 1 to 2 units of RBCs is not an uncommon therapeutic intervention for a hemoglobin of 8 g per deciliter in a symptomatic cancer patient. In immunosuppressed persons, RBCs are irradiated to avoid the occurrence of life-threatening post-transfusion graft-versus-host disease (GVHD).

A unit of RBCs (non-leukocyte-reduced) has 100% of the RBCs, 100% of the WBCs, and 20% of the plasma originally present in the donated unit of whole blood. There is an increasing worldwide trend toward using blood products leukocyte-reduced by filtration. The leukocytes present in donated blood have been implicated in many transfusion complications, including febrile transfusion reactions, HLA alloimmunization, immunosuppression and immunomodulation, transmission of CMV, development of post-transfusion GVHD, and viral activation (see also Complications of Transfusion).

If the desired outcome is an increase in hemoglobin or hematocrit, the physician should order 1 to 2 units of RBCs. Whole blood is generally no longer available and has been replaced by infusion of additive-solution RBCs or RBCs plus crystalloid. Because of changes during storage, whole blood contains insufficient amounts of viable platelets and factors V and VIII. If a patient needs factor replacement, the following blood components are indicated: fresh frozen plasma for clotting factor deficiencies, cryoprecipitate for fibrinogen replacement, and platelets for thrombocytopenia or thrombocytopeny.

Occasionally, a physician may wish to avoid transfusing plasma to a patient, such as a patient who has had a prior allergic or anaphylactic reaction to plasma. Patients with a congenital IgA deficiency may develop an IgG anti-IgA antibody and may have severe anaphylactic reactions after exposure to plasma. The physician dealing with this problem should contact the blood bank to inform them that the recipient is IgA deficient and has an anti-IgA antibody. The blood bank can provide washed cellular components or obtain special-order IgA-negative components, including fresh frozen plasma.

Because of high costs and potential complications associated with RBC transfusions, attempts have been made to find an alternative method of increasing a patient's hematocrit. Erythropoietin is a glycoprotein that stimulates RBC production. It is produced in the kidney and stimulates the division and differentiation of committed erythroid progenitors in the bone marrow. Recombinant erythropoietin has been available for clinical use since 1989 and has become increasingly popular. Remarkably well tolerated, one of the most important uses of recombinant erythropoietin therapy has been the correction of anemia associated with renal failure. Over 300,000 renal patients worldwide are now receiving this treatment.

Chronic renal failure is the prototypic erythropoietin-deficient state. More than 95% of patients with renal failure have a positive response to recombinant erythropoietin treatment. Moreover, with the commonly used weekly maintenance dose, this treatment can be cost-effective compared with RBC transfusions. Several studies have also demonstrated an improvement in quality of life in dialysis patients receiving erythropoietin and whose hemoglobin concentration increases from 6 to 7 g per deciliter to 9 to 10 g per deciliter. Besides its usage in renal failure patients, recombinant erythropoietin therapy can be used in other clinical settings as well, although with varying degrees of effectiveness.

Three other indications for use of recombinant erythropoietin therapy are approved by the Food and Drug Administration. They are, in decreasing order of evidence for their effectiveness, HIV-related anemia induced by zidovudine treatments with an erythropoietin level less than 500 mU per milliliter; chemotherapy-induced anemia in nonmyeloid malignancies; and reduction of perioperative allogeneic blood transfusions, limited to noncardiac and nonvascular elective surgeries in patients with hemoglobin higher than 10 and lower than 13 g per deciliter. Although only approximately 50% of unselected anemic cancer patients respond sufficiently to recombinant erythropoietin treatments, studies have shown that those who do respond have a significant increase in their energy level, functional status, and overall quality of life. Further studies are needed to define the optimum dose and schedule of recombinant erythropoietin administration and also to identify better predictors of response.

Other clinical settings in which the use of recombinant erythropoietin may provide benefit include the following: autologous blood collection, multiple myeloma, non-Hodgkin's lymphoma, myelodysplastic syndrome, rheumatoid arthritis, inflammatory bowel disease, acceleration of erythroid repopulation after allogeneic bone marrow transplantation, hyporegenerative anemia in patients undergoing organ transplantation and receiving cyclosporin A, and sickle cell anemia or thalassemia. Further studies are needed, however, to establish firm guidelines for the use of recombinant erythropoietin under these varied clinical circumstances.

PLATELETS

Platelet transfusions are indicated for treating patients with bleeding associated with thrombocytopenia or with a thrombocytopeny. For treating qualitative defects of platelet function, the indications for transfusion are complex. Often, because there is an excess of nonfunctional platelets, platelet transfusion may not correct the bleeding time to a measurable extent. Since the life span of platelets is about 8 days, this may mean that repeated platelet transfusions may be required if the clinical situation is life threatening. In general, the bleeding time begins to prolong as the platelet count falls below 100,000/μL and increases linearly down to a platelet count of 10,000 platelets/μL. In general, at a platelet count of 75,000/μL, the bleeding time is about 10 minutes; at 50,000/μL, it is about 15 minutes; and at 25,000/μL, it is about 20 minutes. At any given platelet level, patients with thrombocytopenia due to decreased production have a greater tendency to bleed than do patients with thrombocytopenia due to increased destruction, such as with idiopathic thrombocytopenic purpura. Circulating platelets in conditions with decreased production are older and physiologically less active, whereas in conditions associated with increased destruction, the marrow responds by markedly increasing its production of platelets. These circulating platelets generally are younger and more hemostatically effective.

In certain special clinical circumstances, such as life-threatening surgical bleeding or intracranial hemorrhage, a patient with 50,000 to 75,000 platelets/μL may benefit from a platelet transfusion. Patients who are actively bleeding after a major surgical procedure at a platelet count below 50,000/μL might benefit from a platelet transfusion as well. Patients who are severely thrombocytopenic (less than 10,000 to 15,000 platelets/μL), particularly when the condition is due to decreased production, are often given prophylactic platelet transfusions to prevent intracranial or other serious bleeding. This practice must be balanced against the risk that frequent prophylactic platelet transfusions may result in alloimmunization, which limits the efficacy of further platelet transfusion (refractoriness). In non-neoplastic conditions such as aplastic anemia, 80% of patients given non-leukocyte-reduced random-donor platelets will develop HLA alloantibodies. In contrast, in cancer patients undergoing chemotherapy, the incidence of HLA alloimmunization is less than 30% (13% in some series). Single-donor platelets, either cross-matched or

HLA-matched, are usually sufficient to improve low post-transfusion increments in HLA-alloimmunized patients. Use of leukocyte reduction filters for all blood transfusions will substantially reduce or eliminate the risk of HLA alloimmunization in these patients.

In immunosuppressed patients, including patients on chemotherapy, irradiation of blood products including platelets is recommended to avoid post-transfusion GVHD, which is associated with life-threatening bone marrow aplasia in addition to the usual skin, liver, and gastrointestinal tract manifestations of GVHD disease. Platelet sensitization also leads to febrile and allergic reactions. Platelet transfusions pose a risk of bacterial infections. About 1 in 1,500 to 1 in 2,500 units of platelets are believed to be contaminated with some type of bacteria.

Prophylactic platelet transfusions are designed to prevent serious bleeding episodes in persons with a platelet count below 10,000 to 15,000/ μ L. A pool of 4 to 6 units of random-donor platelets or a unit of single-donor platelets given once each day when the platelet count is below 10,000 to 15,000/ μ L is a reasonable clinical plan. If the patient is bleeding, repeated platelet transfusions may be indicated until the platelet count is above 50,000/ μ L or until the bleeding stops.

Platelet concentrates are prepared by centrifugation of whole blood or by platelet apheresis. One platelet concentrate contains 60% to 80% of the platelets originally present in the unit of whole blood and raises the post-transfusion platelet count by 5,000 to 10,000/ μ L. Apheresis platelets are collected by automated blood cell separators and contain the equivalent of 6 to 8 units of random-donor concentrates. There are several disease-related and other reasons why a patient may show poor post-transfusion platelet count increments, including HLA alloimmunization, splenomegaly, poor-quality platelets, use of ABO-incompatible platelets, rapid platelet consumption due to bleeding, sepsis, DIC, mucositis, antibiotics and other drugs, and antiplatelet antibodies. These causes all should be considered and the blood bank medical director consulted before committing a patient to a course of single-donor cross-matched platelets.

In patients suspected of having poor post-transfusion platelet count increments, platelet counts should be checked before, 1 hour after, and 24 hours after transfusion to ensure that an adequate increment has been attained. Patients who become alloimmunized (as evidenced by a less-than-expected increment in platelet count at 1 hour) can be treated with cross-matched, compatible, single-donor or HLA-matched platelets. The increment in platelet count achieved after transfusion can be calculated with the formula known as the corrected count increment (CCI):

$$CCI = \frac{(\text{Post-tx plt ct}) - (\text{pre-tx plt ct})}{\times BSA / (\text{Platelets transfused} \times 10^{11})}$$

where pre-tx plt ct = pretransfusion platelet count, post-tx plt ct = post-transfusion platelet count, and BSA = body surface area in square meters. A CCI higher than 7,500 is considered an acceptable outcome. Each unit of random-donor platelet concentrate is estimated to contain 6×10^{10} platelets and a unit of apheresis platelets 3×10^{11} platelets. In individuals with qualitative defects of platelet function, a single transfusion of 4 to 6 units of random-donor platelets or a unit of single-donor platelets may have no significant clinical effect if a large excess of nonfunctional platelets is circulating at that time. Therefore, in patients who are being prepared for surgery, more frequent transfusion or pheresis of nonfunctional platelets from the recipient coupled with platelet transfusion from a normal donor may be required to correct the prolonged bleeding time associated with severe defects of platelet function.

Platelets lack Rh antigens. However, platelets from Rh-positive donors still should not be transfused to Rh-negative women of childbearing potential because Rh-positive RBCs are present in platelet concentrates and may immunize the mother. If there is no alternative to an Rh-incompatible platelet transfusion, the patient could receive intravenous or intramuscular Rh immune globulin to prevent formation of an active D antibody.

GRANULOCYTES

Over 200 billion granulocytes are circulating in the intravascular volume of a 70-kg person and another equal number of granulocytes is adherent to the endothelial surface. Since the life span of granulocytes is only 6 hours, the marrow usually has a reserve of nearly mature granulocytes that is six times the circulating granulocytes mass in the marrow ready for release. Granulocytes in stored whole blood are not viable. If granulocytes are needed, they must be freshly collected by apheresis technology. The efficacy of granulocyte transfusions is further limited by the following: the small number of neutrophils that can be collected from untreated normal volunteer donors, only 1 to 1.5×10^{10} /collection; their short transfused half-life (6 hours); their short (24-hour) shelf-life; and the reactions encountered with their use, including acute respiratory distress. Higher doses of granulocytes can be collected from donors who are treated with granulocyte-colony stimulating factor (G-CSF) or granulocyte macrophage-colony stimulating factor (GM-CSF) (6 to 8×10^{10} PMN/collection). Transfusion of these granulocytes from G- or GM-CSF mobilized donors produces greater measurable post-transfusion neutrophil increments of 1 to 3,000/ μ L, even in adults.

Clinical trials of prophylactic granulocyte transfusions, however, conducted before G-CSF was available for donor mobilization did not show an impact on survival for the septic patient with leukemia. Studies using G-CSF-stimulated donors who are able to provide much larger numbers of neutrophils have not been reported. At this time, the indication for the use of granulocyte transfusions is restricted to the clinical settings of progressive local infection that is life threatening in patients who have been temporarily rendered neutropenic (≤ 500 PMN per microliter) for a period of several days in response to their chemotherapy. Such patients should have a reversible clinical condition, and should exhibit progression of local infection despite appropriate antibiotics. Some clinicians have reported a negative interaction between the concomitant administration of amphotericin B and granulocyte transfusions. These two therapeutic interventions are best administered separately.

COMPLICATIONS OF TRANSFUSION

Transfusion of ABO-incompatible blood (e.g., type A blood given to a patient with type O blood) can generate a dangerous acute intravascular hemolytic transfusion reaction. Biologic response modifiers released during such a reaction in association with the fixation of complement, such as inflammatory cytokines interleukin-1 (IL-1), interleukin 6 (IL-6), and tumor necrosis factor- α (TNF- α), cause rapid intravascular hemolysis and may result in DIC, acute renal failure, bronchospasm, hypotension, shock, and death. Symptoms suggestive of evolving intravascular hemolysis include low back pain, chest pain, restlessness, shortness of breath, and pain at the site of transfusion. Physical signs may include fever, chills, tachypnea, wheezing, rash, hypotension, arrhythmia, tachycardia, oliguria or anuria, diaphoresis, hemoglobinuria, and generalized bleeding due to DIC. If a major hemolytic transfusion reaction is suspected, the clinician should do the following:

1. Stop the blood transfusion immediately.
2. Take measures designed to reverse potentially life-threatening conditions generated by the transfusion reactions: administer intravenous fluids and vasopressors as needed to support the blood pressure, including possibly renal-dose dopamine (5μ g per kilogram per minute); ensure an adequate airway, provide oxygen and administer diphenhydramine, steroids, and epinephrine to reverse the bronchospasm. Use of diuretics should be considered after establishing adequate intravascular volume replacement. Diuretics, such as mannitol or furosemide will help to ensure adequate urine output to prevent oliguric renal failure and acute tubular necrosis. Mannitol should be avoided if renal failure has already begun.
3. Notify the blood bank.
4. Check the identification of the blood unit and patient.
5. Send the remaining blood to the blood bank.
6. Draw blood samples from another vein to check for hemoglobinemia and to repeat the typing and cross-match.
7. Obtain a urine sample to check for hemoglobinuria.

If the patient develops DIC and is bleeding with an increased prothrombin and partial thromboplastin time, replacement clotting factor therapy should be initiated using fresh frozen plasma. Cryoprecipitate should be given if the fibrinogen level is less than 50 to 80 mg per deciliter; platelet transfusion should be considered if the platelet count is less than 50,000 platelets/ μ L and the patient is bleeding. The patient's fluid intake and output, serum electrolytes, blood urea nitrogen, and creatinine should be monitored.

Patients exposed to blood transfusions may form antibodies against RBC antigens other than ABO. A transfusion reaction due to infusion of incompatible RBC antigens other than those antigens in the ABO system rarely results in acute intravascular hemolysis. Such patients, however, may have an acute or delayed extravascular reaction. Indeed, most non-ABO alloantibodies are IgG and are not present in high enough titers, or the antigen density on the RBC is not high enough, to activate the full C1-C9 complement sequence. If a patient has preexisting alloantibody from previous transfusions or pregnancies and blood containing the implicated blood group antigen is given, the patient usually does not have an acute intravascular hemolytic reaction. Instead, the transfused RBCs become coated with IgG and are removed by the spleen and the reticuloendothelial system, resulting in a shortened life span. Associated with this extravascular reaction, the transfused blood undergoes relatively rapid destruction, with an increase seen in the recipient's level of indirect and total bilirubin and lactic dehydrogenase, but without signs of hemoglobinemia or hemoglobinuria. Also absent with an extravascular hemolytic reaction is the life-threatening clinical scenario seen with acute

intravascular hemolysis as previously discussed.

RBC alloantibody actually may be present in a recipient at such low titer that it is not detected by the routine antibody screen or cross-match. This phenomenon is sometimes seen with alloantibody against antigens in the Kidd system (Jk^a or Jk^b). After transfusion with Jk^a antigen-positive RBCs, such a patient may have an anamnestic rise in antibody titer to high levels—usually in 5 to 7 days—and experience a rapid fall in hemoglobin and increases in the levels of bilirubin and lactic dehydrogenase. This is due to hemolysis of the previously transfused and still circulating Jk^a-positive RBCs, now hemolyzing because of the increased titer of Jk^a antibody in the recipient. This is termed a *delayed hemolytic transfusion reaction*. If the antibody binds complement to C9, the reaction produces hemoglobinemia and is considered a delayed intravascular hemolytic transfusion reaction; if complement is not fixed or is fixed only to C3, it produces an extravascular transfusion reaction. Similar reactions can be seen in patients with antibodies to antigens of the Rh, Kell, Duffy, and other blood group systems.

The most common transfusion reactions are febrile and allergic reactions. Febrile reactions are due to the reaction of the recipient to the foreign HLA and the leukocyte antigens present on transfused WBCs and to cytokines in non-leukocyte-reduced products ([Table 257.2](#)). HLA alloantibodies to transfused leukocytes occur in at least 20% of previously pregnant women and in up to 60% of multiply transfused patients. Since fever may be the presenting sign of a major hemolytic or septic transfusion reaction, when a patient develops a fever during transfusion the physician must stop the transfusion and send a blood sample to the blood bank for workup.

Infected Cause	Estimated Frequency (per unit)
Viral	
HIV	1:260,000
Hepatitis A	1:1,000,000
Hepatitis B	1:80,000
Hepatitis C	1:300,000
Parvovirus B19	1:50,000
HTLV types I and II	1:800,000
Bacterial (Contamination)	
Platelets	1:2,500
Red cells	1:500,000

TABLE 257.2. DIFFERENTIAL DIAGNOSIS OF ACUTE TRANSFUSION REACTIONS

Although a serious concern, most post-transfusion chills and fever are rarely due to infusion of blood contaminated with bacteria. Normally, aseptic technique, cold storage, and the natural antibacterial effects of the neutrophils and plasma prevent bacterial growth in stored RBCs. Occasionally, however, gram-negative bacteria that can grow in the cold, such as *Yersinia enterocolitica*, contaminate a unit of blood and produce endotoxin, both of which can cause DIC and shock after transfusion. Rarely, these contaminated units can be detected by visual inspection of the blood before transfusion. Any units with an unusual color, blood clots, or hemolysis must be quarantined or returned to the blood bank if the problem is not detected before arrival at the bedside. Platelets are also at risk of bacterial contamination since they are stored at 20° to 24° C. They can become contaminated with a variety of skin flora as well with enteric organisms. Infusion of such contaminated units can also produce septic shock.

Urticaria or hives may occur in 3% to 5% of transfusions and is thought to be due to reaction to plasma protein constituents. The transfusion must be stopped when these reactions are first noted. The transfusion may be resumed *only* if there are no signs of respiratory involvement or cardiovascular instability. If severe allergic signs are encountered or if wheezing, hypotension, or fever is noted, the transfusion must be stopped and the blood bank contacted. For serious allergic reactions, laryngeal edema, wheezing, dyspnea, or hypotension and tachycardia can occur, and a major hemolytic transfusion reaction should be ruled out. Diphenhydramine, hydrocortisone, and possibly epinephrine should be given as needed for treatment of other anaphylactic reactions.

The most severe post-transfusion anaphylactic reactions are occasionally fatal. They are usually due to IgA deficiency in a recipient who has developed anti-IgA antibodies. IgA deficiency is common (1:1000 persons), but antibody formation is rare. Patients with known IgA deficiency and an IgA antibody should receive washed RBCs and washed platelets; if these patients require plasma or plasma constituents, they should be derived from IgA-deficient donors.

Immunocompetent donor lymphocytes in donated blood can result in transfusion-associated GVHD in a susceptible recipient. Post-transfusion GVHD usually results in bone marrow aplasia and a minor rash, rather than conjugated serum hyperbilirubinemia or diarrhea, as usually seen in post-transplant engraftment syndromes. Post-transfusion GVHD is primarily restricted to severely immunosuppressed patients, such as those with congenital immunodeficiency syndromes, those with recent bone marrow or organ transplantation, and those with Hodgkin's disease or non-Hodgkin's lymphoma who are receiving intensive radiation and chemotherapy. Post-transfusion GVHD may also occur if immunocompetent patients receive blood from haplo-identical first-degree relatives. As a precaution, all such recipients should receive only irradiated cellular blood products.

With progressive storage, RBCs accumulate lactic acid and slowly leak potassium into the extracellular fluid. The increase in potassium rarely causes problems in adults. However, when transfusing patients in anuric renal failure or premature infants, blood less than 2 weeks old or washed RBCs have a lower extracellular potassium and may be preferred; the blood bank director should be consulted in such cases. In adults, major clinical problems associated with massive transfusion (more than 7 to 10 units within 24 hours) are thrombocytopenia and, if administration is too rapid, hypothermia. Hyperkalemia and acidosis after massive transfusion are problems primarily in newborns. Citrate toxicity resulting in hypocalcemia is primarily restricted to massively transfused patients with severe liver dysfunction who cannot metabolize the citrate in the anticoagulant/preservative solution. The routine administration of calcium to massively transfused patients is rarely necessary, however, because of the rapid metabolism of citrate in most patients.

Another important adverse event associated with transfusion is the transmission of infectious disease. Currently, blood donors are tested for hepatitis B surface antigen (HbsAg), hepatitis B core antibody (anti-HBc), human T-cell lymphotropic virus antibody (anti-HTLV-I/II), anti-hepatitis C virus antibody (anti-HCV), HIV antibody-1/ -2, HIV-1 p24 antigen (Ag), and syphilis. Blood components can also transmit diseases caused by bacteria and parasites, mainly malaria, babesiosis, and trypanosomiasis. Changes to ensure the safety of the blood supply include addition of new-donor screening tests, elimination of paid donors, and the routine screening of blood donors using updated donor history questionnaires. Risks of disease transmission are presented in ([Table 257.3](#)). It is known that virus can be transmitted from a blood donor who has recently acquired a viral infection and who is infectious but whose donor screening tests are still negative. This is known as the "window period." The length of the window period of infection has been substantially shortened even further by inception of nucleic acid testing (NAT) to screen donors for HIV and HCV. NAT testing is basically PCR testing for HIV and HCV. Eventually, all donor blood testing for infectious diseases will be performed by NAT (PCR) testing. Such testing can shorten the window period for HCV from the current 70 days to 11 days, and HIV from 16 days to 10 days.

Infected Cause	Estimated Frequency (per unit)
Viral	
HIV	1:260,000
Hepatitis A	1:1,000,000
Hepatitis B	1:80,000
Hepatitis C	1:300,000
Parvovirus B19	1:50,000
HTLV types I and II	1:800,000
Bacterial (Contamination)	
Platelets	1:2,500
Red cells	1:500,000

HTLV, human T-cell leukemia virus. (Adapted from Goodnough LT, Brecher ME, Kentler MH, AuBuchon JP. Transfusion medicine. *N Engl J Med* 1999;340:438.)

TABLE 257.3. INFECTIOUS RISKS OF BLOOD TRANSFUSION

CMV infection causes a mononucleosis-like syndrome in normal hosts and can cause severe pneumonia, bone marrow failure, colitis, retinitis, and hepatitis in immunocompromised or bone marrow transplant patients. CMV disease can be largely prevented by the use of CMV-seronegative blood products or by the use of third-generation leukocyte depletion filters. Because CMV is a virus that resides in leukocytes, many medical centers are now using prestorage or in-laboratory leukocyte-depleted blood as an equivalent product to CMV-seronegative blood.

Each unit of blood contains 250 mg of iron, whereas the daily excretion of iron from the body is about 1 mg. Patients with a chronic hemolytic anemia and an ongoing transfusion requirement, such as patients with thalassemia major, may receive more than 80 to 100 units of blood over many years. These patients have a significant risk of transfusion hemosiderosis, which can lead to congestive heart failure, diabetes, liver dysfunction, and impotence. Patients with a reasonable life expectancy who are expected to receive large numbers of transfusions should be considered to be candidates for prophylactic iron chelation therapy such as desferroxamine infusion.

prolonged fatigue, and 0.1% to 0.3% have major or life-threatening complications. The risk of death from marrow donation has been estimated at 1 in 15,000 to 1 in 20,000, approximately one-third to one-half the yearly risk of driving an automobile.

Umbilical cord blood is another source of allogeneic stem cells. Blood is collected from the umbilical cord and placenta at the time of delivery, samples are taken from the mother and baby for infectious disease testing and tissue typing, and the units are cryopreserved for later use. Because of the limited number of stem cells available in the small volume of cord blood, concerns about the ability to engraft adults have restricted this procedure primarily to pediatric patients. Several central repositories are now banking cord blood for transplantation. Data suggest that the risk of acute GVHD is less than with stem cells obtained from older donors, but platelet engraftment is delayed. The reduction in GVHD risk may allow the use of products with higher degrees of incompatibility than is otherwise tolerable.

The normal dose of nucleated cells infused is 1 to 5×10^8 per kilogram of recipient weight. All available evidence suggests that this inoculum is sufficient for regeneration of adequate hematopoiesis to last the patient's lifetime. When bone marrow, peripheral blood, or cord blood is infused into the patient, still undefined adhesion molecules allow the stem cells to infiltrate into marrow cavities, where expansion occurs. No detectable recovery of peripheral counts is visible until 8 to 21 days later. In fully engrafted allogeneic recipients, all hematopoietically derived elements including blood components, tissue macrophages, Kupffer's cells in the liver, dermal Langerhans' cells, and probably some microglial cells are donor derived. However, the bone marrow stroma and any remaining thymic tissue remain host-derived. Although not common, allergies, immunities, and autoimmune diseases and predispositions may also be transplanted with an allogeneic stem cell graft. Unfortunately, little donor immunity against infectious agents is transferred, necessitating substantial immune reconstitution and reimmunization against common pathogens.

PREPARATION FOR TRANSPLANTATION

Unlike the situation facing solid organ recipients where a limited, nonregenerable supply of organs exists, no triage system in stem cell transplantation determines priority. However, the procedure is rigorous, and patients must be carefully screened. The high doses of chemotherapy and radiation, need for extensive polypharmacy, and inevitable complications of transplantation place significant strains on the cardiac, pulmonary, hepatic, and renal systems, which will be exacerbated by underlying dysfunction. Patients typically undergo a full battery of tests to determine suitability for transplantation and to detect any correctable deficits before the procedure. Echocardiograms or MUGA (multigated angiogram) scans and pulmonary function tests are performed. Patients are tested for evidence of exposure to herpes simplex virus, cytomegalovirus, Epstein-Barr virus, varicella zoster, hepatitis B and C, human T-cell lymphotropic virus 1 (HTLV-1), HIV, *Treponema pallidum* infection, *Toxoplasma* infection, and tuberculosis. Detection of HIV has generally been an absolute contraindication to transplantation. Before admission, patients must be made aware of the real possibility of serious and fatal side effects of the therapy. In most hospitals, full informed consent is required.

Patients are conditioned for transplantation using a variety of chemotherapy- and irradiation-based regimens. The goal of conditioning, which usually takes place in the 7 to 10 days before infusion of the stem cells, is to provide antitumor effects, to create "space" in the marrow by depletion of host hematopoiesis, and, in the case of allogeneic transplants, to immunosuppress patients enough to allow engraftment of the donor stem cells. Commonly used chemotherapy agents are cyclophosphamide, etoposide, busulfan, melphalan, carmustine, and thiotepe, often in combination. Fractionated total body irradiation is given in doses of 1200 to 1400 cGy. For the most part, no established conditioning regimen is clearly superior to the others.

After conditioning is accomplished, reinfusion of stem cells is by simple transfusion. It is not currently known how the cells home to the marrow. Evidence of engraftment occurs approximately 8 to 21 days after stem cell infusion and is influenced by the stem cell source, cell count, use of hematopoietic growth factors, and the type of GVHD prophylaxis (in allogeneic transplantation). Engraftment is defined as the day that the absolute neutrophil count is greater than 500 per milliliter. Platelet and red cell engraftment usually occurs after neutrophil engraftment.

SUPPORTIVE CARE

Most centers have dedicated teams of physicians, nurses, social workers, nutritionists, and other support personnel who care for transplantation patients. Early after transplantation, the acute toxicities of the conditioning regimen and the complications of neutropenia dominate. During the time period waiting for engraftment, patients require transfusions of red cells and platelets, broad-spectrum antibiotics and often antifungal agents if fevers develop, and pain medication and parenteral nutrition if mucositis is severe. Central venous catheters allow intravenous access, given the extensive infusion needs. Patients remain in sterile environments, typically in specialized units where they are cared for by specially trained nurses. Some centers are now performing outpatient transplantations for low-risk patients, but even these centers must have access to adequate inpatient facilities to manage any emergency complications.

ISSUES IN AUTOLOGOUS TRANSPLANTATION

Autologous transplantation is used primarily for patients with non-Hodgkin's and Hodgkin's lymphomas, multiple myeloma, and solid tumors including breast, ovarian, testicular, non-small-cell lung cancer, and neuroblastoma. These tumors are thought to have a dose response to chemotherapy. Thus, administering high doses of conditioning may increase the response rate while marrow toxicity is ameliorated with the stem cell infusion. Patients with chemotherapy-responsive disease in a minimal disease state are the best candidates for autologous transplantation.

The advantages of autologous over allogeneic stem cell sources are the immediate availability of a donor, relative lack of toxicity, and faster lymphohematopoietic recovery. The duration of neutropenia is often briefer, and since the reconstituting graft is genotypically identical to the patient, there is no risk of GVHD. However, the overwhelming cause of treatment failure after an autologous transplantation is relapse of the original disease. Tumor cells contaminate both peripheral blood and bone marrow collections. Investigators have tried to reduce the number of tumor cells infused back to the patient with the graft by either negative selection (purging using tumor-specific antigens or in vitro chemotherapy agents) or positive selection (retaining only cells with markers for early progenitor cells). None of these techniques has proved to reduce relapse rates. Indeed, it is unlikely that most of the infused cells are biologically capable of causing disease. Most patients recur in original tumor sites, suggesting that it is residual disease and not reinfused cells that is responsible for most relapses. The lack of a graft-versus-tumor effect (see below) probably also contributes to the high relapse rates. If the conditioning regimen is not sufficient to eliminate the tumor, there is no immunologic barrier to eventual relapse.

ISSUES ALLOGENEIC TRANSPLANTATION

The theoretical advantages of allogeneic transplantation include (a) replacement of the hematopoietic system in patients in whom stem cell damage or disease preclude autologous transplantation, (b) no risk of relapse from the stem cell source, and (c) the new immune system offers the possibility of a graft-versus-tumor effect and lower relapse rates. However, it is acknowledged that these advantages come with a variety of disadvantages, including higher treatment-related mortality and risk of acute and chronic GVHD. Although relapse is the single most likely cause of treatment failure after allogeneic transplantation, most deaths are due to transplant-related mortality such as infection, GVHD, and organ failure. More people die from the procedure itself than from relapse of their original disease.

One problem with allogeneic transplantation is that most patients do not have suitable family member donors. Since both maternal and paternal HLA alleles are expressed and a child inherits one allele from each parent, full siblings have a 25% chance of matching each other. Given the average family size in the United States, only 30% of patients have sibling donors. For a patient with multiple siblings, the chance of having an HLA-identical sibling donor is equal to $1 - (0.75)^n$, where n is the number of siblings. The chances of finding a nonsibling family member who would be an appropriate donor is approximately 5% and makes typing of the extended family reasonable in certain circumstances. Nevertheless, two-thirds of patients need to look beyond their families for their donors.

For those unable to find a related donor, identification of a matched unrelated donor is a possibility. Almost 3 million volunteers are in the National Marrow Donor Registry, the major registry in the United States. Many other registries exist around the world. Cooperation among them through an organization called Bone Marrow Donors Worldwide allows transplantation centers to search the world for the most appropriate donors. Approximately 85% of white patients, 59% of African American, 62% of Asian American, and 76% of Hispanic patients initiating unrelated donor searches eventually find donors. Allogeneic donors are selected on the basis of the degree of match with the patient, their relationship to the patient (sibling, other family member, unrelated individual), age, gender, prior history of pregnancy or transfusion, and infectious disease status.

The human major histocompatibility complex (MHC) is located on the short arm of chromosome 6 and codes for the HLAs. These highly polymorphic glycoproteins are found on almost all cells and are critical to the immune response. Class I (HLA-A, -B, -C) and class II antigens (HLA-DR, -DP, -DQ) may be identified by either serologic or molecular methods. Although the traditional "perfect" match is 6/6 (HLA-A, -B, -DR), more refined HLA typing is changing this definition so that people

now speak of 10/10 or even 12/12 matches. Failure to be completely matched at known loci is associated with greater degrees of GVHD, graft rejection, and poorer immune reconstitution, resulting in higher morbidity and mortality. Efforts to cross HLA barriers using 5/6 matched or other alternative donors have met with difficulty in overcoming these complications. Even when completely matched allogeneic donors are used, differences in minor histocompatibility antigens can result in serious GVHD.

GVHD occurs when a cascade of events, triggered by immunologic differences between patient and donor, cause tissue damage. Alloreactive T cells play a critical role in this complication, and allogeneic recipients require either chemoprophylaxis (cyclosporine and methotrexate) or T-cell removal to prevent severe acute GVHD. In contrast to solid-organ transplantation, immune tolerance eventually occurs in most allogeneic recipients, allowing discontinuation of all immunosuppressive therapy. Either clonal deletion of alloreactive cells or induction of anergy may be the mechanism for this tolerance.

Patients undergoing allogeneic transplantation do not recover substantial immune function until at least 1 year after transplantation, whereas those receiving stem cells from an unrelated donor are considered severely compromised for at least 2 years. Before immune recovery, patients have defects in both cellular and humoral immunity. They are often hypogammaglobulinemic, do not respond to immunizations appropriately, and have a risk of overwhelming infections. In patients with chronic GVHD, which is also associated with ongoing need for immunosuppression, the immune defects may last indefinitely.

SPECIFIC COMPLICATIONS OF HEMATOPOIETIC STEM CELL TRANSPLANTATION

By definition, high-dose therapy carries a much higher risk of mortality and toxicity than conventional-dose chemotherapy. Estimated treatment-related mortality rates vary from 1% to 5% for autologous procedures to 10% to 50% for allogeneic procedures. [Table 258.2](#) summarizes the most common complications of hematopoietic stem cell transplantation.

Early
Nausea, vomiting
Mucositis
Diarrhea
Pancytopenia
Failure to engraft, graft rejection
Deep venous thrombosis—catheter-related
Pericarditis, cardiomyopathy
Hemorrhagic cystitis
Acral dermatitis
Alopecia
Infections: bacterial, viral, fungal
Interstitial pneumonitis
Venoocclusive disease (allogeneic)
Acute graft-versus-host disease (allogeneic)
Late
Infections: bacterial, viral, fungal, protozoal
Chronic graft-versus-host disease (allogeneic)
Graft failure
Myelodysplasia
Secondary malignancies
Cataracts
Avascular necrosis
Infertility
Hypothyroidism

TABLE 258.2. COMPLICATIONS OF HEMATOPOIETIC STEM CELL TRANSPLANTATION

EARLY COMPLICATIONS

Early complications account for most treatment-related deaths. Most conditioning regimens, by virtue of their effects on actively dividing cells, result in mucositis and alopecia. Nausea and vomiting are common despite use of serotonin antagonists. During the period of neutropenia, patients have a significant risk of developing gram-positive, gram-negative, and fungal infections, and antibiotics and antifungal agents are used frequently. The herpesviruses tend to reactivate during and after transplantation and require prophylactic treatment or careful observation and prompt treatment of infection.

Failure to engraft is a rare but dire complication. In autologous transplantation patients, this is usually due to a poor harvest or to progenitor damage when multiple chemotherapy regimens deplete stem cells before collection. In allogeneic transplantation patients, failure to engraft may be due either to an inadequate dose of stem cells or to graft rejection by residual host T lymphocytes. Additional infusions of stem cells, with or without further conditioning of the patient, is required in these situations. Because of the intensity of the conditioning regimen, graft rejection occurs in less than 1% of matched sibling transplants when cyclosporine and methotrexate are used for GVHD prophylaxis. The use of T-cell-depleted grafts has been associated with a higher rate of graft rejection.

Veno-occlusive disease (VOD) occurs in 5% to 50% of patients and is a syndrome characterized by elevation in bilirubin, hepatomegaly, right upper quadrant pain, weight gain, and ascites. Pathophysiologically, endothelial damage from the conditioning regimen results in microthromboses in hepatic venules and sinusoids. Patients develop jaundice and have a capillary leak syndrome with third spacing of fluids. They are intravascularly volume-depleted despite total body fluid overload. Treatment is supportive and usually resolves without sequelae, although VOD may be fatal if severe. Predictive factors include a history of hepatic insults, hepatitis, and hepatotoxic medications (including estrogens and busulfan).

Pulmonary complications are common and often serious. Pulmonary edema may occur even in those with normal cardiac function because of the aggressive fluids administered during transplantation and capillary leak from the conditioning regimen. Bacterial and fungal pneumonias may occur. Interstitial infiltrates and hypoxia not due to fluid or bacterial or fungal infection is known as *interstitial pneumonitis*. One type of interstitial pneumonitis is caused by reactivation of cytomegalovirus, which may also be associated with hepatitis and myelosuppression. Although cytomegalovirus was a major cause of death in the past, better antiviral agents and strategies for detecting early reactivation have dramatically decreased the incidence of this complication. Another type of interstitial pneumonitis is *diffuse alveolar hemorrhage*, a syndrome characterized by bleeding into the alveoli with resultant respiratory distress. The cause is unknown, and the syndrome is associated with high mortality. Treatment is largely supportive, but high-dose corticosteroids are often used to reduce any damage from immunologic injury or cytokines.

Acute GVHD occurs in 30% to 70% of sibling donor recipients and 40% to 90% of unrelated donor recipients despite prophylaxis. Incidence depends on many patient and donor factors, such as source of stem cells, degree of HLA match, type of prophylaxis, patient and donor age, gender, cytomegalovirus status, and donor parity and transfusion history. GVHD is thought to be due to donor T cells that are triggered by contact with minor histocompatibility antigens. These cells interact with host tissues, either through direct cellular attack or cytokine-mediated changes (tumor necrosis factor- α [TNF- α] and γ -interferon) affecting the skin, liver, and gastrointestinal tract. Patients exhibit rashes, nausea, diarrhea, or liver abnormalities. The severity of acute GVHD is expressed as individual organ stages (0 to 4) combined to render an overall grade (0 to IV). Treatment is with increased immunosuppression (usually corticosteroids), and most cases respond. Nevertheless, severe GVHD may be refractory to treatment and can be fatal, either from direct organ damage or from infection related to the intensified immunosuppression.

LATE COMPLICATIONS

The chemotherapy and radiation delivered in the conditioning regimen and rigors of transplantation may have long-term effects. Children may suffer stunted growth and intellectual deficits, especially patients receiving cranial and total body irradiation. Many of the conditioning regimens are sterilizing for both men and women and result in infertility. Patients receiving extended corticosteroid therapy may suffer from avascular necrosis, osteoporosis, hypertension, and diabetes in addition to ongoing risk for infection.

Chronic GVHD is a complication of allogeneic transplantation occurring in 30% to 70% of survivors and is a major cause of late morbidity and mortality. Prior acute GVHD, older patient age, use of a mismatched donor, and peripheral blood as a stem cell source all have been associated with higher rates of this complication. Chronic GVHD can affect almost any organ and is largely treated with increased immunosuppression and supportive care. Some examples of chronic GVHD manifestations are skin rashes, joint contractures, mouth ulcers, fatigue, myalgias, gastrointestinal symptoms, bronchiolitis obliterans, and interstitial pneumonitis. Laboratory evaluation may show thrombocytopenia and evidence of cholestasis and transaminitis. Onset is usually between 100 days and 6 months after transplantation, although earlier and later development is possible. Patients with chronic GVHD are severely immunosuppressed, and infection is the major cause of death in this population. However, in most patients with chronic GVHD, organ involvement eventually resolves after 1 to 2 years, allowing discontinuation of immunosuppression.

Myelodysplasia is a late complication of autologous transplantation, particularly after cyclic pretransplantation chemotherapy and in patients who have evidence of

clonal hematopoiesis before transplantation. Prognosis is grim, and affected patients often do poorly even with subsequent allogeneic transplantation.

Late malignancies are increased after transplantation compared with the normal population, but adequate studies using patients treated with nontransplant chemotherapy as controls have not been conducted. The quoted late malignancy rates (primarily cutaneous malignancies, brain tumors, and head and neck cancers) for allogeneic recipients are up to 2.2% at 10 years and 6.7% at 15 years. Patients treated with autologous transplants for Hodgkin's disease have a 5% rate of secondary malignancies at 5 years.

LONG-TERM ISSUES

Most studies document reasonable quality of life after autologous and allogeneic transplantation, although many patients continue to report significant side effects. Most autologous and allogeneic patients return to work, resume their pretransplantation social relationships, and report good health. However, many continue to notice fatigue, sexual difficulties, skin changes, susceptibility to colds, and sleep disturbances. Autologous patients probably recover faster than allogeneic or unrelated-donor patients. In allogeneic transplantation, chronic GVHD is a major impediment to return to normal function.

Patients have ongoing risk of infection long after transplantation. They receive prophylaxis against *Pneumocystis carini* pneumonia for at least 1 year after transplantation and longer if they remain on corticosteroids. Herpes simplex and varicella zoster virus may reactivate, and many centers continue antiviral therapy for a prolonged period. Varicella virus may present clinically in unusual patterns, including visceral reactivation (causing severe abdominal pain), viral meningitis, or early dissemination. Patients with chronic GVHD have a particularly high risk of infections due to hypogammaglobulinemia and immune dysfunction. These patients are often given daily penicillin prophylaxis against pneumococcus and immunoglobulin replacement if found to be deficient in IgG² and IgG₄ subclasses.

After transplantation, patients lose their immunity to prior vaccinations and must be reimmunized at 1 and 2 years for tetanus, diphtheria, polio, pneumococcus, meningococcus, and *Haemophilus influenzae* type B. Immunizations earlier than 1 year after transplantation are not likely to be effective because of inadequate immune recovery. Influenza A vaccinations may begin 6 months after transplantation and should be given annually. At 2 years after transplantation, patients receive immunizations for measles, mumps, and rubella if they are off immunosuppression and free of chronic GVHD (since this is a live virus vaccine). If patients are returning to work in occupations in which they may be exposed to hepatitis B, immunity should be confirmed and reimmunization undertaken, if necessary.

Patients must continue to be monitored for primary disease relapse, secondary malignancies, chronic GVHD, and long-term effects of chemotherapy and radiation, such as cataracts and hypothyroidism. Patients with chronic GVHD on prolonged immunosuppression have a higher incidence of cutaneous and mucosal malignancies. They should avoid excessive sun exposure, given their predisposition to skin cancers and risk of exacerbating chronic GVHD. All survivors should have routine eye examinations, dental checkups, mammograms, Papanicolaou (Pap) smears, sigmoidoscopies, and prostate examinations at recommended intervals. Aggressive treatment for hypertension, osteoporosis, and hyperlipidemia should not be neglected. Most women treated with total body irradiation undergo premature menopause, and hormone replacement therapy should be addressed. However, rare patients retain fertility, and appropriate family planning should be offered to these individuals.

SPECIFIC APPLICATIONS

Since transplantation results vary considerably, depending on the stage of disease, type of transplant, and other clinical factors, broad ranges of statistics are available in the literature. Care must be taken in interpreting these numbers because significant selection bias confounds comparison with conventional therapy and among institutions. For specific details regarding these diseases, see individual chapters. General concepts for the major indications are presented in the following sections.

ACUTE MYELOGENOUS LEUKEMIA AND ACUTE LYMPHOBLASTIC LEUKEMIA

Despite encouraging remission rates, most adult patients with acute myelogenous leukemia (AML) and acute lymphoblastic leukemia (ALL) treated with conventional chemotherapy still suffer relapse and eventually die of their disease. This observation has provided the impetus to intervene with stem cell transplantation before refractory disease develops. Transplantation statistics for disease-free survival (DFS) at 3 to 5 years include the following:

Autologous transplantation (AML or ALL)—first complete remission (CR1) 30% to 50% (AML or ALL, greater than CR1, 10% to 30%).

Allogeneic transplantation (AML or ALL), CR1 40% to 70% AML, first relapse or greater than CR1, 30% to 40%; ALL, greater than CR1, 20% to 40%.

It is notable that as the ability to give higher-dose consolidation chemotherapy has improved, transplantation has been reserved for patients with high-risk disease in the first complete remission and for those who relapse. Results for patients with AML in first relapse are about the same as when the procedure is performed in those in second remission, so patients in early relapse often proceed straight to transplantation without reinduction. In contrast, ALL patients in relapse have a much poorer outcome, and every effort is made to get patients back into remission before performing the transplantation procedure. Transplantation physicians consider a patient's age, physical status, disease characteristics (subtype, cytogenetic abnormalities, response to therapy, duration of remission), donor availability, and preferences when evaluating appropriateness for transplantation.

CHRONIC MYELOGENOUS LEUKEMIA

Chronic myelogenous leukemia (CML) is a major indication for stem cell transplantation because it is incurable by any other means. The best results are obtained when the procedure is performed within the first year after diagnosis for patients in the early phase of the disease. Ten-year DFS is approximately 40% to 80% using sibling donors, and results of unrelated donor transplantation are approaching these figures. Patients in accelerated phase have an approximately 20% to 40% DFS, whereas the success rate drops to 0% to 20% for patients in blast crisis. CML seems to be exquisitely sensitive to graft-versus-leukemia effects, and relapses after stem cell transplantation may be salvaged with donor lymphocyte infusions.

APLASTIC ANEMIA

Although aplastic anemia was a common indication for transplantation early in the development of the field, it is actually a rare disease with multiple causes. Survival rates with allogeneic transplantation approach 60% to 90% with little toxicity in young (under 30 years) persons. Early difficulties with higher rates of graft rejection, presumably due to the immunologic activity associated with the disease, have been largely overcome. Although most patients present with profound pancytopenia, transfusions before transplantation may sensitize patients and increase mortality, so they should be avoided in transplantation candidates. Patients who develop aplastic anemia in the setting of Fanconi's anemia must be recognized before the transplantation procedure. Impaired DNA repair mechanisms makes these patients much more susceptible to alkylator therapy, and they will suffer fatal organ toxicity if given standard doses of cyclophosphamide during conditioning.

MYELOYDPLASTIC SYNDROME

Patients with a diagnosis of myelodysplastic syndrome constitute a growing percentage of the transplant population, since other options are largely supportive. Patients with less biologically aggressive disease (refractory anemia or refractory anemia with ringed sideroblasts) do much better (50% to 70% DFS) than patients transplanted with more advanced disease (refractory anemia with excess blasts, refractory anemia with excess blasts in transformation), who tend to have much higher rates of transplant-related mortality and relapse (20% to 30% DFS). Patients with secondary AML do poorly with any therapy. The new international prognostic scoring system (which uses number of cytopenias, cytogenetic abnormalities, and blast count) was developed in patients treated with nontransplantation therapies. However, this system also has prognostic importance after allogeneic transplantation.

CONGENITAL DISORDERS

Allogeneic transplantation has been successfully performed in patients with inherited disorders of hematopoiesis, immune function, and metabolism. In most of these disorders, the timing of transplantation is complicated because many patients can survive with reasonable quality of life for prolonged periods. Transplantation should be performed once the poor trajectory of the disease is established, but before irreversible deficits occur and significant organ damage substantially increases the

risks. Recurrent infections, iron overload from transfusions, and neurologic damage all decrease the success of the procedure.

MULTIPLE MYELOMA

Both autologous and allogeneic transplantations have been performed for multiple myeloma. Studies thus far have not shown a plateau on the survival curve, although transplantation does seem to delay progression of disease and prolong survival, but with high transplantation-related mortality. However, most patients undergoing allogeneic transplantation eventually suffer relapse, with only 5% to 20% remaining alive and disease-free more than 4 years after the procedure. Results are somewhat better in patients undergoing autologous transplantation with a 6-year DFS of approximately 25%.

NON-HODGKIN'S LYMPHOMAS AND HODGKIN'S DISEASE

Non-Hodgkin's lymphomas and Hodgkin's disease are usually approached by autologous transplantation unless extensive bone marrow involvement or other mitigating circumstances are present. Randomized studies have shown that transplantation results in better DFS in patients who relapse after a short duration. Estimates of DFS are approximately 10% to 50%, depending on stage, prior therapy, chemotherapy responsiveness, and histology. The role of autologous transplantation in patients with slowly responding disease or high-risk disease in first complete remission is being studied.

SOLID TUMORS

Autologous transplantation has been used for a variety of solid tumors, including breast cancer, testicular cancer, small-cell lung cancer, ovarian cancer, neuroblastoma, and brain tumors. Breast cancer constitutes the most rapidly growing indication for autologous transplantation and has been the reason for several highly publicized lawsuits against health maintenance organizations and insurance companies who have denied women coverage for the procedure. Ongoing randomized national trials will help define the role of hematopoietic cell transplantation in the management of high-risk primary and metastatic solid tumors. Nonrandomized trials report a DFS of 10% to 20% in patients with metastatic breast cancer after limited follow-up.

CHAPTER 259: ANTICOAGULANT AND FIBRINOLYTIC THERAPY

BRUCE FURIE

Oral Anticoagulants

Three pharmacologic agents predominate in the treatment or prevention of thromboembolic disease. Warfarin is unique in that it is administered by the oral route and thus can be taken long term by outpatients. Because it inhibits the synthesis of biologically active blood-clotting proteins, it does not work instantaneously nor does it act on existing thrombi. Heparin, administered by the intravenous or subcutaneous route, acts immediately to inhibit the active enzyme forms of the blood-clotting proteins. However, it does not cause existing clots to dissolve but prevents their enlargement. Fibrinolytic therapy using streptokinase, urokinase, or tissue plasminogen activator is administered parenterally. Because these enzymes digest fresh existing thrombi, such therapies rapidly accelerate the clearance of the vessel blockage that thrombi cause. The indications, complications, advantages, and disadvantages of these drugs dictate their proper use.

Anticoagulant therapy is used for two distinct indications. In one application, anticoagulants are used to prevent the development of thromboembolic disease in patients predisposed to such problems. This includes patients with an hereditary tendency to hypercoagulability due to protein C deficiency, proteins S deficiency, antithrombin III deficiency, or resistance to activated protein C. In addition, atrial fibrillation, prosthetic heart valves, and heart failure are among the medical problems that can lead to thrombus formation and subsequent embolization. These patients require *prophylactic* anticoagulant therapy to prevent the development of thromboembolic disease. Other patients with *active* thromboembolic disease, including deep venous thrombosis and pulmonary embolism, require anticoagulant therapy to prevent extension of existing thrombi and to allow reversal of vessel occlusion by physiologic fibrinolytic mechanisms.

ORAL ANTICOAGULANTS

The coumarin anticoagulants, specifically warfarin, are popular antithrombotic agents, which function as antagonists of the action of vitamin K in the synthesis of the vitamin K–dependent blood coagulation proteins (prothrombin, factor VII, factor IX, and factor X), proteins that contain *g*-carboxyglutamic acid. After synthesis, these proteins undergo post-translational processing in a vitamin K–dependent reaction in which glutamic acid residues on the protein are modified to *g*-carboxyglutamic acid. Warfarin inhibits enzymes in the vitamin K cycle, thus inhibiting *g*-carboxylation and leading to the synthesis of inert forms of the blood-clotting proteins ([Fig. 259.1](#)). Because warfarin inhibits the biosynthesis of the vitamin K–dependent proteins but not the activity of already synthesized protein, the effect of warfarin is delayed until the fully active blood-clotting proteins are cleared from the blood. Warfarin must be administered for 4 to 5 days before the antithrombotic action is therapeutic.

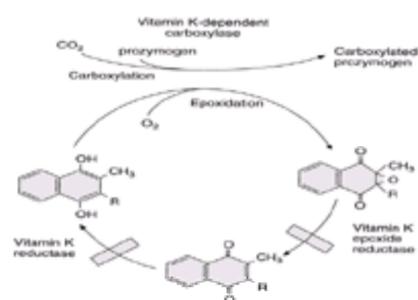

FIGURE 259.1. Vitamin K cycle and its inhibition by warfarin. Vitamin K is reduced to the vitamin K hydroquinone by a vitamin K reductase inhibited by warfarin. The vitamin K hydroquinone is a cofactor for the vitamin K–dependent carboxylase. In this reaction, the hydroquinone is oxidized to the vitamin K epoxide, and glutamic acid is converted to *g*-carboxyglutamic acid. The carboxylase is not inhibited by warfarin. The vitamin K epoxide is salvaged by a vitamin K epoxide reductase, an enzyme sensitive to warfarin inhibition, and is recycled back to vitamin K.

Warfarin sodium, administered orally, is completely absorbed, although there remains variation in the rate of absorption. In the blood, 97% of warfarin circulates bound to albumin; the unbound fraction is biologically active. The prothrombin time, which measures the extrinsic pathway, is used to monitor therapy with warfarin. Decreases in the activities of factor VII, factor X, and prothrombin prolong the prothrombin time. Warfarin is administered to prolong the prothrombin time into the therapeutic range. The international normalized ratio (INR) corrects for the variation in potency of different thromboplastins. The recommended therapeutic range varies with the indication for warfarin anticoagulation ([Table 259.1](#)).

Prevention of	
Deep venous thrombosis	2.0–3.0
Subclavian venous thrombosis	2.0–3.0
Pulmonary embolism	?
Prophylaxis Against Systemic Thromboembolic Disease	
Atrial fibrillation	2.0–3.0
Cardiac valve replacement	
Mechanical valves	2.5–3.5
Tissue valves	2.0–3.0

INR, international normalized ratio.

TABLE 259.1. INTENSITY OF ANTICOAGULANT THERAPY: RECOMMENDED INR VALUES

Warfarin is contraindicated in patients who will not take the drug reliably or will not obtain regular laboratory measurement of the prothrombin time. In addition, patients with either hereditary or acquired bleeding disorders or with anatomical lesions that predispose them to serious bleeding should not be given warfarin. This drug should not be used in pregnancy because it is teratogenic and is associated with the fetal warfarin syndrome.

Bleeding complications occur in 10% to 20% of warfarin-treated patients. Bleeding includes epistaxis, purpura, hematuria, retroperitoneal bleeding, large hematomas, or gastrointestinal bleeding. Intracranial bleeding can be life-threatening. Overdosage of warfarin is a common cause of excessive bleeding. Proper action varies from the withholding of warfarin, administration of vitamin K, or the administration of fresh frozen plasma, depending on the seriousness of the bleeding complication.

HEPARIN

Heparin is a widely used anticoagulant that inhibits the active enzyme forms of most of the blood clotting proteins. A high-molecular-weight sulfated glycosaminoglycan (mean molecular weight 12,000) isolated from porcine intestinal mucosa or bovine lung, heparin accelerates the binding of antithrombin III, a plasma protease inhibitor, to factor Xa, thrombin, and other proteases in the blood coagulation pathways.

Heparin, most frequently used to treat thromboembolic disease, is administered by either the intravenous or subcutaneous route. Intravenous heparin by bolus injection or by continuous infusion leads to immediate anticoagulation. This results in a prolongation of the partial thromboplastin time, the prothrombin time, and the thrombin time. By convention, the adjustment of therapeutic heparin doses are titrated against the partial thromboplastin time, which is maintained at about 1.5- to 2 times the control value. Heparin prevents the extension of existing thrombi but does not dissolve these thrombi.

Heparin is also used prophylactically to decrease the risk of the development of thromboembolic disease. Patients at risk of thromboembolic disease who are undergoing intra-abdominal surgery benefit from mini-dose heparin prophylaxis. Some patients requiring chronic anticoagulation in whom warfarin is either not satisfactory or not indicated receive chronic subcutaneous heparin. Prophylactic low-dose heparin need not be monitored with the partial thromboplastin time, but adjusted-dose subcutaneous heparin therapy depends on the regular monitoring of the partial thromboplastin time.

The most common complication of heparin therapy is bleeding. This may occur when excessive heparin therapy has been used but can also be associated with therapeutic heparin doses. Bleeding may be limited to ecchymoses and purpura or may be more serious gastrointestinal, retroperitoneal, or intracranial bleeding. In about 5% of patients, thrombocytopenia complicates heparin therapy. Heparin-induced thrombosis is a rare but serious complication. Osteoporosis is a complication of long-term heparin therapy. Heparin may be used in pregnancy when an anticoagulant is required. With a half-life of about 2 hours, heparin is cleared by the reticuloendothelial system. When heparin therapy is discontinued because of mild bleeding complications, the anticoagulant effect is reversed over a course of hours. For serious bleeding complications, the heparin effect can be reversed with protamine.

Low-molecular-weight heparins, such as enoxaparin, are fractionated from heparin and enriched for their anticoagulant activity. Low-molecular-weight heparin is administered subcutaneously. Enoxaparin is given every 12 hours at a dose of 30 mg for prophylactic therapy and at 60 mg for treatment of thromboembolic disease. Another low-molecular-weight heparin, dalteparin (Fragmin), is given on a daily schedule. No monitoring of either the prothrombin time or the partial thromboplastin time is required with low-molecular-weight heparins, since neither is affected.

HIRUDIN

Hirudin, the anticoagulant component of the saliva of the medicinal leech, is a polypeptide that inhibits the action of thrombin. Prepared by recombinant DNA techniques, it is now available for clinical use as an alternative to heparin. Because hirudin is structurally unrelated to heparin, it can be used in patients requiring anticoagulant therapy who have heparin-induced thrombocytopenia or heparin-induced immune responses. Hirudin is given intravenously and is used only for short-term anticoagulation.

FIBRINOLYTIC THERAPY

In contrast to warfarin and heparin, fibrinolytic therapy involves the infusion of enzymes into the blood to digest arterial and venous thrombi. Flow, blocked by thrombi, is rapidly restored when fibrinolytic therapy is effective. Urokinase, streptokinase, and tissue plasminogen activator are three agents used for fibrinolytic therapy ([Fig. 259.2](#)). Streptokinase is derived from b-hemolytic streptococci, urokinase is purified from human urine, and recombinant tissue plasminogen activator is expressed in heterologous mammalian cells based on the gene for human tissue plasminogen activator. These enzymes convert plasminogen to plasmin, and plasmin digests fibrin within the clot. Although the indications for fibrinolytic therapy vary, hemodynamically compromised patients with pulmonary emboli may benefit greatly from this therapy. Fibrinolytic therapy with acute myocardial infarction and acute arterial thrombosis or thromboembolic occlusion has been well established. The use of fibrinolytic therapy for deep venous thrombosis is controversial.

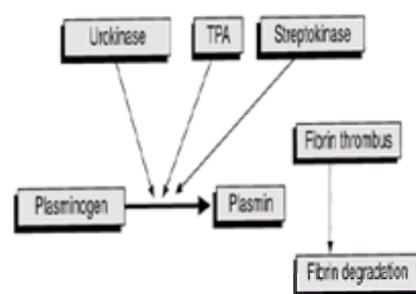

FIGURE 259.2. Mechanism of fibrinolytic therapy. Urokinase, tissue plasminogen activator (*TPA*), or streptokinase catalyze the conversion of plasminogen to plasmin. Plasmin digests the fibrin thrombus.

Fibrinolytic therapy is administered by the intravenous route. Therapy can be administered systemically through a peripheral vein or instilled through a catheter adjacent to the site of thrombus.

The dosage of fibrinolytic therapy is monitored by measuring the thrombin time, the fibrinogen level, or the plasminogen level. In general, measurement of the thrombin time is the preferred method, where the thrombin time is maintained at two- to five times the control level.

The major complication of fibrinolytic therapy is bleeding. Urokinase, streptokinase, and tissue plasminogen activator digest fibrinogen, thus leading to hypofibrinogenemia and increased risk of bleeding. Because of this risk, fibrinolytic therapy is contraindicated in patients who have had recent surgery, who have thrombocytopenia, and who are actively bleeding or predisposed to bleeding. Patients with central nervous system abnormalities should not receive fibrinolytic therapy. Streptokinase, derived from bacteria, may be associated with allergic reactions.

CHAPTER 260: CANCER PAIN MANAGEMENT

JANET L. ABRAHM

[Transmission of the Pain Signal](#)
[Evaluation of the Complaint of Pain](#)
[Therapy for Pain](#)
[Choice of Medication](#)
[Adjuvant Medications](#)
[Specific Clinical Problems](#)

Pain is often the first thing that comes to mind when patients are told they have cancer; families want to know if the patient will suffer. In fact, the fear of prolonged, unrelieved suffering may prevent patients from accepting potentially curative therapies. It is therefore reassuring to know that with current techniques, pain can be relieved in 90% of cancer patients, even when the cause of the pain cannot be eliminated. To accomplish this, the clinician must perform a thorough evaluation and assessment of the pain complaint, select the correct combination of therapies, and prevent and treat side effects caused by pain-relieving medications.

TRANSMISSION OF THE PAIN SIGNAL

For a patient to feel “pain,” a signal arising from a noxious stimulus in the periphery must be transmitted to the centers in the brain that create the experience of pain. Histamine, serotonin, and bradykinin released at the site of tissue injury initiate the transmission of the signal, and prostaglandins, which do not themselves activate these fibers, sensitize them to lower levels of mechanical and chemical stimulants.

After activation of peripheral receptors, the signal passes along myelinated A_δ or unmyelinated C fibers and enters the spinal cord through the dorsal root. Substance P and the excitatory neurotransmitters glutamate, aspartate, and adenosine diphosphate mediate and enhance the transmission of this signal. The pain signal next usually crosses over and ascends in one of the two contralateral spinothalamic tracts to the hypothalamus and the somatosensory cortex.

Transmission of the pain signal can be inhibited at several places along this course. The dorsal longitudinal fasciculus is the descending pathway that inhibits transmission of the pain signal as it enters and ascends the spinothalamic tracts. Endogenous and exogenous opiates inhibit transmission and provide pain relief by binding to opiate receptors in the dorsal horn of the spinal cord, the ventromedial thalamic nuclei, and the periaqueductal gray.

EVALUATION OF THE COMPLAINT OF PAIN

Every effort should be made to detect, treat, and, if possible, eliminate the cause of the pain. Some of these causes, however, are not anatomical. The pain complaint may be the only manner in which the patient can express to the physician nonspecific feelings of distress. In patients with cancer, for example, Chapman has recognized three categories of such distress: anxiety, arising from fear of disfigurement, uncontrollable pain, loss of social position, loss of self-control, or fear of death; anger at the failure of physicians to provide a cure; and depression from loss of physical ability, a sense of helplessness, and the impact of financial problems. Because these concerns may exacerbate any concomitant painful sensations, alleviating them can significantly reduce distress and decrease the need for pain therapies.

Effective pain management requires repeated comprehensive assessment of the patient's pain. Pain reports by patients should be believed. Health care providers may not know that the clinical presentation of a patient suffering from chronic pain is very different from that of a patient in acute pain. If a patient does not manifest the common autonomic manifestations of acute pain (e.g., tachycardia, sweating, elevated blood pressure) or facial grimacing, the health care provider may not believe the patient is suffering from severe pain. A patient with severe but chronic pain does not manifest these autonomic findings, but is often withdrawn, quiet, and depressed or irritable. He or she moves very little spontaneously and complains of discomfort when moved. When the pain is relieved, such patients often exhibit completely different behaviors, becoming mobile, engaged, and involved with other people. Therefore, the first component in the assessment is to believe the patient's complaint.

Patient reports of pain are valid, reliable, and reproducible. They should be used, much as a blood sugar measurement is used in diabetes, to monitor the efficacy of therapy. Various assessment tools that generate results can be completed in 5 to 10 minutes. These should be used to determine several aspects of the pain: its location, intensity, quality, onset, and duration; what relieves or exacerbates it; and its functional consequences, including how it affects the patient's ability to sleep or eat and how it affects physical activity, relationships with others, emotions, and concentration.

The goal is to lower the pain to a level acceptable to the patient. For instance, in the Visual Analog Scale, 0 represents “no pain” and 10 is “the worst pain I can imagine” (Fig. 260.1) The change in the rating an hour after pain medication indicates what needs to be done next. Communication between nurse and physician is greatly improved by using these tools rather than qualitative descriptors such as “the pain is better” to guide pain management.

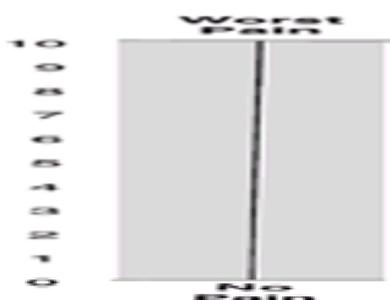

FIGURE 260.1. Visual analogue scale can be used to assess the effectiveness of pain interventions. The patient is asked to indicate on the scale the number that best corresponds to the intensity of his or her pain before and after the intervention and whether the degree of relief is satisfactory. Further adjustments in the regimen are then made, if needed.

THERAPY FOR PAIN

A major component of any pain therapy is the attempt to reverse the underlying cause of the pain. Recurrent cancer may be discovered that is still responsive to surgery, chemotherapy, or radiation therapy. However, during diagnostic testing to define the cause, during specific therapy, or after all disease-related therapies are exhausted, pain still can be treated effectively.

The goal is to relieve patients' pain while preserving their ability to perform normal activities. The treatment regimen often includes nonpharmacologic approaches, the correct use of various medications that relieve pain with a minimum of side effects, and patient and family education throughout to foster communication and cooperation with the therapeutic plan. In addition, neurosurgical and anesthetic techniques are often useful.

NONPHARMACOLOGIC METHODS OF PAIN MANAGEMENT

Education and Reassurance

Patients with cancer often must undergo extensive diagnostic testing, which may include painful procedures. A rehearsal of the planned test or procedure, including the appearance of the room, the length of time to be spent in the test apparatus, and so forth, can minimize the patient's anxiety. Such explanations given preoperatively lessen the need for postoperative medication and shorten the patient's hospital stay. For procedures such as venipuncture, lumbar puncture, thoracentesis, or paracentesis, which occur in the physician's office or in the patient's room, distraction procedures can be very helpful. The physician can encourage the patient to bring a portable tape player with earphones to listen to music or a book on tape during the procedure. Alternatively, the physician might play the television or radio in the patient's room and encourage him or her to pay attention to that rather than to the procedure. Patients with a good imagination can pretend to be someplace they have previously enjoyed, such as a beach or the mountains. They can dissociate themselves by concentrating on those pleasant memories, thereby diminishing the painfulness of the procedure.

Hypnosis

Practitioners with formal hypnotic training can use more elaborate hypnotic techniques to help their patients deal with painful procedures or conditions. Hypnosis takes advantage of the natural ability to enter a trancelike state, such as an athlete does when "playing through the pain." Patients who are trained to enter a trance at will can modify their perception of pain and diminish sleeplessness, anxiety, and anticipation of discomfort.

DRUG THERAPY

Drugs useful for pain relief include the non-opioid analgesics, opioid, and adjuvant drugs that either potentiate the actions of opioid analgesics or prevent or treat their side effects. A combination of medications is usually needed to provide optimal pain relief ([Fig. 260.2](#)).

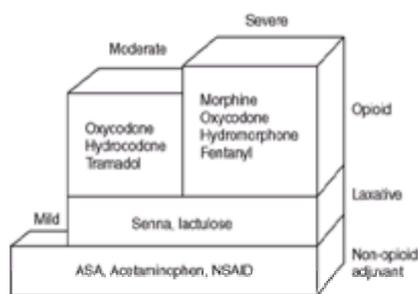

FIGURE 260.2. Mild pain should be treated with nonsteroidal anti-inflammatory drugs, acetylsalicylic acid (ASA), or acetaminophen. Moderate or severe pain requires the addition of a laxative and an opioid. For moderate pain, low-dose oxycodone (5 mg per tablet) is available in fixed-drug combinations that include ASA or acetaminophen. For severe pain, one of the other opioids listed, or higher doses of pure oxycodone, can be used.

Bone Pain

Non-opioid Analgesics

Non-opioid analgesics should be given to patients with mild pain of any cause. Aspirin, acetaminophen, and nonsteroidal anti-inflammatory drugs (NSAIDs), however, are especially useful in patients with bone pain, because they decrease local prostaglandin release and may thereby reduce the sensitization of pain receptors. Because NSAIDs cause renal insufficiency in some patients, renal function should be assessed 1 or 2 weeks after initiation of any of these agents. Ketorolac tromethamine (Toradol) is a particularly useful NSAID in relieving moderate to severe acute pain. An intramuscular dose of 30 mg ketorolac equals the pain-relieving potency of 12 mg intramuscular morphine; however, ketorolac has all the side effects of the NSAIDs and is not recommended for long-term use. If that degree of pain relief is needed chronically, an opioid agent should be substituted.

The non-opioid analgesics should be continued in appropriate patients when opioid analgesics are added, because they potentiate the pain-relieving effects of the opioids ([Fig. 260.2](#)).

Other Agents

Several effective new agents have recently become available, including the bisphosphonates (e.g., pamidronate), which reverse hypercalcemia from bony metastases and also relieve bone pain, and the injectable radionuclides (e.g., strontium 89, samarium-153-EDTMP).

Neuropathic Pain

Tricyclic antidepressants (amitriptyline), gabapentin, phenytoin, carbamazepine, and corticosteroids are non-opioid adjuvants with particular efficacy in relieving pain from nerve injuries. Corticosteroids can provide relief for patients with cord compression or plexus infiltrations. Doses of 16 to 100 mg of dexamethasone are needed to reduce vasogenic edema in spinal cord compression, but lesser doses (6 to 20 mg per day) can be helpful in patients with plexus injuries.

Opioid Analgesics

Narcotic analgesics are the mainstay of therapy for patients with moderate to severe pain of malignant or nonmalignant origin. To ensure compliance with an opioid prescription, however, education of other members of the health care team, the patient, and the family is often required to dispel the many misconceptions associated with opioid therapy. Even physicians who are cancer specialists hesitate to prescribe opioids as needed for patients with severe pain.

The fear of addiction is a common cause of inadequate dispensing of opioids and a barrier to their acceptance by patients. The physician can increase compliance by providing a full explanation of the differences between addiction and physical dependence, along with reassurance that research has repeatedly indicated that patients with malignancies who take opioids do not become addicts. Patients may also fear that if they allow themselves to take opioid medications for moderate pain, such medications will no longer be effective if more severe pain occurs. Because this fear can lead to undertreatment, the topic should be addressed whether or not the patient raises the question. A functional goal of therapy, such as returning to a favorite hobby or reinstating normal activities of everyday life, may enable the patient and the family to accept the opioid.

Misconceptions about religious teachings may prevent health care personnel, patients, and their families from giving or accepting adequate pain medication. Roman Catholics, for example, may not be aware of the Church's position, as stated in the 1994 catechism, that opioids may be used at the approach of death, even if their use results in a shortening of life. The Church does not consider this use of pain medication to be suicide or euthanasia.

CHOICE OF MEDICATION

Because a wide variety of medications are available, pharmacokinetic considerations and side-effect profiles should be considered when choosing opioid agents ([Table 260.1](#)). Intermittent moderate to severe pain lasting hours to several days responds to oral analgesics with short half-lives (3 to 4 hours) with appropriate potency. Severe pain of relatively constant intensity should be treated with oral sustained-release opioid (taken every 8 to 12 hours) or transdermal fentanyl (renewed

every 48 to 72 hours).

Drug	Parenteral (mg)	POPR (mg)
Morphine	10	30
Oxycodone		20
Hydromorphone	1.5	7.5
Lorazepamol	2	4
Methadone	10	20
Meperidine*	75	300

Fentanyl (µg/hr)	Morphine (mg)	
	IV/IM	PO
25	10-30	30-90
50	31-50	91-150
75	51-70	151-210
100	71-90	211-270
125	91-110	271-330
150	111-130	331-390

IM, by intramuscular route; IV, by intravenous route; PO, by mouth; PR, by rectum.
 *Not recommended for long-term use.

 ‡Dorner B, Zenz M, Eyles M, et al. Direct conversion from oral morphine to transdermal fentanyl: a multicenter study in patients with cancer pain. Pain 1998;84:527-34.

TABLE 260.1. RELATIVE POTENCIES OF COMMONLY USED OPIOIDS

Drugs with short half-lives should also be used for “rescue doses” given for breakthrough pain and for pain exacerbations between doses. The dose of the rescue medication should be 10% of the total 24-hour dose. For example, if a patient is receiving 300 mg of oral sustained-release morphine twice a day, the rescue dose should be 10% of 600 mg, or 60 mg of short-acting morphine. Agents with short half-lives such as morphine, hydromorphone, and oxycodone should also be used in the elderly and in patients with impaired renal or hepatic function. In patients with a previous history of drug abuse, agents with longer half-lives, such as methadone or levorphanol, are preferred.

The side-effect profiles of the opioid agents differ widely. It is often useful, therefore, to switch to another agent if a patient is experiencing dose-limiting side effects with the initial opioid chosen. For example, if a patient receiving morphine experiences disabling nausea, the physician may consider substituting hydromorphone (Dilaudid) at an equianalgesic dose (Table 260.1). Because of incomplete cross-tolerance, the initial dose for patients on higher doses of opioids should be only two-thirds to one-half of the calculated equianalgesic dose. For example, in the patient who takes 600 mg oral morphine a day, hydromorphone is begun at 75 or 100 mg a day (one-half or two-thirds of the 150-mg dose that would be equianalgesic).

Meperidine (Demerol) is the least useful opioid for patients with long-lasting moderate to severe pain. It provides pain relief for only about 1 to 2 hours and gives rise to an active metabolite, normeperidine, which induces dysphoria, excites the central nervous system, and can cause seizures. Normeperidine has a half-life of 13 to 24 hours, which can lengthen with renal failure. Thus, with the frequent administration of meperidine needed for pain control, normeperidine levels rise and the likelihood of seizures increases. The seizure incidence is further increased if the opioid antagonist naloxone (Narcan) must be given. If hyperirritability or a seizure occurs in a patient receiving meperidine, intravenous diazepam (Valium) rather than phenytoin should be used to control the seizure, and a new opioid should replace the meperidine for pain control.

ROUTES OF DELIVERY

Opioids can be delivered noninvasively (orally, rectally, or transdermally) or invasively (subcutaneously, intravenously, or by spinal infusion). Those interested in spinal delivery techniques are referred to the review by Hogan and associates, noted in the bibliography. Patients switched from oral or rectal to parenteral medication or vice versa must have the dose altered accordingly to avoid overdose or undertreatment (Table 260.1). No matter which route is chosen, patients who have continuous pain should receive the analgesics regularly, being awakened if necessary, to prevent pain recurrence.

The oral route is preferred for analgesic medications. Most patients can achieve excellent pain relief with either short-acting or sustained-release oral opioid preparations. Rectal opioids (morphine, oxymorphone, and hydromorphone) have about the same potency and half-life as oral agents and therefore must be given frequently.

For patients who cannot take oral medication and whose opioid requirement precludes rectal delivery, the transdermal route is preferred to intravenous or subcutaneous drug delivery. The clinical usefulness of fentanyl in a transdermal delivery system (Duragesic) is well established. The transdermal system is a patch that adheres to the skin; fentanyl, a very lipophilic opioid, is rapidly absorbed from the contact adhesive into the skin. The drug then continuously diffuses from the patch reservoir into the skin through a rate-controlling membrane and is absorbed from the skin depot into the bloodstream (Fig. 260.3). There is, therefore, a significant delay (about 12 hours) before the drug begins to provide pain relief. A relatively constant plasma concentration of fentanyl is reached an average of 14 to 20 hours after the initial patch is placed. Rescue medication must therefore be provided during the first 48 hours of patch use.

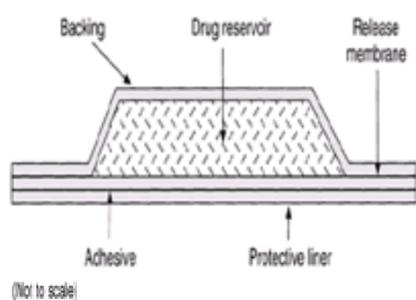

FIGURE 260.3. Duragesic patch. After the unit is placed on the chest wall, fentanyl, contained in the drug reservoir, diffuses through the release membrane into the skin. The drug is absorbed from the skin reservoir into the bloodstream. By 14 to 24 hours after the first patch is applied, fentanyl blood levels are sufficient to provide pain relief. New patches are usually applied every 72 hours.

Converting patients from an oral or parenteral opioid to the patch is easily accomplished using the information provided in Table 260.1. Most patients will require dose escalations, because the conversion is a conservative one. A new patch is applied every 72 hours, although a few patients require changes every 48 hours. Side effects include those due to the contact adhesive along with those commonly associated with other opioids.

The transdermal delivery system is not efficacious for patients with acute pain or for those with markedly fluctuating narcotic requirements. Lower doses may be required in elderly patients or those with respiratory insufficiency. Opioid overdoses can occur in patients using the system who develop fever or who have unstable hepatic function, because the drug's absorption or metabolism may be affected. Because the fentanyl continues to be absorbed from the skin, serum fentanyl levels remain at 50% as long as 14 to 25 hours after patch removal. In overdose, a naloxone infusion may be required until drug is eliminated from the skin depot.

For patients with severe or uncontrolled pain, continuous subcutaneous or intravenous administration of opioids should be used to provide pain relief in the shortest amount of time with the minimum amount of oversedation (see Management of Severe Pain). The drugs can be delivered by a portable infusion pump, initiated or continued at home. Patient-controlled analgesia systems for subcutaneous or intravenous drug delivery respond to the patient's pain threshold and eliminate the delays involved when nurses must administer supplemental medication.

ADJUVANT MEDICATIONS

Adjuvant medications are used to add to the analgesic effect of opioids and to prevent the complications opioids induce.

ADJUVANT ANALGESICS

The tricyclic antidepressants are among the most effective psychotropic analgesics. It has been suggested that they produce these effects by raising the concentration of the endogenous pain inhibitors, serotonin and norepinephrine, and increase the bioavailability of morphine. As opioid adjuvants, they act more promptly and at lower doses than those required for their antidepressant actions (e.g., amitriptyline is effective within 2 to 3 days at 50 to 100 mg per day).

The addition of dextroamphetamine (2.5 to 7.5 mg orally or 10 mg intramuscularly, twice daily) permits lowering the opioid dose by one-third to one-half while maintaining equivalent analgesia and less sedation. Methylphenidate (10 mg orally with breakfast and 5 mg orally with lunch) also can increase the analgesic effect and reduce sedation in patients receiving opioids. Pemoline, a chewable psychostimulant, is chemically unrelated to amphetamines but may be as useful in reversing opioid-induced sedation. Patients are started on one tablet (18.75 mg) in the morning and at noon, and the daily dose is gradually increased to a maximum of 75 mg. These combinations are very useful for patients who need to be more alert for a short period of time without interrupting their pain relief—for example, to attend a wedding.

LAXATIVES

Constipation is the most common opioid-induced side effect. Laxatives should be given routinely, not only on an as-needed basis, to patients treated with any of the drugs listed in [Table 260.1](#). Detailed bowel preparation recommendations can be found, but none has been studied in a controlled fashion.

SLEEP MEDICATIONS

Sleep medications that themselves produce sedation (benzodiazepines, barbiturates, chloral hydrate) are not good choices for patients receiving opioids, because they produce excessive daytime sedation. Tricyclic antidepressants (e.g., 10 to 50 mg amitriptyline) are preferred, because they produce only night-time sedation and act as opioid adjuvants.

NALOXONE

Respiratory depression can occur in patients with mild to moderate pain during the initial use of opioids, although it is rare in patients with severe pain or in patients receiving long-term opioids. Caution should be used before giving naloxone to a patient receiving long-term opioids, because severe withdrawal may be precipitated. In such patients, rather than giving the usual dose of 0.4 mg per milliliter, the 0.4 mg of naloxone should be diluted with 10 mL of saline, and the minimum amount should be given that reverses respiratory depression. In a comatose patient, endotracheal tube placement is recommended to prevent aspiration from the salivation and bronchial spasm that will be induced.

SPECIFIC CLINICAL PROBLEMS

COAGULATION DISORDERS

Patients with coagulation disorders, whether inherited or acquired, have excessive bleeding risk if aspirin-containing pain relievers are used. If acetaminophen is ineffective, such patients may obtain significant relief from ibuprofen or the nonacetylated salicylates such as salsalate (Disalcid) or choline magnesium trisalicylate (Trilisate), which do not prolong the bleeding time.

PROBLEMS OF THE ELDERLY

Pain management in the elderly is complicated by difficulties in pain assessment, as well as the altered pharmacokinetics of opioids and psychotropic adjuvant medications. Elderly patients may underreport pain. Physicians may ascribe observed limitations in social contact and physical activity to age-related changes, when in fact they are pain-induced limitations.

Elderly patients are particularly susceptible to the side effects of NSAIDs, and patients taking them should be monitored closely. In general, in elderly patients (age 70 to 89), the volume of distribution for opioids is smaller, the drugs have a longer plasma half-life, and clearance is decreased, all of which lead to a prolonged duration of effect. Therefore, the effective doses for these patients are one-half to one-fourth of those needed in younger patients. Drugs without active metabolites are used (e.g., oxycodone or hydromorphone), and the initial doses should be low. Patients should be monitored carefully for the development of sedation or confusion, especially if they are receiving antihistaminic agents (e.g., cimetidine, diphenhydramine) or drugs with anticholinergic activity.

The acute urinary retention due to opioids (especially in patients with prostatic hypertrophy) and hypotension and tachycardia caused by tricyclic agents can be more frequent and of more clinical severity in the elderly population. The starting dose of the tricyclic should be low (for amitriptyline, usually 10 mg at bedtime), and the dose should be slowly increased as tolerated. Doxepin, which does not share these side effects, may be a better-tolerated opioid adjuvant.

PATIENTS WITH OPIOID ADDICTION

Drug requirements may be significantly higher and dosing intervals shorter in the addict. In patients on methadone maintenance, therapeutic dosing must be provided over and above their baseline dose. In all cases, the goal should be to deliver adequate medication to relieve the pain. The physician should always work from a written treatment plan. One physician should prescribe all psychotropic medication, and information about the patient's drug use should be obtained from sources in addition to the patient. When the question of "addiction" first arises, consultation should be obtained from an addiction medicine specialist. If opioids are needed, patients should be given limited quantities of long-acting medications on a scheduled basis.

MANAGEMENT OF SEVERE PAIN

Opioid therapy is the cornerstone of managing the patient with severe pain. We begin by reassuring patients and their families and explain that to relieve the pain as quickly as possible, intravenous narcotic medications will be started immediately, but oral pain medication will begin as soon as the pain is well controlled. Without this explanation, patients may misinterpret the morphine drip as an indication that they were thought to be terminal. The starting dose is calculated from the patient's baseline opioid requirement or weight (e.g., morphine, 0.05 mg kilogram per hour). A bolus is given, the drip is begun, and every 20 to 30 minutes the degree of pain relief is reassessed. If the relief is inadequate, another bolus is given, and in patients without severe underlying chronic obstructive pulmonary disease, the drip is increased in increments of 2 to 3 mg per hour. There is no maximal dose; we give whatever is required to relieve the pain. If the patient falls asleep, this usually indicates that pain relief has been achieved, not that the dose should be lowered. The dose is lowered if the respiratory rate falls below 10 to 12 breaths per minute.

Adjuvant agents are begun along with the opioid ([Fig. 260.2](#)). All patients are given one or two pills of senna concentrate (Senokot) orally each day, or one for every 30 mg morphine, to a maximum of eight pills daily. If more laxative effect is needed, lactulose is added; the starting dose is 15 to 30 mL orally at bedtime, repeated, if necessary, in the morning. Lactulose is effective and, unlike other agents, does not produce cramping or a feeling of fullness. Amitriptyline (10 to 50 mg orally) is usually ordered as a "patient may refuse" sleep medication. In opioid-naïve patients, prochlorperazine (Compazine), 10 mg orally twice or three times daily, is offered for the first 48 hours to prevent the otherwise common development of nausea. In patients with bone or nerve pain, appropriate adjuvants are added.

When pain relief is adequate, the patient medication is converted to an equivalent dose of oral opioid ([Table 260.1](#)). For example, a patient who required 5 mg of intravenous morphine per hour (120 mg in 24 hours) will need 360 mg per day of the oral long-acting agent (120 mg × 3). This can be given as 180 mg orally every 12 hours or 120 mg orally every 8 hours. Two hours after the oral opioid is begun, the drip is discontinued. Short-acting, immediate-release morphine should be available for rescue dosing. If the amount of opioid taken as a rescue dose is significant, the daily dose of long-acting agent is increased accordingly.

CHAPTER 261: ANTIEMETIC TREATMENT

RICHARD J. GRALLA

[Common Emetic Problems](#)
[The Neuropharmacology of Emesis](#)
[Preventing Emesis](#)
[Combination Regimens with Corticosteroids](#)
[Conclusion](#)

Many of the recent advances in oncology have occurred in supportive care. Although debate continues concerning the value of some supportive care agents, all agree that available antiemetics contribute markedly to the quality of life of patients with cancer and allow outpatient treatment that was not previously possible. Most patients given chemotherapy now need not experience vomiting. These improvements have been the result of a better understanding of the role of antiemetic drugs, the availability of a new class of antiemetic agents, and an increased knowledge of the neuropharmacology of emesis.

COMMON EMETIC PROBLEMS

As the control of emesis in patients receiving chemotherapy has improved, several different problems have become apparent. These include acute chemotherapy-induced emesis, delayed emesis, conditioned or anticipatory emesis, and emesis not related to chemotherapy. The most common problem is acute emesis.

Acute chemotherapy-induced emesis typically occurs 1 to 2 hours after chemotherapy in previously untreated patients not given effective antiemetics and can persist for several hours. Several schemes for assessing the potential of a chemotherapeutic agent for causing emesis have been devised. It is practical to divide the emetic risk into the following four categories: (a) severe, occurring in at least 99% of untreated patients (as seen with cisplatin); (b) moderate to high, occurring in 30% to 90% (as seen with dacarbazine, nitrogen mustard, carboplatin, cyclophosphamide, and doxorubicin); (c) low, occurring in 10% to 30% (as seen with agents such as the taxanes, irinotecan, etoposide, and gemcitabine); and (d) very low, occurring in 0% to 10% (as seen with 5-fluorouracil, vincristine, bleomycin, vinblastine, and methotrexate). The most progress has been evident in the control of acute emesis, which must be treated prophylactically in all patients receiving chemotherapy with more than a very low risk of emesis.

Both delayed and acute emesis begin after the administration of chemotherapy. *Delayed emesis* is often defined as that beginning 24 hours after chemotherapy. The potential of chemotherapeutic agents to cause delayed emesis parallels that seen with the acute problem, occurring in 60% to 80% of patients treated with cisplatin and in 20% to 30% of those receiving carboplatin or doxorubicin. *Conditioned* or *anticipatory emesis* is the result of poor control of acute or delayed emesis. It is typically associated with anxiety before the next chemotherapy treatment, followed by nausea or vomiting before or during chemotherapy administration.

Commonly, all nausea or vomiting is attributed to chemotherapy. When the pattern of emesis is not typical of the chemotherapy administered, other causes should be considered. Medications (opiates, bronchodilators, antibiotics), tumor-related complications (intestinal obstruction, brain metastases), or other problems such as gastritis are often the cause of the emesis and require proper evaluation and a different approach.

Central to controlling chemotherapy-induced emesis is an understanding of how emesis is initiated and the mechanism of action of antiemetics.

THE NEUROPHARMACOLOGY OF EMESIS

Several neurotransmitters and their receptors are involved with this phenomenon in the brain and in the gut. Recently, interest has focused on serotonin and the type 3 serotonin receptor, (or 5-hydroxytryptamine [5-HT₃] receptor). Agents that block this receptor are potent antiemetics and generally have few side effects ([Table 261.1](#)). The 5-HT₃ receptors are found adjacent to enterochromaffin cells in the small intestine, in vagal nerve fibers, and in the medulla. Controversy exists concerning which site is the most important for stopping emesis. In addition, the duodenum contains a large amount of serotonin, which is liberated after cisplatin administration (but apparently not after cyclophosphamide). It is not clear whether the serotonin itself is important in causing emesis. Other receptors or mechanisms are also involved. This conclusion is reached because agents that do not affect 5-HT₃ receptors (corticosteroids and dopamine-blocking agents) can be useful antiemetics and because emesis is not controlled in all patients.

Antiemetic Agent	Dose Range	Schedule for Acute Chemotherapy-Induced Emesis
Serotonin Receptor Antagonists		
Dolasetron	125 mg or 1.2 mg/kg intravenously	One time, before chemotherapy
Dolasetron	125 mg orally	One time, before chemotherapy
Granisetron	1 mg or 0.1 mg/kg intravenously	One time, before chemotherapy
Granisetron	1 mg or 2 mg orally	One time, before chemotherapy
Ondansetron	8 mg or 0.15 mg/kg intravenously	One time, before chemotherapy
Ondansetron	8 mg (oral dose not indicated for acute emesis)	One to three times daily in hospital or at home
Tropisetron	5 mg intravenously	One time, before chemotherapy
Tropisetron	5 mg orally	One time, before chemotherapy
Corticosteroids		
Dexamethasone	8 mg or 20 mg* intravenously	One time, before chemotherapy
Dexamethasone	4 mg or 20 mg* orally	One time, before chemotherapy
Methylprednisolone	40 mg or 100 mg intravenously	One time, before chemotherapy

*The 20-mg dexamethasone dose is preferred for emetic situations of moderate or greater risk; the 4-mg dose is generally sufficient in settings of low emetic risk.

TABLE 261.1. ANTIEMETIC AGENTS, DOSES, AND ADMINISTRATION SCHEDULES FOR PREVENTION OF ACUTE CHEMOTHERAPY-INDUCED EMESIS

PREVENTING EMESIS

The principles involved in the prevention of emesis include (a) selection of the most active antiemetics, (b) combination antiemetic therapy of a 5-HT₃ antagonist with a corticosteroid in appropriate settings, and (c) use of the most effective doses and schedules with minimization of side effects. Metoclopramide provided the first serotonin receptor antagonist antiemetic. Although metoclopramide also affects dopamine receptors, in high doses its efficacy is mediated by blocking 5-HT₃ receptors. With the development of the selective 5-HT₃ receptor antagonists, more specific treatment with fewer side effects and greater convenience became the standard.

Are there differences among the selective serotonin antagonists? In structure, potency per milligram, and pharmacokinetic profile, differences exist. In efficacy and side effects, the agents appear similar. Large, multicenter, randomized studies reveal equivalence among the three approved 5-HT₃ receptor antagonists in the United States, ondansetron, granisetron, and dolasetron. Tropisetron, another serotonin antagonist, is not available in the United States, but with a therapeutic profile similar to the three latter agents. Trials report a low incidence of side effects shared by these drugs, such as mild headache, constipation, and a transient rise in transaminases.

Controversy persists concerning the ideal doses for the serotonin antagonists. The most practical and cost-effective approach is the single-dose regimen, as outlined in [Table 261.1](#). The drugs are not schedule-dependent, and treatment can begin immediately before chemotherapy. Trials have repeatedly indicated that a single administration of an antiemetic regimen is as effective as multiple dosing in preventing acute chemotherapy-induced emesis. Evidence indicates that there is a "threshold" effect for these agents. After the relevant receptors are blocked, there is no value in increasing the dose, and lower doses are less effective. This threshold is in the range indicated in [Table 261.1](#). In addition, the dose and regimen should be the same for chemotherapy with a severe, high, or moderate potential for causing emesis.

Location of relevant receptors in the gut may also be of importance. Large trials with serotonin antagonists in patients receiving either cisplatin or agents of moderate to high risk demonstrated that these agents given orally are as effective as the same agents given intravenously. Oral administration of a single dose of an antiemetic regimen provides the greatest flexibility for use in any chemotherapy setting. It also saves both pharmacy and nursing time. These considerations, together with lower acquisition costs for the oral agents, provide the background for making these equally efficacious combinations the regimens of choice for patients receiving most chemotherapy.

In those instances in which an antiemetic is needed with chemotherapy of a low emesis potential, a single dose of an oral or intravenous antiemetic is usually sufficient (generally a corticosteroid). Corticosteroids are active parenterally and orally and are active in various settings. Although the mechanism of action is not defined, it is different from that of other antiemetics. Thus, corticosteroids are easy to use in combination antiemetic regimens and enhance the activity of other active antiemetics. Side effects are generally mild and are well described for these agents. A recent trial indicates that a single dose of dexamethasone at 20 mg as a total dose is more effective than lower doses when added to a serotonin antagonist in patients receiving cisplatin.

In the past, many agents other than those just discussed have been used for chemotherapy-induced emesis. The phenothiazines, such as prochlorperazine, are commonly used in general medicine. High intravenous doses are better than the oral and intramuscular phenothiazines; however, orthostatic hypotension is a common toxicity. Other side effects include sedation and dystonic effects.

Lorazepam has only modest antiemetic effects, but with its antianxiety and amnesic properties has high subjective acceptance. It is also effective in reducing akathisia and is useful in decreasing dystonic reactions. The major side effect of lorazepam is sedation. It is recommended as an addition to effective antiemetics and not as a single agent.

Cannabinoids such as dronabinol (d-9-tetrahydrocannabinol [THC]) have activity similar to oral phenothiazines but are markedly less effective than metoclopramide or the 5-HT₃ receptor antagonists. Side effects are greater with cannabinoids than with serotonin antagonists or metoclopramide. The cannabinoid toxicities include sedation, dizziness, ataxia, orthostatic hypotension, dry mouth, and dysphoria. Although these agents have some antiemetic properties, other available agents have more activity and fewer side effects; thus, the role of cannabinoids in antiemetic treatment has not been well defined. Cannabinoids have great popularity in the lay press, aside from their tested properties. In addition, one well-conducted (random assignment, double-blind, crossover) study compared oral THC with inhaled marijuana. Both agents had similar but low activity, with a trend toward patient preference for the oral THC.

COMBINATION REGIMENS WITH CORTICOSTEROIDS

Antiemetic regimens combining a single dose of dexamethasone with either a serotonin antagonist ([Table 261.1](#)) or with metoclopramide are more effective than a single agent. This has been demonstrated in at least a dozen studies and for emesis induced by cisplatin and other chemotherapeutic agents. Typically, antiemetic efficacy with cisplatin rises from the 40% to 50% range of complete control to 70% to 80% when dexamethasone is added to a 5-HT₃ antagonist. With moderately emetogenic agents (e.g., cyclophosphamide, anthracyclines, or carboplatin), the complete control rate rises to over 90% with the combination regimen when compared with either a 5-HT₃ antagonist or dexamethasone alone.

After more than a decade of use of combination regimens, few negative factors have emerged for the use of dexamethasone in this single-dose setting. Specifically, no evidence exists of impaired therapeutic response from chemotherapeutic agents, and there are only minor side-effects. Combination antiemetic regimens with corticosteroids should be considered treatments of choice for moderately emetogenic chemotherapy and cisplatin-containing regimens.

Treatment of delayed emesis differs from the approach to acute emesis ([Table 261.2](#)). The key agents for this problem are corticosteroids. Adding oral metoclopramide can enhance this activity. Serotonin antagonists are no more effective than metoclopramide when added to dexamethasone for preventing delayed emesis. The markedly greater cost of the serotonin antagonists without improved efficacy argues against their routine usage in the delayed emesis setting.

Indication

For patients who receive chemotherapy of moderate to severe risk

Antiemetic for Day of Chemotherapy

Use an effective combination antiemetic regimen of a serotonin antagonist plus a corticosteroid, as outlined in [Table 261.1](#)

Delayed Emesis Regimen

Beginning the morning after chemotherapy (approximately 12–24 hours after treatment)

Dexamethasone 8 mg orally BID for 2–3 days (2 days for moderate to high risk; 3 days for severe risk)

PLUS

Metoclopramide 30–40 mg BID orally for 2 days

TABLE 261.2. RECOMMENDATIONS FOR THE PREVENTION OF DELAYED EMESIS

Anticipatory emesis is best approached by preventing this problem through the use of the most effective antiemetics with each course of chemotherapy. If, however, the problem occurs, treatment can be helpful. Behavior therapy techniques with desensitization can be useful. The usefulness of antianxiety agents has not been well studied.

CONCLUSION

Future directions of antiemetic treatment and research are taking many different paths. Better understanding of the roles and interactions of neurotransmitter receptors in emesis will allow for different approaches to this problem. Serotonin or dopamine pathways appear unlikely to be the only ones involved in chemotherapy-induced emesis. With 25% or more of patients not having complete control despite the use of active antiemetics, investigation of antiemetics with different mechanisms of action is a logical approach. Recent clinical studies indicate that the neurokinin antagonists are effective for both acute and delayed emesis. These trials have enlisted only a small number of patients, but, to date, the data are encouraging and indicate that these drugs will be useful additions to the serotonin antagonist plus corticosteroid combination regimens.

CHAPTER 262: DESIGN AND CONDUCT OF CANCER CLINICAL TRIALS

MICHAEL A. FRIEDMAN AND RICHARD SIMON

[Human Protection Issues](#)
[Design Principles for Phase I Trials](#)
[Design Principles for Phase II Trials](#)
[Design Principles for Phase III Trials](#)

Cancer clinical trials involve at least two broad objectives. The first is to identify promising new interventions; this objective is addressed by phase I and II trials. The second is to determine whether a promising treatment actually provides patient benefit; this is the objective of phase III trials. The design considerations for these two categories of trials are vastly different but are often confused.

Physicians play too limited a role in critically evaluating the treatments they dispense. Logically, the physician's responsibility to patients should demand discriminating analyses of all intentions, both old and new, but the traditional impediments to obtaining proper evaluation remain. These include the lack of recognition that treatments that "should work" often do not and in fact may be harmful; the desire to offer the patient a new treatment; the desire to shield the patient from uncertainties; and the desire to appear knowledgeable.

HUMAN PROTECTION ISSUES

The participation of a subject in a formal clinical trial is defined by an agreement embodying the highest medical, legal, and ethical principles. By enrolling a person in a study, the researcher assumes a set of obligations that transcend the conventional responsibility to provide proper medical attention. Participation in research is an active, voluntary choice; it is a commitment that may be withdrawn at any time without prejudicing ongoing care. The research subject has relatively complete autonomy. He or she can exercise choice limited only by access to services, the financial ability to pay for such services (private means or insurance), and a medical staff willing to provide these services. This active choice may be influenced by patient preference for one of the competing therapeutic options with similar efficacy (e.g., the choice of mastectomy or lumpectomy and irradiation for stage I breast cancer), or there may be no recognized effective option (e.g., in advanced pancreatic cancer). No matter what the clinical situation, the subject should be given relevant information by the medical staff to assist in the choice.

The informed consent process is an initial and fundamental interaction. The goal is to provide information in a clear, understandable, noncoercive manner. The essential elements of this process are defined by federal regulations and include a complete description of the therapy being offered, both standard care and investigational. The known, suspected, and potential risks and benefits should be fairly presented, as well as other reasonable alternatives worth considering by the subject. A pledge is made to preserve the subject's confidentiality, and a description is given of the circumstances under which access to medical records is permitted. Information describing compensation (if any) for toxicities encountered is also given, as well as specific means by which further information may be obtained.

DESIGN PRINCIPLES FOR PHASE I TRIALS

Historically, phase I studies define the distribution and metabolism (pharmacokinetics) and the toxicity (pharmacodynamics) characteristics of a new treatment to identify a safe but biologically active dosage and schedule of administration. Such studies of antitumor therapeutics are conducted in patients with refractory or resistant malignancies who lack any more efficacious option. The chance of patient benefit is less and the risk of toxicity greater than would be anticipated in later clinical trials.

Many new agents entering phase I trials are being selected more rationally to affect specific biologic (molecular) targets. Consequently, patients who have the targeted tumor or physiologic characteristics are the most appropriate candidates for early clinical trials. Such patients are more likely to benefit, and they also provide the opportunity to conduct relevant correlative laboratory studies.

To provide the most complete information for subsequent clinical trials, the pharmacologic characteristics of the new agent should be explored in populations of special interest; studies should be performed in both genders, in the young and the old, in those with coexisting organ dysfunction, and in specific racial or ethnic groups if relevant. These important clinical issues should be explored more thoroughly in phase II and III studies, but initial clues should be sought in the phase I setting.

DESIGN PRINCIPLES FOR PHASE II TRIALS

The primary purpose of a phase II study is to determine whether a treatment exhibits promising antitumor activity; the secondary purpose is to provide a more complete toxicity experience. Using a dose and schedule considered tolerable in phase I studies, relatively homogeneous populations of patients are entered into phase II studies. Phase II trials are generally conducted with patients for whom no curative therapy exists, so it is likely that the agent being tested will temporarily benefit only some of the patients. Moreover, there are no a priori means of identifying the responsive patients. Therefore, phase II trials are designed to detect specified rates of objective tumor shrinkage (or surrogate thereof). Although the assessment of transient, incomplete tumor regression (so-called partial response) is subject to observer misinterpretation, it is typically used.

The major methodologic problem for phase II studies is the reliable identification of antitumor activity (although incomplete) in the fewest number of patients. Typically, better-risk patients are more likely to benefit from any intervention, especially those who are younger, are more fit, or have been exposed to little prior antitumor therapy. Such patients are considered ideal candidates for phase II studies, as long as they are not being denied some other curative or highly effective therapy. The sort of biologic targeting described in the design of modern phase I trials should be carefully considered for phase II as well.

Before initiating the trial, a response rate representing an activity level of interest should be defined, because this will influence the study sample size and the interim monitoring procedure. This targeted response rate is determined by such factors as the inherent sensitivity of the disease to other therapies, the number of standard treatment options available, and the perceived benefits of these standard approaches. For example, a new agent with a 20% partial-response rate in patients with pancreatic cancer (for which no reasonable alternatives exist) would probably be of interest, but that level of activity might be of little benefit in lymphoma patients.

Two-stage designs provide simple, reasonably efficient frameworks for phase II trials. An initial cohort of patients is treated. If the response rate observed is inconsistent with the activity level of interest, then accrual is terminated. Otherwise, an additional cohort of patients is accrued. For an activity level of interest of 25% and a high probability of rejecting a drug with an activity level of 5%, a maximum sample size of 25 to 30 patients is needed. Such designs limit the chance that a study will be terminated prematurely (mistakenly assuming lack of antitumor activity) and also limit the chance that inappropriately large number of patients will be needlessly exposed to an ineffective regimen.

Phase II trials can provide only a general impression of activity; confidence intervals for the true response rate are generally wide. This level of specificity is acceptable because identifying phase II activity is not an end in itself but more properly is a means toward achieving survival or improvement in quality of life. Rather than expanding the size of phase II trials, efforts should be directed to moving smoothly and rapidly to definitive phase III trials, which hold the promise of providing information that improves medical practice.

DESIGN PRINCIPLES FOR PHASE III TRIALS

The key principle for the design of phase III clinical trials is to ask an important question and obtain a reliable answer. Asking an important question generally means identifying a hypothesis that may influence medical practice; using an experimental treatment that is promising, widely applicable, and substantially different from the control treatment; using a control treatment as a reference standard that is widely accepted; using an endpoint that is a direct measure of patient benefit; and studying patients who are broadly representative of the patients seen in practice by community physicians.

Survival is generally the endpoint most directly related to patient welfare. Tumor response may be appropriate for phase II trials as a measure of promising biologic

activity, but it is only an indirect measure of patient benefit and therefore is generally unsuitable for phase III trials. Symptomatic relief or preservation of organ function can represent meaningful patient benefit, but direct measures of such effects are best used as endpoints rather than attempting to validate partial response as a valid surrogate.

Formerly, it was common in reports of uncontrolled phase II trials to see comparisons of the survivals of responders to the survivals of nonresponders. The fact that responders had longer survivals than nonresponders was inappropriately assumed to imply that the treatment extended survival. This analysis is invalid. To make valid inferences about the effect of a treatment on survival, the survivals of all the treated patients (not just the responders) must be compared with the survivals of a comparable control group receiving some control treatment.

If a clinical trial is to influence medical practice, the patients included in the trial must be representative of the population of patients to whom the results will be applied. Consequently, unduly narrow selection criteria for phase III clinical trials are generally inappropriate.

Getting a reliable answer also has several important components. Probably most important is the use of randomized treatment assignment. Most treatment improvements achieved for patients with solid tumors are relatively small compared with the natural variations in prognosis among patients. Many oncologists believe that nonrandomized trials are appropriate for determining what treatments are sufficiently promising to warrant evaluation in randomized clinical trials, but that we should not base major public health policies or patterns of care on methodologies that have led us astray so often.

A second important component of getting a reliable answer is an adequate sample size. Many clinical trials that are reported as negative are really just noninformative because they did not include enough patients to detect a medically important treatment effect. The use of confidence intervals to describe the magnitude of treatment differences that are consistent with the observed results are helpful in avoiding the common misinterpretation of "not statistically significant".

Intent-to-treat analysis is also an important component of getting a reliable answer. In this type of analysis, all eligible randomized patients are included in the group to which they were randomized, with no exclusions for noncompliance with treatment. Exclusions permit the results to be biased, because the excluded patients are usually prognostically different than the nonexcluded patients. A classic example of such bias occurred in the Coronary Drug Project in which placebo patients who were good compliers had much lower cardiovascular mortality than placebo patients who were poor compliers.

Performing numerous subset analyses is a cause of erroneous conclusions in many clinical trials. If the chance of a false-positive conclusion for a single question in a single analysis is 5%, then the chance that at least one false-positive conclusion will be obtained in 10 independent comparisons is about 40%. Many clinical trial reports describe more than 10 comparisons, considering the multiple endpoints and multiple subsets often considered. Such analyses should be viewed as exploratory, generating hypotheses that require independent testing in a focused clinical trial.

If a clinical trial of two equivalent treatments is analyzed repeatedly over the course of accrual and follow-up, then the probability that a $p < 0.05$ will be found in at least one interim or final analysis may exceed 25%, rather than the 5% expected. A powerful body of statistical methodology has been developed for interpreting interim data while keeping the type I error rate below 5%. Major multicenter clinical trials should also use data-monitoring committees to review accumulating data and to make recommendations about whether the trial should be changed, terminated, or reported. During the trial, interim efficacy results are withheld from physicians entering patients in the study (except possibly for the study chair) to protect both the patients and the study. The patients are protected because decisions on whether to continue, change, or terminate the trial are made by persons with no vested professional or financial interest in the trial. The study is protected from inappropriate early termination, which might occur if participating physicians were to become nervous about unreliable interim trends. Because physicians entering patients do not see the interim efficacy results, they remain free to interact with their patients honestly and to encourage their patients and colleagues to participate in the trial.

CHAPTER 263: APPROACH TO THE PATIENT WITH CELLULITIS AND OTHER SOFT-TISSUE INFECTIONS

RONALD T. LEWIS

Presentation
Pathophysiology
Investigation
Strategies for Optimal Management

Focal or diffuse soft-tissue infections are usually recognized easily, and they are well treated by local debridement and antibiotic therapy. However, infections may appear in many forms (Fig. 263.1). Those secondary to defined anatomical skin lesions, wounds, or dermatitis are usually obvious. But most infections are primary, and because they usually start with a break in the skin associated with minor trauma, they may be confused with inflammation without infection caused by trauma and other conditions. More important are severe, life-threatening, necrotizing soft-tissue infections, which may simulate nonoperative cellulitis. The astute clinician must be familiar with the usual modes of presentation of soft-tissue infections and should know and recognize the more serious conditions requiring aggressive management.

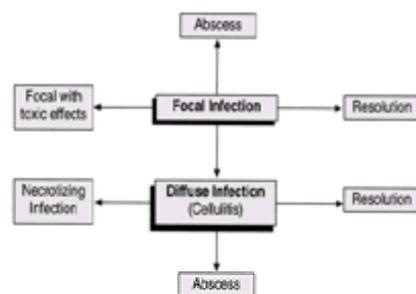

FIGURE 263.1. Presentation of soft-tissue infection.

PRESENTATION

FOCAL CUTANEOUS INFECTIONS

The common focal lesions are readily diagnosed. Most lesions are seen as pyodermas without systemic signs, localized to the skin or to skin structures (Fig. 263.2).

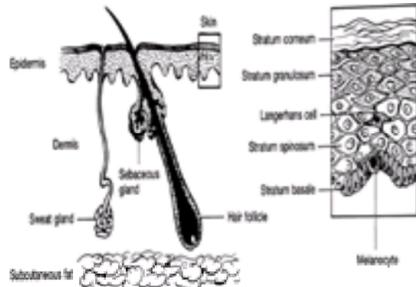

FIGURE 263.2. Anatomy of skin, skin structures, and subcutaneous fat. Soft-tissue infections are localized as follows: impetigo—epidermis; folliculitis, furunculosis, and carbuncle—hair follicle; focal infections with toxic effects—stratum granulosum; cellulitis—skin and subcutaneous fat; erysipelas—dermis. (Modified from Lookingbill DP, Marks JG. *Principles of dermatology*. Philadelphia: WB Saunders, 1993:4.

Impetigo contagiosa is a highly communicable skin infection that occurs mainly on the face and legs of children. It begins as small vesicles with inflammatory halos that pustulate and dry out within 4 to 6 days, forming itchy but painless “stuck-on” crusts. Most lesions are streptococcal in origin; the 10% caused by *Staphylococcus aureus* are bullous rather than vesicular at onset.

Folliculitis manifests as a pyoderma centered in one or more hair follicles, with mild surrounding inflammation, which culminates in a superficial pustule. A furuncle forms by deep extension of the perifollicular infection. A carbuncle results from coalescence of furuncles and still deeper extension of inflammation into the subcutaneous tissues. Fever and malaise are usually associated.

FOCAL INFECTIONS WITH TOXIC EFFECTS

Focal conditions include the staphylococcal scalded skin syndrome (SSSS) and toxic shock syndrome (TSS) and are characterized by remote staphylococcal infections associated with severe toxicity.

SSSS is usually found in young children; it is rare in adults and may occur in epidemic form in neonates (pemphigus neonatorum). A few days after a staphylococcal infection, fever develops, and an erythematous rash appears on the face 2 to 3 days later. Soon, the entire body is covered with a weeping rash that develops into large bullae. When the bullae break and slough, they leave denuded, wet, raw areas that heal within 10 days.

In TSS, vaginitis and vaginal discharge are associated with fever and a generalized macular erythematous rash that eventually desquamates. Hypotension occurs, and three or more organ systems may fail (Table 263.1). Rarely, TSS may follow other soft-tissue infections.

Fever >38.8°C	Three or more of the following:
Rash	Gastrointestinal—vomit, diarrhea
Hypotension (BP <90 mm Hg)	Muscle—myalgias, CPK >2 × UUN
Negative	Renal—BUN, serum Cr >2 × UUN
Culture of blood, throat, CSF	Liver—bilirubin ALT >2 × UUN
serology for leptospirosis, Rocky	Blood—platelets <100,000 ml ⁻³
Mountain spotted fever, measles	Neurologic—disorientation without focal signs

ALT, alanine aminotransferase; BP, systolic blood pressure; BUN, blood urea nitrogen; CPK, creatine phosphokinase; Cr, creatinine; CSF, cerebrospinal fluid; UUN, upper limit of normal.

TABLE 263.1. CRITERIA FOR DIAGNOSIS OF TOXIC SHOCK SYNDROME

DIFFUSE INFECTIONS—CELLULITIS

Cellulitis is a spreading acute infection of the skin and subcutaneous tissues characterized by erythema, warmth, swelling, and tenderness. It may be primary or may be secondary to a local lesion or, uncommonly, to hematogenous spread of infection from a remote area. Cellulitis may be classified as mild and uncomplicated, severe, high risk, or necrotizing.

Most cellulitis is mild and uncomplicated and is caused by group A streptococci or by *S. aureus*. Diffuse erythema, swelling, and tenderness develop over 2 to 4 days. In an extremity, a red line along the course of the lymphatics indicates accompanying lymphangitis; enlarged, tender regional lymph nodes are common. Fever, malaise, and chills are often present. Cellulitis is potentially dangerous because of the rapidity with which infection spreads to the bloodstream.

Severe infections must be recognized, and patients must be admitted to the hospital for intravenous antibiotic therapy. The key signs are systemic: fever, chills, toxicity, and leukocytosis. Underlying disease (e.g., diabetes) and ischemia worsen the risk and should be sought specifically. Severity may also be graded in units by the intensity of each of its four elements (fever, erythema, swelling, and tenderness). Each element is rated as absent (0), mild (1), moderate (2), or severe (3), and the total score in severity units is the sum of scores for each element.

Some infections are designated as high risk because the sites at which they occur predispose to serious complications. These infections include orbital cellulitis, erysipelas, and other facial cellulitis; postadenectomy cellulitis and postvenectomy cellulitis in the extremities; and erysipeloid and infected human and animal bites on the hands.

Facial cellulitis is especially common in infants and children and is classified as odontogenic or nonodontogenic. Eighty percent occurs in the upper face. Odontogenic cellulitis refers to orofacial lesions originating from the teeth and periodontal structures. It accounts for 50% of all facial cellulitis, but 80% of lower facial cellulitis, and it occurs typically in older children of mean age 9 years. In contrast, nonodontogenic cellulitis occurs especially in infants and younger children. Thus, erysipelas usually follows a streptococcal sore throat in infants and young children. The anatomical location of the infection in the dermis and lymphatics accounts for the characteristic pain and the bright-red *peau d'orange* lesions whose advancing raised borders are sharply demarcated from normal skin.

Haemophilus influenzae type B (HIB) cellulitis occurs in the face and extremities of small children with fever and bacteremia from upper respiratory tract infections; recently, similar cases have been reported in adults. The typical lesion is painful, swollen, and purplish-red—the “bruised-cheek syndrome.” It is unilateral when associated with ipsilateral otitis media, but it may be bilateral. Secondary meningitis may develop.

Orbital and periorbital cellulitis are marked by pain, redness, and swelling of the eyelids. Periorbital infections associated with minor trauma are common in childhood. Orbital cellulitis is a rare complication of acute sinusitis. The Chandler classification defines five stages: stage I, preseptal characterized by eyelid swelling only; stage II, postseptal orbital cellulitis in which infection has crossed the anterior orbital septum; stage III, subperiosteal abscess; stage IV, in which rupture of the periosteum allows extension of the abscess into the orbital cavity producing proptosis, chemosis, reduced eye motion, and a risk of blindness and of progression to stage V; and stage V, in which further complications such as meningitis and brain abscess occur. *S. aureus*, streptococci, and occasionally gram-negative aerobic bacteria are found.

Postadenectomy and postvenectomy cellulitis manifest as recurrent cellulitis in the lymphedematous extremity. Most patients with postadenectomy cellulitis have had a remote lymph node dissection for carcinoma of the breast, malignant melanoma, or gynecologic cancer. Postvenectomy cellulitis occurs in the legs of patients whose saphenous veins have been harvested for coronary artery bypass surgery. In both conditions, systemic signs such as fever, chills, and toxicity are prominent. Non-group A streptococci, particularly groups C and G, are usually implicated.

Erysipeloid is a form of cellulitis that occurs in workers handling fish, meat, and poultry. It is caused by the gram-positive bacillus *Erysipelothrix rhusiopathiae*. About 1 week after a minor injury to the hand, a violaceous painful area appears. As the central area clears, the lesion spreads outward with distinct raised borders. A more insidious marine infection caused by *Mycobacterium marinum* follows abrasions or puncture wounds in aquatic environments. Its presentation is a flat, macular, red area that disappears spontaneously or progresses to nodular and ulcerated lesions, which may extend along lymphatics or tendon sheaths and even to bone.

Animal and human bites are potentially dangerous because of tissue damage and secondary infection. Deep infections such as tenosynovitis are particularly common after human bites.

In some patients, cellulitis poses a high risk because of concurrent impaired host defense. This form of cellulitis is unusual, and the bacteria involved are unusual causes of primary soft-tissue infection. Pneumococcal cellulitis is associated with bacteremia and may resemble erysipelas. Cellulitis caused by Enterobacteriaceae is more insidious in onset. Examples include *Escherichia coli* cellulitis in immunodeficient children or adults, *Aeromonas hydrophila* cellulitis (which follows minor lacerations acquired while swimming in fresh water), and *Serratia marcescens* cellulitis in immunocompromised patients with organ failure.

The most serious variant of cellulitis is *necrotizing cellulitis*, a term used for a variety of gangrenous soft-tissue infections often associated with anaerobic bacteria, tissue toxins, and bacterial synergy (Chapter 273).

The key to recognizing these infections is an awareness of underlying risk factors and of local signs: edema out of proportion to erythema, skin vesicles, crepitus on palpation or air in the tissues on radiologic examination, and local anesthesia or patchy gangrene of the skin.

PATHOPHYSIOLOGY

The pathophysiology of soft-tissue infections depends on anatomical localization (Fig. 263.2) and on the interaction of factors related to the invasiveness of the microorganism and to host defenses. Of the focal infections, impetigo is caused in 80% of cases by *Streptococcus pyogenes*, in 10% by *S. aureus*, or by both. Skin colonization favored by poor hygiene is followed by inoculation through minor abrasions, leading to clinical illness. Upper respiratory tract colonization occurs in the next 2 to 3 weeks but does not cause pharyngitis; in fact, the M-serotype skin strains are different from the throat strains that cause pharyngitis and tonsillitis.

The focal nature of the skin lesions is in keeping with poor lytic enzyme activity of the bacteria. In contrast, the large flaccid bullae typical of impetigo caused by group II phage-type *S. aureus* are a response to the exfoliative toxin (ET) produced by the organism. ET, also produced by *S. aureus* in SSSS, splits the epidermis in the stratum granulosum, resulting in large bullae and separation of sheets of skin (Nikolsky's sign). In TSS, group I phage *S. aureus* strains produce enterotoxin F (EF), which is responsible for the fever, skin rash, hypotension, and diarrhea. Most cases of TSS are associated with menstruation and with the use of superabsorbent tampons. A similar clinical picture has been described recently in extremity infections caused by group A streptococci, which produce a pyrogenic toxin similar to EF.

In diffuse cellulitis hyaluronidase, a and b toxins produced by *S. aureus* and DNase, hyaluronidase, streptokinase, and streptolysins produced by group A streptococci

facilitate the spread of infection through tissue planes. A disparity exists between the intensity of the inflammatory response and the low density of bacteria found on culture or direct immunofluorescence techniques. These findings were previously attributed to lymphatic overload or failure, impaired protein clearance, and an exaggerated inflammatory response to the excess denatured protein. A better explanation has been found recently in a unique set of lymphoid and reticular cells in the skin (dendritic cells of Langerhans; Fig. 263.2) and keratinocytes. When exposed to bacterial cell components, these cells release cytokines such as interleukin-1 and tumor necrosis factor. In turn, these cytokines increase phagocytosis and cytotoxicity, causing rapid bacterial clearance, and they evoke an enhanced inflammatory response in the tissues.

In the severe cellulitis of diabetic foot infections, neuropathy, vascular insufficiency, and hyperglycemia combine to promote synergistic spreading infections, tissue necrosis, and delayed wound healing. Motor and sensory neuropathy causes altered weight-bearing and impaired sensation and proprioception. Vascular insufficiency impairs the healing of fissures and breaks in the skin, and hyperglycemia is associated with decreased neutrophil migration and phagocytosis, reduced fibroblast replication, and decreased collagen formation and strength.

The pathogenesis of HIB buccal cellulitis is unclear. Because the condition usually follows otitis media, lymphatic spread of HIB to buccal nodes has been suggested. Hematogenous spread has also been suggested because bacteremia is common in children with HIB cellulitis. However, bacteremia is uncommon in HIB cellulitis in the lower extremities of adults. In periorbital and orbital cellulitis, spread of infection occurs directly from the sinuses or by retrograde thrombophlebitis along valveless facial veins.

In postadenectomy and postvenectomy cellulitis, stagnated lymph fluid favors bacterial growth. This may explain why local infection and toxicity are more common in limbs with lymphedema than in normal limbs.

High-risk hand infections owe their severity to the depth of invasion of specific bacteria. These bacteria include the gram-negative coccobacillus *E. rhusiopathiae* in fish and meat handlers, *Pasteurella multocida*, and occasionally the gram-negative bacillus dysgonic fermenter-2 (DF-2) in dog and cat bites and the gram-negative bacillus *Eikenella corrodens* in human bites. DF-2 can produce fulminant bacteremia and disseminated intravascular coagulation in patients who have had splenectomy.

High-risk cellulitis in immunosuppressed patients is important for several reasons. First, in HIV-positive patients, the edema of Kaposi's sarcoma may simulate cellulitis, particularly in dark-skinned persons, in whom the neoplasm may not be noticeable. Second, gram-negative bacterial cellulitis and necrotizing infections occur with increased frequency in HIV-positive and other immunocompromised patients. Third, a recently described syndrome in the immunocompromised patient can cause lesions similar to those of Kaposi's sarcoma. The causative agent, *Rochalimaea henselae*, may be isolated from the cutaneous lesions and blood of patients with the syndrome.

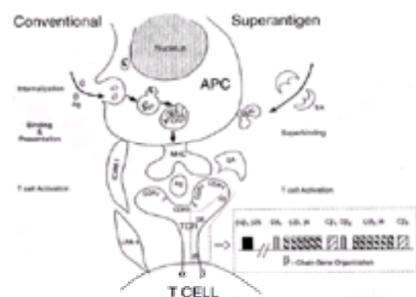

FIGURE 263.3. Activation of T lymphocytes by superantigens compared with that by conventional antigens. Ag, antigen; APC, antigen-presenting (mononuclear) cell; L, lysosome; V, vesicle; MHC, major histocompatibility class II molecule; SA, superantigen; ICAM, intracellular adhesion molecule; LFA, lymphocyte functional associated molecule; CDR, complementarity determining region; TCR, T cell, receptor. Inset: Gene organization on b-chain of the T cell receptor. V, variable region; C, constant region; D, diversity segment; J, junctional zone. (From Lewis RT. Soft tissue infections. *World J Surg* 1998;22:146-151.)

In necrotizing cellulitis, impaired host resistance, anaerobic wound conditions, bacterial synergy, and lytic enzymes and toxins produced by the microbes involved are responsible for the rapidity of onset or progression. More recently, the streptococcal toxic shock syndrome has gained notoriety as a life-threatening "flesh-eating disease" in young adults. The pathogenesis is related to specific streptococcal pyrogenic exotoxins, which stimulate mononuclear cells and lymphocytes to produce cytokines that promote fever, shock, and tissue injury. The effect on the lymphocytes is greatly amplified because the exotoxins serve as "superantigens," interact with T lymphocytes in ways that are swifter and more universal than occur with conventional antigens, resulting in massive activation of lymphocytes and profuse release of damaging lymphokines.

INVESTIGATION

In all but the simplest cases of uncomplicated cellulitis, the physician should follow the ABCs of investigation of soft-tissue infection: aspiration of pus or deep tissue fluid for culture, blood tests for risk evaluation, culture of deep tissue specimens and blood, and diagnostic imaging.

ASPIRATION

Although superficial cultures are positive for pathogenic bacteria in two-thirds of cases, they are of little value in management because most are found in open lesions that respond to blind therapy with semisynthetic penicillins. Deep tissue culture is preferable, and needle aspiration is the best method of obtaining a satisfactory specimen of tissue fluid or pus. In patients without an obvious collection of pus, a fine-needle aspiration technique should be used.

BLOOD TESTS

Blood tests for risk evaluation should include a complete blood count and random blood sugar. In febrile or toxic patients, the blood urea nitrogen and serum creatinine levels should be determined; blood tests of liver function may be performed, if indicated. Blood cultures are usually negative and should therefore be done selectively. Leukocytosis is common. Organ dysfunction may be found in TSS and in necrotizing infections.

CULTURE

After deep tissue fine-needle aspiration, 0.5 mL thioglycolate broth is aspirated into the syringe and a few drops are inoculated onto plates of sheep blood agar, chocolate agar, and MacConkey agar and into a glass tube containing a semisolid thioglycolate medium. The agar plates and tube are then incubated for 48 hours at 35° C in 5% carbon dioxide, and a separate sheep blood agar plate is incubated in an anaerobic jar. Only 20% to 30% of cultures are positive in cellulitis; blood cultures are positive still less often.

DIAGNOSTIC IMAGING

Methods used include plain x-ray films, isotope and ultrasound imaging, and occasionally CT and MRI.

Plain films show air in the tissues in 90% of patients with necrotizing soft-tissue infection, so they are of great value in identifying these infections. Furthermore, when x-rays show medullary lysis, endosteal scalloping, or cortical erosion, they resolve immediately the issue of bony involvement. However, plain x-rays may be normal within the first 7 to 10 days of bony infection; therefore, bone scans are often obtained. In practice, it is best to delay scanning until soft-tissue infection has been controlled by intravenous antibiotics.

Isotope imaging may be performed with technetium (^{99m}Tc) pyrophosphate or gallium-indium. ^{99m}Tc pyrophosphate accumulates in areas of increased blood flow or new bone formation and may be positive within 48 hours of bone infection. Gallium citrate and indium chloride become fixed to sequestered polymorphs and macrophages, and to transferrin, which leaks from the bloodstream into areas of inflammation. Neither gallium nor indium accumulates specifically in areas of reactive bone. A 3-minute ^{99m}Tc scan is therefore preferable to the use of gallium-indium for differentiating clearly between soft-tissue and bone inflammation. When scans using both isotopes are available in a patient with osteomyelitis, ^{99m}Tc pyrophosphate shows a disproportionate concentration in bone, best seen when the studies are delayed until soft-tissue infection has subsided. In fact, when it is available MRI offers the greatest accuracy in diagnosing osteomyelitis. Secondary signs of bone involvement—ulcer, sinus, or cortical interruption—augment diagnostic confidence when an abnormal marrow signal is present.

Duplex scanning is the best method for identifying superficial and deep venous thrombosis. The study should be performed in patients with severe extremity inflammation to rule out venous thrombosis simulating or complicating cellulitis. MRI with gadolinium differentiates necrotizing from non-necrotizing soft-tissue infections by the absence of gadolinium contrast enhancement in T1-weighted CT imaging is mandatory in managing orbital infection. In particular, it identifies Chandler stage III disease and shows the details of stage V involvement.

STRATEGIES FOR OPTIMAL MANAGEMENT

In managing soft-tissue infections, the first priority is to identify necrotizing infection. [Figure 263.4](#) emphasizes the central role of risk factor analysis and clinical markers of necrotizing infection in the management scheme. A second priority is to rule out noninfectious conditions that may simulate or complicate cellulitis. A third priority is to identify complications such as bone or joint infection in extremity cellulitis and orbital and intracranial infection in facial cellulitis. These priorities are met by attention to clinical presentation and to the ABCs of investigation. Treatment itself should include antibiotic therapy, local care, and resuscitation of some patients.

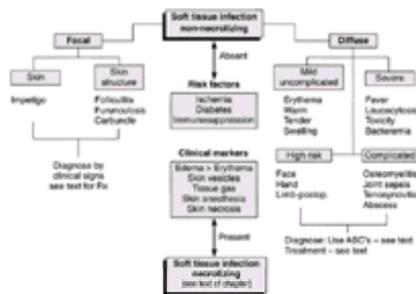

FIGURE 263.4. Management of soft-tissue infection.

FOCAL NONTOXIC INFECTIONS

Impetigo is treated either by a single intramuscular injection of penicillin (300,000 to 600,000 units) or by oral penicillin V (15,000 units per kilogram) every 6 hours for 10 days. In penicillin allergy, oral erythromycin (10 mg per kilogram every 6 hours) should be given for 10 days. Local care is important and includes washing with soap and water to soften and remove crusts. In bullous impetigo, oral cloxacillin (15 mg per kilogram every 6 hours) is given for 10 days.

Folliculitis and furuncles are generally treated satisfactorily by local measures only; saline compresses speed regression or spontaneous drainage. Topical antibiotics may be helpful. Oral cloxacillin (500 mg every 6 hours) for 7 to 10 days is indicated for recurrent or facial furunculosis and for surrounding cellulitis or associated fever. In the penicillin-allergic patient, oral erythromycin (250 to 500 mg every 6 hours) for 7 to 10 days is a suitable alternative. Surgical drainage is required for large and fluctuant furuncles or carbuncles. In patients with recurrent disease, additional measures are recommended:

- Shower daily with hexachlorophene soap to reduce skin colonization and autoinfection.
- Cover draining lesions with sterile dressings to reduce the spread of contamination.
- Discard dressings promptly after removing them.
- Apply nasal bacitracin to decrease nasal carriage, shedding, and skin contamination.

FOCAL INFECTIONS WITH TOXIC EFFECTS

The initial treatment of SSSS and TSS is resuscitation by appropriate fluid replacement. Intravenous antibiotic therapy is given for the staphylococcal skin lesions of SSSS (cloxacillin 20 mg per kilogram every 6 hours for the newborn or 50 mg per kilogram every 6 hours for older children). Cold saline compresses aid separation of exfoliated skin and crusts. In TSS, gentle vaginal examination should be performed to remove any vaginal tampon and to culture the cervix for *S. aureus*. In variant TSS, the focus of infection may require surgical drainage. Intravenous cloxacillin is given (2 g every 6 hours) for 10 days.

DIFFUSE INFECTIONS

Most cases of cellulitis can be managed simply on an outpatient basis. However, severe infections, high-risk infections, and complicated infections usually require aggressive inpatient antibiotic therapy and often surgery. Patients with necrotizing infections must be admitted for surgery.

Uncomplicated mild cellulitis, commonly caused by *S. pyogenes* or *S. aureus*, responds well to oral cloxacillin or cephalexin (500 mg every 6 hours for 7 to 10 days). In patients allergic to penicillin, oral erythromycin (500 mg every 6 hours) is an alternative. Although various quinolones have been investigated for treating uncomplicated cellulitis, no advantage over less expensive antibiotics has been found. Local therapy includes cleansing the area and resting the extremity.

In severe cellulitis, treatment should start with intravenous cloxacillin (1 g every 6 hours). Intravenous vancomycin (500 mg every 8 hours) or the related glycopeptide antibiotic teicoplanin (1 g daily) are alternatives for the penicillin-allergic patient. An aminoglycoside such as gentamicin may be added when the clinical setting suggests that a gram-negative bacillus may play a role, for instance, in patients with failed oral cloxacillin therapy, in those with cellulitis after injury and exposure to contaminated fresh water, in those with perianal cellulitis, and in those who have risk factors for gram-negative bacterial infection (neutropenia, diabetes mellitus, organ failure, and corticosteroid treatment). However, many physicians now avoid aminoglycosides, particularly in diabetic and other patients who may have renal impairment. Second-generation cephalosporins such as cefoxitin (1 to 2 g every 6 hours) or cefotetan (1 to 2 g every 12 hours) have been used successfully and are particularly attractive in patients in whom anaerobic bacteria may play a role. Others prefer third-generation cephalosporins, particularly ceftazidime (2 g every 6 hours) or ceftriaxone (1 to 2 g daily), or the combination antibiotics piperacillin-tazobactam (3.375 g every 6 hours), ticarcillin-clavulanate (3.1 g every 8 hours), or ampicillin-sulbactam (3 g every 6 hours).

Some authors have suggested the use of nonsteroidal anti-inflammatory drugs in cellulitis, based on the role of cytokines in the pathophysiology of soft-tissue infections. However, benefit is unproved, and caution has been suggested because of the risk of promoting bacterial multiplication and because of an observed association with necrotizing skin infection. Local measures include elevation and immobilization of the part. Surgical drainage of focal lesions may be required.

Among high-risk facial infections, erysipelas usually responds to intravenous penicillin G (1 million units every 6 hours). Traditionally, HIB cellulitis is treated initially with intravenous ampicillin, but most institutions now favor intravenous cefuroxime (125 mg twice daily). Orbital cellulitis is also treated with broad-spectrum antibiotics. CT evidence of abscess or intracranial involvement and failure to respond to antibiotics within 48 hours are indications for prompt exploration and decompression of the orbit. Postadenectomy and postvenectomy cellulitis are treated as severe cellulitis. Of the high-risk hand infections, erysipeloid responds to amoxicillin-clavulanate or erythromycin. Animal and human bites require oral cloxacillin and local debridement. Neither *P. multocida* nor *E. corrodens* responds to

erythromycin. Debridement is particularly important in human bites and clenched-fist injuries because of the major role of anaerobic bacteria in these states.

The treatment of complicated cellulitis is discussed in the following text, and necrotizing soft-tissue infection is considered in [Chapter 273](#). In streptococcal toxic shock syndrome, evidence now favors use of intravenous high-dose penicillin and clindamycin, and human immunoglobulin is given to neutralize exotoxin.

COMPLICATIONS

Soft-tissue infection may be complicated by deep abscesses, tendon sheath infection, osteomyelitis, and other site-specific deep infections. In severe cellulitis, a deep abscess may be suggested by failure to respond to intravenous antibiotics or by clinical signs and results of investigation. A foreign body may serve as a nidus for abscess formation. The history may suggest it, and an x-ray film of the part or an ultrasound examination may confirm the diagnosis. Treatment includes removal of the foreign body, surgical drainage, and continued antibiotic therapy.

Tenosynovitis should be sought in all hand infections but is particularly likely after human bites of the hand. Kanavel's four signs suggest the diagnosis: uniform swelling of the digit, tenderness along the line of the tendon sheath, flexion of the resting digit, and worsening of the pain on extension. In early cases, intravenous antibiotics such as cloxacillin (1 g) or cefoxitin (2 g) every 6 hours may permit resolution, but surgical drainage is required if this fails and in advanced cases.

A classification of soft-tissue, bone, and joint infections has been suggested to aid in the diagnosis and management of infections of bone and joint complications ([Table 263.2](#)).

Anatomical Type	Soft Tissue	Bone	Joint
Simple	Cellulitis	Mild/moderate osteomyelitis	Acute septic arthritis
Diagnosis	Red, edema, tenderness	3 days—bone pain Bone scan—variable ++	3 days—joint swelling Joint scan—variable ++
Treatment	Antibiotics	Antibiotics +/- drainage	Antibiotics +/- drainage
Superficial	Shin	Superficial osteomyelitis	Septic arthritis with chondrolysis
Diagnosis	Shin lesion	3 days—mild changes Bone scan—variable ++	3 days—loss of joint space Joint scan—variable ++
Treatment	Debridement, antibiotics	Antibiotics +/- debridement	Antibiotics +/- drainage
Localized	Abscess	Local osteomyelitis	Septic arthritis with osteomyelitis
Diagnosis	Fluctuance, aspirate/abscess pus/abscess	3 days—cortical erosion Bone scan—variable ++	3 days—cortical erosion, loss of joint space Bone scan—variable ++ in bone & joint
Treatment	Drainage, antibiotics	Antibiotics, debridement	Antibiotics, debridement
Diffuse	Compromised	Diffuse osteomyelitis	Stable joint
Diagnosis	Edema +/- gas in tissue, skin lesions, vesicles	3 days—medullary bone erosion Bone scan—variable +++	3 days—cortical erosion, loss of joint space Bone scan—variable +++ Stable joint
Treatment	Debridement, antibiotics	Debridement/antibiotics	Stabilize joint Antibiotics

TABLE 263.2. COMPLICATED CELLULITIS GRADES OF INFECTION IN SOFT TISSUE, BONE, AND JOINT

COST-EFFECTIVENESS

In an era of cost containment and managed health care, outpatient antibiotic therapy is playing an increasing role in the management of soft-tissue infection ([Table 263.3](#)). Evidence is increasing that parenteral antibiotics can be given effectively and safely to patients at home or in an ambulatory setting at substantially lower cost than inpatient care. Such therapy is made possible by antibiotics of prolonged half-life, which provide tissue drug levels higher than the minimal inhibitory levels required for most pathogens that cause cellulitis. In addition, some new antibiotics are equally effective when given by mouth or by the intravenous route. More studies are required to define the best strategies for dealing with disease of varying grades of severity; particularly in diabetic foot infections where therapy for 3 or 4 weeks is recommended, it is convenient to start with intravenous therapy and continue with oral therapy. MRI is cost-effective in diagnosing osteomyelitis in providing the anatomical localization necessary for the aggressive surgical intervention that minimizes above-ankle amputation.

Antibiotic therapy by mouth only
 Single-dose parenteral antibiotic, followed by oral therapy
 Daily parenteral antibiotic therapy until favorable response, followed by oral therapy

TABLE 263.3. STRATEGIES FOR COST-EFFECTIVE OUTPATIENT ANTIBIOTIC THERAPY IN SEVERE CELLULITIS

Other strategies suggested for reducing costs but are as yet unproven include the use of granulocyte colony-stimulating factor or hyperbaric oxygen therapy in diabetic foot infection and the use of platelet-derived growth factor to hasten healing of diabetic foot ulcers.

CHAPTER 264: INTRA-ABDOMINAL ABSCESS: DIAGNOSIS AND MANAGEMENT

MARIANNE CINAT AND SAMUEL E. WILSON

[Pathogenesis](#)
[Microbiology](#)
[Site](#)
[Diagnosis](#)
[Treatment](#)
[Management of Specific Abscesses](#)
[Mortality Rate and Risk Factors](#)

An intra-abdominal abscess develops when infection within the greater or lesser peritoneal spaces becomes localized by a pyogenic membrane containing leukocytes, cellular debris, fibrin, and bacteria or fungi. This walling-off process represents temporary control of a potentially overwhelming peritonitis. Intraperitoneal abscesses often stem from perforation of a hollow viscus. Examples of enterogenous sources of intra-abdominal abscess are appendicitis, diverticulitis, and Crohn's disease. Intra-abdominal abscesses may develop as a result of invasive procedures, most commonly after gastrointestinal or biliary surgery ([Figure 264.1](#) and [Figure 264.2](#)).

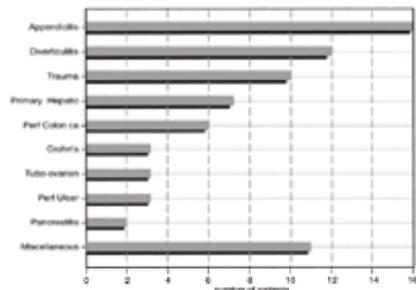

FIGURE 264.1. Origin of intra-abdominal abscesses arising from enterogenous disease or trauma. (From Saini S, Kellum JM, O'Leary MP, et al. Improved localization and survival in patients with intra-abdominal abscesses. *Am J Surg* 1983;145:136–142, with permission.)

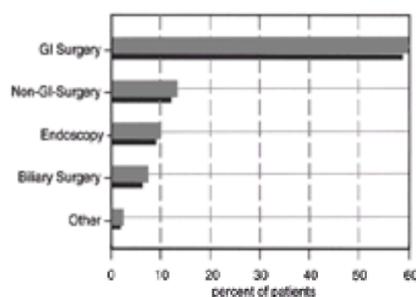

FIGURE 264.2. Origin of intra-abdominal abscess arising as a complication of surgical procedures. (From Saini S, Kellum JM, O'Leary MP, et al. Improved localization and survival in patients with intra-abdominal abscesses. *Am J Surg* 1983;145:136–142, with permission.)

PATHOGENESIS

Secondary peritonitis results from loss of integrity from the gastrointestinal tract. It is usually due to a perforation of the intestine, is polymicrobial in nature, and may take the form of an intra-abdominal abscess or generalized peritonitis. Three forms of host defense occur after initial peritoneal contamination. Within minutes of bacterial contamination, microorganisms are cleared by lymphatics and are exposed to systemic defenses. Peritoneal macrophages become activated and act as phagocytic cells. If the invading microorganisms prevail, polymorphonuclear leukocytes migrate toward the area of infection. In addition, there is an increase in splanchnic blood flow and capillary permeability, leading to an exudation of 300 to 500 milliliters of fluid per hour, massive third-space fluid losses, and resultant hypovolemia. Fibrin produced from inflammatory cells entraps bacteria and limits their spread. These events help control generalized peritonitis, but they also promote the development of intra-abdominal abscesses.

MICROBIOLOGY

Pathogens isolated from intra-abdominal abscesses are derived from the flora of the gastrointestinal tract. Bacterial cultures are usually polymicrobial, commonly containing *Escherichia coli*, *Enterococcus*, anaerobes, and *Klebsiella* species. Anaerobic bacteria are found in up to 80% of intra-abdominal abscess cultures, with *Bacteroides fragilis* and *Clostridium* species identified most often. Initial antimicrobial therapy is usually presumptive, but subsequent modification is based on culture results. Pathogens other than bacteria may be involved, such as *Candida* or *Aspergillus* species, or parasites, such as *Pneumocystis carinii* or *Cryptosporidium*.

SITE

An abscess within the peritoneal cavity is not always located adjacent to the source of infection. Diaphragmatic movement draws peritoneal fluid upward, whereas gravity acts to pull peritoneal fluid into the pelvis. Accordingly, the subphrenic and pelvic areas are the most common sites of intra-abdominal abscess formation ([Fig. 264.3](#)). Twenty percent of patients have several sites of involvement, which is important to remember when deciding between image-guided and open treatment.

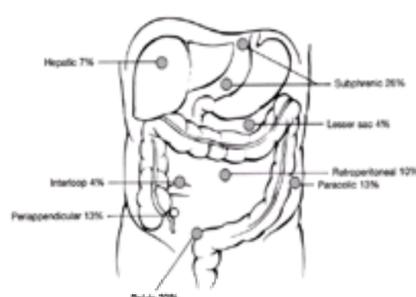

FIGURE 264.3. Distribution of 130 abscesses in 100 patients (3% were in other locations) (From Saini S, Kellum JM, O'Leary MP, et al. Improved localization and survival in patients with intra-abdominal abscesses. *Am J Surg* 1983;145:136–142, with permission.)

survival in patients with intra-abdominal abscesses. *Am J Surg* 1983;145:136–142, with permission.)

DIAGNOSIS

By means of a thorough history and physical examination and the appropriate noninvasive studies, the physician can localize intra-abdominal abscess with a high degree of accuracy. Enterogenous intraperitoneal abscess should be suspected when the patient has a history of diverticulitis, inflammatory bowel disease, peptic ulcers, pancreatitis, cancer, or long-term steroid use. The patient usually reports fever, anorexia, nausea, vomiting, and abdominal pain. Physical examination, estimated to be helpful or diagnostic in up to 75% of intra-abdominal abscesses, may pinpoint decreased or absent bowel sounds, indicating an ileus, distention, and a mass with localized or diffuse tenderness. Peritoneal signs, such as rebound tenderness, may not be present, especially in those patients who are immunocompromised. Signs of peritonitis may have resolved by the time an abscess associated with a perforated viscus develops. Rectal and pelvic examinations are always carried out and can aid in localizing a pelvic or paracolic abscess. Abdominal tenderness is not to be expected with subphrenic abscesses; pulmonary symptoms, such as cough, dyspnea, and basilar rales, may be the only diagnostic clues. Diagnosis of a postoperative intra-abdominal abscess also represents a challenge, because these patients are receiving narcotics, have peri-incisional tenderness and postoperative ileus, and may have low-grade fever unrelated to infection. Postoperative intraperitoneal abscess should be suspected when ileus, fever, and elevated leukocyte count are present beyond the fifth to seventh postoperative day in a patient who has had an intraperitoneal operation.

Imaging techniques have improved both diagnosis and treatment of intra-abdominal abscess. Plain film radiography will at best make visible only 50% of the abscesses that are present. Plain film findings suggestive of intra-abdominal abscess include displacement of bowel or other organs, extraluminal fluid collection with air-fluid level, or extraluminal air indicative of perforation. An elevated hemidiaphragm and pleural effusion seen on a chest radiograph may be the only findings suggestive of subphrenic abscess.

Computed tomography (CT) is the study of choice in imaging intra-abdominal abscesses, yielding up to 97% sensitivity and specificity in localizing intra-abdominal abscesses, with the added benefit of potentially identifying the primary disease process leading to abscess formation, such as appendicitis or diverticulitis. CT is superior to ultrasonography in making visible pelvic abscesses or several abscesses. CT findings of abscess include a well-defined fluid collection with a peripheral enhancing rim ("rind sign"), displacement of surrounding organs, and extraluminal air ([Figure 264.4](#) and [Figure 264.5](#)).

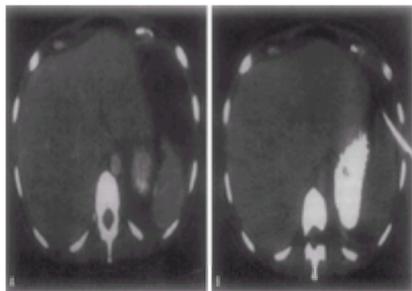

FIGURE 264.4. A: Computed tomographic (CT) scan of a 52-year-old woman, showing a large left subphrenic abscess caused by a perforated gastric ulcer. Note the extraluminal air within the fluid-filled abscess cavity. **B:** Follow-up CT scan 72 hours after CT-guided placement of a percutaneous drainage catheter into the left subphrenic abscess. The catheter is in a good position, and the abscess is almost completely resolved.

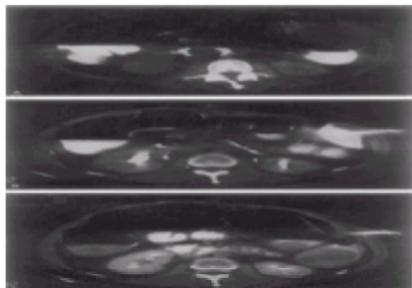

FIGURE 264.5. A: Computed tomographic (CT) scan of a 68-year-old woman with perforated diverticulitis, showing a left pelvic abscess. The abscess is well defined, with an enhancing rim, or "rind sign." **B:** Thirty-six hours after CT-guided placement of a drainage catheter, the catheter is injected with contrast to evaluate accurately the abscess response to drainage. With a 50% reduction in abscess size, drainage was continued for several more days. **C:** CT scan 72 hours after drain placement shows complete resolution of the left pelvic abscess.

When it is target directed, ultrasonography is useful in imaging intraperitoneal abscesses. Ultrasonography is less sensitive than CT, however, when used as a survey test and has a higher incidence of false-positive results. Saini and colleagues found no benefit from combined CT and ultrasonography when compared with CT alone in diagnosing intra-abdominal abscesses; they recommend CT as the sole imaging study whenever feasible. Intraluminal gas, subcutaneous fat, and postoperative inflammation pose limitations to the use of ultrasonography. Nevertheless, with reported sensitivities greater than 82%, portability of equipment, and lack of radiation exposure, ultrasonography does have clinical utility, especially in pregnant patients and in patients too critically ill to be transported to a CT scanner.

Several radionuclides have been used to image intra-abdominal abscesses with some success. Both gallium 67 and indium 111 bind to leukocytes, localizing inflammation and abscesses as areas of focal uptake on scanning images. The great disadvantage of radioisotope scans is the high false-positive rates that occur because of localization of isotope in normal bowel, liver, and kidneys as well as in recent surgical sites and in neoplasms. On the other hand, a negative study result usually rules out significant intra-abdominal sepsis. With more rapid, accurate diagnosis using CT and ultrasonography, radionuclide localization of intra-abdominal abscesses is not routinely performed today.

TREATMENT

Drainage of the infected fluid collection is the definitive step in treatment of an intra-abdominal abscess, but initial resuscitation with intravenous fluids and antimicrobial therapy must first be instituted without delay. Before the widespread use of CT and ultrasound technology, surgical drainage was the sole treatment of intra-abdominal abscesses. Since the mid-1970s, CT- or ultrasound-guided percutaneous drainage has been preferred to operative therapy in selected patients ([Figure 264.4](#) and [Figure 264.5](#)). Patients matched for severity of illness, surgical drainage, and image-guided percutaneous drainage have similar mortality rates and lengths of hospital stay. Potential benefits of the percutaneous approach include reduced cost, avoidance of general anesthesia, and increased acceptance by the patient. Johnson and colleagues established the following criteria for percutaneous abscess drainage: a well-established unilocular fluid collection evident on CT or ultrasonography, a safe route for the percutaneous approach, joint evaluation and agreement by surgical and radiologic services, reassessment within 72 hours by CT or ultrasonography, and ready surgical support for any complication or failure.

Surgical drainage is the method of choice when the percutaneous approach is deemed unsafe, several abscesses exist, frank peritonitis is present, or a definitive

operation to correct the primary underlying pathologic condition is feasible. The viscous nature of fungal abscesses, infected hematomas, and concomitant tissue necrosis make collections with these characteristics better suited for surgical drainage. Initial drainage is more frequently successful with surgical intervention, especially in centers where routine percutaneous abscess drainage is not performed.

Percutaneous and surgical abscess drainage can lead to similar complications, including fistulas, sepsis, bleeding, and recurrent abscesses. Olak found a 48% incidence of fistula formation associated with percutaneous drainage catheter placement, compared with 18.5% in the surgical group. Johnson and colleagues reported a 4% complication rate for percutaneous drainage and a 16% rate of complication for surgical drainage, mostly related to erosion caused by the indwelling catheter.

MANAGEMENT OF SPECIFIC ABSCESES

PANCREATIC ABSCESS

At onset pancreatitis is a noninfectious, inflammatory process. Infection is the result of translocation of bacteria across ischemic bowel and secondary hematogenous or lymphatic spread of pathogens to pancreatic pseudocysts or to necrotic pancreatic parenchyma, with ultimate formation of a pancreatic abscess. The additional burden of a pancreatic abscess in a patient with fulminant pancreatitis can be devastating, as reflected in reported mortality rates of 14% to 57%. Malangoni and colleagues have found CT to be the most sensitive diagnostic test for pancreatic abscess; findings of peripancreatic fluid collections and gas in the area of the pancreatic bed are predictive of the presence of a pancreatic abscess. Use of CT-guided diagnosis, broad-spectrum antibiotics, and early surgical debridement and drainage has led to a decline in mortality rates from 38% to 18% since 1980. Freeny and colleagues had a 91% success rate in treating pancreatic abscess with percutaneous catheter drainage under CT guidance in well-selected patients. They concluded that in those patients with pancreatic abscesses but no extensive pancreatic necrosis, percutaneous drainage is an appropriate management choice. They recommend predrainage endoscopic retrograde cholangiopancreatography in all stable patients, to further delineate abscess location before choosing between percutaneous and surgical drainage. Pancreatic abscesses that have accompanying soft-tissue necrosis require open drainage and debridement.

PERIAPPENDICEAL ABSCESS

Chronic periappendiceal abscess is a complication of acute appendicitis in 2% to 3% of cases. Whereas acute appendicitis and its complications of perforation, peritonitis, or abscess mandate appendectomy, the presence of a subacute or chronic periappendiceal abscess indicates that perforation has already occurred and has been successfully walled off. Operation for periappendiceal abscess is effective in resolving the abscess, and appendectomy can usually be accomplished provided the ruptured appendix can be located. Percutaneous drainage under CT or ultrasonography guidance in carefully selected patients has proved effective in resolving periappendiceal abscesses. Interval appendectomy can then be safely performed approximately 6 weeks later.

DIVERTICULAR ABSCESS

Abscess resulting from diverticulitis and perforation has traditionally been surgically treated. Patients with small abscesses confined to the colonic wall or mesentery can undergo a one-stage procedure to remove the diseased segment and restore bowel continuity. If more extensive infection is present, it may be necessary to undertake a two-stage procedure involving resection of the diseased colon with temporary colostomy, followed by colostomy reversal at a later operation. Large, simple diverticular abscesses previously treated with a two-stage procedure are now successfully managed by initial percutaneous drainage, followed by an elective one-stage operation. Stable and colleagues found percutaneous drainage followed by elective single-stage surgery to be successful in 75% of patients with contained diverticular abscesses. Percutaneous drainage followed by a one-stage operation is not appropriate when percutaneous catheter output is grossly feculent, which is associated with poor outcome.

SUBPHRENIC ABSCESS

The subphrenic spaces are common sites for development of intra-abdominal abscess; 40% are located on the left side. Subphrenic abscess typically arises as a complication of gastric or biliary tract surgery, which was the source in 52% of abscesses in one series. Less common causes include pancreatitis, colon surgery, trauma, and appendicitis. The clinical picture is often subtle, and findings on plain films may be confined to the chest radiograph, which may show pleural effusion, elevated hemidiaphragm, and atelectasis, thus prompting erroneous treatment of pneumonia. Abscess drainage can be carried out surgically via the transperitoneal or extraperitoneal approach or by image-guided percutaneous placement of drainage catheters. Percutaneous drainage is successful for 85% of unilocular subphrenic abscesses that are safely accessible. Surgical drainage is advocated if several abscesses or persistent infection is present and if no safe percutaneous route exists. Although there has been improvement in mortality rates from 40% in the 1960s to 30% in the 1990s, the mortality rate from subphrenic abscess remains high, probably because of the difficulty of establishing an early diagnosis.

PELVIC ABSCESS

Symptoms of pelvic abscess may include changes in bowel function, urinary urgency, and pelvic pain. Pelvic anatomy has necessitated more unusual routes of percutaneous drainage, such as the anterior, transgluteal, transrectal, and transvaginal methods, when intervening bowel, bladder, and pelvic vasculature complicate the anterior approach. The transgluteal route accesses the pelvis via the sciatic foramen, through which the sciatic nerve and superior gluteal artery travel. Because the gluteal musculature must be traversed, this approach is associated with increased discomfort for the patient. Gazelle and colleagues, who reported successful treatment of ten patients using CT-guided transrectal drainage of pelvic abscesses, contend that the transrectal approach avoids contamination of the peritoneum or the gluteal musculature and is tolerated well by patients. VanSonnenberg and colleagues reported superior visibility and cannulation of pelvic abscesses when using transvaginal ultrasonography.

POSTOPERATIVE INTRA-ABDOMINAL ABSCESS

A postoperative abscess typically develops about 7 days after contaminated intraperitoneal surgery, but it may not be diagnosed until some time later, owing in part to postoperative pain and fever, administration of pain medications, and inflammation that prevents detection on diagnostic studies. Operation for trauma is the most common antecedent, but 10% of postoperative abscesses follow elective operations. Certain risk factors identified at initial operation increase the likelihood of postoperative intra-abdominal sepsis and abscess formation, including emergency operation for peritonitis, abdominal operation for trauma, surgical procedures performed on elderly or unstable patients, and undue delay in original diagnosis. Increased vigilance through early use of CT for suspected abscess and prompt drainage by surgical or percutaneous means may result in improved outcomes.

MORTALITY RATE AND RISK FACTORS

Formation of an intra-abdominal abscess can be regarded as a host defense mechanism, confining potentially overwhelming or lethal peritonitis within a fibrinous capsule. Thus, the mortality rate from peritonitis is significantly lessened when intraperitoneal infection can be contained within an abscess. Nevertheless, an untreated intra-abdominal abscess will almost always eventually lead to death. Studies before the mid-1970s reported 30% to 50% mortality rates for intra-abdominal abscess. Since then, widespread application of CT and ultrasonography has afforded earlier diagnosis by rapid, accurate localization of abscesses and has led to a major decline in mortality rates for intraperitoneal abscess. Advances in microbial transport and culture have permitted more rapid identification of pathogens, including anaerobic bacteria, and broad-spectrum, low-toxicity antimicrobial therapy is highly effective. Through early diagnosis, resuscitation, and treatment, reported mortality rates for intra-abdominal abscess have decreased by half—from 12% to 30%.

The prognosis is predicted more by host-related factors than by the type and source of infection. A large retrospective review identified the APACHE II score, the Mannheim Peritonitis Index, hypoalbuminemia, hypocholesterolemia, and preoperative organ impairment as independent predictors of death. In another study, the preoperative serum albumin level was a good predictor of surgical outcome; mortality rates increased from 1% to 29% as the preoperative serum albumin level declined from 4.6 to 2.1 g per deciliter.

ANTIMICROBIAL THERAPY

Definitive treatment for intra-abdominal abscess is drainage of the infected fluid collection, either surgically or percutaneously. Appropriate adjuvant antimicrobial

therapy directed at the suspected pathogens is also important. Both monotherapy and combination regimens have been shown to be effective and should be directed at the most prevalent organisms in intra-abdominal infections: gram-negative bacilli (*E. coli*, *Klebsiella*, *Enterobacter*, *Proteus* species), gram-positive cocci (*Enterococcus*, *Staphylococcus*, *Streptococcus*), and obligate anaerobes (*Bacteroides* and *Clostridium*). A large review of 480 patients with secondary bacterial peritonitis evaluated patients' outcomes as a function of intra-operative culture and sensitivity data and antibiotics used. Inadequate empiric antibiotic therapy was associated with increased rates of wound infection, deep abscess formation, need for re-operation, and prolonged length of hospital stay. Thus, adjuvant treatment with appropriate antimicrobials is of the utmost importance. Duration of therapy for complicated intra-abdominal infections with abscess should be 5 to 14 days and should continue until the patient is afebrile for 24^o, the white blood count is less than 12.5, and bowel function has returned.

SUMMARY

Intra-abdominal abscess represents a broad spectrum of disease processes and locations. Early recognition based on clinical suspicion and imaging studies facilitates prompt treatment. Regardless of the underlying source or location of the abscess, antimicrobial therapy in conjunction with timely drainage constitute the essentials of management. Image-guided percutaneous drainage is often as effective as surgical evacuation in stable patients whose abscesses are well localized and accessible by the percutaneous route. Intra-abdominal abscess continues to be associated with significant morbidity and mortality but has declined by about half because of imaging technology and effective antimicrobials.

CHAPTER 265: APPROACH TO THE PATIENT WITH OSTEOMYELITIS

LAYNE O. GENTRY

[Classification](#)
[Pathophysiology](#)
[Etiology](#)
[History and Physical Examination](#)
[Diagnosis](#)
[Optimal Management](#)
[Special Circumstances](#)
[Economic Considerations](#)

In the past 20 years, we have witnessed remarkable changes in the causes and antibiotic therapy of osteomyelitis. In the 1970s, most cases of osteomyelitis were caused by susceptible strains of *Staphylococcus aureus* and were cured with surgical debridement and a 4- to 6-week course of parenteral therapy with a b-lactamase-resistant penicillin, such as methicillin. In the 1990s, gram-negative organisms, frequently from nosocomial sources, often have been found, especially in cases of posttraumatic osteomyelitis. Polymicrobial infections are also common. In addition, coagulase-negative staphylococci, once considered saprophytic contaminants in bone, are now identified as virulent, persistent pathogens that require aggressive surgical debridement and parenteral therapy. Because many of these staphylococcal strains are resistant to methicillin, vancomycin may be the only effective antibiotic available to treat these infections. Furthermore, in the past, most cases of osteomyelitis were associated with severe bone trauma; the increase in the number of total joint replacements, however, has made osteomyelitis a dreaded complication of elective placement of orthopedic prostheses. These changes in causes and epidemiologic characteristics, combined with the introduction of safer and more effective antimicrobial agents, require us to reexamine the traditional treatment of patients with osteomyelitis.

CLASSIFICATION

Osteomyelitis, defined as inflammation of the bone marrow, the surrounding cortical bone, and the periosteum, has been classified on the basis of pathogenesis, duration of disease, extent or type of bone involvement, anatomy of bone infection, and host characteristics. In the pathogenesis scheme, most infections either are hematogenous (predominantly in children) or result from spread from a contiguous focus of infection. The latter type of infection usually results from direct infection of the bone from an external source, such as surgery or open fracture, or from the progressive and continuous spread of infection from an adjacent focus, such as a soft-tissue abscess, a septic joint, or a bursa.

Many methodologies have been used to differentiate acute and chronic osteomyelitis. At our institution, we use a simple definition to distinguish the two. Acute osteomyelitis is defined as the first clinical episode, complete with the signs, symptoms, and radiographic, histologic, and microbiologic confirmation of bone infection. Chronic osteomyelitis is the diagnosis for all bone infections, based on these same criteria, that have failed one or more treatment attempts. Cierny and Mader have proposed a universal clinical staging system based on four anatomic types of bone infection and three physiologic conditions, where the clinical stage is defined by the combination of type and class ([Table 265.1](#)). This system permits the development of comprehensive treatment guidelines for each stage and allows for comparison of patients from different institutions.

Anatomic Type	Description
I Simple	Medullary osteomyelitis
II Superficial	Superficial osteomyelitis
III Localized	Local osteomyelitis
IV Diffuse	Diffuse osteomyelitis
Physiologic class	
A	Normal immune response in host
B	Systemic compromise (B _s)
	Local compromise (B _l)
C	Minimal disability; treatment worse than disease; not a surgical candidate

(From Levine SE, Esterhai JL, Heppenstall RB, et al. Diagnosis and staging: osteomyelitis and prosthetic joint infections. *Clin Orthop Rel Res* 1993; 295:77, with permission.)

TABLE 265.1. CIERNY AND MADER CLASSIFICATION SYSTEM FOR OSTEOMYELITIS

PATHOPHYSIOLOGY

Pathogens gain access to bone in three ways: by hematogenous dissemination, by direct inoculation, or by extension from contiguous sites. Bone infections in children and in intravenous drug users are usually hematogenous and not associated with open fractures or a significant injury. In contrast, direct inoculation of microbes at the site of fracture or injury is a common initiating event in osteomyelitis in adults. Direct inoculation may also occur after human bites and orthopedic surgery. Finally, osteomyelitis extending from contiguous infected sites is often seen in diabetic patients with foot infections or in patients with decubitus ulcers.

Regardless of the route of entry, the initial bone infection causes inflammation, vascular compromise, local hypoxia, and eventually the death of bone tissue. Infection may result in the formation of avascular tissue, or bone sequestrum, which forms a nidus for persistent infection and often prevents effective penetration of antibiotic into the area. If the periosteum is involved, soft tissue usually becomes infected, and localized abscesses result in a sinus tract that drains fluid and necrotic tissue from the deep focus of infection.

ETIOLOGY

S. aureus is the most common infecting organism causing hematogenous osteomyelitis in children and intravenous drug users. Other organisms that cause hematogenous osteomyelitis include gram-negative bacilli, coagulase-negative staphylococci, and pneumococci. In newborns, group B streptococci and gram-negative bacilli are common. The incidence of *Haemophilus influenzae* type B has declined as a result of *H. influenzae* vaccination.

In adults, the most common pathogens causing osteomyelitis are listed in [Table 265.2](#). As in children, *S. aureus* is the most common single pathogen in adults, accounting for 50% to 70% of cases of osteomyelitis. The number of infections with gram-negative bacilli, either as a single infectious agent or as part of a polymicrobial infection, has increased recently; these organisms have been cultured in up to 50% of infections in some studies. Gram-negative pathogens are more likely to cause osteomyelitis in patients with open fractures and a history of prolonged hospitalization, in patients who have undergone several hospital procedures, and in those who have had a prolonged stay in the intensive care unit. Nosocomial gram-negative bacilli are a problem in osteomyelitis stemming from postsurgical wounds.

Posttraumatic osteomyelitis
 Staphylococcus aureus
 Staphylococcus epidermidis

 Enterococcus faecalis

* Pathogens are listed in order of frequency of occurrence.

TABLE 265.2. COMMON PATHOGENS CAUSING OSTEOMYELITIS IN ADULTS^a

Osteomyelitis caused by methicillin-resistant *Staphylococcus epidermidis* and *S. aureus* is a growing concern. Infection with *S. epidermidis* is common after implantation of an orthopedic prosthesis. At our institution it is the most common cause of poststernotomy osteomyelitis in cardiovascular patients because of persistent infection around wired sutures of the sternal bone. Anaerobic bacteria should be considered when infection follows a human bite or is contiguous to a dental, intra-abdominal, foot, or ear-nose-throat infection. Polymicrobial aerobic and anaerobic infections are common in diabetic patients and in patients with decubitus ulcers.

HISTORY AND PHYSICAL EXAMINATION

A thorough history and physical examination are essential for diagnosing osteomyelitis. Most patients are adults who often have localized pain unresponsive to nonsteroidal drugs, heat, or rest. Swelling and redness may also be present at the site. Patients with vertebral osteomyelitis often have back pain; however, patients with infection of the larger cortical bones or patients with peripheral neuropathy, such as those with severe diabetes, may not experience pain. The extremity involved should be examined for local signs of venous stasis, acrocyanosis, edema, draining sinus tracts, erythema, induration, tenderness, range of motion, and sensory perception.

Children with osteomyelitis may have similar initial symptoms, but drainage is not usually present. Typical clinical findings in a child with hematogenous osteomyelitis include tenderness over the involved bone and decreased range of motion. The long bones, such as the femoral and tibial metaphyses, are typically involved. Systemic sepsis and fever may be present. Often, children with osteomyelitis have an associated infection; therefore, the history and physical examination should focus on evidence of both osteomyelitis and another focus of infection.

DIAGNOSIS

Diagnosis of osteomyelitis calls for a combination of clinical awareness, appropriate laboratory tests, and radiographic and radionuclide scanning studies. Diagnosis should be confirmed by histologic examination and microbiologic culture of bone specimens obtained either by surgery or percutaneous needle biopsy. Laboratory examinations should include a complete blood cell count with differential, erythrocyte sedimentation rate (ESR), urinalysis, and serum chemistries, including albumin and total protein. Although they are important in assessing health status, none of these tests specifically indicates the diagnosis of osteomyelitis. The white blood cell count is usually elevated only in the early stages of osteomyelitis. The ESR is usually elevated, but this finding is nonspecific and the ESR often returns to normal levels with successful therapy. The ESR is less reliable in newborns and in children with sickle cell anemia. In the early stages of osteomyelitis, specific findings on conventional radiography may be absent, since radiographic changes do not manifest for at least 2 weeks. Within 4 weeks of infection, one or more of the following radiographic changes should be evident: periosteal elevation, lytic bone destruction, sclerosis, or the presence of sequestrum or overlying soft-tissue mass.

Computed tomography (CT) is a useful adjunct to conventional radiography in selected patients. CT studies have been effective in determining early periosteal proliferation in soft-tissue extension in patients who may have early injury or postoperative infection of bone and in whom conventional radiographic examination shows normal results. CT reliably detects destruction of cortical bone and the presence of sequestra. In addition, CT is helpful in evaluating bones, such as the spine, that are difficult to view.

Magnetic resonance imaging (MRI) is a highly sensitive tool for detecting and assessing the extent of infection of the musculoskeletal system. In addition to its sensitivity in detecting early infection, MRI has excellent specificity, especially in distinguishing bone tumor or infarction from osteomyelitis. The expense of this technique, however, precludes its use on a routine basis. Nevertheless, MRI is the technique of choice for detecting and assessing the site and extent of infection in the spine. In addition, MRI is the favored technique for staging the extent of infection in long cortical bones before definitive open debridement.

Bone scanning using technetium Tc 99m sulfur colloid, a readily available tool for radionuclide imaging, has excellent sensitivity for the diagnosis of osteomyelitis, especially within the first 2 weeks, but the specificity is relatively low. There may be false-positive results in patients with tumors or infarction or in patients with bone injury affecting the periosteum. Another disadvantage is that bone scan results remain positive for 6 weeks to 6 months after noninfectious bone injury or surgery.

In an attempt to increase the specificity of radionuclide imaging, gallium citrate Ga 67 scanning was introduced to detect osteomyelitis. Because the radiotracer binds to proteins associated with inflammation and infection, gallium uptake is nonspecific for infection. Thus, the specificity of this technique was enhanced by the combined interpretation of gallium and bone scans. Although initial results were promising, the accuracy rate of sequential scanning has approached only 70%. Advanced infections are more reliably detected with this method because of the increased numbers of white blood cells, whereas the number of white blood cells may be too few to detect in early stages of infection.

Indium In 111 altumomab pentetate white blood cell scanning, in which in vitro-labeled white blood cells are injected and imaging is performed 24 to 48 hours later, has been used to diagnose osteomyelitis. This technique may be useful in complicated cases or as an adjunct for detecting infections associated with orthopedic prostheses. The specificity of white blood cell scanning is higher than that of gallium imaging, and the sensitivity is moderate, even in the first 2 weeks. False-positive results may be seen in patients with infarction. The disadvantages of this technique include time-consuming ex vivo blood-handling techniques, special training of personnel, and the need for a large quantity of blood. In addition, white blood cell scanning is expensive. Immunoscintigraphy with technetium-99m-labeled monoclonal antigranulocyte antibodies (AGAb) has been used to image osteomyelitis; the sensitivity, specificity, and diagnostic accuracy compare favorably to those of white blood cell scanning. In a recent study, positron emission tomography with 2-18F-fluoro-2-deoxy-D-glucose was comparable to combined 99m-technetium-AGAb/99m-technetium-MDP in diagnosing chronic osteomyelitis in the peripheral skeleton and superior to AGAb imaging in the central skeleton.

There has been much debate on the diagnostic accuracy of specimens obtained for culture from various sites of infection and with various techniques. The gold standard for diagnosis of osteomyelitis is aerobic and anaerobic culture of a biopsy specimen taken under direct vision during surgery. Alternatively, at our center, culture of several specimens obtained by needle biopsy with a bone biopsy needle under fluoroscopic or CT guidance has been the most reliable, cost-effective means of diagnosing osteomyelitis. Combining surgical debridement and removal of sequestra with culture specimen acquisition is even more cost-effective. Specimens for culture should be obtained before beginning antibiotic therapy or at least 96 hours after ending therapy.

Blood cultures may show positive results during the acute phase of the disease, when bacteremia is present, and results usually indicate the etiologic agent in these cases. Bacteremia is rare in adults. Swab cultures of sinus tracts are not usually accurate because organisms not present in the bone may colonize the sinus tract. However, swab cultures may be more accurate in the diagnosis of osteomyelitis caused by a single pathogen than in osteomyelitis caused by several pathogens. In fact, some investigators have suggested that a presumptive diagnosis of *S. aureus* osteomyelitis may be justified when this organism is grown from culture of material from a sinus tract. At our center, however, experience has shown there is no substitute for a biopsy specimen.

OPTIMAL MANAGEMENT

Treatment of either acute or chronic osteomyelitis requires prolonged antibiotic therapy and complete surgical debridement of necrotic bone and soft tissue where

there is evidence of residual sequestrum or foreign material. Even with appropriate therapy, relapses may occur. Broader-spectrum agents are frequently necessary for treatment of chronic osteomyelitis because polymicrobial infection is more common in such cases. These agents must be able to penetrate bone and must have limited toxicity over the course of administration.

The most effective strategy for the patient with osteomyelitis is the institution of appropriate antimicrobial therapy ([Table 265.3](#)) based on culture and sensitivity results, after complete surgical debridement of necrotic bone and soft tissue and after confirmation of the microbiologic diagnosis by biopsy. Typically, therapy fails if this routine is not strictly followed, regardless of the antimicrobial regimen. Empiric therapy for suspected organisms or for those grown from a sinus tract culture, however, may be necessary if the patient is acutely ill.

TABLE 265.3. ANTIMICROBIAL THERAPY FOR OSTEOMYELITIS IN ADULTS

The type of surgical therapy depends on the extent of infection. In true cases of acute osteomyelitis, especially in children, antibiotic therapy alone may be sufficient. In most cases, however, complete surgical debridement is of paramount importance. Sequestered dead bone may serve as a focus for persistent infection. In our experience, inadequate surgical debridement is the most common cause of treatment failure. Removal of foreign bodies is essential for successful treatment. If the bone is unstable after debridement, external fixation devices may be necessary. If the remaining bone is inadequate and debridement is extensive, reconstructive surgery with bone grafts and muscle flaps may be required. In cases of unrelenting osteomyelitis, amputation must be considered.

Although the cornerstone of therapy for osteomyelitis has been the intravenous administration of antibiotics through an indwelling catheter for 4 to 6 weeks, the oral fluoroquinolones, which are relatively nontoxic and are active against many of the typical pathogens that cause osteomyelitis, may be effective when susceptible organisms are isolated. Ciprofloxacin, the most actively studied fluoroquinolone, has been approved by the Federal Drug Administration as monotherapy for osteomyelitis. Particularly active against gram-negative pathogens, oral ciprofloxacin should be the antibiotic of choice when treating osteomyelitis caused by Enterobacteriaceae. Reports of resistance in some strains of *S. aureus* and *S. epidermidis* raise justifiable concerns about the use of ciprofloxacin in treating staphylococcal osteomyelitis. Recent studies have suggested that ofloxacin and lomefloxacin may be effective in treating osteomyelitis; however, neither agent has been approved for use in osteomyelitis. The combined administration of quinolones or fusidic acid and rifampin for prosthesis-related infections is promising.

In addition to the obvious economic benefits of reducing pharmacy and supply costs, the use of oral antibiotics eliminates the need for surgical insertion of a catheter and decreases catheter-associated complications. In children with acute hematogenous osteomyelitis, short-term parenteral therapy followed by long-term oral therapy is successful. Sequential intravenous–oral antibiotic therapy usually involves about 2 weeks of intravenous treatment followed by 3 to 6 weeks of oral treatment.

If parenteral therapy is necessary, outpatient home health nursing services can administer antibiotics at a significant savings over inpatient stays. In these cases, patients should be educated in the care, use, and administration of antibiotics via the catheter while they are still in the hospital. Outpatient care should include laboratory tests performed at 7- to 10-day intervals; a reduction in the ESR may be the only early indicator of improvement. Radiographs or radionuclide scans need to be performed only at the 4- to 6-month follow-up examination.

Newer, more powerful agents for treating serious gram-positive infections, including those resistant to methicillin, are under study. Teicoplanin, a glycopeptide, has been efficacious in treating osteomyelitis caused by resistant gram-positive organisms; however, teicoplanin has not been approved for any indication. In addition to the introduction of new antibiotics, novel approaches to medical therapy also have become available. Home intravenous therapy programs with belt-mounted, computer-controlled pumps for the intravenous delivery of antibiotics shorten hospital stays. In addition, this method allows the patient to resume daily activities during the long therapy period. Local antimicrobial therapy with antibiotic-impregnated acrylic beads has been effective in sterilizing local areas of infection. Used in open fracture wounds and in the management of dead space in resection of infected joint implants, antibiotic-impregnated beads may lessen some of the untoward side effects associated with the intravenous use of certain antibiotics, such as the aminoglycosides. Although antibiotic beads are not approved as a therapeutic treatment, orthopedic services often use homemade gentamicin beads. Japanese investigators have used porous pieces of calcium hydroxyapatite impregnated with antibiotics to treat patients with chronic osteomyelitis successfully.

SPECIAL CIRCUMSTANCES

PATIENTS WITH DIABETES MELLITUS

Osteomyelitis of the foot, common in patients with diabetes, often arises from extension of an infected soft-tissue ulceration. Bacteremia is rare in these patients. The infection, often polymicrobial, may include such pathogens as staphylococci, enterococci, anaerobes, and gram-negative bacilli and can be complicated by impaired wound healing and immune responses. Distinguishing bone infection from noninfectious neuropathic bony lesions is a diagnostic challenge. The most useful diagnostic tests in diabetic patients are the indium In 111–labeled leukocyte scan and MRI. In our center, the presence of diabetes does not affect outcome in patients with acute osteomyelitis; however, in patients with chronic osteomyelitis, diabetes significantly reduces long-term success rates for antimicrobial and surgical therapy ([Table 265.4](#)).

Clinical Success	Acute Osteomyelitis (%)	Chronic Osteomyelitis (%)
With diabetes	83	45
Without diabetes	84	67*

* $p < 0.01$.

TABLE 265.4. EFFECT OF DIABETES MELLITUS ON PROGNOSIS IN 124 PATIENTS WITH OSTEOMYELITIS (24-MONTH FOLLOW-UP)

IMMUNOCOMPROMISED PATIENTS

The number of cases of osteomyelitis caused by unusual pathogens, such as fungi and mycobacteria, is increasing because of the rise in prevalence of

immunocompromised patients. For fungal osteomyelitis, newer agents, such as fluconazole and itraconazole, should provide successful treatment with less toxicity than amphotericin B; however, these agents have not been approved for this indication. The resurgence in the incidence of tuberculosis has been accompanied by the development of resistant organisms. The most common skeletal sites for tuberculous infection are the hips, sacroiliac joints, and sternocostal joints. Tuberculous osteomyelitis, accompanied by pulmonary symptoms only half the time, may be difficult to diagnose, especially without vigilance and awareness on the part of the clinician. DNA probes, when used as a complementary tool to culture, may enhance the laboratory's chances of identifying the organism.

In AIDS patients with osteomyelitis, suppressed clinical manifestations and compromised host defenses may result in dramatic and unusual radiographic findings. Usually, these infections are detected late and respond poorly to therapy. In addition, a wider array of sites and pathogens may be involved. Needle or surgical bone biopsies are essential to establishing the exact source in AIDS patients.

ECONOMIC CONSIDERATIONS

Long-term intravenous antibiotic regimens and the many surgeries associated with osteomyelitis therapy can be expensive. In this era of prospective reimbursement of providers, the goal should be to reduce health-care costs. Obviously, to hospitalize a patient with osteomyelitis who is afebrile and clinically stable for the sole purpose of administering parenteral antibiotics is not economical. Outpatient antibiotic therapy, by either clinic visits or a home health agency, can substantially minimize costs (Table 265.5). Because of the trend toward outpatient therapy, antibiotics that can be given every 8, 12, or 24 hours are preferred for treating osteomyelitis. Further economic benefits can be gained by using an orally administered agent, such as one of the fluoroquinolones.

Outpatient therapy	
Inpatient room charge	
Four weeks at \$250/day	\$7,000
Outpatient clinic fees	
Eight visits at \$60 each	480
Savings for outpatient therapy	\$7,480
Oral Therapy	
Cost differential of using oral quinolone vs. third-generation cephalosporin	\$1,640
Credit for four fewer clinic visits at \$60 each	240
Credit for no insertion of Broviac catheter	1,560
Further savings for oral therapy	\$3,380

Assume 2 weeks initial hospital stay completed and 4 additional weeks of therapy required. Prices are from St. Luke's, Episcopal Hospital, Houston.

CHAPTER 266: APPROACH TO THE FEBRILE PATIENT

PHILIP A. MACKOWIAK

[Normal Body Temperature](#)
[Thermoregulation](#)
[Pyrogenic Cytokines](#)
[Hyperthermia](#)
[Antipyretic Therapy](#)
[Febrile Convulsions](#)
[Fever of Unknown Origin](#)
[Drug Fever](#)

NORMAL BODY TEMPERATURE

Although fever is a complex physiologic process involving numerous metabolic and immunologic reactions, it is recognized and characterized clinically predominantly by its thermal qualities. Implicit in such characterizations is the concept that the temperature of higher animals is tightly controlled within a narrow, species-specific range during the disease-free state. In healthy, young, human adults, this oral temperature range extends from 36.5°C (96°F) to 37.7°C (99.9°F).

Body temperature has a circadian rhythm, reaching its apogee during the evening and its nadir during the early morning. The circadian temperature rhythm is established during the first months after birth and retained throughout life. For as yet unclear reasons, children display exaggerated diurnal swings in temperature. Additional variability in the normal temperature may be seen as a result of transient elevations in temperature in response to meals, ovulation, or strenuous exertion. Generally, core temperature continues to exhibit diurnal variability during fever, although the median daily temperature is higher. Furthermore, circadian variations in temperature persist even during the course of such infections as bacterial endocarditis, in which levels of circulating exogenous pyrogens (i.e., bacteria) are constant throughout the day.

Clinicians typically regard temperature readings obtained at various anatomic sites as equivalent approximations of “body temperature,” ignoring the fact that no one temperature provides a complete picture of the thermal status of the human body. This is because body temperature is actually a pastiche of many different temperatures, each representing a particular body part. Of the three sites most commonly used to estimate core temperature, none is universally accepted as the best. The mouth is generally preferred, because it is accessible, responds promptly to changes in core temperature, and has a long tradition of use in monitoring temperature in clinical practice. Nevertheless, there is also a general perception that rectal temperature provides a better approximation of core temperature, because the rectum is better insulated from the external environment. Unfortunately, rectal measurements are inconvenient, socially awkward, and associated with a higher risk of injury and cross-infection than oral determinations.

In theory, the tympanic membrane is the ideal site for measuring core temperature, because it is perfused by a tributary of the artery that supplies the body's thermoregulatory center. Unfortunately, numerous studies of many different tympanic membrane thermometers have shown that while they are convenient to use, such instruments give highly variable readings that correlate poorly with simultaneously obtained oral or rectal measurements. Because the temperature of the rectum, mouth, and tympanic membrane are related but not identical, it would be useful to have a reliable formula for converting data obtained at one site to those from another. On average, rectal readings of healthy young adults exceed concurrent oral readings by 0.4°C (0.7°F) and tympanic membrane readings by 0.8°C (1.4°F). Considerable individual variability exists in these relationships, however, especially in frail elderly patients.

THERMOREGULATION

Core temperature in higher animals is regulated by physiologic and behavioral means. In non-fur-bearing animals, the physiologic mechanisms that distinguish homeotherms (warm-blooded animals) from poikilotherms (cold-blooded animals) are concerned primarily with regulating heat loss by altering the amount of blood brought into contact with the skin surface. When excess thermal energy must be released during the thermoregulatory process, circulation to the skin and subcutaneous tissues is increased so that heat exchange with the external environment is potentiated. Sweating increases heat loss by providing water for vaporization. In fur-bearing animals, heat exchange by evaporation from the respiratory tract is the primary physiologic mechanism for effectuating heat loss. When thermal energy must be conserved to maintain normal core temperature, circulation to surface structures is reduced. When the demand for heat is great, either because the ambient temperature is low or because internal requirements are high (e.g., during sepsis), shivering may accompany peripheral vasoconstriction as a means of augmenting heat production. In higher animals, behavioral responses (moving to warmer or cooler environments) are also important features of the thermoregulatory response.

The neural mechanisms involved in thermoregulation are only partially understood. Although the spinal cord can initiate thermoregulatory responses, the preoptic area of the hypothalamus appears to be the primary site of integration of thermal stimuli and, through its input into the autonomic nervous system, initiation of thermal homeostatic mechanisms. As such, the anterior hypothalamus is generally regarded as the control center responsible for establishing a thermal set point for the body and for coordinating physiologic and behavioral responses that bring core temperature in line with that set point. Nevertheless, at least some thermophysicists contend that the concept of a single, central set-point temperature oversimplifies the actual process of thermoregulation. They propose instead that core temperature is regulated within its narrow range by a composite set point of several thermosensitive neural networks, each controlling its own thermoregulatory response.

PYROGENIC CYTOKINES

Exogenous pyrogens, such as bacteria, viruses, or bacterial lipopolysaccharide, do not appear to cause fever by a direct action on the hypothalamic thermoregulatory center. Indeed, most exogenous materials enter brain tissue only with difficulty (the blood–brain barrier phenomenon). Rather, the weight of available evidence favors an indirect effect of exogenous pyrogens on the hypothalamus that is mediated by endogenous pyrogens (pyrogenic cytokines) produced by phagocytic leukocytes (Fig. 266.1). The most important cytokines in this regard are interleukin-1, tumor necrosis factor α , interferon, interleukin-6, and interleukin-2.

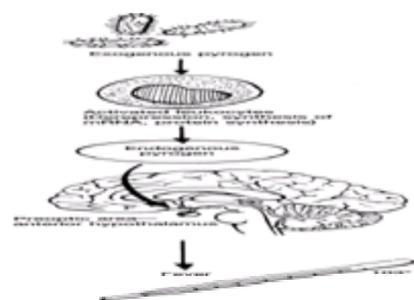

FIGURE 266.1. Postulated physiologic pathway for fever.

Production of pyrogenic cytokines by phagocytes appears to involve de-repression of specific genomes. After synthesis, molecules, such as interleukin-1, are released without significant storage and appear to act in specialized vascular areas of the hypothalamus as calcium ionophores, stimulating arachidonic acid release and thereby synthesis of prostaglandin E_2 . Although prostaglandin E_2 exerts a direct pyrogenic effect on the hypothalamic thermoregulatory center, it is not yet clear whether this effect is essential for the febrile response or whether endogenous pyrogens act through some other process requiring protein synthesis. Early investigations focused on the capacity of endogenous pyrogens to increase core temperature. More recently, it has become apparent that pyrogenic polypeptides,

such as interleukin-1, have a wide array of biologic ([Table 266.1](#)) and immunologic activities ([Table 266.2](#)).

Fever	Hypercupremia
Muscle proteolysis	↓ Hepatic albumin synthesis
Hypoferremia	Leukocytosis
Fibroblast proliferation	↑ Lipoprotein lipase activity
Hypozincemia	↑ Hepatic acute-phase proteins
↑ PGE ₂ production	

PGE₂, prostaglandin E₂.

TABLE 266.1. BIOLOGIC ACTIVITIES ATTRIBUTED TO ENDOGENOUS PYROGENS

Immune Cell	Activity Potentiated by PCs
T lymphocyte	Lymphokine production, chemotaxis, maturation
B lymphocyte	Maturation, clonal expansion, differentiation, chemotaxis
Natural killer cell	Killing
Macrophage	Prostaglandin production, tumoricidal activity
Polymorphonuclear leukocyte	Bone marrow release, margination, extravasation, chemotaxis, adherence, release of lysosomal enzymes

TABLE 266.2. EXAMPLES OF IMMUNE POTENTIATION BY PYROGENIC CYTOKINES (PCs)

HYPERTHERMIA

Fever is a complex physiologic process mediated by the action of various pyrogenic cytokines on the anterior hypothalamus and characterized by a regulated rise in core temperature. There are also a number of disorders involving marked increases in core temperature, in which pyrogenic cytokines do not appear to play a major role ([Table 266.3](#)). Such increases in temperature are referred to as *hyperthermia* to distinguish them from *fever*, because they are unregulated (temperature exceeds the thermoregulatory set point), are not defended by physiologic mechanisms, and do not respond to standard antipyretic agents. In fact, physiologic mechanisms designed to lower core temperature usually are activated maximally during hyperthermia. The term *fever* is appropriately applied only to increases in temperature that are mediated by pyrogenic cytokines.

Hyperthermia due to increased heat production
Exercise-induced hyperthermia
Malignant hyperthermia
Neuroleptic malignant syndrome
Pheochromocytoma
Thyrotoxicosis
Hyperthermia due to decreased heat dissipation
Absence of sweat glands (congenital, extensive burns)
Autonomic dysfunction
Dehydration
Drug-induced (atropine)
Heart failure (low-grade hyperthermia)
Heatstroke (also ↑ heat production)
Occlusive dressings
Severe anemia (low-grade hyperthermia)
Hypothalamic disorders (rare)
Drug-induced (phenothiazines)
Infections (granulomas)
Tumors
Trauma
Vascular accidents

TABLE 266.3. HYPERTHERMIC DISORDERS NOT MEDIATED BY PYROGENIC CYTOKINES

Heatstroke is typical of the hyperthermias. In its classic form, heatstroke affects very young or very old persons. Many of those in the latter group have underlying chronic illnesses and are taking diuretics, antipsychotic medications, or drugs that inhibit sweating. In such patients, hyperthermia is typically the result of a combination of unusually high ambient temperatures and a defective cooling response. The syndrome that follows is characterized by a prodrome of chills and cutis anserina (goose bumps), hyperthermia, absence of sweating, and respiratory alkalosis. Lactic acidosis, if present, is not usually severe, and acute renal failure and rhabdomyolysis are either absent or mild. Confusion, delirium, seizures, and coma are common and reflect the special susceptibility of the central nervous system to hyperthermia-induced dysfunction.

The exertional form of heatstroke most commonly affects young to middle-aged men during episodes of unusually heavy exercise. Patients with exertional heatstroke are generally otherwise healthy, though many are using amphetamines at the time of the attack of heatstroke. Unlike patients with classic heatstroke, those with exertional hyperthermia rarely give histories of prodromal chills or goose bumps. They have only mild respiratory alkalosis but often have marked lactic acidosis, hypocalcemia, prominent rhabdomyolysis, and a 30% incidence of acute renal failure. Because the pathogenesis of both forms of heatstroke involves thermoregulatory failure, the core temperature can be lowered only by physical means. This may be accomplished either while briskly rubbing the body surface or by wetting body surfaces and then placing the patient in the wake of a powerful fan. The latter method is preferred by some authorities because it is less likely to cause shivering or frank seizures. In either case, vital signs should be monitored closely along with appropriate fluid and electrolyte replacement and continued until core temperature is reduced to 38.3°C (101°F).

ANTIPYRETIC THERAPY

In most clinical contexts, antipyretic drugs alone are sufficient to reduce fever. Of the many such agents available, aspirin and acetaminophen have the most extensive clinical history. Numerous studies comparing the antipyretic efficacy of these two agents have not found substantial differences. Moreover, both are probably equally effective in alleviating accompanying symptoms, such as malaise, headache, and myalgias. Neither drug lowers core temperature in the afebrile state. Thus, from a therapeutic standpoint, there is no compelling reason to choose one over the other. This decision is more often made on the basis of toxicity. Because of its adverse effects on the gastric mucosa and platelet function and its role in Reye's syndrome, aspirin should be avoided by patients with peptic ulcer disease and bleeding disorders and by children. Likewise, because of its potential for causing hepatotoxicity, acetaminophen should be avoided by patients with underlying liver disease.

During extreme pyrexia, physical methods are sometimes combined with antipyretic drugs to lower temperature. In hyperthermia, such measures may be the only therapy that is effective in lowering core temperature. When sponging is used to promote heat dissipation during fever, tepid water is preferred over ice water, because it is less likely to cause intense vasoconstriction, which acts to conserve body heat. In treating fever (as opposed to hyperthermia), lowering the hypothalamic thermal set point with antipyretic agents should be combined with physical measures to minimize physiologic reactions (shivering and peripheral vasoconstriction) that

are working to maintain the elevated core temperature. Because external cooling measures have the capacity to induce coronary vasoconstriction as part of a cold pressor response, some investigators have questioned whether this form of antipyretic therapy should ever be used to treat fever (much less to treat patients hospitalized in intensive care units, for whom it is most commonly prescribed). If external cooling is used to treat fever, care must be taken to prevent shivering, which causes an increase in oxygen consumption. Unfortunately, even if shivering is prevented, there is no guarantee that a cold pressor response will be averted. Indomethacin likewise has been reported to cause coronary vasoconstriction in patients with coronary artery disease. For this reason, nonsteroidal anti-inflammatory drugs should be administered with caution to suppress fever in such patients.

FEBRILE CONVULSIONS

In experimental animals, fever has been shown to enhance survival in the context of a variety of infections. When fever is extreme, however, this beneficial effect is reversed. Although the former observation suggests that fever is a natural defense against infection and should not be suppressed pro forma, the latter observation argues for more liberal use of antipyretic therapy. Likewise, concern about febrile convulsions has led many clinicians to regard fever more as a liability than an asset in the infected patient. Approximately 3% of children experience febrile convulsions; as many as 11% of those who have febrile illnesses between the ages of 6 months and 5 years have such convulsions. Febrile seizures tend to run in families and are most often generalized. Simple febrile convulsions are characteristically brief, require no special treatment, and do not appear to cause brain damage.

Prophylactic anticonvulsant medication in general is not recommended for children with simple febrile convulsions. Epilepsy precipitated by fever, however, does require therapy with antiepileptic drugs and is distinguished from simple febrile convulsions by one or more of the following symptoms: prolonged seizures, focal convulsions of any duration, convulsions associated with fever in a child older than age 5 years, or electroencephalographic abnormalities suggestive of overt epilepsy.

FEVER OF UNKNOWN ORIGIN

Initially, all febrile illnesses are fevers of unknown origin (FUOs). To the internist, however, FUOs are an unusual and heterogeneous group of prolonged febrile disorders that elude diagnosis even after intensive investigation. Most published series of FUOs have considered only patients with temperatures above 38.3°C (more than 101°F). In general, a febrile illness is not designated a FUO unless fever is a dominant feature of the illness, has persisted for at least 2 to 3 weeks, and has defied diagnosis despite intensive investigation.

Most fevers either resolve spontaneously or are diagnosed quickly. Surprisingly, fevers that persist and defy intensive diagnostic scrutiny are more often the result of common diseases with unusual manifestations than exotic disorders (Table 266.4). Causes of FUO in children are similar to those in adults, except that in pediatric series, juvenile rheumatoid arthritis and chronic viral infections have been seen more often than in adult series. The three most common causes of the syndrome are infections (which account for more than a third of the cases reported in most series), malignant neoplasms (which account for about a fifth of such cases), and connective tissue disorders (which account for 8% of cases).

TABLE 266.4. CAUSES OF FEVER OF UNKNOWN ORIGIN IN 154 PEDIATRIC AND 234 ADULT PATIENTS IN FIVE PUBLISHED SERIES

Familial Mediterranean fever is one of the few exotic diseases that must be considered in patients with FUO. This hereditary disorder is characterized by recurrent episodes of unexplained fever, frequently accompanied by peritonitis, pleuritis, or arthritis (generally monoarticular). It is a syndrome of unknown origin seen predominantly in Armenians, Sephardic Jews, and Arabs, in whom it affects males three times as often as females. Symptoms usually begin at puberty. Late complications include spontaneous abdominal adhesions and amyloidosis. During acute attacks, leukocytosis, an elevated erythrocyte sedimentation rate, and increases in various acute-phase reactants are characteristic. Laboratory test abnormalities are not seen between attacks. Long-term colchicine therapy reportedly lessens the incidence of such attacks and minimizes the likelihood of long-term complications.

The evaluation of the patient with FUO must be systematic. A detailed history and careful physical examination are its cornerstones. The epidemiologic history is especially important; knowledge of communicable diseases among contacts, recent travel, animal exposure, food consumption, and occupation may provide important insight into the origin of the illness. When conducting the physical examination, close attention must be paid to the fundoscopic findings (which may show choroid tubercles suggestive of miliary tuberculosis), the less prominent chains of lymph nodes (such as those along the inner aspect of the iliac crest), and the prostate, epididymis, and testicles (which may exhibit abnormalities signifying the presence of a prostate abscess, extrapulmonary tuberculosis or polyarteritis nodosa).

Laboratory evaluation must also be undertaken in a methodical fashion. Initial studies should include a complete blood count; urinalysis; biochemical tests; serologic studies for fungal infections and for connective tissue disorders; examination of the stool for the presence of occult blood; bacterial cultures of urine, sputum, and blood; testing of thyroid function; chest radiography; electrocardiography, and lumbar puncture. A tuberculin skin test should also be carried out.

The source of abnormalities detected in one or more of the initial studies should be pursued with more specific investigations. If these tests do not give conclusive results, empiric examinations, such as oral cholecystography and gastrointestinal endoscopy, should be considered. Biopsy of the liver, bone marrow, or skin may be indicated for some patients. Computed tomography scans of the brain, chest, and abdomen also may be helpful in such evaluations. Occasionally, lymphangiography or gallium scintigraphy identifies important abnormalities not apparent in other examinations. If these studies fail to yield a diagnosis, the physician has three options. The entire evaluation may be repeated in anticipation of the development of abnormalities on tests that previously showed normal results; a therapeutic trial directed against a probable but unproved diagnosis (e.g., a therapeutic trial of isoniazid and rifampin for suspected occult tuberculosis) may be initiated; or the patient may be observed for new signs or symptoms meriting further assessment.

DRUG FEVER

Many drugs—perhaps all—have the capacity to induce fever as an adverse reaction. Such fever may be the result of a pharmacologic effect of the drug, an idiosyncratic reaction, or a complication related to drug administration (phlebitis, chemical meningitis, sterile abscess). If fevers due to complications of drug administration are excluded, it is apparent that certain drugs, such as α -methyl dopa, quinidine, and the penicillins, are more likely causes of the disorder than others, such as the aminoglycoside antibiotics and cardiac glycosides (Table 266.5). Although the list of drugs capable of inducing fever is long, the list of agents that actually cause the disorder is considerably shorter. Important former causes of drug fever, such as laxatives, bromides, arsenical agents, and vancomycin, are now rarely incriminated in the disorder, either because they are no longer used or because new preparations of the drugs are less pyrogenic (e.g., vancomycin).

Agent	Number of Cases	Percentage of Total
Antibiotics	15	30.0%
Cardiac drugs	10	20.0%
Chemotherapy	8	16.0%
Antipsychotics	5	10.0%
Antidepressants	3	6.0%
Anticonvulsants	2	4.0%
Diuretics	2	4.0%
Other	5	10.0%
Total	50	100.0%

TABLE 266.5. AGENTS REPORTED AS CAUSES OF DRUG FEVER

Although patients with drug fever often have high, hectic fevers with chills and myalgias, suggesting sepsis, their course and general appearance generally reflect a less severe disorder. There is considerable variability in the length of time between the initiation of specific agents and the onset of drug-induced fever. In general, antineoplastic drugs are associated with the shortest lag times and cardiac drugs with the longest. The median lag time between the initiation of antibiotics causing drug fever and the onset of antibiotic-induced fever is 6 days.

Generally, drug fever is a diagnosis of exclusion, made in febrile patients whose fever abates within 48 to 72 hours of discontinuing the suspected pyrogenic drug. Even though some authors have emphasized the potential danger of rechallenging with the offending agent to confirm the diagnosis, the actual risk of such rechallenges is probably low. The uniformly rapid resolution of fever after discontinuation of the offending drug argues strongly against the need for other measures in treating the condition.

Two forms of drug-induced pyrexia are sufficiently distinctive to warrant separate consideration. The first, malignant hyperthermia, is a rare hereditary disorder characterized by rapidly evolving hyperthermia, muscular rigidity, and acidosis in patients undergoing general anesthesia. Although various inhalational anesthetic agents have been incriminated in the disorder, halothane (alone or in conjunction with succinylcholine) is the most common offender. The condition is often presaged by sudden ventricular ectopic activity, tachycardia, circulatory instability, and a sharp rise in core temperature. Metabolic acidosis and rhabdomyolysis are typical and often severe symptoms. The mortality rate in acute cases varies between 28% and 70%. Although the specific mechanisms of action responsible for the disorder are uncertain, a defect in the regulation of intracellular calcium appears to be involved. In susceptible patients, the sarcolemmic reticulum of skeletal muscle seems to be unstable and releases calcium inappropriately in response to certain anesthetic agents.

The other drug-induced pyrexia not generally included among the classic examples of drug fever is the neuroleptic malignant syndrome. The syndrome is characterized by hyperthermia (values more than 106°F have been observed and have been confused with heatstroke), diffuse muscular rigidity, autonomic instability, and altered consciousness. It most often develops as a side effect of haloperidol but also has been reported in association with other antipsychotic drugs, such as the phenothiazines and thioxanthenes. The primary defect responsible for the disorder appears to be inhibition of central dopamine receptor blockade, which causes sustained muscle contraction, excessive heat production, and inappropriate cutaneous vasoconstriction. Hyperthermia, dehydration, and exhaustion ensue and, if uncontrolled, may be fatal.

Treatment of neuroleptic malignant syndrome and malignant hyperthermia is the subject of controversy. Most authorities recommend administration of the peripheral muscle relaxant dantrolene for both conditions, in conjunction with external cooling and other supportive measures. Bromocriptine reportedly is effective in some cases of neuroleptic malignant syndrome.

CHAPTER 267: APPROACH INFECTION IN THE IMMUNOCOMPROMISED HOST

KENNETH V. I. ROLSTON AND GERALD P. BODEY

[Specific Immunologic Deficits](#)
[Management of Fever in the Immunocompromised Host](#)
[Management of Infection at Specific Sites](#)
[Infection Prevention](#)

Immunocompromised patients pose special challenges because of the wide spectrum of infections encountered, the difficulties in establishing a diagnosis, and the limited efficacy of therapeutic regimens. Management strategies may differ based upon the underlying immunologic deficit. In patients with severe neutropenia, the risk of fulminant fatal infection is so great that the overriding factor in management is the prompt administration of empiric antibiotic therapy. In contrast, the spectrum of potential pathogens is so wide in patients with impaired cellular immunity (lymphoma, AIDS) that establishing a specific diagnosis is of paramount importance. [Table 267.1](#) lists many of the important factors that predispose patients to infection and the specific infections frequently associated with them.

Disease	Deficiency	Common Infections
Hereditary complement deficiency	Complement	Neisseria species
Multiple myeloma	Hypogammaglobulinemia	Pneumococcus, meningococcus, Haemophilus influenzae
Hodgkin's disease	Increased suppressor monocytes	Cryptococcus, Listeria, Mycobacterium, Toxoplasma species
Mucopolysaccharidosis	T-lymphocyte function	Candida albicans
Bone marrow transplant	Increased suppressor T-lymphocyte activity	Gram-positive cocci, pneumococci, cytomegalovirus
Acute leukemia	Neutropenia	Gram-positive cocci, gram-negative bacilli, Candida or Aspergillus species
Chronic granulomatous disease	Neutrophil bactericidal activity	Staphylococcus, Seratia, Acetabacillus species
Job syndrome	Impaired neutrophil chemotaxis	Staphylococcus species, Aspergillus species
AIDS	Decreased CD4 lymphocyte	Pneumococci, cytomegalovirus, superficial Candida

TABLE 267.1. DEFICIENCIES IN HOST-DEFENSE MECHANISMS AND ASSOCIATED INFECTIONS

SPECIFIC IMMUNOLOGIC DEFICITS

DEFICIENCIES IN HUMORAL FACTORS

Humoral immunity includes protection afforded by such substances as immunoglobulins, opsonins, and complement, which attach to pathogens and/or facilitate phagocytosis by macrophages, monocytes, or neutrophils. Deficiencies in humoral immunity (multiple myeloma, Waldenström's macroglobulinemia) increase the likelihood of infections caused by encapsulated bacteria, such as pneumococci, meningococci, and *Haemophilus influenzae* organisms.

DEFICIENCIES IN CELLULAR FUNCTION

Specific defects in neutrophil function have been identified in some patients, including chemotaxis (Job syndrome) and bactericidal activity (chronic granulomatous disease, Chédiak–Higashi syndrome). These patients are especially susceptible to pyogenic bacterial infections, which are often chronic or relapsing. Patients with Hodgkin's disease have impaired monocyte function and are susceptible to infections caused by intracellular pathogens, among them, mycobacteria, *Listeria monocytogenes*, and *Cryptococcus neoformans*. Some patients with chronic mucocutaneous candidiasis have defects in T-lymphocyte function, including failure to mount a blastogenic response to multiple antigens or specifically to *Candida* antigens. Patients undergoing long-term adrenal corticosteroid therapy are especially susceptible to *Aspergillus* infections because steroids interfere with the ability of macrophages to kill *Aspergillus* spores.

DEFICIENCIES IN CELL NUMBERS

Although some diseases cause neutropenia, it is most often a consequence of myelosuppressive antineoplastic chemotherapy. The risk of infection is inversely related to the degree of neutropenia and directly related to its duration. Although the risk of infection begins to rise when the absolute neutrophil count falls below 1,000 per cubic millimeter of blood, most severe infections, including bacteremias, occur when the absolute neutrophil count is below 100 per cubic millimeter. Because the neutrophil is the primary defense against bacteria, *Candida* and *Aspergillus* infections caused by these organisms develop most often in neutropenic patients.

MANAGEMENT OF FEVER IN THE IMMUNOCOMPROMISED HOST

Immunocompromised patients with fever can be divided into two groups, each requiring different treatment strategies. The first group comprises patients with neutropenia, splenectomy, and other underlying deficiencies. In these patients, infection is usually acute in onset, bacteria are the predominant cause, and delaying therapy can result in fulminant infection and death. The second group includes patients with impaired lymphocyte or macrophage–monocyte function. In this group, infections are generally chronic in nature, the possible pathogens are myriad and diverse, and establishing the correct diagnosis is critical to selecting appropriate antimicrobial therapy. It is important to establish the diagnosis expeditiously in these patients because infection can progress rapidly if left untreated. This is especially true for AIDS patients, who are susceptible to many infectious agents that have atypical signs and symptoms.

TREATMENT OF THE NEUTROPENIC PATIENT

When a neutropenic patient has fever, it should be considered indicative of infection unless it is associated with another obvious cause. A practical definition of fever is a temperature of at least 38.3°C (101°F) persisting for 2 hours. Appropriate cultures should be collected at the onset of fever, and a careful physical examination should be carried out. If the patient is acutely ill or has signs of infection, broad-spectrum antibiotic therapy should be initiated immediately ([Fig. 267.1](#)). Neutropenic patients cannot mount an adequate inflammatory response and can have extensive infection without characteristic signs and symptoms. Hence, patients who have fever that persists for 2 hours without other signs of infection should receive antibiotic therapy at that time, after the collection of a second blood culture specimen. This approach prevents the administration of antibiotics to patients who have a single temperature elevation for unknown reasons but avoids inappropriate delays in therapy for most infected patients. Prompt administration of therapy is critical: patients may die quickly if untreated, and delays diminish the efficacy of antibiotic therapy.

FIGURE 267.1. Approach to fever in neutropenic patients.

Selection of empiric antibiotics requires a knowledge of the usual organisms that cause infection in neutropenic patients. These infections are listed in [Table 267.1](#). Although the most common bacterial pathogens are *Staphylococcus epidermidis*, *Staphylococcus aureus*, viridans streptococci, *Escherichia coli*, *Klebsiella pneumoniae*, and *Pseudomonas aeruginosa*, there are local institutional differences in the spectrum of infection. Antibiotic selection therefore should be guided by knowledge of the pathogens prevalent in the hospital as well as local susceptibility/ resistance patterns. Extensive use of some antibiotics has resulted in the emergence of vancomycin-resistant enterococci, *Stenotrophomonas maltophilia*, *Candida krusei*, and other multi-drug-resistant pathogens.

Various antibacterial regimens can be used for the empiric treatment of neutropenic patients, and no single regimen can be considered optimal. The current choices include combination regimens either with (vancomycin plus ceftazidime) or without (an aminoglycoside plus a broad-spectrum b-lactam) vancomycin or therapy with certain broad-spectrum agents (cefepime, imipenem, meropenem) used alone. Aminoglycosides are unreliable in the treatment of neutropenic patients even when the infecting organism is susceptible in vitro, and they are associated with substantial ototoxicity and nephrotoxicity. Suitable alternatives include the quinolones (ciprofloxacin, trovafloxacin) and trimethoprim-sulfamethoxazole (TMP-SMX). The current predominance of gram-positive pathogens has led to increased use of vancomycin-containing regimens. Vancomycin should be discontinued promptly if it is not needed, to reduce the selection of organisms (VRE, GISA) resistant to this agent.

If the patient responds to initial antibiotic therapy within a few days and never shows signs of local infection, therapy can be changed to oral medications, and the patient can be discharged from the hospital. Therapy should be continued for a week or until 4 days after the patient becomes afebrile, whichever is longer. The duration of therapy may be shorter if the neutrophil count recovers. If the patient is likely to remain neutropenic for a prolonged period, antibiotic prophylaxis should be considered, but therapeutic antibiotics need not be continued until the neutrophil count recovers. If the patient has signs of localized infection, the duration of therapy depends on the rapidity of response.

Treatment of the neutropenic patient who has no evidence of infection but remains febrile despite taking broad-spectrum antibacterial antibiotics is difficult. Potential sources of fever in these patients include drug, transfusion, tumor, or infection caused by antibiotic-resistant bacteria, viruses, mycobacteria, protozoa, or fungi. The most common cause of persistent fever in neutropenic patients is fungal infection. Because fungal infection may have no characteristic clinical findings and culture specimens often are not diagnostic, a therapeutic trial of antifungal therapy is appropriate. At least 30% of these patients respond, and therapy should be continued in such patients until their neutrophil counts recover or they remain afebrile for at least 10 days. Obviously, all patients with persistent fevers should be carefully evaluated for obscure infections, such as cytomegalovirus, tuberculosis, or toxoplasmosis. Judicious use of computed tomography and ultrasonography may pinpoint unsuspected sites of infection.

Risk-prediction models have enabled clinicians to classify febrile neutropenic patients into high-, moderate-, and low-risk categories at the onset of a febrile episode. High-risk patients (with hematologic malignancy with prolonged neutropenia or those with allogeneic bone marrow transplants) are treated in the standard manner with hospital-based, broad-spectrum parenteral, empiric antibiotic therapy. Moderate-risk patients (those who have solid tumors and have undergone intensive chemotherapy followed by autologous bone marrow transplantation or PBSCT) can be stabilized in the hospital over a 48- to 72-hour period and then discharged to complete therapy at home. Low-risk patients can be treated with broad-spectrum parenteral, sequential, or oral regimens without admission to the hospital at all. This risk-based therapy is becoming the new standard of care for febrile neutropenic patients: it is cost effective, is associated with fewer multi-drug-resistant superinfections, and results in more appropriate resource utilization ([Table 267.2](#)).

Risk Group	Therapy
High risk	Standard, hospital-based, parenteral, broad-spectrum antibiotic therapy for duration of febrile episode
Moderate risk	Initial stabilization in hospital (48-72 hr) with standard therapy, followed by early discharge on outpatient regimens
Low risk	Outpatient (clinic/home) parenteral, sequential, or oral antibiotic therapy

TABLE 267.2. RISK-BASED THERAPY FOR FEBRILE NEUTROPENIC PATIENTS

TREATMENT OF OTHER IMMUNOSUPPRESSED PATIENTS

Although patients with impaired lymphocyte and monocyte function may experience fulminant infection, usually the infections are more indolent. Because of the variety of infectious processes that can arise in these patients, it is not usually advisable to treat them empirically. [Table 267.3](#) lists important aspects in the evaluation of these febrile patients. The specific deficiency in host-defense mechanisms and the infections associated with this deficiency are critical to the selection of the proper diagnostic procedures. Often the pathogens are not ubiquitous, nor are they usually acquired in the hospital. Hence, it is important to obtain a careful history, paying attention to potential exposures. Special stains and culture procedures are often needed for patients' specimens, serologic tests, or skin tests. For example, *Nocardia* species may not be detected without special stains and processing of cultures, and cryptococcal meningitis occasionally is diagnosed only if the cerebrospinal fluid is tested for the presence of antigen. Biopsy of infected tissue is the most rapid and reliable diagnostic procedure and should be performed expeditiously when necessary. Routine dosages and schedules of antimicrobial agents for normal hosts may be inappropriate for immunocompromised patients. The duration of therapy is determined by the patient's response and not by predetermined schedules derived from experience in normal hosts.

- Knowledge of specific deficiency and likely associated infections
- Careful history, including travel and exposure to potential pathogens
- Complete physical examination
- Collection of appropriate culture specimens, with attention to special procedures
- Attention to indicated serologic tests, skin tests, roentgenographic examination
- Expedient tissue biopsy for histologic examination and appropriate cultures
- Correction of deficient host responses, if possible

TABLE 267.3. CONSIDERATIONS IN THE MANAGEMENT OF INFECTION IN NON-NEUTROPENIC IMMUNOCOMPROMISED PATIENTS

MANAGEMENT OF INFECTION AT SPECIFIC SITES

CENTRAL NERVOUS SYSTEM

Acute bacterial meningitis is rare and occurs most often in asplenic or neutropenic patients. In the former case, pneumococci (20% to 60% of which are now penicillin resistant), meningococci, and *H. influenzae* are the most likely pathogens. In neutropenic patients, gram-negative bacilli, especially *P. aeruginosa*, predominate. Staphylococci are isolated most often from patients with shunt or other foreign-body-related meningitis. *L. monocytogenes* is a typical cause of meningitis in patients with lymphocyte or monocyte dysfunction. Other possible bacterial pathogens include *Salmonella* species and mycobacteria. Immunosuppressed and/or neutropenic patients may not have the characteristic clinical features of meningitis, and often there is a paucity of inflammatory cells in the cerebrospinal fluid. An appropriate empiric regimen for the treatment of meningitis in immunosuppressed patients is vancomycin plus ceftazidime plus TMP-SMX. Adjustments can be made based on specific microbiologic information.

Cryptococcal meningitis is the most common fungal infection of the central nervous system (CNS) in immunocompromised patients, especially in those with AIDS. The infection may arise suddenly or insidiously. *Candida* meningitis develops in about 20% of neutropenic patients with disseminated candidiasis. Often, the only symptoms are fever, disorientation, and stupor. The cerebrospinal fluid often shows no characteristic feature, except for an elevated protein concentration, and *Candida* species are seldom cultured. Meningitis due to histoplasmosis or coccidioidomycosis is also prevalent in AIDS patients.

Intracerebral infections are usually a consequence of disseminated infection. Nearly all are caused by uncommon pathogens, including *Nocardia* species, *Toxoplasma gondii*, mycobacteria, cytomegalovirus, or *Aspergillus* species. These infections may be accompanied by symptoms of increased intracranial pressure or focal neurologic defects. Aspergillosis and other mold infections should be suspected in patients with prolonged neutropenia or those on long-term adrenal corticosteroid therapy who suffer strokes. These organisms invade blood vessels, causing thrombosis and infarction. Rare patients with lymphoma or chronic lymphocytic leukemia acquire progressive multifocal leukoencephalopathy, caused by polyoma virus. These patients experience progressive, fatal neurologic defects. No therapy is available for this disease.

SINUS INFECTIONS

Neutropenic patients occasionally have acute bacterial sinus infections, but these infections may be overlooked because of the diminished inflammatory response in such patients. *P. aeruginosa* is an infrequent cause of chronic sinusitis, otitis externa, otitis media, and mastoiditis. The most commonly recognized causes of sinus infection are molds (*Aspergillus*, *Fusarium*, *Mucorales*), seen primarily in neutropenic patients. These organisms can penetrate fascial planes, cartilage, and bone. Often the infected patient shows signs of a black necrotic ulcer on the exterior or interior of the nose or on the palate. Infection may erode through the base of the skull into the brain. The orbit often is affected in the process, and endophthalmitis may be a late complication. Amphotericin B therapy is indicated, and surgical debridement or excision should be performed if possible, though control of the infection depends on recovery of host defenses. Control may be effected in part with the use of hematopoietic growth factors and/or granulocyte transfusions.

OROPHARYNGEAL INFECTION

Most oropharyngeal infections arise in neutropenic and AIDS patients, though local factors can precipitate infections in other immunocompromised patients. Other susceptible patients are those who receive antitumor agents or radiation therapy that damages the epithelial cells, causing ulceration and infection. About 10% of leukemic patients experience bacterial infections in the oropharynx, many caused by gram-negative bacilli. Gingivitis, dental abscess, pericoronitis, pharyngitis, and, occasionally, gangrenous stomatitis may develop. *Capnocytophaga*, an anaerobic gram-negative bacillus that inhabits the oropharynx, causes bacteremia in neutropenic patients with mouth ulcers. Infections caused by *Stomatococcus mucilaginosus* are also common in this context. Severe mucositis may result in a-hemolytic streptococcal septicemia with shock, renal failure, or acute respiratory distress syndrome.

Thrush is the most prevalent oral infection in immunocompromised patients; it is seen in neutropenic patients (acute leukemia, marrow transplantation) and in patients with deficiencies in T-lymphocyte numbers or function (AIDS, mucocutaneous candidiasis). Thrush can be treated with topical antifungal agents (clotrimazole troches, nystatin suspension) or oral absorbable agents (fluconazole, itraconazole). Chronic and recurrent infection is the rule in patients with T-lymphocyte deficiencies (especially AIDS patients, who ultimately often require prolonged fluconazole prophylaxis). The emergence of resistant *Candida* species in this situation is a significant problem.

Serious herpes simplex infections occur in transplant recipients, AIDS patients, and neutropenic patients. They take the form of localized vesicular lesions but may progress to large hemorrhagic and necrotic lesions involving the oropharynx, lips, and surrounding facial tissues. Rarely, herpes simplex infection disseminates to internal organs, including the trachea, lungs, liver, and CNS. Another potentially serious complication of orocutaneous herpetic infection is bacterial superinfection, often caused by *S. aureus*. Intravenous acyclovir is an effective therapeutic agent, but some severely immunocompromised patients, such as bone marrow transplant recipients, may suffer from prolonged infection that responds slowly. Localized infections can be treated with oral agents, such as valaciclovir or famciclovir.

PNEUMONITIS

Pneumonitis is the most common infection in the immunocompromised host and has one of the highest mortality rates. Its management is challenging and difficult because of the diversity of causative organisms (Table 267.4). Bronchoalveolar lavage is often a useful diagnostic procedure, except in neutropenic patients, in whom even open lung biopsy often fails to establish a diagnosis. Infection may arise locally by inhalation of respiratory pathogens, such as *Aspergillus* organisms; by aspiration; or as a consequence of hematogenous dissemination, as in most cases of candidiasis. Some infections (*Pneumocystis pneumonia*, cytomegalovirus) may represent reactivation of latent infections.

Infection	Agent
Bacterial	Gram-positive cocci, gram-negative bacilli, and <i>Legionella</i> , <i>Nocardia</i> , and <i>Mycobacterium</i> species
Fungal	<i>Candida</i> species, <i>Aspergillus</i> species, and <i>Phycomycetes</i> , <i>Cryptococcus</i> , <i>Histoplasma</i> , <i>Coccidioides</i> organisms
Viral	Cytomegalovirus, herpes simplex, varicella zoster, respiratory syncytial virus, community respiratory viruses
Protozoal	<i>Toxoplasma</i> , <i>Pneumocystis</i> species
Parasitic	<i>Strongyloides</i>
Noninfectious	Drug toxicity, hemorrhage, malignancy, nonspecific interstitial pneumonitis

TABLE 267.4. PNEUMONITIS IN THE IMMUNOCOMPROMISED PATIENT

Clues to the cause of pneumonitis can be derived from determination of the deficiency in host defenses, history of exposure, presenting signs and symptoms, extrapulmonary findings, and appearance of the chest roentgenogram. Neutropenic patients are most likely to have pneumonitis caused by gram-negative bacilli, *Candida* organisms, or *Aspergillus* species, whereas patients with impaired T-lymphocyte or monocyte function are susceptible to cryptococcosis, histoplasmosis, toxoplasmosis, pneumocystosis, mycobacteriosis, and cytomegalovirus. Community respiratory viruses, such as respiratory syncytial virus, influenza viruses, parainfluenza viruses, and adenoviruses, have been recognized as important sources of respiratory disease in immunocompromised patients.

Because *Aspergillus* species and other molds invade blood vessels, causing thrombosis and infarction, infected patients may show signs and symptoms of acute pulmonary embolism, including pleuritic chest pain and a pleural friction rub. Candidiasis usually occurs in patients with progressive debilitation who show signs of first-time or progressive pneumonitis while receiving antibacterial antibiotics. Patients with pneumonitis caused by cytomegalovirus or *Pneumocystis carinii* often experience severe tachypnea and cyanosis, with few abnormalities on chest auscultation. Pneumonia associated with CNS symptoms suggests infections such as cryptococcosis, listeriosis, or toxoplasmosis. Pneumonitis associated with myocarditis or hepatitis suggests the possibility of cytomegalic inclusion disease or

toxoplasmosis. Pneumonitis caused by *Candida* or *Aspergillus* species or *P. aeruginosa* may be associated with characteristic skin lesions.

The chest roentgenogram also can provide clues to the cause of pneumonitis. Hilar or mediastinal lymphadenopathy would suggest such infections as histoplasmosis, coccidioidomycosis, or mycobacteriosis. Evidence of preexisting granuloma also indicates these infections. The earliest manifestation of pulmonary aspergillosis or other mold infection is the appearance of a single or several nodules that may progress to cavitation and formation of fungus balls. The presence of necrotizing pneumonia reflects infection by gram-negative bacilli. Abscess formation occurs in various infections, including those caused by *S. aureus*, gram-negative bacilli, or *Nocardia* species. Bilateral, diffuse pneumonitis in the neutropenic patient can be produced by bacteria, fungi, viruses, or protozoa. AIDS patients may have atypical initial roentgenographic manifestations. Empiric therapy is appropriate in neutropenic patients, but in most other immunocompromised patients, a vigorous approach to establishing the diagnosis is critical. Diagnosis should be expeditious, because apparently indolent infections can become fulminant.

ESOPHAGEAL INFECTION

Esophagitis has become a relatively common infection in recent years as a consequence of intensive myelosuppressive chemotherapy and AIDS. Esophageal candidiasis can develop in the absence of oral thrush. Initial signs are pain on swallowing and retrosternal discomfort. Barium contrast radiographic examination shows ulceration, spasm, and a cobblestone appearance to the esophageal mucosa. White patches and hemorrhagic ulcers can be seen on esophagoscopy. Esophagitis is usually caused by *Candida albicans* or herpes simplex virus; other causes include cytomegalovirus, bacteria, and peptic esophagitis. The diagnosis can be confirmed only by scrapings or a biopsy sample obtained during esophagoscopy. Fluconazole is the preferred therapy for *Candida* esophagitis and may be used empirically in susceptible patients, reserving esophagoscopy for patients who fail to respond after several days of therapy.

GASTROINTESTINAL INFECTIONS

A few infections of the gastrointestinal tract represent special problems for the immunocompromised patient. Colitis stemming from *Clostridium difficile* occasionally develops in patients receiving cancer chemotherapy who have not been exposed to antibiotics. Although it is not certain that *Salmonella* infections occur more frequently in patients with hematologic diseases, they affect extragastrointestinal sites in 50% of these patients. They arise primarily in patients with lymphoma, hemolytic anemia, autoimmune disorders, or AIDS. The common predisposing factor is impaired function of lymphocytes or the reticuloendothelial system. Most of the infections are caused by *S. typhimurium* and *S. enteritidis*. Chronic and relapsing infection is not uncommon, despite appropriate therapy.

At autopsy, signs of gastrointestinal candidiasis are often found in neutropenic patients, but it is seldom recognized clinically because most patients remain asymptomatic. Gastrointestinal infection often serves as the source of disseminated candidiasis. Cytomegalovirus can cause severe and even fatal infection of the gastrointestinal tract, especially in children. Occasionally, patients have died of protracted severe diarrhea that resulted in an uncontrollable electrolyte imbalance. Other patients have had ulcerations with severe hemorrhage or perforation. Strongyloidiasis is a rare problem in lymphoma and transplant patients, causing recurrent septicemia due to enteric organisms or hyperacute strongyloidiasis with pulmonary involvement.

Typhlitis is a unique and potentially serious infection in neutropenic patients. It is a patchy inflammatory disease characterized by well-demarcated ulcers, hemorrhage, and masses of organisms in the bowel wall, with a paucity of inflammatory cells. Usually, it is limited to the cecum, but it may affect the entire intestine. The typical presenting signs and symptoms are fever, abdominal pain, watery or bloody diarrhea, stomatitis, abdominal distention, tenderness (often in the right-lower quadrant), and diminished or absent bowel sounds. More than 70% of patients have septicemia caused by gram-negative bacilli or *Clostridium septicum*. Therapy consists of nasogastric suction, intravenous fluids, analgesics, and broad-spectrum antibiotic regimens that provide coverage against gram-negative bacteria, including *P. aeruginosa* and anaerobes. Surgical intervention may be necessary. The mortality rate is high unless the neutrophil count recovers.

Perirectal infections resulting in neutropenia develop in 5% to 10% of patients with hematologic diseases, but they are especially common in patients with acute monocytic and acute myelomonocytic leukemia. Perirectal infections and proctitis are prevalent infections in AIDS patients. The initial symptoms are pain aggravated by defecation, local tenderness, and septic or hectic fever. Infection often arises at the site of a hemorrhoid or fissure and may extend into the rectum, with extensive necrosis. Most of these infections are caused by aerobic gram-negative bacilli, especially *P. aeruginosa* and *E. coli*. In most cases, therapy consists of sitz baths or warm compresses, stool softeners, analgesics, and broad-spectrum antibiotics.

CUTANEOUS INFECTION

Infections of the skin and soft tissues may be localized or a manifestation of disseminated disease. Because many immunocompromised patients require frequent intravenous medications and blood tests, they often experience cellulitis. Some cancer chemotherapeutic agents are vesicants and lead to extensive tissue necrosis if they extravasate. Most local infections are caused by *S. aureus*, *S. epidermidis*, and gram-negative bacilli. Among the gram-negative bacilli that have a special propensity for generating localized infections are *P. aeruginosa*, *Aeromonas hydrophila*, and *S. maltophilia*. Occasionally, infections are caused by gram-positive organisms, such as *Bacillus* species and *Corynebacterium jeikeium*. Aspiration and biopsy of infected areas should be undertaken, but despite these procedures the pathogen often cannot be determined. Fungi that sometimes prompt local infections are *Candida*, *Aspergillus*, *Fusarium*, and *Mucorales* species. From time to time, genital herpes is seen in immunocompromised patients. Women may suffer extensive vulvovaginal infection that is disfiguring and painful. Genital condylomas may also develop in immunocompromised women, including renal transplant recipients and patients with hematologic malignancies. These lesions in immunocompromised patients are often difficult to eradicate by conventional methods.

Herpes zoster occurs in up to 25% of patients undergoing therapy for Hodgkin's disease. Most cases develop within a year after completion of therapy. Although zoster is considered a reactivation of latent infection, there have been outbreaks of infection in susceptible populations, suggesting exogenous acquisition of the virus. Infection tends to manifest where tumor is in close proximity to the nerve trunk or at sites of previous radiation therapy. Cutaneous dissemination takes place in 20% to 40% of patients; visceral dissemination is rare. Intravenous acyclovir should be given to patients with disseminated infection; it is also appropriate for patients with localized infections, to facilitate healing, minimize scarring, and prevent postherpetic neuralgia, which is more common in these patients than in normal hosts. Combination therapy (acyclovir plus foscarnet) may be beneficial in patients who fail to respond to acyclovir alone.

DISSEMINATED FUNGAL INFECTIONS

Disseminated candidiasis is especially common in neutropenic patients because the neutrophil is the primary defense against *Candida* organisms. Other factors predisposing to this infection include indwelling catheters, parenteral alimentation, broad-spectrum antibiotics, and adrenal corticosteroid therapy. There is nothing characteristic about the clinical picture of disseminated candidiasis in most patients. They often have fever as the only sign of infection, but some show symptoms suggestive of endotoxic shock, including shaking chills, tachycardia, tachypnea, and hypotension. *Candida* species is one of the more common sources of hematogenous pneumonia in neutropenic patients. A chronic form of candidiasis primarily involving the liver and spleen develops in some patients who achieve remission of leukemia or lymphoma. The infection arises when they are neutropenic but persists as a chronic, debilitating infection for prolonged periods after hematologic remission, despite the administration of antifungal therapy.

Diagnosing candidiasis is often difficult. The organism can be cultured from blood specimens of only 40% of patients with disseminated infection. Serologic tests of antibody or antigen have not been reliable for establishing the diagnosis. Because *C. albicans* is ubiquitous in patients receiving antibiotics, its recovery from several body sites often represents colonization rather than infection; recovery of *Candida tropicalis* from body sites appears to be more indicative of infection. Other *Candida* species, such as *C. glabrata*, *C. parapsilosis*, and *C. krusei*, have emerged as prevalent pathogens, especially among neutropenic patients. Computed tomography of the abdomen may pinpoint abscesses in the liver, spleen, or kidney. A definitive diagnosis often can be established only by tissue biopsy.

Aspergillus infection disseminates in about 30% of cases and mucormycosis less frequently. *Fusarium* species have emerged as a significant source of disseminated fungal infection in neutropenic patients. Because *Aspergillus* organisms invade blood vessel walls, causing thrombosis and infarction, symptoms of acute vascular events are typical. Conditions that are associated with disseminated infection include Budd–Chiari syndrome, myocardial infarction, cerebral infarction, gastrointestinal hemorrhage, and necrotic skin lesions. Although the diagnosis may be suspected from the clinical symptoms, it usually cannot be confirmed without tissue biopsy.

Although cryptococcosis usually appears as meningitis, it can also lead to disseminated infection of the lung, lymph nodes, skin, bone, liver, kidney, spleen, and adrenal glands. Skin lesions are acneiform, nodular, plaque-like, or ulcerated. Pneumonia may take the form of miliary, nodular, or cavitory lesions on chest roentgenograms. Reactivation of pulmonary granulomas caused by histoplasmosis or coccidioidomycosis may result in disseminated infection.

Amphotericin B has been the standard therapy for most fungal infections, but infusion-related toxicity and nephrotoxicity are significant limitations. The newer lipid formulations of amphotericin B are at least as effective and much less toxic, but they also are much more expensive than standard amphotericin B. The azole compounds (fluconazole, itraconazole) are alternative therapies for some fungal infections, but the appearance of resistant organisms (*C. krusei*) is a concern. Unfortunately, antifungal therapy may be ineffective unless the underlying immunologic defects can be corrected. The use of hematopoietic growth factors (granulocyte colony-stimulating factor and granulocyte–macrophage colony-stimulating factor) and granulocyte transfusions in addition to antifungal therapy may be of benefit in patients with disseminated fungal infections.

TRANSFUSION- AND TRANSPLANTATION-RELATED INFECTIONS

Organ transplantation has been associated with the acquisition of various chronic infections, including hepatitis B, cytomegalic inclusion disease, rabies, Creutzfeldt–Jakob disease, AIDS, and herpes simplex infection. Some immunocompromised patients require extraordinary numbers of transfusions; hence, they are susceptible to acquiring infections via this route. Herpes simplex, Epstein–Barr virus, and cytomegalovirus can be acquired from infected donor leukocytes. Babesiosis, malaria, leishmaniasis, and toxoplasmosis have been transmitted via blood products.

INFECTION PREVENTION

Programs to prevent infection have been developed for highly susceptible patients, such as organ transplant recipients and patients undergoing chemotherapy for acute leukemia. These programs include laminar air-flow rooms, special food preparation, skin-cleansing products, and antimicrobial agents. Conventional isolation is of little benefit and interferes with optimal patient care. Laminar air-flow rooms are expensive but effective in preventing exposure to respiratory pathogens, such as molds. Simple HEPA filtration units may be as effective and less costly. Foods may be contaminated with potential pathogens (gram-negative bacilli, *Candida* species). Special cooked diets can minimize this exposure, but they may be unnecessary for patients who are receiving antimicrobial prophylaxis.

Antimicrobial agents have been effective for prophylaxis in prospective, randomized trials. Fluoroquinolones and TMP-SMX are useful for antibacterial prophylaxis, but the former drugs are more effective where resistance to TMP-SMX is prevalent. Fluconazole is effective prophylaxis for *Candida* infections, though the emergence of resistant species is a concern. Ganciclovir can prevent cytomegalovirus infection, and acyclovir can prevent herpes simplex infection. The major worry with the use of prophylactic regimens is the potential for colonization and infection with resistant organisms. No regimen can provide protection against all potential pathogens or eliminate the risk of antimicrobial resistance.

Immunizations are a valuable measure for the prevention of some infections in immunocompromised patients. Because bone marrow transplant recipients and patients who have undergone splenectomy are susceptible to overwhelming pneumococcal infection, they should be given the pneumococcal vaccine. It should be administered before splenectomy for optimal benefit. The antibody response in patients receiving chemotherapy and in patients with impaired antibody synthesis is blunted, so vaccines are of limited value for them. Influenza vaccine is probably useful for patients taking immunosuppressive drugs, provided there is an interval between administration of the vaccine and the immunosuppressive therapy, to permit an adequate antibody response. The colony-stimulating factors (granulocyte colony-stimulating factor and granulocyte–macrophage colony-stimulating factor) may prevent infection during myelosuppressive chemotherapy by shortening the duration of neutropenia. Their role in infection prophylaxis remains the subject of controversy, primarily because of their expense.

[Pathogenesis of Sepsis](#)
[Factors Predisposing to Bacteremia and Sepsis](#)
[Optimal Management](#)
[Prevention of Bacteremia](#)

More than 400,000 cases of bacteremia and sepsis occur each year in the United States, and they are associated with significant morbidity and mortality. In recent years, there has been a dramatic increase in the number of bacteremic infections due to gram-positive bacteria and fungi compared with infections due to gram-negative bacteria. This alteration in microbiology reflects, to a large extent, the widespread use of intravascular devices and extended-spectrum antimicrobial agents.

In some patients, bacteremia leads to a widespread inflammatory response now termed the systemic inflammatory response syndrome (SIRS). Only when SIRS stems from infection is it called sepsis. This distinction is crucial: many other conditions, such as trauma, severe burns, and pancreatitis, can result in SIRS and mimic sepsis, but they are unrelated to infection. Patients who become hypotensive as a result of sepsis are considered to have septic shock. The term multiple organ dysfunction syndrome has been coined for patients in septic shock who require intervention to maintain hemodynamic stability.

EPIDEMIOLOGY

Bacteremia occurs in both community- and hospital-acquired infections. Community infections commonly associated with bloodstream invasion include pneumonia, pyelonephritis, meningitis, and infections associated with perforating injuries of abdominal and thoracic viscera and lesions that obstruct the gastrointestinal or genitourinary tract. Patients with skin or soft-tissue infections, especially in association with diabetes mellitus, malnutrition, and HIV-1 infection, and those on corticosteroid therapy or other immunosuppressive agents (cyclosporine, azathioprine) are also at increased risk.

Nosocomial infections are those that develop in patients after admission to the hospital that were not present or were incubating at the time of admission, though this distinction is becoming blurred as more seriously ill patients are treated in the ambulatory setting. About 5% of patients admitted to hospitals experience an infection while hospitalized. These infections typically involve the urinary tract or are related to surgical wounds or pneumonia; at present, nosocomial bloodstream infections account for 14% of hospital-acquired infections. Manipulation of the genitourinary tract and the use of indwelling bladder catheters are associated with an increased risk of infection. Among catheterized patients, the most important risk factor is the duration of catheterization. Few of these infections result in bacteremia. Although women are infected most often, elderly men are the most likely to experience bloodstream infection.

Most surgical wound infections occur 3 to 7 days after surgery and are caused by bacteria introduced during the operation; however, decreasing lengths of hospital stay often make it difficult to identify these infections. Antibiotic prophylaxis administered in the perioperative period has had a significant effect on minimizing these infections. Less than 1% of surgical wound infections are complicated by bacteremia. Elderly men are at greatest risk after prolonged hospitalization, especially for surgery of the gastrointestinal or genitourinary tract.

Although nosocomial pneumonias occur less frequently than urinary tract infections or surgical wound infections, this form of pneumonia is the most lethal of the hospital-acquired infections, with a 30% to 50% mortality rate. Bacteremia is a consequence of nosocomial pneumonia more often than other nosocomial infections and is the reason for the higher mortality rate associated with this infection. The overall risk of dying from pneumonia is greatest for patients older than 60 years and those with multilobe involvement, respiratory failure, or severe underlying illness.

Primary bloodstream infection most often develops in patients with intravascular catheters, especially central venous access devices. Infection generally arises at the entry site, and the risk rises with frequent manipulation or prolonged duration of catheterization. Intravenous, arterial, and central venous catheters should be changed according to institutional infection-control guidelines. The introduction of antimicrobial impregnated catheters has been shown to lower this risk. Nosocomial bloodstream infection is associated with significant mortality rates, prolongs hospitalization, and increases costs. It is estimated that each nosocomial bloodstream infection increases the length of hospital stay by an average of 7.4 days and costs in excess of \$5,000.

ETIOLOGY

The microbiology of bacteremia is evolving constantly. In the era before antibiotics, the pyogenic gram-positive cocci, *Streptococcus pneumoniae*, *Staphylococcus aureus*, and group A streptococci were common causes of bacteremia. In the late 1950s, nosocomial bacteremia due to gram-negative bacilli became more prevalent. The organisms most frequently isolated from blood cultures were *Escherichia coli*, *Serratia marcescens*, *Pseudomonas aeruginosa*, and *Proteus*, *Klebsiella*, and *Enterobacter* species. In the 1970s, renewed interest in anaerobic bacteriology resulted in the recognition of bacteremia due to *Bacteroides* species. Since the late 1980s, the gram-positive organisms, including *S. aureus* (especially methicillin-resistant species) and *Staphylococcus epidermidis*, as well as other coagulase-negative staphylococci, are being identified more frequently. The coagulase-negative staphylococci, many of which are methicillin-resistant, are a growing problem in patients with intravenous catheters, arteriovenous shunts or fistulas, prosthetic grafts, or cardiac valves. Enterococci, both *Enterococcus faecalis* and *Enterococcus faecium*, have emerged as important nosocomial pathogens with intensifying resistance to antimicrobial agents. The percentage of enterococci that are vancomycin resistant continues to rise in medical centers throughout the United States. It is of some concern that vancomycin resistance has occurred as enterococci have developed increasing resistance to penicillins and aminoglycosides. Even more of a problem is the recent identification of *S. aureus* with decreased susceptibility to vancomycin.

The site of the infection and the underlying disease often predict the organism that will be isolated from the blood. Examples include *S. epidermidis* in association with intravascular devices, *P. aeruginosa* with severe burns, aerobic enteric bacteria or *S. aureus* with neutropenia, anaerobic organisms with intra-abdominal disease, and encapsulated bacteria with defective humoral immunity. Bacteremia due to *Streptococcus bovis* is associated with carcinoma of the colon or inflammatory bowel disease; thus, radiologic or endoscopic examination is necessary in patients with *S. bovis* bacteremia.

In patients with sustained gram-positive bacteremia, infective endocarditis or another intravascular site of infection must be considered. The organisms that most commonly cause endocarditis include viridans streptococci, enterococci, staphylococci, and *S. bovis*. Because bacteremia is continuous in patients with endocarditis, all or nearly all blood cultures show positive results. In the absence of previous antibiotic treatment, more than 95% of patients with endocarditis have positive results on blood cultures. Aerobic gram-negative bacilli, though they are a frequent cause of bacteremia, rarely infect heart valves. Persistent bacteremia due to these organisms suggests an intra-abdominal focus of infection, a perinephric abscess, septic phlebitis, or "pseudobacteremia" from a contaminated intravenous infusion or blood culture system. Patients with HIV-1 infection are predisposed to recurrent nontyphoid *Salmonella* species bacteremia. Bacteremia and sepsis due to *S. pneumoniae*, *Haemophilus influenzae*, and *Neisseria meningitidis* are associated with asplenia.

CLINICAL MANIFESTATIONS

It is impossible to identify patients with bacteremia exclusively on clinical grounds. It is necessary for the clinician to be vigilant and acutely aware to detect bloodstream infection, especially in the elderly, in patients who have low-grade fever, and in those who do not appear to be particularly ill. The initial symptoms in patients with bacteremia are nonspecific and may include fever, lethargy, fatigue, nausea, and mental status changes. Although fever is nonspecific, rigors suggest bacteremia. In the elderly, confusion, incontinence, or falls can provide subtle evidence of bacteremia. Blood cultures should be obtained from patients suspected of having bacteremia, even in the absence of fever. In fact, hypothermia (<36°C) can occur in the context of bacteremia (though it is more common in sepsis) and indicates a poor prognosis.

In some patients, a focal site of infection is evident because of symptoms, physical findings, or laboratory results. Examples include dysuria and pyuria in patients with

urosepsis, productive cough and radiographic abnormalities in patients with bacteremic pneumonia, and rebound and guarding in patients with an intra-abdominal source of bacteremia. The skin of patients suspected of having bacteremia should be carefully examined, since some systemic infections manifest with cutaneous lesions. Many purpuric lesions can be seen in patients with meningococemia or other gram-negative bacteremias. Ecthyma gangrenosum is associated with *P. aeruginosa*, and scattered maculopapular (or pustular) lesions suggest disseminated gonococcal infection. Multiple petechiae, Osler nodes, or Janeway lesions suggest infective endocarditis.

There may be many laboratory test abnormalities in patients with bacteremia, and they often reflect the source of bloodstream invasion. Like the clinical findings, they are nonspecific and should not be used to gauge the need for obtaining cultures. An elevated white blood cell count with an increase in immature forms suggests infection, though leukocytosis may be absent in elderly or immunocompromised patients. Furthermore, leukopenia can occur with overwhelming infection and portends a poor prognosis.

DIAGNOSIS

Blood cultures must be carried out when bacteremia is suspected ([Table 268.1](#)), because isolation of bacteria from the blood is the only way to confirm the diagnosis. The volume of blood is the most important factor in the accurate detection of bacteremia. Because bacteremia in adults is generally low grade (1 to 10 colony-forming units per milliliter), 10 to 20 mL of blood should be drawn. The yield of blood cultures is directly proportional to the volume of blood; results may be false-negative if the volume of blood is less than 10 mL.

Patients with signs/symptoms of bacteremia
 Patients with fever or hypotension not explained by noninfectious causes
 In the absence of fever
 Patients with focal infection (pneumonia, meningitis, osteomyelitis)
 Children or elderly with failure to thrive
 Elderly patients with change in mental status from baseline
 Patients with renal insufficiency and unexplained leukocytosis or altered mental status
 Immunocompromised patients looking ill or with unexplained pulmonary, renal, or hepatic dysfunction
 Patients receiving antibiotic therapy for documented bacteremia to confirm clearance of microorganisms from the blood

(From Chandrasekar PH, Brown WJ. Clinical uses of blood cultures. *Arch Intern Med* 1994;154:841, with permission.)

TABLE 268.1. INDICATIONS FOR BLOOD CULTURES

Appropriate techniques for conducting blood culture are important, to avoid contamination with cutaneous flora. The skin should be prepared initially with an alcohol swab, followed by iodophor or tincture of iodine. Once applied, the iodine should be allowed to dry and should not be removed. The venipuncture should be made with sterile gloves; if nonsterile gloves are used, the site must not be palpated. It is unnecessary to change needles between venipuncture and inoculation into blood culture tubes, but a new needle must be used for each successive attempt. A separate venipuncture site should be used for each set of cultures. All blood collected from a single venipuncture represents one set, regardless of the number of tubes or the volume inoculated. Ideally, blood cultures should be taken 15 to 30 minutes apart, though there is little evidence that this increases the chance of a positive culture. In patients suspected of having infective endocarditis, three sets of cultures taken during a 24-hour period are sufficient.

One of the most difficult challenges facing clinicians is determining whether a positive blood culture result represents clinically significant bacteremia or contamination. Depending on the technique used and the experience of the person obtaining the culture, contamination occurs in up to 3% of all blood cultures. In general, contamination is suspected when only one culture is positive with normal skin flora (coagulase-negative staphylococci, *Corynebacterium* species, or *Propionibacterium acnes*) and isolation occurs after prolonged incubation. This is particularly important for patients whose clinical course is inconsistent with bacteremia associated with one of these organisms. For example, in an alcoholic patient with community-acquired pneumonia and a sputum Gram's stain with abundant gram-positive diplococci, isolation of *S. epidermidis* from blood probably represents contamination. On the other hand, a positive culture for *S. pneumoniae* would confirm the diagnosis of bacteremic pneumonia. In immunocompromised patients or those with prosthetic devices, the identification of coagulase-negative staphylococci may represent true infection and should alert the physician to the possibility of intravascular infection. Obviously, if several sets of blood cultures show positive results, there is a greater likelihood that bacteremia is present. Certain bacteria rarely represent contamination, including *S. pneumoniae*, *Streptococcus pyogenes*, *S. aureus*, *P. aeruginosa*, and the Enterobacteriaceae (enteric gram-negative bacilli).

Repeated cultures of blood are generally unnecessary in patients with stable clinical symptoms. Nevertheless, in immunocompromised patients, especially febrile persons with neutropenia, several cultures may be useful in detecting bacteremia or fungemia. If a patient with bacteremia is improving and receiving appropriate antimicrobial therapy, follow-up cultures are rarely indicated. On the other hand, if the patient does not respond to treatment, repeatedly positive cultures may indicate an undrained focus or an intravascular infection.

The diagnosis of sepsis is based on the early recognition of the systemic inflammatory response to infection—fever, tachycardia, tachypnea, and hypotension. As this syndrome progresses, there may be evidence of organ hypoperfusion, manifested by change in mental status, decreased urine output, hepatic dysfunction, and myocardial depression. If this inflammatory response continues, septic shock may develop, characterized by hypotension requiring vasopressors to maintain adequate organ perfusion, lactic acidosis, and worsening abnormalities of renal, hepatic, and central nervous system function. Insertion of a pulmonary artery catheter in such patients demonstrates a markedly increased cardiac index and low systemic vascular resistance and is useful to guide therapy.

PATHOGENESIS OF SEPSIS

The most serious complication of bacteremia, especially in association with gram-negative infections, is the development of sepsis and septic shock. It is estimated that sepsis is the thirteenth leading cause of death in the United States and accounts for at least \$10 billion in annual health care costs. Despite advances in medical technology and the introduction of new antimicrobial therapy, the sepsis-related mortality rate has increased 83% in the past 15 years. Sepsis is defined as clinical evidence of infection associated with tachypnea, tachycardia, and fever or hypothermia ([Table 268.2](#)). Septic shock occurs when sepsis results in hypotension associated with organ hypoperfusion.

Infection. Microbial pathogenesis characterized by an inflammatory response to the presence of microorganisms or the invasion of normally sterile host tissue by these organisms.
Bacteremia. The presence of viable bacteria in the blood.
Systemic inflammatory response syndrome. The systemic inflammatory response to a variety of sources (trauma, surgery, pancreatitis) by two or more of the following conditions:
 Temperature $\geq 38^{\circ}\text{C}$ or $\leq 36^{\circ}\text{C}$
 Heart rate ≥ 90 beats/min
 Respiratory rate ≥ 20 breaths/min or $\text{Pao}_2 \leq 32$ mm Hg
 White blood cell count $\geq 12,000/\text{mm}^3$, $\leq 4,000/\text{mm}^3$, or $>10\%$ immature (band) forms
Sepsis. The systemic response to infection, manifested by two or more of the following conditions as a result of infection:
 Temperature $\geq 38^{\circ}\text{C}$ or $\leq 36^{\circ}\text{C}$
 Heart rate ≥ 90 beats/min
 Respiratory rate ≥ 20 breaths/min or $\text{Pao}_2 \leq 32$ mm Hg
 White blood cell count $\geq 12,000/\text{mm}^3$, $\leq 4,000/\text{mm}^3$, or $>10\%$ immature (band) forms
Severe sepsis. Sepsis-related hypotension despite adequate fluid resuscitation, along with perfusion abnormalities that may include, but are not limited to, lactic acidosis, oliguria, or an acute alteration in mental status. Patients receiving vasopressors or inotropic agents may not be hypotensive at the time that perfusion abnormalities are recognized.
Septic shock. Hypotension. A systolic blood pressure ≤ 90 mm Hg or a reduction of ≥ 40 mm Hg from baseline in the absence of other causes for hypotension.
Multiple organ dysfunction syndrome. At least two organ functions are abnormally ill (defined as) that hemodynamic control for stabilization without intervention.

TABLE 268.2. AMERICAN COLLEGE OF CHEST PHYSICIANS AND THE SOCIETY OF CRITICAL CARE MEDICINE CONSENSUS CONFERENCE DEFINITIONS

The initial event in the sepsis cascade is the release of mediator or mediators from infecting bacteria at the site of infection or after invasion of the bloodstream ([Fig.](#)

268.1). These exogenous mediators initiate the inflammatory process that results in sepsis. The lipopolysaccharide (LPS) of the cell wall of gram-negative bacteria, or endotoxin, has been implicated as the primary exogenous mediator in the pathogenesis of gram-negative sepsis. Other bacterial components or products that may play a significant role in the pathogenesis of sepsis include peptidoglycan, muramyl dipeptide, lipoteichoic acid, staphylococcal enterotoxin B, toxic shock toxin 1, and *Pseudomonas* exotoxin A. Infusion of endotoxin in primates mimics much of the clinical picture of gram-negative shock seen in humans. The fact that symptoms in patients with gram-negative bacteremia initially worsen when antimicrobial agents are started suggests that endotoxin is released as bacterial cell walls are lysed as a result of therapy.

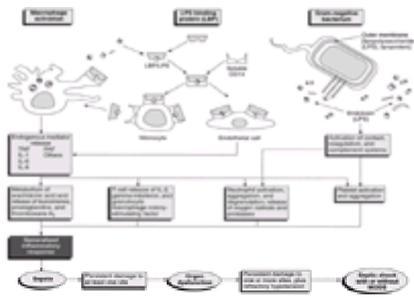

FIGURE 268.1. Schematic representation of the sepsis cascade. (From Bone RC. The pathogenesis of sepsis. *Ann Intern Med* 1991;115:457–469, with permission.)

In the pathogenesis of sepsis, endotoxin activates monocytes and macrophages to secrete inflammatory cytokines and other mediators. These endogenous mediators of sepsis act on various target cells, leading to shock and multiorgan system failure. Two lipid A binding proteins have been identified that play an important role in sepsis—LPS binding protein (LBP) and bactericidal/permeability-increasing protein (BPI). Although LBP and BPI share similar DNA homology, they have different chemical properties. LBP potentiates the binding of endotoxin to CD14 receptors on monocytes, neutrophils, and endothelial cells necessary for the release of cytokines that mediate the sepsis syndrome. In contrast, BPI is a protein with bactericidal, endotoxin-neutralizing properties and blocks binding of LPS and LBP and hence the LPS/CD14 interaction. BPI is considered essential for polymorphonuclear cells to destroy gram-negative bacteria.

A series of observations have significantly advanced our knowledge of the pathophysiology of this syndrome. It appears that the signaling unit of the LPS receptor is a member of the Toll-like receptor (TLR) family. Expression of a member of the human TLR family, TLR2, confers LPS responsiveness. This responsiveness is dependent on LBP and CD14. Mutation or deletion of murine TLR results in a phenotype with markedly reduced or absent responses to LPS.

There are many potentially important endogenous mediators of sepsis in humans, such as tumor necrosis factor (TNF), interleukin-1 (IL-1), IL-6, IL-8, and platelet-activating factor. Secreted by mononuclear cells, TNF may be the most important endogenous mediator. In animal models, injection of TNF results in hypotension, neutropenia, and enhanced capillary permeability. Administration of TNF to healthy human volunteers produces signs of sepsis. Recent evidence, however, suggests that endotoxemia may produce the manifestations of sepsis independently of TNF. Therefore, the exact role of TNF in sepsis has not been elucidated completely. To complicate matters, despite the high circulating levels of TNF found in sepsis, increased levels also occur in the context of congestive heart failure, rheumatoid arthritis, and HIV wasting syndrome.

Other endogenous mediators of sepsis released after macrophage activation are IL-1, IL-6, and IL-8. In addition, arachidonic acid is metabolized to release leukotrienes, prostaglandins, and thromboxane A₂, which result in endothelial damage leading to hemodynamic instability in patients with septic shock. Another endogenous mediator, platelet-activating factor, exacerbates the generalized inflammatory response. These endogenous mediators have complex interactions and contribute to the end-organ damage that increases the mortality rate in patients with multiple organ dysfunction syndrome.

Nitric oxide (NO) has been investigated for its role in the pathophysiologic course of sepsis. In inflammatory conditions, NO production is catalyzed by the enzyme-inducible nitric oxide synthetase (iNOS). In animal models of infection, pneumococci induce NO, iNOS, and TNF production. Further studies are necessary to elucidate better the role of NO in the pathogenesis of sepsis.

FACTORS PREDISPOSING TO BACTEREMIA AND SEPSIS

Invasive bacterial infections occur more frequently in patients with a defect in a natural protective barrier to infection or a deficiency in the inflammatory response or in the cellular or humoral immune system relevant to these infections. With most bacteria, control of infection depends on normal numbers and function of polymorphonuclear leukocytes (PMNs) and the serum opsonins, complement components, or specific antibody. Various conditions and therapies alter the normal functioning of these components of the host inflammatory response. Furthermore, serious underlying illnesses are also a major determinant of prognosis. The classification system of McCabe and Jackson, published in 1962, documented that patients with a rapidly fatal illness (acute leukemia) and an ultimately fatal illness (uremia) have a progressively worse prognosis than patients with bacteremia without underlying disease. Although there has been a marked improvement in the results of therapy for bacteremia over the past 30 years, this principle remains valid.

The most serious condition predisposing patients to bacteremia is neutropenia. The incidence and the lethality of bacteremia due to gram-negative bacilli and, to a lesser extent, gram-positive cocci, are directly proportional to the absolute neutrophil count. Although neutropenia is defined as an absolute neutrophil count less than 500 per microliter, the risk is greatest when the count is below 100 per microliter. Ultimate survival in all series correlates most directly with bone marrow recovery and restoration of normal white blood cell counts. The introduction of granulocyte colony-stimulating factors has lessened the duration of neutropenia in many patients after chemotherapy and bone marrow transplantation; however, their use has not been accompanied by a decreased risk of infection.

Age is another important determinant of bacterial invasion. This association has been most clearly documented in the case of nosocomial infections. The deficiency in older adults has not been delineated completely; although deterioration of the immune system has been postulated, the most plausible explanation is the increased incidence of cardiac, pulmonary, cerebrovascular, and neoplastic diseases and diabetes that occurs with advancing age. Catheterization of the urinary tract has also been shown to be a significant risk factor for bacteremia in the elderly.

Other conditions frequently associated with bacteremia include alcoholism with or without cirrhosis and diabetes. Acute alcohol intoxication impairs PMN function, as does hepatic disease. Diabetes mellitus is also associated with defective PMN responses to chemotactic stimuli, even if glucose metabolism is well controlled. In addition, phagocytosis and bacterial killing are defective in some patients with diabetes and in all patients with acidosis. Although *Candida* infections or staphylococcal skin infections develop with increased frequency, there is little evidence that infections are more prevalent in persons with well-controlled diabetes. Increased morbidity with infection has been documented in these patients, however.

In addition to the neutropenia due to malignant hematologic disease or cytotoxic chemotherapy, patients with neoplasms are at higher risk of serious infection. The hypogammaglobulinemia of lymphoproliferative diseases is associated with bacteremia due to encapsulated organisms. Obstruction of the gastrointestinal or genitourinary tract by tumors is a major cause of sepsis, and alteration in PMN function is also observed with certain solid tumors. Inhibitors of PMN chemotaxis have been described in patients with bronchogenic carcinoma and Hodgkin's disease. Malnutrition as a consequence of carcinoma also results in alteration in white cell function and serum opsonic capacity.

Treatment with medications other than cytotoxic chemotherapy also can be associated with an increased risk of sepsis due to abnormalities in white cell function. Corticosteroids have many effects on host defenses but clearly interfere with PMN function. Administration of glucocorticoids is associated with the release of cells from marrow reserves, but these agents also inhibit adhesion of PMNs to endothelial cells. Therefore, PMNs cannot leave the vascular compartment to reach the site of infection. Initial studies advocated the use of steroids as adjunctive therapy in patients with gram-negative bacteremia, especially those with septic shock. Subsequently, large, well-controlled, multicenter investigations clearly have shown no beneficial effect from the use of steroids in the treatment of sepsis.

Asplenic patients are particularly susceptible to bacteremic infections with encapsulated organisms, such as *S. pneumoniae* and *N. meningitidis*. These patients often

have high-grade bacteremia, and organisms are identified frequently by examination of the peripheral blood smear. The exact mechanism of action responsible for this deficiency, which is also found in patients with sickle cell disease, is unclear. It is believed to be due to a deficiency of the alternate complement pathway, failure of antibody production, or failure of clearance mechanisms by the remaining reticuloendothelial system. For this reason, patients undergoing splenectomy should receive vaccination against *S. pneumoniae* before the procedure.

Deficiency of the terminal complement pathway is associated with an increased risk of bacteremic infections due to *Neisseria* species. This is a consequence of a defective lytic capacity of serum in the absence of the complement components 5 through 9. Deficiency of C3, the primary component in opsonization of *S. aureus* and gram-negative bacilli, results in a clinical picture resembling that seen in patients with neutropenia.

Patients with HIV-1 infection are also at increased risk of bacteremia, primarily due to encapsulated organisms. Although bacteremia traditionally has been considered a T-cell deficiency, HIV-1-infected persons also have defects in B-cell function. With disease progression, these patients often show signs of neutrophil dysfunction as well as abnormalities in cytokine production. These altered host defenses raise AIDS patients' risk of bacteremia due to encapsulated organisms, *S. aureus*, gram-negative bacilli, *Listeria monocytogenes*, and *Salmonella* species. In addition, infection due to *Rochalimaea henselae* and *Rochalimaea quintana*, the recently identified sources of bacillary angiomatosis and peliosis hepatis, are more common in HIV-1-infected persons.

Another predisposing factor for bacteremia is previous antibiotic therapy. Bloodstream infections due to enteric gram-negative bacilli, enterococci, and fungi are more common in patients with previous antimicrobial exposure. Examples include the association of second- and third-generation cephalosporins with enterococcal bacteremia and the relationship of vancomycin and vancomycin-resistant enterococci. *Klebsiella* sepsis has been noted in neurosurgical patients receiving antibiotic prophylaxis, *Enterobacter* sepsis has been associated with broad-spectrum antibiotic use, and *Stenotrophomonas (Xanthomonas) maltophilia* bacteremia can result from administration of imipenem.

The increased use of medical devices, such as intravenous and bladder catheters, is a major cause of nosocomial bacteremia, sepsis, and fungemia. It is estimated that 0.3% of all patients with an indwelling bladder catheter experience urosepsis. Devices that breach the natural protective barrier of the skin predispose patients to bloodstream infections with normal cutaneous flora, especially staphylococci. Although it rarely happens, intravenous fluids contaminated with bacteria also have been implicated as a source of bacteremia. Finally, prolonged survival of seriously ill patients, invasive diagnostic and therapeutic procedures, and increased use of immunosuppressive medications are all important risk factors for sepsis.

OPTIMAL MANAGEMENT

Diagnosis of bacteremia requires extreme vigilance and awareness, especially in patients who are afebrile or have low-grade fever. Therefore, blood cultures should be undertaken for all patients admitted to the hospital with an infectious disease. Prompt initiation of antimicrobial therapy is important in preventing death in patients with gram-negative sepsis and the complications that may result from bacteremia, such as endocarditis, osteomyelitis, or abscesses. In acutely ill patients, especially those in shock, a multidisciplinary approach is appropriate, often calling on clinicians with expertise in infectious disease and critical care medicine and, in some instances, surgeons.

After obtaining appropriate cultures, initial antimicrobial therapy should be directed at the most likely etiologic agent that results in the specific infection. No single antibiotic or combination of agents is effective for all patients with bacteremic infections. Ultimately, empiric therapy should be guided by the organisms most likely responsible for each infection and susceptibility patterns within each institution. When final identification and susceptibility are determined, however, therapy should be adjusted to provide the most narrow-spectrum, cost-effective antibiotic.

For patients in shock, a rapid assessment to determine the probable site of infection or portal of entry is critical. Careful attention should be paid to the respiratory and urinary tracts as possible foci of infection. To this end, examination of the urine for pyuria and bacteriuria and a chest radiograph are useful adjuncts to Gram's stain and cultures of blood, urine, and sputum. Empiric antibiotics and intravenous fluids should be administered concomitantly with the initial assessment. If the patient is hypotensive and does not respond to fluid resuscitation, vasopressors should be initiated.

For suspected intravenous device infections, a penicillinase-resistant penicillin (oxacillin or nafcillin) or vancomycin is appropriate. Oxacillin is preferred if the infection is community acquired and vancomycin for nosocomial infections or for penicillin-allergic patients. For patients with an intra-abdominal focus of infection, antibiotics that provide coverage against enteric gram-negative bacilli, enterococci, and anaerobes are necessary. In the febrile patient with neutropenia, an antipseudomonal β -lactam antibiotic in combination with an aminoglycoside is preferred, but monotherapy with ceftazidime is effective. Empiric antifungal therapy is often required for patients with neutropenia who remain febrile on broad-spectrum antibiotics. Owing to delays in the diagnosis of fungemia, empiric antifungal therapy also may be warranted in patients with severe intra-abdominal infections, those on prolonged courses of antibiotics, and those receiving parenteral nutrition or corticosteroids.

Antibiotics should be administered at the highest dose consistent with the patient's physiologic condition. In general, the maintenance dose and interval should be based on the half-life of the agent and the expected clearance. With antibiotics that have narrow therapeutic windows, such as the aminoglycosides, serum concentrations should be monitored to prevent toxicity. The duration of antibiotic therapy in patients with bacteremia varies with the host and the specific organism. Guidelines have been developed through experience or clinical trials, but the duration of parenteral therapy requires clinical judgment. An exception is *S. aureus* bacteremia, for which 2 weeks of parenteral antistaphylococcal therapy is recommended in a normal host with a removable focus of infection. The greatest risk of inadequate therapy for staphylococcal bacteremia is the development of endocarditis or osteomyelitis. With bacteremic pyelonephritis, parenteral antibiotics can be discontinued when the patient is afebrile and clinically stable. In the febrile patient with neutropenia, parenteral antibiotics should be continued until the neutropenia resolves. If blood culture gives positive results, the duration of antibiotic therapy should be 14 days, even if neutropenia resolves. Patients with bacteremic pneumonia can be switched from parenteral to oral therapy when fever and toxicity abate. Patients with bacteremia should be monitored carefully for evidence of metastatic foci of infection, such as meningitis, endocarditis, osteomyelitis, and arthritis.

In addition to appropriate antibiotics, the management of bacteremia complicated by shock requires supportive care to alter the physiologic effects of sepsis. Initially, aggressive fluid replacement is necessary to reverse the cardiovascular collapse that can accompany shock. Saline is as effective as colloid solutions. Adequate volume replacement can best be determined by monitoring the pulmonary arterial wedge pressure with a pulmonary artery (Swan-Ganz) catheter in a critical care unit. Pulmonary artery wedge pressures should be maintained between 12 and 18 mm Hg.

Failure of adequate fluid administration to reverse hypotension is an indication for the use of vasopressors, such as dopamine. In doses below 5 g per kilogram per minute, dopamine increases renal artery and mesenteric blood flow. At higher infusion rates (5 to 10 g per kilogram per minute), dopamine exerts β -adrenergic effects; at rates above 10 g per kilogram per minute, α -adrenergic effects predominate. If dopamine fails to raise blood pressure, norepinephrine should be administered. Dobutamine and isoproterenol can be used to increase cardiac output, but they should not be given alone because they diminish peripheral vascular resistance.

Many patients with septic shock require intubation and mechanical ventilation to correct hypoxia. Intubation should be considered for patients with a Pa O₂ below 50 to 60 mm Hg despite supplemental oxygen or increasing respiratory muscle fatigue. A careful balance must be maintained between excessive positive end-expiratory pressure, causing barotrauma, and a high fraction of inspired oxygen, leading to oxygen toxicity.

Improvement in disseminated intravascular coagulation and the acidosis stemming from hypoperfusion results from control of infection and restoration of hemodynamic status. For this reason, only rarely is sodium bicarbonate or heparin indicated. In patients with severe depletion of clotting factors or platelets, infusion of fresh frozen plasma or platelets can be used to stop serious bleeding until the underlying infection is controlled.

One of the most exciting but controversial issues in the treatment of sepsis is the use of therapies aimed at blocking the deleterious effects of exogenous and endogenous mediators of sepsis (endotoxin, TNF, IL-1). Despite initial optimism, none of the controlled clinical trials using such agents provided a therapeutic benefit to all enrolled patients. With subgroup analysis, however, the evidence suggests that blocking mediators of sepsis might be of therapeutic value.

Monoclonal antibodies directed at the lipid A component of endotoxin have been the most rigorously investigated. E5 is a murine antibody and HA-1A is of human origin. Initially, HA-1A appeared to be effective in limiting mortality rates, and E5 seemed to be effective in minimizing organ dysfunction in patients with gram-negative bacteremia, but subsequent studies could not reproduce these initial results. The most recent large, multicenter, placebo-controlled trial with HA-1A failed to show improvement in the 14-day mortality rate in patients with gram-negative bacteremia and septic shock. There was a trend toward increased mortality rates among patients treated with HA-1A who had gram-positive bacteremia or fungemia.

Despite impressive results in animals, anti-TNF monoclonal antibodies have shown mixed results in humans. In a large multicenter study, anti-TNF antibodies were of no benefit in patients without circulatory (hemodynamic) collapse, but there was a reduction in mortality rates among patients with septic shock. Because of the different doses used, a statistically significant difference was not established, and another trial evaluating this agent is under way.

An IL-1 receptor antagonist (IL-1RA) has been shown to improve mortality rates in animal models of infection. In one large, multicenter, placebo-controlled trial, there was no benefit to IL-1RA in all patients enrolled or in the subgroup with shock. A retrospective review of this study found that IL-1RA lowered mortality rates in patients whose predicted mortality rate by APACHE III exceeded 24%. A prospective trial will be needed to confirm the usefulness of this agent in this subset of patients.

A recombinant protein has been developed that corresponds to the amino-terminal 23-kd fragment of BPI (rBPI₂₃). This protein has established antibacterial properties and has neutralized LPS activity in vitro. In animal models of sepsis, rBPI₂₃ has prevented binding of LPS to monocytes, thereby inhibiting the release of inflammatory cytokines. Experimental studies suggest that monoclonal antibodies directed at CD14 protect rabbits against organ injury and death after exposure to LPS. Additional animal studies and, ultimately, human trials will be necessary to evaluate the efficacy of these proteins in sepsis.

PREVENTION OF BACTEREMIA

The physician can do little to prevent bacteremia in community-acquired infections other than to administer prophylactic antibiotics to patients with valvular heart disease undergoing elective procedures associated with bacteremia. It is not as clear that patients with prosthetic joints should be treated in a similar fashion. There is increasing evidence that patients receiving chemotherapy who show signs of neutropenia are protected in part by prophylactic antibiotics; however, this benefit is counterbalanced by the increased risk of selection of resistant organisms. Widespread use of quinolones for prophylaxis has been associated with intensifying resistance to this class of antibiotics in *E. coli* and coagulase-negative staphylococci. In addition, the use of these agents predisposes patients with neutropenia to streptococcal bacteremia. More worrisome is the indiscriminate use of these and other antibiotics, which may lead to the dissemination of multidrug-resistant bacteria among the general population.

Nosocomial bacteremias can be limited by the recognition of known risk factors and adherence to proper infection-control procedures. An important vector for the transmission of nosocomial pathogens is the hands of hospital personnel: vancomycin-resistant enterococci can survive at least 1 hour on the hands of healthy adults and up to 1 week on environmental surfaces within the hospital. Therefore, major educational efforts and room design to facilitate hand washing can lessen the nosocomial spread of gram-negative bacilli, enterococci, and staphylococci.

The indiscriminate use of antibiotics also contributes to infection. The administration of second- or third-generation cephalosporins to hospitalized patients may predispose them to enterococcal bacteremia. In addition, pharyngeal colonization by gram-negative bacilli increases with prolonged antibiotic use; these organisms often are highly resistant to antimicrobial agents. The efficacy of antimicrobial prophylaxis before a surgical procedure is well established, but prolonged postoperative use of antibiotics should be discouraged.

Another determinant of bacteremia is the widespread use of intravenous and intra-arterial catheters. The incidence of local infection associated with vascular catheters varies from 4% to 57%, and the rate of bacteremia ranges from 4% to 14%. Infection rates increase with the length of time catheters are left in place. Guidelines regarding the proper use and maintenance of these devices have been published.

Various therapeutic methods used in the care of critically ill patients have been implicated as risk factors for bacteremia. Ventilatory equipment, nebulizers, pressure transducers, hyperalimentation fluids, blood, disinfectants, and irrigation fluids all have been associated with nosocomial infection. The advent of disposable equipment, appropriate sterilization, and single-use bottles and vials have helped control this problem. Patients infected or colonized with resistant organisms should be isolated according to standard infection-control procedures. Patients with enteric infections, draining wounds, and respiratory tract infections also require isolation. Standard guidelines outlining the proper methods of isolation and cohorting of patients during an outbreak have been published.

A surveillance program led by a knowledgeable physician is necessary for optimal infection control. Ongoing monitoring of bacterial flora causing nosocomial infections, their antimicrobial susceptibility, and the location of such infections can detect an early outbreak and prevent large or prolonged problems. The infection-control department must be committed to education, have authority, and be actively supported by hospital staff and administration. Prevention of infection and bacteremia in the hospital is difficult but necessary. Patients admitted to the hospital are increasingly ill, have more complex problems, and require aggressive support. Not all infections and bacteremias can be prevented, but careful attention to proper infection-control procedures can help manage this major problem.

CHAPTER 269: APPROACH TO THE PATIENT WITH RECURRENT INFECTIONS

BURKE A. CUNHA

[Clinical Approach](#)
[Nonimmune-Mediated Recurrent Infections](#)
[Immune-Mediated Recurrent Infections](#)
[Immunodeficiency Screening Tests](#)

Recurrent infections are defined as repeated infections due to the same or different microorganisms, which may be immunologically or nonimmunologically related. Recurrent infections may be due to reinfection or relapse. Relapse refers to recurrent infection by the same organism, whereas reinfection refers to repeated infections caused by different microorganisms. Recurrent infections must be differentiated from coincidental recurrences that appear to have a recurrent pattern, for example, viral upper-respiratory tract infections. Furthermore, many multisystem disorders are characterized by exacerbations and remissions that mimic recurrent infections, among them, sarcoidosis and systemic lupus erythematosus. Noninfectious conditions that mimic recurrent infections are very common. Most recurrent infections are not immunologically mediated.

GENERAL CONCEPTS

Immunologically based recurrent infections are uncommon. Immunodeficiency disorders causing recurrent infections may be congenital or acquired. Acquired immunodeficiency syndromes are encountered more often in clinical practice (e.g., HIV-, drug-induced, malignancy-associated conditions), whereas congenital primary immunodeficiencies are very rare. Historical clues to immune-mediated, recurrent infections include repeated infections by encapsulated organisms or unusually severe, persistent infections by low-virulence hallmark organisms that are always associated with impaired host defenses, among them, invasive aspergillosis, *Pneumocystis carini* pneumonia (PCP), and *Toxoplasma* meningoencephalitis. Immune-deficiency screening tests should not be undertaken for patients with coincidental or clustered recurrences of infection, especially those with repeated upper-respiratory viral illnesses. Immunologically mediated recurrent infections have characteristic histories and patterns of infection due to specific microorganisms. Screening for immune defects should be obtained only if there is an appropriate antecedent history of infectious pathogens associated with immunodeficiencies.

CLINICAL APPROACH

The most common recurrent infections are meningitis, otitis, pharyngitis, pneumonia, urinary tract infection, cellulitis, device-related infections, and chronic osteomyelitis. Recurrent meningitis may have an immune or nonimmune source. Most recurrent infections encountered by the internist are associated with structural defects, foreign bodies, inadequately drained abscesses, inadequate antimicrobial therapy (inadequate spectrum, dose/duration, or tissue penetration).

After coincidental recurrences have been eliminated from diagnostic consideration, noninfectious conditions that resemble recurrent infections should be ruled out. The differential diagnosis of noninfectious mimics of recurrent infection is best approached from a regional or organ system perspective. In multisystem disorders (e.g., systemic lupus erythematosus), with predominant findings in one organ system, there will be evidence of disease elsewhere, which should provide clues to the origin of the primary disease process. After eliminating recurrent infectious sources that are not immunologically mediated, the diagnostic approach should be directed toward immunologically based disorders. Either the pattern of organ involvement or the type of microorganism should suggest a defect in humoral (HI) or cell-mediated immunity (CMI).

NONIMMUNE-MEDIATED RECURRENT INFECTIONS

Urinary tract infections are a common cause of recurrent infection. Recurrent cystitis is usually due to repeated reinfection, but chronic prostatitis/pyelonephritis, genitourinary anatomical defects, and stones are prone to relapse. Recurrent pharyngitis is usually viral in origin and not due to group A streptococci (GAS). GAS frequently colonize patients with viral pharyngitis. The finding of GAS by rapid antibody testing or culture does not distinguish colonization from infection. Recurrent GAS colonization is a common problem among teachers and caretakers of children. Look for a viral source underlying *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, or recurrent pharyngitis with/without GAS colonization. Chronic osteomyelitis in the context of diabetes is one of the most common recurrent infections in adults. Chronic, deeply penetrating ulcers or draining sinus tracts are indicative of chronic osteomyelitis, which can be cured only by adequate surgical debridement. Infections associated with foreign bodies or prosthetic materials usually cannot be relieved by antimicrobial therapy—surgical removal is necessary.

IMMUNE-MEDIATED RECURRENT INFECTIONS

The medical history is important in establishing the pattern of recurrent infections due to immunity defects. Children with CMI problems often have initial signs of severe varicella, invasive fungal infections, or acute reactions to live vaccines. Older children and adults have histories of anergy or several malignancies. Children and adults with conditions related to CMI typically have recurrent infections due to intracellular organisms (herpes simplex, PCP, *Listeria*, *Aspergillus*).

Children with humoral defects often have a long history of recurrent sinopulmonary infections, meningitis, bacteremias, diarrhea, or cellulitis. Adults frequently give a family history of severe or recurrent infections, autoimmune diseases, or B-cell malignancies. Children and adults with HI defects have unusually severe infections due to common organisms (*Giardia*, enteroviruses, *Mycoplasma pneumoniae*) or repeated infection due to encapsulated organisms (*Neisseria meningitidis*, *Streptococcus pneumoniae*, or *Haemophilus influenzae*). The history together with the type of organism determine whether the recurrent infection is based on an HI or a CMI defect ([Table 269.1](#)).

TABLE 269.1. CLINICAL APPROACH TO THE PATIENT WITH RECURRENT INFECTIONS

IMMUNODEFICIENCY SCREENING TESTS

Tests for HI deficiencies should identify antibody, complement, or phagocytic defects. Antibody defects are the most common and are identified by quantitative serum immunoglobulins. Serum IgA levels are the single most important determination, because they are depressed in all immunodeficiency disorders with significant antibody defects. HI may also be assessed by measuring IgG antibody titers to protein/polysaccharide vaccines. Patients with defective or inadequate antibody responses will have low titers (or none at all) after common immunizations (diphtheria, tetanus, *Haemophilus*, *Streptococcus pneumoniae*). IgG subclass determinations should not be part of the antibody defects workup. Since IgG subclass deficiencies are associated with autoimmune diseases, not infectious diseases, complement defects can be screened by the serum CH 50 level. If the CH 50 level is low, the individual complement components (C2, C3 and C4) can be measured.

Terminal components of the complement cascade (C6-7) are associated with recurrent *Neisseria* infections. Phagocytic defects in HI can be detected by the white blood cell and differential count, which provides a quantitative measurement of circulating phagocytes. The nitroblue tetrazolium reduction test is used to assess phagocyte function. A serum IgE level is also helpful in identifying hyperimmunoglobulin E syndrome (Job's syndrome). CMI requires intact T-lymphocyte and macrophage function and can be assessed by total lymphocyte count and T-lymphocyte subsets. Anergy testing for impaired delayed-type hypersensitivity with PPD or *Candida* should be undertaken for patients with suspected CMI defects. HIV serologic studies should be carried out for patients who might have HIV. The focus of the diagnostic approach is to arrive at a definitive diagnosis of the immunodeficiency disorder responsible for recurrent infections after other causes have been excluded. The diagnosis of immunodeficiency disorders is syndromic ([Table 269.2](#)).

TABLE 269.2. SYNOPSIS OF IMMUNODEFICIENCY SYNDROMES CAUSING RECURRENT INFECTIONS AND ASSOCIATIONS

TREATMENT

The treatment for nonimmune recurrent infections is appropriate antibiotic therapy. Consideration should be given to the location of the infection and to whether the infection is intracellular, extracellular, or in a protected location. Pharmacokinetic considerations regarding intracellular tissue penetration are important in selecting optimal antimicrobial therapy. The duration of treatment is also important; it is prudent to treat patients with congenital or acquired immunodeficiency disorders for longer periods of time than usually are recommended.

Patients with some antibody deficiencies can be treated with intravenous gamma globulin therapy. Immunoglobulin replacement therapy is most useful in patients with agammaglobulinemia, antibody deficiencies with near normal immunoglobulin concentrations, Wiskott-Aldrich syndrome, severe combined immunodeficiency, and X-linked immunodeficiency with increased levels of IgM. Intravenous immunoglobulin preparations contain primarily IgG, and 400 mg per kilogram per month should be administered to approximate physiologic IgG levels. It is not possible to replace defects in secretory IgA with immunoglobulin therapy. Serum immunoglobulin contains very little IgA, and immunoglobulin therapy is contraindicated for IgA deficiency because of the high incidence of anti-IgA antibodies in intravenous immunoglobulin.

Primary immunodeficiency syndromes with CMI defects can be treated by bone marrow transplantation. The main concern of prolonged immunosuppression or treatment with chemotherapy is the development of subsequent malignancies. Patients with HIV have relapsing, recurrent infections. The infecting microorganisms are predictable by the degree of impaired CMI, as measured by the CD4 count. Prophylaxis or early treatment of infections in HIV/AIDS patients minimizes further T helper lymphocyte loss. Antigenic-induced stimulation of the immune system should be avoided in HIV patients. Purified protein derivative (PPD) testing also should not be undertaken in HIV patients, since it results in rapid destruction of T helper cells, hastening the patient's demise. Since most HIV patients are anergic, there is no point to PPD testing; tuberculosis should be diagnosed in other ways (sputum, blood, bone marrow, AF smears/culture).

CHAPTER 270: ENDOCARDITIS, INTRAVASCULAR INFECTIONS, PERICARDITIS, AND MYOCARDITIS

C. GLENN COBBS AND MICHAEL SACCENTE

Infective Endocarditis
Suppurative Thrombophlebitis
Myocarditis and Pericarditis

INFECTIVE ENDOCARDITIS

DEFINITION

Infective endocarditis (IE) refers to microbial invasion of the endocardium, including both valvular and nonvalvular surfaces. The term *infective endocarditis* is preferred to the older term *bacterial endocarditis* because the latter ignores microbial pathogens, such as rickettsiae, mycoplasma, chlamydiae, and fungi. Previously, the terms *acute bacterial endocarditis* and *subacute bacterial endocarditis* were used to distinguish varieties of the disorder with different clinical courses. Acute bacterial endocarditis referred to a clinical entity that was rapid in onset, was associated with toxicity and early complications, and typically was caused by *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Streptococcus pyogenes*, or *Neisseria gonorrhoeae*. Subacute bacterial endocarditis described an illness with a more indolent and protracted course that was caused most often by viridans streptococci. These terms are no longer particularly useful, because there is a great deal of overlap, particularly with certain microorganisms. IE is also categorized as native valve endocarditis (NVE) or prosthetic valve endocarditis (PVE).

INCIDENCE AND EPIDEMIOLOGY

At present, the incidence of IE is approximately one case per 1,000 hospital admissions. The epidemiologic picture of IE is a function of the frequency of bloodstream invasion by pathogens and the prevalence of predisposing endocardial diseases. In developed countries during the past 50 years, there have been important changes in the sources of bacteremia and the prevalence of underlying endocardial lesions. The average age of patients with IE has increased from 35 in the era before antibiotics to the current mean age of about 55. This trend reflects the declining prevalence of rheumatic heart disease, the growing prevalence of degenerative valvular lesions, and the increased use of procedures in older patients that predispose to bacteremia. Mitral valve prolapse has been recognized more frequently as a predisposing lesion, especially in older men. Patients with the murmur of mitral regurgitation and/or valvular redundancy and thickening on echocardiography appear to be at highest risk.

Other factors that have resulted in changes in the epidemiologic characteristics of IE include the increased use of intravascular or intracardiac devices, such as prosthetic valves, pacemaker wires, pulmonary artery catheters, hemodialysis shunts, and intravenous catheters. Nosocomially acquired IE is becoming more prevalent. Parenteral drug use continues to be a significant problem in our society, and approximately 25% of patients with IE have injected illicit drugs. One episode of IE predisposes to a subsequent episode, and as increasing numbers of patients survive first episodes of IE, more cases of recurrent IE are being seen.

ETIOLOGY AND BACTERIOLOGY

Before 1960, *S. viridans* caused 60% to 70% of episodes of NVE, and staphylococci were responsible for 15% to 20% of cases; other microorganisms were less common. Since the 1970s, the percentage of cases caused by viridans streptococci has declined to about 35% (Table 270.1). The incidence of cases of staphylococcal and enterococcal IE has risen to account for 25% and 10% of cases, respectively.

Microorganism	Incidence (%)		
	NVE	Early PVE	Late PVE
Streptococci	50	10 ^a	30
Viridans	35	—	25
<i>S. bovis</i>	15	—	5
Enterococci	10	—	5
Staphylococci	25	50	40
<i>S. aureus</i>	22	15	10
Coagulase negative	2	35	30
Gram-negative bacilli	6	15	10
Diphtheroids	—	10	5
Fungi	1	10	5
Other and culture negative	8	5	5

NVE, native valve endocarditis; PVE, prosthetic valve endocarditis.
^a Incidences are approximate; local experience will vary.
^b Includes all streptococci and enterococci.

TABLE 270.1. MICROBIAL ORIGIN OF NATIVE AND PROSTHETIC VALVE INFECTIVE ENDOCARDITIS^a

Streptococci

Overall, streptococci are still the most commonly reported cause of NVE, with viridans streptococci predominating. About 80% of patients have underlying cardiac disease. Viridans streptococci are normal oral flora that gain access to the bloodstream through breaches in the oral mucosa. *Streptococcus bovis* IE is associated with bowel lesions, including colon cancer, and isolation of this organism from the blood should prompt an evaluation of the gastrointestinal tract. Ninety percent of patients with streptococcal IE are cured with appropriate therapy.

Enterococci

Enterococci are reported more and more often as the cause of IE. Older men undergoing genitourinary procedures, women undergoing gynecologic procedures, and parenteral drug users are at particular risk. The course is usually subacute but can be aggressive. Forty percent of patients have no known underlying heart disease.

Staphylococci

Overall, staphylococci cause 25% of cases of NVE; 90% are due to *S. aureus*. In some community hospitals, *S. aureus* is the most common microbe associated with IE. No previous valvular abnormality is found in about one-third of patients. The clinical course is often acute, and the mortality rate is 25% to 40% in non-addicts with mitral or aortic valve disease. In parenteral drug users with right-sided valvular infection, the clinical course is often less fulminant, and the prognosis is quite good. Complications more typically accompany *S. aureus* endocarditis than IE provoked by other bacteria; they include myocardial abscess, valve ring abscess, conduction defects, purulent pericarditis, and peripheral emboli. Metastatic suppuration in the brain, kidney, or spleen is seen in up to 40% of patients with left-sided *S. aureus* IE. Coagulase-negative staphylococci are the most prevalent source of PVE. They are unusual in the context of NVE.

Aerobic Gram-negative Bacteria

Aerobic gram-negative bacteria cause 5% to 10% of cases of IE. Intravenous drug abusers and patients with prosthetic valves are at greatest risk. When Enterobacteriaceae or *Pseudomonas aeruginosa* infect left-sided valves, the clinical course is frequently acute, and the mortality rate is high. The acronym HACEK is used to designate a special group of fastidious, aerobic, gram-negative bacteria that produce a characteristic clinical variety of NVE. This group includes *Haemophilus* species, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella* species. Clinical features include previous valvular

disease, a subacute clinical course, embolic complications, large vegetations, and the frequent need for valve replacement.

Culture-negative Endocarditis

In 5% to 10% of patients with presumed IE, no etiologic microorganism is isolated from blood. The usual reason for this inability to identify the responsible microorganism is previous antimicrobial therapy. Fastidious microorganisms, such as HACEK group bacteria, nutritionally deficient streptococci, anaerobic bacteria, bartonellae, rickettsiae (*Coxiella burnetii*), and fungi, may not be detected with routine culture methods. When culture-negative IE is suspected, the clinician should discuss the case with clinical microbiology laboratory personnel. Appropriate use of special culture media and techniques and serologic studies can help identify the source of IE in some patients with negative results on blood culture. For example, the lysis centrifugation technique increases the yield of blood cultures in IE caused by intracellular fungi.

PATHOGENESIS

The initiating event in the pathogenesis of IE is disruption of the endocardial surface; this leads to exposure of underlying collagen, to which platelets and fibrin adhere to form a sterile platelet/fibrin complex. The endocardial surface is disrupted by turbulent blood flow caused by acquired (rheumatic heart disease, degenerative valvular disease) or congenital valvular lesions. Direct endocardial injury can occur with central intravenous catheters, pacemaker wires, or other intravenous devices that reside in the heart. IE results when circulating microorganisms colonize the endocardial surface.

Microorganisms (usually bacteria) can invade the blood in several ways. In some instances, bloodstream invasion results from microbial extension past local anatomic barriers (skin, mucous membrane, and subcutaneous tissues) to lymphatics and the thoracic duct. A second mechanism of invasion is direct inoculation into capillaries and venules, as happens during dental or periodontal surgery. Bacterial adherence to a platelet/fibrin complex depends on the interaction between bacterial surface components and tissue receptors and may vary considerably for different bacteria. Staphylococci and streptococci possess the virulence factors necessary for adherence (the FimA surface protein of oral streptococci) more often than enteric gram-negative bacilli.

CLINICAL FEATURES

Clinical features of IE reflect host responses to acute or subacute heart valve inflammation, complicated by microbial invasion of the bloodstream, altered cardiac physiology due to valve damage, and remote tissue injury caused by immune complex disease, emboli, ischemia, and infarction.

History

There may be a history of underlying heart disease and a preceding bacteremic event, such as dental work, instrumentation of the gastrointestinal or genitourinary tract, or parenteral drug use. Fever is present in more than 90% of patients. Most patients with subacute disease have other nonspecific symptoms, such as malaise, arthralgias, myalgias, and fatigue. Symptoms of heart failure are present in about 50% of patients with NVE. Emboli to the lungs or abdominal organs may provoke chest or abdominal pain.

Physical Examination

Most patients with left-sided valvular disease have heart murmurs at some point in their illness, but they may not be evident initially. Classic peripheral signs of IE include petechiae, Roth's spots (oval retinal hemorrhages), splenomegaly, clubbing, Osler's nodes (painful, purple to red nodules found on the pads of the fingers or toes), linear splinter hemorrhages beneath the fingernails or toenails, and red, macular Janeway lesions on the palms or soles.

LABORATORY FINDINGS

Blood Cultures

Blood culture is the most important laboratory test for the diagnosis of IE. Bacteremia associated with IE is typically low grade and constant. One of the first two sets of blood cultures yields the etiologic bacteria in 90% of patients. At least three sets of blood cultures should be obtained within the first 24 hours from patients suspected of having IE.

Other Laboratory Tests

Several nonspecific laboratory test abnormalities can be found in patients with IE; they generally reflect inflammation and/or immune injury. Anemia of chronic disease occurs in about 80% of patients with IE and is more likely to be present in patients with subacute disease. Leukocytosis, unusual in the context of subacute IE, is more likely to develop in acute endocarditis due to staphylococci, pneumococci, or gonococci. The sedimentation rate is generally elevated. IgM antibody against IgG (rheumatoid factor) has been confirmed in almost half of patients with subacute IE. Concentrations of C-reactive protein and circulating immune complexes have been used in monitoring response to therapy. Patients with IE may have abnormal results of urinalysis, including hematuria in about 40% and proteinuria in 50%. These abnormalities reflect immune complex injury and infarction.

Echocardiography

Echocardiography has proved very useful in the diagnosis of IE. Transthoracic echocardiography shows vegetations in about 50% to 60% of patients with IE diagnosed clinically. Transesophageal echocardiography (TEE) is more accurate, with a sensitivity approaching 90%. TEE more readily identifies small vegetations and vegetations on pulmonary and prosthetic valves. A single negative TEE result does not exclude IE, but more than one negative result has a high negative predictive value. Echocardiography is also useful for defining the severity of valvular destruction, detecting complications (fistula, myocardial abscess, and proximal aortic mycotic aneurysm), and assessing the hemodynamic effects of IE. TEE is more sensitive than transthoracic echocardiography for identifying myocardial abscess. Some investigators have found that the presence, size, and mobility of vegetations correlate with adverse events, including arterial emboli, heart failure, valve destruction, and death.

DIAGNOSIS

The gold standard for diagnosis of IE is histopathologic and/or microbiologic analysis of a vegetation obtained surgically or at autopsy. Because the majority of patients with IE do not undergo surgery, the antemortem diagnosis of IE typically depends upon clinical features, especially evidence of endocardial involvement, immunologic and vascular phenomena, and blood culture positivity. In 1981, von Reyn and colleagues proposed criteria for the diagnosis of IE based upon strict case definitions. These criteria do not include a category for definitive IE based solely on clinical data. Apparent shortcomings of the von Reyn criteria include the failure to consider parenteral drug use as an underlying condition, failure to use echocardiographic findings in diagnosis, difficulty classifying acute cases, and lack of prospective validation.

In 1994, Durack and colleagues at Duke University proposed diagnostic criteria that include a category of definitive IE based solely on clinical findings ([Table 270.2](#)). The von Reyn and Duke criteria have been directly compared in several large studies. The Duke criteria consistently classify more cases as definite and are more sensitive for the diagnosis of pathologically proven IE. The Duke system also appears to be highly specific in diagnosing IE.

Major criteria
 Positive blood culture results for infective endocarditis
 Typical echocardiogram features from separate blood cultures
 Positive serologic studies in acute, HACEK groups, or congenitally acquired bacterial endocarditis or subacute bacterial endocarditis
Minor criteria
 Predisposing condition (alcohol use, intravenous drug use, or immunosuppression) suggestive of infective endocarditis
 Blood culture drawn more than 12 hours apart
 All three of a majority of four or more peripheral blood cultures, with the first and last drawn at least 1 hour apart
 Evidence of embolic phenomena
 Echocardiogram showing non-commissural vegetations on the absence of alternative etiologic explanations, abscesses, or other cardiac abnormalities on a gross/atomic basis
 New valvular regurgitation (increase or change in previously documented regurgitation)
Minor criteria
 Predisposing factor (alcohol use, intravenous drug use, fever, or IV drug use)
 Valvular perforation
 Intracardiac abscesses
 Microbiologic evidence not meeting a major criterion or minor criteria
 Consistent echocardiogram not meeting a major criterion
 * IE is classified as definite if two major and three minor, or five major criteria are met or if two major and three minor criteria are met and pathologic criteria are shown in this patient.
 † From Shoenberger, JT, Libman MC, Bhatnagar J. New criteria for diagnosis of infective endocarditis: Update on the current state of the art. *Circulation* 2000;102:598-604.

TABLE 270.2. DUCK CRITERIA FOR THE CLINICAL DIAGNOSIS OF INFECTIVE ENDOCARDITIS^a

SPECIAL SITUATIONS

Infective Endocarditis Associated with Parenteral Drug Use

The microbiologic and anatomic features of IE in intravenous drug users are shown in [Table 270.3](#). Most cases occur in patients with no previously recognized valvular abnormality. *S. aureus* is the most common causative agent and most often infects the tricuspid valve. The microbiologic picture of IE provoked by gram-negative bacilli in intravenous drug users has shown geographical and temporal variation. For example, outbreaks of IE due to *P. aeruginosa* have occurred in Detroit and Chicago, while IE caused by *Serratia marcescens* seems to be unique to San Francisco.

Bacteria	Number of Cases (% of Total)	Valve Involved		
		Right	Left	Mixed
<i>Staphylococcus aureus</i>	45 (51)	40	3	2
Oxacillin susceptible	27 (30)	25	1	1
Oxacillin resistant	18 (20)	15	2	1
Streptococci	10 (13.5)	3	7	0
Enterococci	2 (2.7)	2	0	0
<i>P. aeruginosa</i>	10 (13.5)	3	2	5
<i>Corynebacterium JK</i>	1 (1.4)	1	0	0
Polymicrobial	6 (9)	4	1	1

^aBased on 74 cases from 1982 to 1983. (From Levine DP, Crane JK, Zieror M. Bacteremia in narcotic addicts at the Detroit Medical Center. II. Infectious endocarditis: a prospective comparative study. *Rev Infect Dis* 1986;8:374, with permission.)

TABLE 270.3. ETIOLOGY AND ANATOMY OF INFECTIVE ENDOCARDITIS ASSOCIATED WITH INTRAVENOUS DRUG ABUSE IN THE UNITED STATES^a

Patients with tricuspid IE due to *S. aureus* typically experience acute onset of fever, pleuritic chest pain, dyspnea, and cough. A systolic murmur is usually heard, but classic signs of tricuspid regurgitation are present in at most 50% of patients at the time of admission. The initial chest radiograph shows abnormal results in about two-thirds of cases and may show nodular opacities, abscesses with cavitation, patchy areas of pneumonitis, or pleural effusions. Left-sided IE takes much the same form as IE in other populations. Infection of valves on both sides of the heart by *P. aeruginosa* is associated with severe illness and high mortality rates. The overall mortality rate associated with IE in intravenous drug users is less than 10%. This observation is best explained by the relatively good prognosis of tricuspid IE compared with left-sided IE and the relatively young age of these patients compared with other patients with IE.

Prosthetic Valve Endocarditis

PVE develops in about 2% of patients after valve replacement. About one-third become ill within the first 2 months after surgery (early PVE) and two-thirds after this time (late PVE). The pathogenesis of early-stage PVE involves microbial colonization of the prosthesis at the time of surgery. Late-stage PVE more closely resembles NVE with regard to pathogenesis and origin ([Table 270.1](#)). Overall, staphylococci are the most common cause. Streptococci are an uncommon source of early PVE; they more often cause late disease. Gram-negative bacilli and fungi are relatively more common in PVE than in NVE.

Patients with PVE have many of the same clinical features as patients with NVE. A new or changing murmur is present initially more often in PVE, reflecting the higher incidence of local suppurative complications, such as valve ring abscess. A valve ring abscess may extend to form a myocardial abscess, septal abscess with perforation, or pericarditis. Most important, it may cause valve dehiscence. Overall, the mortality rate in PVE is 25% to 30%. The mortality rate is higher in patients with early-stage PVE and in PVE caused by gram-negative bacilli, staphylococci, or fungi.

COMPLICATIONS

Cardiac

Valvular damage resulting in hemodynamically important valvular dysfunction is the most critical cardiac complication of IE. Valvular insufficiency is most common, but in the context of large vegetations, such as those seen in fungal endocarditis and in PVE, obstruction may occur. The mechanism of valvular insufficiency in NVE is destruction of the valve itself or disruption of the valve annulus by a valve ring abscess. With aortic IE and aortic insufficiency, the stream of regurgitant flow can lead to damage, infection, and rupture of the mitral valve chordae tendineae or papillary muscles.

The most serious consequence of valvular dysfunction in patients with IE is heart failure, which is the predominant cause of death in patients with IE. The rapidity of the development of valvular insufficiency as well as the valve involved determine hemodynamic consequences. Acute IE, especially if it is associated with acute aortic insufficiency, is more likely to be hemodynamically significant than subacute disease or IE complicating chronic aortic regurgitation. Mechanisms of congestive heart failure not involving valvular dysfunction include embolic myocardial infarction, myocarditis, and conduction disturbances. Extension of a paravalvular abscess into the conduction system may produce varying degrees of atrioventricular block and bundle-branch block. These complications are prevalent in aortic valve IE because of the proximity of the aortic valve ring to the conduction system. Pericarditis is found at autopsy in 15% to 20% of patients with IE. This condition is especially common in the context of staphylococcal disease.

Extracardiac

Emboli, which arise during the course of IE in about one-third of patients, may be bland (uninfected) or septic. In left-sided IE, symptomatic emboli most often involve the spleen, kidney, brain, and heart. Emboli appear to be more prevalent in IE caused by *S. aureus*, HACEK bacteria (especially *Haemophilus parainfluenzae*), anaerobes, and fungi. In fungal endocarditis, peripheral emboli may provide the only source of diagnostic material because of the difficulty of recovering certain fungi from routine blood cultures.

Neurologic abnormalities are seen in about 30% of patients with IE, and such patients experience higher mortality rates than those without neurologic complications. Neurologic complications most frequently accompany IE due to pyogenic organisms, such as *S. aureus*, enterococci, gram-negative bacilli, and anaerobes. Clinical syndromes include embolic stroke, subarachnoid hemorrhage, brain abscess, meningitis, encephalopathy, seizure, and psychiatric disturbance. Strokes represent 10% to 15% of neurologic complications and most often occur in the middle cerebral artery distribution. Brain abscess develops infrequently, and meningitis, due to bacteremic localization in the subarachnoid space or rupture of a parameningeal focus, is unusual. Encephalitic symptoms may be due to emboli, bleeding, or

Complication	Point Rating	
	Native Valve Infection	Prosthetic Valve Infection
Heart failure		
Severe	5	5
Moderate	3	3
Mild	1	2

Unstable prosthesis	N/A	5
Early PVE	N/A	2
Periprosthetic leak	N/A	2

TABLE 270.5. POINT SYSTEM FOR ASSESSING THE NEED FOR CARDIAC SURGERY IN INFECTIVE ENDOCARDITIS^a

Treatment of Complications

Heart failure is treated in the usual manner, with afterload reduction, diuretics, and inotropic support and with surgical intervention if necessary (see later discussion). In patients with abnormal results on neurologic examination, the initial evaluation should include a thorough assessment for such systemic disorders as acidosis, hypoxia, and uremia. In most instances, computed tomography (CT) should be the initial diagnostic procedure. If no bleeding or mass lesion is noted, a lumbar puncture should be done to exclude meningitis. Angiography is indicated if cerebrospinal fluid analysis or the CT scan suggests subarachnoid hemorrhage or mycotic aneurysm.

Medical therapy alone is adequate for the treatment of mycotic aneurysms in about 30% of cases. Peripheral aneurysms, aneurysms that continue to enlarge on medical therapy, and ones that have bled should be debrided and clipped or resected if possible. This is not always feasible with aneurysms deep in the brain. An asymptomatic mycotic aneurysm in a difficult position for resection (e.g., the circle of Willis) and multiple mycotic aneurysms should be followed with another angiographic study after 1 to 2 weeks.

PROPHYLAXIS

Because of the significant morbidity and mortality associated with IE, prevention of this infection in susceptible persons has been emphasized for many years. Prophylactic antimicrobial therapy is based on two principles: bacteremia is common after certain invasive procedures, and particular patients appear to be at risk of IE after an episode of bacteremia. Although the use of prophylactic antibiotics to prevent IE is recommended in specific situations, it should be noted that no randomized, controlled trials addressing this issue have been performed among humans and that most cases of IE do not occur in association with an invasive procedure.

Prophylactic antibiotics should not be given if the risk of acquiring IE is lower than the risk of an adverse reaction to the antibiotic. The risk of bacteremia is highest for some dental and oral procedures, intermediate for genitourinary procedures, and lowest for most gastrointestinal procedures, including those that involve biopsy. Exceptions to the last generalization are esophageal dilatation and variceal sclerotherapy, both of which are associated with bacteremia rates of 30% to 40%. According to the American Heart Association, high-risk cardiac conditions include prosthetic valves, previous IE, complex cyanotic congenital defects, and surgically constructed systemic pulmonary shunts and conduits. Rheumatic heart disease and mitral valve prolapse with regurgitation are classified as moderate risk.

Antibiotic selection is directed against viridans streptococci for dental, oral, respiratory, and esophageal procedures and against enterococci for other gastrointestinal and genitourinary procedures. Amoxicillin or ampicillin is the preferred antibiotic for most patients undergoing procedures in the former category. For genitourinary or nonesophageal gastrointestinal procedures, ampicillin or amoxicillin with or without gentamicin (depending on risk) is preferred.

SUPPURATIVE THROMBOPHLEBITIS

Inflammation, clot, and microbial infection within a vein characterize suppurative thrombophlebitis. Thrombophlebitis may develop in a previously normal vein or in association with an indwelling device, usually an intravenous catheter. It is more likely to occur the longer the intravenous device is left in place. Symptoms and signs associated with suppurative thrombophlebitis vary. In a few instances, there is no observable abnormality at the intravenous site; in others, there is mild erythema, pain, edema, and tenderness. Some patients may have frank pus at the intravenous site, which can be expressed from the vein after removal of the device. Because most intravenous catheters are placed in an upper extremity, this is the most common site of disease, and 90% of such patients have evidence of inflammation at the catheter site. In patients with severe burns, suppurative thrombophlebitis is frequently not apparent, even though there may be extensive clot and infection. Patients with suppurative thrombophlebitis involving a central venous catheter often show initial signs of sepsis.

Pelvic vein thrombophlebitis may develop in a previously normal vein as a complication of septic abortion, pelvic inflammatory disease, or the process of giving birth. The usual symptoms include fever accompanied by nausea and abdominal pain (usually the right-lower quadrant). Eighty percent of cases involve right-sided veins alone, and in about 15% of patients thrombophlebitis is bilateral. Only 5% of cases involve left-sided vessels alone.

Staphylococci (including coagulase-negative species) are the most common microorganisms responsible for catheter-related suppurative thrombophlebitis; gram-negative bacilli, enterococci, and *Candida* are also encountered. The incidence of suppurative thrombophlebitis due to *Candida* seems to be on the rise. Aerobic gram-negative bacilli and enterococci are more often responsible in patients with intra-abdominal venous thrombosis. In pelvic suppurative thrombophlebitis, anaerobic organisms, aerobic gram-negative bacilli, and streptococci predominate.

Bacteremia and inflammation or suppuration at an intravenous site support the diagnosis of suppurative thrombophlebitis. The diagnosis is substantiated if the same microorganism is isolated from the blood and catheter site exudate or if differential quantitative blood cultures or semiquantitative catheter cultures implicate the catheter as the source of bacteremia. Bacteremia is documented in 80% to 90% of patients, except in pelvic suppurative thrombophlebitis, where blood cultures show positive results in 20% to 30% of cases. For large central veins (abdominal or pelvic veins or the superior vena cava), venography or CT is useful for diagnosis.

Treatment of suppurative thrombophlebitis associated with an intravenous catheter begins with removal of the device. Further therapy almost always requires a combination of surgical and medical management. The surgical procedure of choice is venotomy and exploration plus removal of the affected segment. Excision is generally followed by defervescence within 24 hours. Initial antimicrobial therapy should include vancomycin plus an antibiotic likely to be active against nosocomial gram-negative bacilli, such as an aminoglycoside or ceftazidime. For central vein or pelvic vein suppurative thrombophlebitis, medical therapy alone is often effective. In the latter case, high doses of penicillin G plus an additional antianaerobic agent (metronidazole) or a b-lactam/b-lactamase inhibitor combination is usually effective. Heparin is often used in patients with pelvic or central vein suppurative thrombophlebitis. When *Candida* is the causative microorganism, excision plus amphotericin B (about 500 mg total) or intravenous fluconazole is recommended.

MYOCARDITIS AND PERICARDITIS

Infective myocarditis and infective pericarditis may be caused by a wide variety of microorganisms (Table 270.6). Many agents produce both myocarditis and pericarditis, but often only one of the syndromes predominates in terms of clinical symptoms. The most commonly identified cause of myocarditis in immunocompetent hosts is coxsackievirus B, an enterovirus. Several lines of circumstantial evidence link viral myocarditis with the later development of idiopathic dilated cardiomyopathy.

Category	Organism
Viral	Coxsackievirus B1, B2, B3, B4, B5, B6

TABLE 270.6. INFECTIOUS CAUSES OF MYOCARDITIS AND PERICARDITIS

The pathogenesis underlying enteroviral myocarditis is not completely understood, but evidence from animal models suggests that direct myocardial damage by the pathogen is followed by a host inflammatory response that persists after the virus is eliminated. Using techniques such as the polymerase chain reaction and in situ hybridization, enteroviral genomic sequences have been identified in myocardial tissue from patients with myocarditis. HIV-1 sequences have been detected in myocardial tissue from patients with HIV-1 infection and left ventricular dysfunction. In patients with Chagas' disease, *Trypanosoma cruzi* causes direct myocardial injury. Other mechanisms include damage by a toxin, as in diphtheria, and damage due to immunologic injury, as in acute rheumatic fever.

Symptoms of viral myocarditis include fever, fatigue, malaise, dyspnea, palpitations, and chest pain. Patients often report symptoms suggestive of antecedent viral illness. Physical examination typically finds nonspecific symptoms, such as fever and tachycardia and, in severe cases, congestive heart failure. Atrial and ventricular dysrhythmias and conduction defects are common electrocardiographic abnormalities in patients with viral myocarditis. Cardiac troponin I levels are more likely to be elevated in patients with biopsy-proven myocarditis than creatine kinase-MB levels. Magnetic resonance imaging and nuclear scanning with gallium 67 or indium-labeled antimyocyte antibodies are potentially useful diagnostic methods.

Only endomyocardial biopsy can confirm active myocarditis, but this procedure is subject to sampling error because myocardial involvement may be patchy. Viruses rarely have been isolated from biopsy specimens, and molecular diagnostic tests generally are not available for clinical use. In practice, the diagnosis of viral myocarditis is made when the clinical course is consistent, the virus is isolated from another site (oropharynx or stool), and there is a fourfold or greater rise in specific antiviral IgG antibody titers. Extracardiac manifestations of infection may implicate the causative agent in cases of nonviral myocarditis.

Antiviral agents as a rule are ineffective in the treatment of viral myocarditis. Because vigorous physical activity has been shown to worsen myocyte damage in animal models, supportive care of patients with myocarditis includes bed rest. Angiotensin-converting enzyme inhibitors and diuretics are the mainstays of therapy for those with congestive heart failure. Immunosuppression with prednisone and azathioprine or cyclosporine has not been shown to be beneficial. Immunosuppression should be reserved for patients with disease that is refractory to conventional measures. Cardiac transplantation can be considered for patients who fail all other therapies. Nevertheless, 1-year survival rates among patients who have undergone transplantation for myocarditis are lower than those among patients who have had the procedure for other reasons. Overall, 56% of patients enrolled in the Myocarditis Treatment Trial either died or had undergone transplantation when assessed at 5-year follow-up. For myocarditis caused by nonviral agents, effective antimicrobial agents are usually available.

Many patients with myocarditis also have pericarditis, especially with viral disease. Pericarditis results from hematogenous spread of the microorganism to the pericardium or contiguous spread to the pericardium from a site in the heart or within the chest. Formerly, bacterial pericarditis developed as a complication of pleuropulmonary disease, and pneumococci, other streptococci, staphylococci, and *H. influenzae* were the most common causative organisms. Since the advent of effective antibacterial therapy, bacterial pericarditis has become less common and is now primarily a nosocomial disorder. Bacteremia, postoperative wound infections, and endocarditis each account for about 25% of cases today. Antecedent noninfectious pericardial effusions predispose patients to bacterial pericarditis. Tuberculous pericarditis is seen in about 1% of patients with tuberculosis and is usually the result of spread from disease in a mediastinal lymph node. Fungal pericarditis, except for cases due to *Histoplasma*, is usually seen only in severely immunocompromised patients.

Chest pain may be absent, and clinical deterioration may be rapid in acute bacterial pericarditis, but in tuberculous pericarditis the onset is insidious, chest pain is usually present, and weight loss, fever, night sweats, and cough are typical. A pleural effusion is more common in tuberculous disease, but it is seen in at least one-third of patients with bacterial and viral sources of infection. Parenchymal pulmonary disease is most suggestive of acute bacterial pericarditis and least suggestive of a viral origin. A pericardial rub is found in half of patients with pericarditis. Jugular venous distention and muffled heart sounds suggest pericardial effusion. A paradoxical pulse and hypotension suggest cardiac tamponade. Initial electrocardiographic changes in patients with pericarditis are PR-interval depression and diffuse ST-segment elevation. T-wave inversion is usually a late finding, after ST-segment normalization. An enlarged cardiac silhouette on chest radiography is suggestive of pericardial effusion. Echocardiography is extremely useful for the detection of pericardial effusions and for the assessment of their hemodynamic significance.

Identification of the specific source of pericarditis depends on isolation of the causative microorganism. In viral pericarditis, isolation is unusual, and pericardiocentesis or pericardiectomy is unwarranted in the absence of hemodynamic compromise. Hemodynamic compromise is more often seen in bacterial and tuberculous pericarditis, and pericardiocentesis or pericardiectomy is often indicated to diagnose and treat these disorders.

Most cases of viral pericarditis are treated with bed rest and nonsteroidal anti-inflammatory drugs. Corticosteroids are indicated only for recurrences. Bacterial pericarditis is treated with antimicrobial agents directed at the causative organism plus surgical drainage. Antibiotics should be continued for 4 to 6 weeks after surgery. Patients with tuberculous pericarditis should receive standard antituberculous medications for 6 months plus corticosteroids for the first 6 weeks. Surgery is indicated for tuberculous pericarditis if there is evidence of hemodynamic compromise (tamponade or constriction). The prognosis for viral pericarditis is good—almost all patients experience spontaneous resolution. The mortality rate with bacterial pericarditis remains high, even with appropriate therapy.

CHAPTER 271: GENITOURINARY TRACT INFECTIONS, INCLUDING PERINEPHRIC ABSCESS AND PROSTATITIS

BALDWIN TOYE AND ALLAN R. RONALD

[Urinary Tract Infections](#)
[Prostatitis](#)
[Epididymitis](#)

URINARY TRACT INFECTIONS

Infections of the urinary tract are among the most often encountered of all bacterial infections; they account for up to 10 million ambulatory care visits and 1.5 million discharge diagnoses yearly in the United States. These infections are experienced by at least 35% of women; many have repeated infections, resulting in substantial morbidity and use of health care services. Urinary tract infections (UTIs) are also the most frequently reported nosocomial infection and the most common source of gram-negative bacteremia.

DEFINITIONS AND PRESENTATIONS

Bacteriuria refers to the presence of bacteria in urine. The term *significant bacteriuria* was introduced to differentiate contaminated from infected urine. The distinguishing criterion has been more than 10^5 colony-forming units per milliliter in a voided urine sample, but urine from patients with symptomatic UTIs may have lower colony counts. *Acute cystitis* is a clinical illness caused by inflammation of the bladder epithelium or urethra as a result of bacterial infection, though other sources produce similar symptoms (the dysuria/frequency syndrome—see [Chapter 136](#)). *Acute pyelonephritis* is a clinical syndrome of flank pain, fever, and chills due to the inflammatory response to bacterial invasion of the renal parenchyma. *Asymptomatic (covert) bacteriuria* is the presence of significant bacteriuria in the absence of any symptoms attributable to infection. *Complicated UTIs* are those that develop in patients with abnormal urinary tracts.

The terms *chronic cystitis* and *chronic UTI* are used to describe recurring infections. Recurrent infections may be categorized as relapse or reinfection. Relapse is the recurrence of bacteriuria with the original infecting organism because of its persistence within the urinary tract. Reinfection is recurrence of bacteriuria caused by entry of bacteria into the bladder from the fecal–perineal reservoir. The term *chronic pyelonephritis* should be restricted to calyceal dilatation with overlying cortical scarring.

MICROBIOLOGY AND EPIDEMIOLOGY

Urine is normally sterile. Most UTIs are caused by Enterobacteriaceae, with about 80% of community-acquired infections caused by *Escherichia coli* ([Table 271.1](#)). Other gram-negative organisms, including *Klebsiella* species, *Proteus mirabilis*, and *Enterobacter* species, together constitute 10% of community-acquired infections. *P. mirabilis* is of particular significance because it predisposes to the formation of struvite calculi. *Staphylococcus saprophyticus*, a novobiocin-resistant, coagulase-negative organism, is the second most common cause of acute cystitis in young, sexually active women. *Enterococcus faecalis* is an important gram-positive pathogen in the elderly and in patients who have had genitourinary tract instrumentation. *Staphylococcus aureus* bacteriuria is frequently the result of bacteremic seeding of the kidneys during the course of hematogenous infection.

Community acquired, uncomplicated (%)	
<i>Escherichia coli</i>	80
<i>Staphylococcus saprophyticus</i>	10
<i>Klebsiella pneumoniae</i>	5
Other	5
Hospital acquired, complicated (%)	
<i>Escherichia coli</i>	30
<i>Enterococcus</i> species	15
<i>Pseudomonas aeruginosa</i>	10
Other Enterobacteriaceae	20–25
<i>Staphylococcus</i> species	5–10
Yeasts	5–10
Other	10–20

TABLE 271.1. MICROBIOLOGY OF URINARY TRACT INFECTIONS

The origin of hospital-acquired UTIs is substantially different. Patients often have indwelling urethral catheters or are receiving antimicrobial agents and thus are at greater risk of acquiring multiply resistant bacteria, often owing to cross-infection from other patients with UTIs. Infections of less susceptible strains of Enterobacteriaceae, *Pseudomonas aeruginosa*, and yeasts are common. Infection due to *E. faecalis* has become prevalent, especially in patients being treated with cephalosporins. Diphtheroids, α -hemolytic streptococci, lactobacilli, and anaerobes are rarely true urinary pathogens, although they are often present if searched for in voided urine.

The prevalence of bacteriuria has been defined in various population groups. In adult women, the prevalence is 3% to 7%, but it rises to 10% to 25% in women older than 60. In adult men, the prevalence is much lower (less than 0.1%) but increases in later years to 2% to 15%. The prevalence of bacteriuria in the elderly depends on the level of functional and anatomic impairment and may exceed 50% in nonambulatory persons. Various risk groups have been found to have an increased incidence of UTI. The association of UTI with sexual intercourse in women is reflected in the term *honeymoon cystitis*. Women who use spermicides have a greater risk of UTI than women who use other contraceptive methods. Infections in men are often related to anatomic abnormalities. The incidence of UTI is higher in uncircumcised men and in men who engage in penetrative anal intercourse. Patients with diabetes mellitus are at a higher than normal risk of asymptomatic and symptomatic UTIs. Does recurrent UTI with onset in adult life lead to renal failure? Although progressive renal scarring occurs in children as a result of infection, the damage takes place mostly before age 5. In adults, renal failure rarely results from recurrent or asymptomatic UTIs unless obstruction, diabetes mellitus, reflux, or analgesic abuse is also present.

PATHOPHYSIOLOGY

Although infection can arise by the hematogenous route (usually due to *S. aureus* or *Candida albicans*), the ascending route is the most important. Migration of uropathogens from the rectum to the vagina with introital and distal urethral colonization precedes the development of bladder infection. Antecedent antimicrobial use and diaphragm/spermicide use facilitate vaginal colonization with UTI pathogens. Bacterial entry into the bladder is enhanced by sexual intercourse. Upper tract involvement ensues when organisms ascend the ureters to reach the kidneys. The interaction between host defenses and the organism determines whether infection takes place. A major host defense is normal urinary flow, especially the flushing effect of micturition. The inherent antibacterial and antiadherent properties of bladder mucin and normal functioning of the ureterovesical junction aid in preventing infection.

The P fimbriae of *E. coli* are a virulence determinant and permit adherence to epithelial cells. Women with the P¹ blood group have increased susceptibility to pyelonephritis when they experience a UTI. Cytokines, specifically interleukin-6 (IL-6) and IL-8, are produced locally by epithelial cells in response to infection with virulent bacteria. These cytokines produce acute-phase proteins, and IL-8 acts as a chemoattractant for neutrophils. Most women with recurrent infection have normal urinary tracts. Any interruption of the normal flow of urine, such as obstruction, a neurogenic bladder, or calculi, results in residual urine and instrumentation, which increases the incidence of infection. Calculi also serve as a nidus for persistent infection. Vesicoureteral reflux contributes to upper UTI. The usual cause of reflux is an abnormality of the insertion of the ureter into the bladder, which often disappears during adolescence. Infection also causes reflux. Reflux alone may lead to renal

damage, presumably from retrograde pressure, but most renal scarring is a complication of infection in patients with reflux.

HISTORY AND PHYSICAL EXAMINATION

Patients with acute cystitis show initial signs of dysuria, urgency, and frequency, sometimes accompanied by suprapubic discomfort or gross hematuria. Fever rarely exceeds 38°C (100.4°F) if infection is confined to the lower tract. The absence of upper tract symptoms is an unreliable marker in excluding renal infection; up to 30% of patients with so-called cystitis have subclinical pyelonephritis, as documented by localization studies.

The classic clinical picture of acute pyelonephritis in adults consists of fever (usually more than 38.5°C [more than 101°F]), chills, and flank pain. Only 60% of patients with this classic triad are subsequently confirmed to have pyelonephritis. Flank pain may radiate to the epigastrium or to the lower abdominal quadrants, but radiation to the groin suggests ureteral obstruction. Constitutional symptoms include malaise, anorexia, nausea, vomiting, diarrhea, myalgias, and headache. Up to 30% of patients have concomitant lower tract symptoms, often antedating upper tract symptoms. Physical features vary, ranging from none to the clinical features of septic shock. There is often percussion tenderness in the costovertebral angle.

The clinical picture of acute pyelonephritis can be confused with many other conditions, including bacterial pneumonia, myocardial infarction, acute hepatitis, cholecystitis, and acute pelvic inflammatory disease. Zoster, in the appropriate dermatome before the onset of vesicles, may also mimic renal pain. Patients with diabetes mellitus may not have flank pain, and loss of blood glucose control may be the sole feature of acute pyelonephritis. These patients are at risk for complications due to renal papillary necrosis and emphysematous pyelonephritis. Although classic features of pyelonephritis are seen in the elderly, flank tenderness is less common, and confusion and bacteremia are more common. Genitourinary sepsis leads to metastatic infection at other sites in 1% to 3% of patients, and patients can have initial symptoms localized to these sites rather than to the urinary tract. Examples of metastatic infection include endocarditis, meningitis, endophthalmitis, and vertebral osteomyelitis.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

The exact diagnosis of UTI requires a culture of urine. The simplest method is to obtain a clean-voided midstream urine specimen. If patients are unable to give a clean-voided specimen, urine may be obtained by catheterization. The urine should be planted on culture media within 1 hour or refrigerated until it can be cultured, to avoid erroneously high colony counts.

Quantification of bacteriuria distinguishes infection from contamination. With voided urine, more than 10⁵ bacteria per milliliter has been the traditional criterion that indicates infection. More than 90% of patients with acute pyelonephritis have bacteriuria of more than 10⁵ per milliliter. A diagnosis of asymptomatic bacteriuria in women requires two voided specimens with more than 10⁵ per milliliter of the same bacterium, to ensure 95% confidence of “true” bacteriuria. In men, a single specimen growing more than 10⁴ per milliliter of a single organism is specific for bacteriuria. In women with symptomatic lower UTI, however, 30% have fewer than 10⁵ per milliliter. The best diagnostic criterion for symptomatic infection with gram-negative aerobes is at least 10² per milliliter with pyuria. Pretherapy cultures do not improve therapeutic outcomes in women with acute cystitis.

Pyuria is the presence of more than five white blood cells (WBCs) per high-power field in centrifuged urine sediment or more than 10 cells per cubic millimeter of unspun urine. Counts of more than 10 cells per cubic millimeter are found in fewer than 1% of asymptomatic patients without bacteriuria, whereas they are present in 96% of symptomatic patients with bacteriuria, including low-count bacteriuria, and in more than 90% of symptom-free patients with bacteriuria (more than 10⁵ per milliliter). The leukocyte esterase dipstick, a widely available office test, is less sensitive but is an acceptable alternative to microscopic diagnosis of pyuria. Microscopic hematuria is present in 50% of patients with acute cystitis.

Urine microscopy for bacteriuria can provide important information before culture results are available. The finding of any organism per oil-immersion field in a Gram's stain of unspun urine correlates with bacteriuria of more than 10⁵ per milliliter with a sensitivity of 93%. Centrifuging urine prior to Gram staining increases the sensitivity to 98%.

Differentiating upper from lower UTIs predicts the response to treatment. Unfortunately, clinical criteria (absence or presence of upper tract signs) are imperfect and unreliable in localizing the site of infection. The Stamey test (ureteral catheterization) and Fairley test (bladder washout) both require instrumentation and are impractical in routine clinical practice. Noninvasive tests, such as measurement of antibody-coated bacteria, maximal urinary-concentrating ability, C-reactive protein or urinary proteins (b₂-microglobulin), or imaging with gallium scans, have limited use in the treatment of individual patients.

More than 90% of women with lower UTIs can be cured by a 3-day course of an antimicrobial agent; 90% of women with only lower tract symptoms who experience relapse (3-day failure) have upper UTIs. Failure to be cured with a short course of therapy may be the most practical measure to diagnose upper UTIs in women with only lower tract symptoms or asymptomatic bacteriuria. Bacteremia is shown to be present in about 20% of patients with acute pyelonephritis. WBC casts are present in two-thirds of patients with pyelonephritis and, when present, they suggest acute renal infection.

Diagnostic imaging is not required in many patients with urinary infection. Both sonography and intravenous pyelography are relatively insensitive, but they can be useful to exclude obstruction, calculi, or anatomic abnormalities in the urinary tract. Repeated evaluation after an initial normal examination result should be discouraged. Computed tomography (CT), specifically helical scanning enhanced with contrast, has become the most important study in patients who require imaging. Pelvic or ureteral calculi, renal parenchymal abnormalities, and perinephric collections of fluid all can be diagnosed readily in this way. Moreover, a proportion of patients with presumed acute renal infection do not have acute pyelonephritis. CT scanning often will confirm the primary diagnosis and substantially alter management. Specific diagnoses, including renal tuberculosis and xanthogranulomatous pyelonephritis, also can be made with sensitivity and specificity with CT scanning. In general, imaging studies are more often obtained in men with UTIs, owing to the higher incidence of anatomic abnormalities among men. Radiographic and cystoscopic examination of women with acute cystitis who have no clinical evidence of urologic disorders or upper tract involvement rarely identifies abnormalities that alter treatment.

DIFFERENTIAL DIAGNOSIS

Acute cystitis must be distinguished from sexually transmitted infections with *Neisseria gonorrhoeae*, *C. trachomatis*, and herpes simplex virus. Patients may confuse the symptoms of urinary infection with those of vulvovaginal moniliasis and other vaginal pathologic conditions. During the first episode of infection, laboratory tests, including urinalysis and urine culture, and a sexual risk assessment, are necessary; if the latter study shows positive results, sexually transmitted diseases should be excluded. Recurring episodes of acute bacterial cystitis are often confused with the diagnosis of interstitial cystitis. This term is a “wastebasket” diagnosis for patients with recurring symptoms that can be severe and are usually accompanied by negative results on urine culture, an absence of pyuria, and no response to treatment. Cystoscopy may show evidence of petechiae after bladder dilatation, but the sensitivity and specificity of cystoscopic diagnosis are still undetermined.

The diagnosis of acute pyelonephritis should always be made with supporting laboratory findings. About one-fifth of patients with an initial diagnosis of pyelonephritis will prove to have other conditions, including acute surgical conditions, acute pelvic inflammatory disease, ectopic pregnancy, diverticulitis, renal calculi, pneumonia, or acute cholecystitis. Because acute pyelonephritis can progress rapidly to the sepsis syndrome with hypotension and multiple organ failure, all patients with this diagnosis must be regarded as representing a medical emergency and should be examined and treated promptly and observed until improvement is confirmed.

STRATEGIES FOR OPTIMAL CARE

The mainstay of treatment is antimicrobial therapy with supportive measures, including hydration and analgesia. The goal of treatment is clinical resolution and bacteriologic cure. In patients with acute invasive renal infections, the antibiotic selected should achieve inhibitory blood and tissue levels. The initial choice of agent depends on local resistance patterns of uropathogens. Optimal treatment regimens and duration of administration for most UTIs remain the subject of controversy. Conventional therapy for UTIs has consisted of 7- to 14-day regimens ([Table 271.2](#)), but most studies have failed to differentiate upper and lower UTIs.

Drug	Dose ^a
Trimethoprim-sulfamethoxazole	160/800 mg p.o. b.i.d.
Trimethoprim	200 mg p.o. b.i.d.
Amoxicillin	500 mg p.o. t.i.d.
Cephalexin	500 mg p.o. q.i.d.
Ofloxacin	400 mg p.o. b.i.d.
Ciprofloxacin	500 mg p.o. b.i.d.
Nitrofurantoin	100 mg p.o. q.i.d.

^aSee text for duration depending on site of infection.

TABLE 271.2. CONVENTIONAL REGIMENS FOR URINARY TRACT INFECTION IN ADULTS

In women with acute cystitis, 3-day treatment courses cure 95% of infections ([Table 271.3](#)), a rate equivalent to more prolonged regimens. Therapy with trimethoprim-sulfamethoxazole (TMP-SMX) or ciprofloxacin is preferred because of the increasing prevalence of amoxicillin resistance. In some areas, TMP-SMX resistance is also at a level that may make the choice of one of the quinolones preferable. Advantages of short-course treatment include lower cost, improved compliance, and fewer and less severe side effects. There is also minimal effect on the fecal flora, so that repeated short courses can be used without emergence of resistant organisms. Self-diagnosis and initiation of short-course therapy is a cost-effective alternative to urine culture and diagnosis and treatment by a physician. Woman with symptoms suggestive of upper tract involvement should be treated with a 7- to 14-day course of an appropriate antimicrobial agent. Furthermore, women at risk of subclinical pyelonephritis (those with a history of genitourinary abnormalities, diabetes mellitus, duration of symptoms more than 7 days, documented relapse) should be treated for 7 to 14 days, as should women whose infections recur within 2 weeks of short-course therapy.

Drug	Dose ^a
Trimethoprim-sulfamethoxazole	160/800 mg b.i.d.
Trimethoprim	200 mg b.i.d.
Ciprofloxacin	500 mg b.i.d.

^aDaily for 3 days.

TABLE 271.3. EFFECTIVE SHORT-COURSE REGIMENS FOR WOMEN WITH ACUTE CYSTITIS

Patients with acute pyelonephritis are now more often being treated as outpatients. Frequently, an initial parenteral antibiotic is prescribed in the office or emergency room and followed with an oral regimen. Although ampicillin together with gentamicin has been the traditional parenteral treatment, monotherapy with various agents is as effective and may be preferred for patients with renal impairment or resistant pathogens ([Table 271.4](#)). The complications of acute pyelonephritis and indications for hospitalization are summarized in [Table 271.5](#).

Drug	Dose ^a
Ampicillin and Gentamicin ^b	1 g q 6 hr 4.5 mg/kg q 24 hr
Cefotaxime	1 g q 8-12 hr
Ceftazidime	1 g q 8-12 hr
Ceftriaxone	1-2 g q 24 hr
Imipenem	500 mg q 6-8 hr
Aztreonam	1 g q 8 hr
Ciprofloxacin	400 mg q 12 hr
Trimethoprim-sulfamethoxazole	160/800 mg q 12 hr
Piperacillin-tazobactam	3:0.375 g 6 hr

^aDoses assume normal renal function.
^bOther aminoglycosides can be used.

TABLE 271.4. INITIAL EMPIRIC PARENTERAL REGIMENS FOR ACUTE PYELONEPHRITIS IN ADULTS

Complications
Bacteremia
Metastatic infection
Renal or perinephric abscess
Pyonephrosis
Papillary necrosis
Severe systemic inflammatory response syndrome
Unilateral/bilateral acute/chronic loss of function
Indications for considering hospitalization
Pregnancy
Diabetes/other metabolic disorders
Immunocompromising illnesses
Sepsis/unstable condition
Persistent vomiting
Unsuitable home environment

TABLE 271.5. ACUTE PYELONEPHRITIS: COMPLICATIONS/INDICATIONS FOR HOSPITALIZATION

Most patients become afebrile with symptom resolution within 48 to 72 hours. Patients with complications or a delayed response to treatment should be investigated to exclude obstruction or other lesions that require urologic consultation. Once the patient is afebrile for 24 hours, therapy can be switched to oral medication and continued to complete the course. About two-thirds of nonpregnant adult patients with acute pyelonephritis are only moderately ill and may be treated initially with oral antibacterial agents, particularly the fluoroquinolone ciprofloxacin.

Asymptomatic infection usually should not be searched for and treated in nonpregnant patients. Treatment may be indicated, however, in selected subgroups of patients at increased risk of morbidity, including patients undergoing urinary tract manipulation, immunosuppressed patients, and patients with diabetes mellitus. Elderly patients and those confined to bed should not be treated, because of the futility of maintaining sterile urine, the probable emergence of resistant organisms, and the lack of evidence that any benefits are associated with treatment. Men with UTIs require treatment regimens similar to those women receive. A proportion of men have a prostatic focus, which may require much more prolonged treatment in order to eradicate a focus of infection.

RECURRENT INFECTIONS

Infections recur in 50% of patients within 1 year of treatment. Relapse results from failure to eradicate the organism from renal or prostatic tissue. The treatment of patients who suffer a relapse after short-course therapy has been discussed. Relapse after a 2-week course of therapy typically can be cured with a 6-week course of therapy. Continuous long-term suppressive therapy should be considered for patients who have relapses after prolonged courses of treatment. Half the usual daily dose of TMP-SMX, amoxicillin, cephalexin, or a fluoroquinolone is often an effective suppressive regimen.

Most recurrent infections are reinfections that result from new organisms entering the bladder from the fecal–perineal reservoir. Prophylaxis or prevention of reinfection is cost effective in women who experience more than two infections per year (Table 271.6). Although resistant organisms replace the fecal flora of patients treated with b-lactams or sulfonamides, selection of highly resistant fecal flora is less common with TMP, nitrofurantoin, and the quinolones. A 6-month trial of prophylaxis is begun after existing infections are eradicated. Taking the medication at the time of intercourse is an alternative strategy. Women with sporadic infections may choose to self-diagnose and self-treat infections (Fig. 271.1). For postmenopausal women, the use of intravaginal estriol cream prevents recurrent UTIs, presumably by minimizing vaginal carriage of Enterobacteriaceae.

Drug	Dose
Trimethoprim-sulfamethoxazole	40/200; mg p.o. daily ^a
Trimethoprim	100 mg p.o. daily
Nitrofurantoin	50 mg p.o. daily
Norfloxacin	400 mg p.o. daily
Ciprofloxacin	250 mg p.o. daily

^a Same dose taken thrice weekly is also effective.

TABLE 271.6. REGIMENS FOR PREVENTION OF REINFECTION IN WOMEN

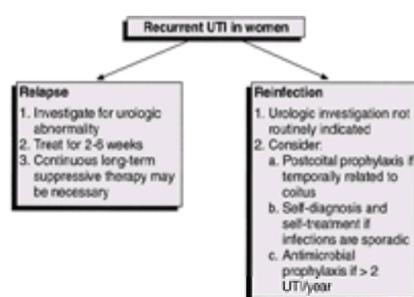

FIGURE 271.1. Recurrent urinary tract infections in women.

CATHETER-ASSOCIATED URINARY TRACT INFECTION

About 40% of nosocomial infections involve the urinary tract, and most are associated with indwelling urethral catheters. They are the most common source of gram-negative bacteremia in hospitalized patients and are associated with longer durations and higher costs of hospitalization. Major risk factors are female sex, advanced age, and severe general debility. The risk of infection after a single in-and-out catheterization is as low as 1% in young, healthy women. Closed sterile drainage significantly lowers the infection rate, but the risk with indwelling catheterization is still about 5% per day. Infection may result from contamination at catheter-collection junctions, with intraluminal proximal migration of bacteria into the bladder, or by periurethral migration of bacteria around the catheter.

Most patients are asymptomatic; lower tract symptoms can be obscured by the presence of the catheter. Although upper tract symptoms or even septic shock may develop, fever may be the only clinical indicator of a catheter-associated UTI. Other sources of fever must be considered, however, before assuming that the source of elevated temperature is an infected urinary tract. Diagnosis is obtained by catheter puncture using a sterile needle and syringe. Any bacterial count after urine is collected by needle aspiration and cultured is generally considered significant in patients with indwelling catheters.

Bacteriuria usually persists after catheter removal and should be treated. If the catheter cannot be removed, asymptomatic bacteriuria should not be treated, because treatment only selects for more resistant organisms. When symptoms develop, they should be treated initially with broad-spectrum agents, since more resistant organisms are often responsible; the spectrum should be narrowed once the antimicrobial susceptibility is known (Fig. 271.2). The most effective method of prevention is to avoid catheterization and to remove the catheter as soon as possible. For management of the neurogenic bladder, intermittent catheterization is preferred over indwelling catheterization. The instillation of antiseptic solutions in drainage bags and meticulous periurethral care with antibacterial ointment have had limited success in lessening the incidence of infection.

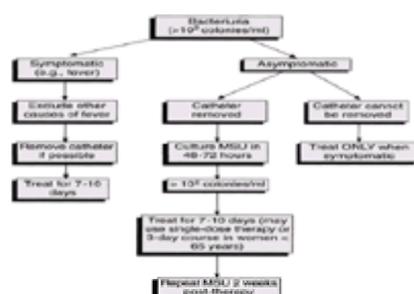

FIGURE 271.2. Approach to indwelling catheter-associated bacteriuria.

PERINEPHRIC AND INTRARENAL ABSCESS

A perinephric abscess is suppuration in the perirenal fascia; an intrarenal abscess is suppuration within the renal parenchyma. The abscesses may coexist, and diagnosis can be difficult and is often delayed. The mortality rate is substantial—up to one-third of cases of perinephric and intrarenal abscess are diagnosed at autopsy. Patients with calculi, obstruction, or diabetes mellitus are predisposed to abscess formation. Intrarenal abscesses may be caused by hematogenous seeding (especially by *S. aureus*) of the renal cortex, but many develop as complications of acute pyelonephritis. In the latter case, gram-negative uropathogens are most

common, with a predilection for the corticomedullary regions. The patient often has initial symptoms of fever and flank pain of acute onset associated with leukocytosis. Normal findings on urinalysis do not exclude the diagnosis, since pyuria is present only when there is communication of the abscess with the collecting system. A slow response to appropriate treatment in a patient with presumed pyelonephritis should suggest the diagnosis.

Most perinephric abscesses result from rupture of an intrarenal abscess into the perirenal space. Hematogenous seeding and direct extension from a nearby focus are less common. The onset is usually more insidious, with a duration of symptoms longer than 14 days in many patients. Fever and flank pain are typical, as are leukocytosis and anemia; a flank mass is found in 50% of patients. Some patients have fever of undetermined origin. Blood cultures show positive results in 20% to 40% of patients. Although chest radiography and renal ultrasonography can provide clues to the diagnosis, a major obstacle to treatment has been delayed recognition. The use of CT permits earlier and more accurate diagnosis, allowing for diagnostic and therapeutic aspiration. Serial studies facilitate monitoring of the response to therapy.

In the case of an intrarenal abscess, treatment with a prolonged course of antimicrobials alone may be effective, but many patients require drainage. For a perinephric abscess, antimicrobials are necessary, but the primary mode of treatment is drainage. In both cases, drainage can be performed percutaneously under sonographic or CT guidance, often eliminating the need for open drainage. Nephrectomy may be required for severe infections with a nonfunctioning kidney.

XANTHOGNULOMATOUS PYELONEPHRITIS

Xanthogranulomatous pyelonephritis is a rare chronic infection of the renal parenchyma. It is characterized by localized or diffuse replacement of the renal parenchyma by inflammatory cells with abundant lipid-laden macrophages. A lysosomal defect interferes with digestion of bacterial products. It is most common in the fifth to sixth decades of life, with a predominance among women. Chronic obstruction and recurrent UTIs are typical; malaise, flank pain, fever, weight loss, pyuria, and nephrolithiasis are common features. Cultures of urine and renal tissue often show positive results for *P. mirabilis*. Xanthogranulomatous pyelonephritis can mimic renal cell carcinoma, renal tuberculosis, renal abscess, or hydronephrosis. CT establishes the diagnosis through the finding of abnormal fatty tissue in the renal mass. Surgical resection of the affected material (total or partial nephrectomy) is curative. Accurate preoperative diagnosis may aid the surgeon in limiting the amount of tissue resection. A more conservative approach using long-term antibacterial therapy also may be successful.

MALACOPLAKIA

Malacoplakia is a rare granulomatous disease that develops in the same clinical context as xanthogranulomatous pyelonephritis, but infection is usually with *E. coli*. Lesions are found in the bladder or kidney and may involve the prostate and ureters. Gross examination shows yellow-brown plaques that form aggregates of large histiocytes (von Hanseman cells) containing intracytoplasmic inclusions (Michaelis–Gutmann bodies) that are believed to be calcified, incompletely digested organisms. Bladder involvement is characterized by irritative symptoms, and cystoscopy may show typical plaques. A patient with upper tract disease has fever, flank pain, or a mass in association with UTI. CT may show unifocal or multifocal masses. The pathogenesis of malacoplakia is incompletely understood, but it is believed to be due to a defect in intracellular killing of ingested microorganisms by macrophages. Bethanechol can reverse this defect in vitro, and treatment with bethanechol combined with TMP-SMX or a fluoroquinolone has been successful. Surgery is required for patients with progressive disease.

URINARY TRACT INFECTION IN PREGNANCY

The prevalence of asymptomatic bacteriuria in pregnancy is similar to the rate of bacteriuria in sexually active non-pregnant women (3% to 8%). Only 1% to 2% of women acquire bacteriuria during pregnancy. About one third of these infections involve the upper tract. If the infection is left untreated, 20% to 30% of bacteriuric pregnant patients experience symptomatic acute pyelonephritis, usually in the third trimester, and 20% of these women are delivered of infants prematurely.

Treatment of asymptomatic bacteriuria in pregnancy significantly lowers the incidence of pyelonephritis. For this reason, all pregnant women should be screened for asymptomatic bacteriuria at their first prenatal visit and again in the third trimester. If bacteriuria is found, a short-course regimen may be used initially. Close monthly follow-up is mandatory. Patients who are not cured should be treated for 2 weeks. Patients who relapse after a 2-week course should be followed closely and either treated with a 6-week regimen or kept on continuous antimicrobial therapy until delivery. After delivery, radiologic investigations are indicated for patients who fail treatment. Extensive experience with penicillins, cephalosporins, and nitrofurantoin have shown them to be safe for use in pregnancy. Sulfonamides may be used except during late pregnancy. Patients with pyelonephritis are frequently hospitalized to allow careful monitoring of mother and fetus. The response to therapy is often slow. If the patient is still febrile and ill after 72 hours of appropriate therapy, ultrasonography may be needed to delineate underlying abnormalities.

PROSTATITIS

Prostatitis is inflammation of the prostate gland. The diagnosis of prostatitis is often made without objective evidence. It is usually classified as bacterial prostatitis (acute and chronic), nonbacterial prostatitis (prostatosis), and prostatodynia. Except for acute prostatitis, it is often difficult to distinguish these categories on clinical criteria; diagnosis depends on microscopic and bacteriologic examination of prostatic fluid. Lower tract localization studies remain the gold standard for the diagnosis of bacterial infection of the prostate. The first-voided 10 mL of urine (VB₁), 10 mL midstream urine (VB₂), expressed prostatic secretions (EPS) obtained by prostatic massage, and the first 5 mL of urine voided immediately after prostatic massage (VB₃) are collected for quantitative culture and microscopic examination. Normal prostatic fluid contains fewer than 10 WBCs per high-power field. Most cases of bacterial prostatitis are caused by Enterobacteriaceae— *E. coli* is the most common pathogen. The most common gram-positive pathogen is *E. faecalis*, which is responsible for up to 10% of infections. A zinc-containing antibacterial factor present in normal prostatic fluid aids in resisting infection, and abnormally low levels of this factor have been found in men with bacterial prostatitis.

ACUTE PROSTATITIS

The typical picture of acute prostatitis consists of fever, chills, malaise, and irritative and obstructive voiding symptoms associated with lower back and perineal discomfort. On physical examination, the prostate is found to be exquisitely tender, warm, and swollen. Prostatic massage should not be performed, because of the risk of bacteremia. Most patients have bacteriuria caused by the same organism, and diagnosis of the source is thus possible.

Although some patients can be treated with oral antibiotic therapy, the acutely ill patient should be hospitalized and treated empirically ([Table 271.4](#)). After clinical response, therapy can be changed to an oral agent, usually TMP-SMX or a fluoroquinolone, depending on the susceptibility of the isolated organism. Therapy should be continued for 6 weeks. Most antimicrobial agents penetrate poorly into prostate tissue, but penetration is satisfactory in the acutely inflamed prostate. Supportive therapy with sitz baths, analgesics, and stool softeners is helpful. Urinary retention should be managed with suprapubic drainage. Other complications include prostatic abscess, pyelonephritis, bacteremia, epididymitis, and seminal vesiculitis.

CHRONIC PROSTATITIS

Patients with chronic prostatitis have irritative voiding symptoms often associated with perineal and lower back pain. This is an important cause of relapsing UTI in men. There are no specific physical features. Diagnosis is based on lower tract localization studies. The EPS has more than 10 WBCs per high-power field, with a few lipid-laden macrophages. Bacterial counts of EPS and VB₃ exceed that of VB₁ by at least tenfold. If the VB₂ shows bacteriuria (more than 10⁵ per milliliter), the site of infection cannot be localized.

Treatment has proved unsatisfactory. A major problem is the inability of many antimicrobial agents to diffuse into the prostatic fluid. Prostatic calculi also may serve as a persistent focus of infection. TMP-SMX and fluoroquinolones penetrate into the prostatic tissue and have the best cure rates (32% to 71%). Treatment must be prolonged (8 to 12 weeks), but relapse is typical. Long-term suppressive therapy is often more successful than cure. Suppressive therapy often consists of a single nightly dose of TMP-SMX or a fluoroquinolone, and relapse can occur after years of successful suppression.

NONBACTERIAL PROSTATITIS

The clinical features of nonbacterial prostatitis (prostatosis) are identical to those of chronic bacterial prostatitis, including microscopic evidence of inflammation in the EPS. Bacterial pathogens are not isolated from EPS and urine cultures, however. Many pathogens, including *Ureaplasma urealyticum* and *C. trachomatis*, have been isolated from EPS, but an etiologic role is unproved. Nonetheless, some physicians recommend a course of therapy with tetracycline or erythromycin, to which some patients respond. Repeated and prolonged courses of therapy are not indicated. Treatment is mainly symptomatic, with a combination of sitz baths, prostatic

massage, and analgesics.

PROSTATODYNIA

Patients with prostatodynia have symptoms that mimic chronic prostatitis, but they lack evidence of prostatic inflammation. Localization cultures show negative results for bacterial pathogens. Some patients have an element of associated emotional stress. The origin of these symptoms is unknown, but evidence suggests that it may be a primary voiding dysfunction due to overactivity of pelvic sympathetic nerves acting at the level of the external urethral sphincter. Antimicrobials are not indicated, and treatment is largely symptomatic, along with reassurance. Some patients obtain relief with α -adrenergic blockers, such as phenoxybenzamine or prazosin.

EPIDIDYMITIS

Epididymitis is the clinical syndrome resulting from inflammation of the epididymis. In men younger than age 35, it is usually sexually transmitted and is often associated with urethritis. The most common etiologic agents are *Neisseria gonorrhoeae* and *C. trachomatis*. In men 35 and older, there is typically underlying structural urologic abnormalities, bacterial prostatitis, or a history of recent genitourinary tract manipulation. Most cases are found to be bacteriuric. *E. coli*, other Enterobacteriaceae, and *Pseudomonas* organisms account for most cases, though there are reports of streptococcal and anaerobic epididymitis.

Clinical symptoms include painful swelling of the scrotum, which usually arises acutely over 1 to 2 days, often in association with irritative lower tract symptoms. Early on, tender swelling is localized to the epididymis alone, but with time inflammation spreads to the ipsilateral testis, making the testes indistinguishable on palpation. A urethral discharge or evidence of inflammation should be sought because asymptomatic urethritis may be present, especially in patients younger than age 35. Urethral discharge should be submitted for culture or nucleic acid amplification, and midstream urine culture should be carried out. Cultures of epididymal aspirates are useful for patients who fail medical therapy or those who experience recurrences without confirmation of the source of disease.

The most important differential diagnosis to be considered is testicular torsion. Doppler ultrasonography, radionuclide scanning, CT, and emergency urologic consultation may be necessary to make the diagnosis. Other diagnostic considerations include testicular tumor, abscess, spermatocele, hydrocele, varicocele, hernia, and trauma. Treatment consists of nonspecific measures: bed rest, scrotal elevation, analgesics, and local ice packs. Specific treatment should be directed against etiologic agents suspected on initial evaluation. If sexually transmitted epididymitis is suspected, an appropriate course of treatment should be prescribed. When urethral Gram's stain or culture shows *N. gonorrhoeae*, one of the recommended treatment regimens (such as ceftriaxone followed by tetracycline) should be administered. Sexual partners should also be evaluated and treated.

Acutely ill men with nonsexually transmitted epididymitis can be treated initially with any of the empiric regimens used in the treatment of renal infections ([Table 271.4](#)). After clinical response, an oral agent is chosen based on the susceptibility of the organism isolated from urine. Men with epididymitis and bacteriuria should receive a 6-week course to minimize the risk of relapse. Surgery is reserved for those with no response to medical therapy or for those in whom testicular torsion is a very real possibility. Complications of epididymitis include abscess formation, testicular infarction, chronic pain, infertility, and bacteremia. Systemic infections that can involve the epididymis include tuberculosis, deep mycoses (blastomycosis, cryptococcosis, histoplasmosis, coccidioidomycosis), brucellosis, and schistosomiasis.

TABLE 272.3. CLINICAL SYNDROMES ATTRIBUTABLE TO SEXUALLY ACQUIRED INFECTION

HISTORY AND PHYSICAL EXAMINATION

An assessment of a patient's STD risks is an essential component of the medical history. This assessment assists in the interpretation of physical findings and laboratory tests and provides information that may be helpful for treatment of the patient and his or her partner. The assessment of risk should be conducted in a sensitive, nonjudgmental manner within the usual context and flow of taking the medical history. Any anxiety or partiality on the part of the clinician toward a patient's sexual practices is likely to be detected and may make the patient reluctant to discuss aspects of his or her sexual behavior and thus impede optimal medical care.

Essential information obtained from the sexual history includes the gender of the patient's sex partners; whether the patient engaged in sexual intercourse with new or several partners in the past 4 weeks (this timeframe includes the usual incubation period for many STDs); whether the patient had vaginal, oral, or anal sex with these partners (and if anal, whether the male patient who had male partners was the insertive or receptive partner); condom use during sex; and past history of STDs, including HIV infection. The patient's history of drug and alcohol use is also relevant, because substance abuse is often associated with sexual risk-taking behaviors and STDs.

For patients who have no symptoms and are being evaluated as part of a routine examination, an assessment of risk is helpful in deciding whether to screen for STDs. All sexually active women under the age of 25 years should be tested annually for chlamydial infections (per the recommendations included in the Health Employer Data Information Set), and women aged 25 years and older should be tested if they have one or more risk factors for infection (new partner or several partners in the past 2 to 3 months, clinical signs or symptoms suggestive of infection, or a sex partner with suspected or documented infection). Adolescent girls tend to have a high prevalence of infection (often 5% to 10%) and may benefit from testing at more frequent intervals, particularly if they have already been found to have infection. The increasing availability and declining cost of urine testing with nucleic acid amplification assays have made more frequent screening feasible and convenient. Men who are considered to be at risk of chlamydial infection also should be screened using urine tests, although specific recommendations for screening men have not yet been established.

Recognition of a patient's risks of STDs is important in considering the differential diagnosis of clinical syndromes for which STD is only one of several possible diagnoses. Sexually transmitted infections should be considered in the differential diagnosis of dysuria in women (which may be caused by chlamydial or gonococcal infection), rashes (secondary syphilis or scabies), arthritis (disseminated gonococcal infection or Reiter's syndrome), and enteritis (*Shigella* or *Giardia* species). Persons who report recent oral or anal intercourse should undergo laboratory testing for gonococcal infection that includes specimens from oral and anal sites. Persons who have had oral-fecal contact are at increased risk of contracting sexually transmitted enteric infections, and those who have had receptive anal intercourse are at increased risk of proctitis.

The decision of whether to provide immediate treatment based on clinical findings or preliminary laboratory results may also depend on the risk assessment. A patient with a high risk of STD is more likely to be infected given a presumptive positive test or clinical findings that suggest the presence of an STD and may be less likely to be adversely affected by a false-positive result. Once a determination has been made that a patient has an STD, information obtained through the sexual history is necessary to begin the process of counseling about risk reduction and assisting in notifying and counseling sex partners.

The physical examination of the patient being evaluated for an STD includes components of the general physical examination: inspection of the skin, including an examination of the palms and soles for lesions that are typical of secondary syphilis; of the mouth for oral lesions; and of the lymph nodes not only for inguinal adenopathy but also for generalized lymphadenopathy that may develop in patients with syphilis or HIV. In women, the lower abdomen is examined for tenderness or an adnexal mass that suggests the diagnosis of pelvic inflammatory disease (PID). The gynecologic examination begins with inspection of the skin of the pubic area for genital warts, ulcerative lesions, and evidence of lice or scabies. With the speculum inserted in the vagina, the quantity and color of vaginal secretions are noted, and the cervix is closely examined for the presence of inflammation or lesions. After specimens are collected, the speculum is withdrawn slowly so that the vaginal epithelium can be seen.

The bimanual examination includes palpation of the Bartholin's glands, examination for cervical motion tenderness, and palpation of the uterus and adnexa for masses or tenderness. The urethra is gently stripped to search for the presence of purulent discharge. The pH of the vaginal secretions is measured using narrow-range pH paper, to assist in the diagnosis of vaginitis. In men, the skin of the inguinal area is examined for lesions. The penis also is examined for lesions, and if no urethral discharge is apparent, the shaft of the penis is stripped lengthwise to look for any discharge. The scrotum is scrutinized and the testicles and epididymis palpated for mass or tenderness. In both men and women, the anus should be inspected for warts, discharge, or ulcers; if proctitis is suspected in light of the patient's history, anoscopy should be performed.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

Until rapid office-based tests are available that are highly sensitive and specific for STDs, gaps will continue to exist between treatment based on results of rapid tests with relatively low sensitivity or specificity and treatment based on results of more reliable tests not available until several days after the patient's visit. Clinicians must rely on an assessment of a patient's risks for STDs and the potential implications of either notifying the patient of false-positive test results when making decisions concerning immediate treatment based on tests with relatively low specificity or accepting the delay and expense involved in performing confirmatory tests. Because most screening tests are imperfect, an estimate of pretest probabilities of disease based on the prevalence of disease in the population and an individual patient's risks is important in evaluating the certainty of infection in view of a positive test result. The nonculture tests for gonococcal and chlamydial infection especially raise this concern; although specificities for most nonculture tests that are used for widespread screening are probably 99.5% or greater, lack of well-defined gold standards has made the true specificity of these tests uncertain.

Even a specificity of 99.5% raises potential problems unless the disease prevalence in the population is high. If a test for chlamydia with a specificity of 99.5% and a sensitivity of 80% is used to screen women with a chlamydia prevalence of 15%, the positive predictive value is 97%. The same test in a population with a 2% prevalence, however, has a positive predictive value of only 77%; nearly one-fourth of patients with a positive test result do not have infection. For this reason, in low-prevalence populations, positive results should be confirmed routinely before notifying the patient or administering therapy, especially if adverse consequences can result from notification of a false-positive result. For chlamydia, enzyme immunoassay results can be verified with a blocking antibody, and nucleic acid probe assays can be verified with a competitive probe. Verification can also be effected by repeating the test; optimally, a second test should be cell culture or a second nonculture test based on a different principle or on a different antigen or nucleic acid sequence from the one used in the initial test.

The Papanicolaou smear (cervical smear) is not a sensitive test for STDs. The finding of a pathogen (*Trichomonas vaginalis*) or cytologic changes suggestive of infection (*T. vaginalis*, *Chlamydia trachomatis*, HSV, HPV), however, can be useful in directing the choice of more specific tests. Diagnostic tests specific for HPV subtypes that have been associated with cervical cancer are commercially available. They are being evaluated for use in cervical cancer screening, triage of women with abnormalities on the Papanicolaou smear, and follow-up of women who have been treated for cervical cancer.

DIFFERENTIAL DIAGNOSIS

Details of the clinical course, pathophysiologic characteristics, and treatment of several STDs are presented elsewhere in this textbook. The treatment of common causes of vaginal discharge and the approach to several of the major STD syndromes and their differential diagnoses are discussed in the following sections. The major syndromes include genital ulcer disease, urethritis, vaginal discharge, cervicitis, and PID.

GENITAL ULCER DISEASE

In the United States, genital ulcers most often are caused by genital HSV infection, *Treponema pallidum* (primary syphilis), and *Haemophilus ducreyi* (chancroid). Lymphogranuloma venereum (caused by *C. trachomatis* serovars L₁, L₂, and L₃) and donovanosis (also called granuloma inguinale, caused by *Calymmatobacterium granulomatis*) are seen rarely in the United States; they are more common in developing countries. In some instances, genital ulcers are caused by trauma or by generalized or localized dermatologic conditions that are not STDs. The distribution of diseases causing genital ulcers varies widely according to the population of patients, the practice setting, and the patterns of local morbidity. Although in most U.S. cities chancroid is rare, in some cities it may be an endemic disease, found most often in association with prostitution and crack cocaine use. Genital ulcers of syphilis and chancroid are detected less often among women than among men, possibly because in some women the lesions manifest only in the vagina or on the cervix and therefore go unnoticed.

Syphilitic ulcers are typically painless and have smooth margins, indurated borders, and a clean, indurated base with serous exudate (Table 272.4). Bilateral, nonpainful inguinal lymphadenopathy is present in 60% to 70% of cases. Ulcers of chancroid usually are painful, deep, and irregular and have rough margins and a purulent exudate. Lymphadenopathy accompanying chancroid is often unilateral, painful, and tender and can become fluctuant, resulting in buboes that drain through the skin in severe cases. Fluctuant nodes should be aspirated, drained, and cultured. Whereas syphilis and chancroid lesions often begin as small papules or macules, ulcers of HSV infection take the initial form of vesicles that lead to superficial ulcers. First clinical episodes of HSV are often accompanied by fever, myalgia, and malaise. Patients who have a first clinical episode of HSV infection with HSV-1 or HSV-2 frequently experience less severe symptoms when they have previously had primary infection with the other subtype.

Disease	Etiology	Incubation Period	Lesion Characteristics	Associated Findings	Diagnosis
Syphilis	<i>T. pallidum</i>	3 weeks	Painless, indurated, clean base	Bilateral inguinal lymphadenopathy	Serology, dark-field
Chancroid	<i>H. ducreyi</i>	3-6 days	Painful, deep, irregular, rough margins	Unilateral tender lymphadenopathy	Culture, PCR
HSV	HSV-1, HSV-2	2-12 days	Vesicles, superficial	Fever, myalgia, malaise	PCR, culture
LGV	<i>C. trachomatis</i> L1-L3	3-30 days	Painful, deep, irregular	Unilateral tender lymphadenopathy	Culture, PCR
Donovanosis	<i>C. granulomatis</i>	1-2 months	Painful, deep, irregular	Unilateral tender lymphadenopathy	Culture, PCR

TABLE 272.4. CHARACTERIZATION AND DIFFERENTIATION OF GENITAL ULCERATION

These symptoms and signs are characteristic of the different genital ulcer diseases, but atypical cases are common, and it is often not possible to distinguish one from another on clinical grounds. Clinical diagnosis of genital ulcers is incorrect in up to 40% of cases. Depending on the local epidemiologic characteristics of these diseases, persons infected with one disease may be co-infected with another. Conventional diagnostic tests identify no etiologic source in 25% to 50% of genital ulcers. For both syphilis and chancroid, diagnostic tests are relatively insensitive with a single examination. New diagnostic tests using DNA amplification for the three main organisms responsible for genital ulcers have been used experimentally, with substantial increases in sensitivity, but they are not yet commercially available. The sensitivity of a single dark-field examination of an ulcer for *T. pallidum* is probably quite low, depending on the quality of the specimen and the experience of the laboratory staff.

The nontreponemal RPR (rapid plasma reagin) card or VDRL (Venereal Disease Research Laboratory) tests have estimated sensitivities of 70% to 80%. If a patient with primary syphilis who has a nonreactive syphilis serologic test result returns for another test in 2 to 4 weeks, the test may be reactive; however, it is possible that the test will remain nonreactive if treatment is instituted very early. The sensitivity of the fluorescent treponemal antibody-absorption test is somewhat higher than that of nontreponemal tests, but it cannot distinguish recent from past infection or exclude the possibility that the lesion is due to HSV or chancroid if the patient has a history of syphilis. The sensitivity of *H. ducreyi* culture (which is difficult and often not available) ranges widely, from about 35% to 80%, depending on the experience of the laboratory team. Tests for HSV have the highest sensitivity when vesicles are present.

In communities where both syphilis and chancroid occur, it is reasonable to presumptively treat a patient with genital ulcers for both diseases if diagnostic testing is not optimal and compliance with a request for a return visit is uncertain. Because chancroid, syphilis, and HSV have been associated with a higher than normal risk of HIV infection, and because HIV infection can result in the need for treatment with higher doses or longer courses of therapy, patients with genital ulcers due to any of these agents should be tested for HIV.

URETHRITIS

Symptomatic men with a visible urethral discharge or asymptomatic men with ≥ 5 leukocytes per oil-immersion field (1,000 \times) on a urethral smear have urethritis. Urethritis is classified as gonococcal urethritis (if it is caused by *Neisseria gonorrhoeae*) or nongonococcal urethritis (NGU). The most common cause of NGU in men 15 to 40 years of age is *C. trachomatis*; this organism is found in 15% to 40% of patients, with *Ureaplasma urealyticum* (10% to 40%) and *T. vaginalis* (2% to 10%) being the next most common organisms. Occasionally, HSV leads to urethritis, but in many cases, the cause is unknown. In men with gonococcal urethritis, 5% to 30% are co-infected with *C. trachomatis*. *Mycoplasma hominis* and *Mycoplasma genitalium* have also been associated with urethritis, but these organisms also can be found in patients without clinical evidence of urethral inflammation.

In symptomatic men a purulent discharge suggests gonococcal infection, and a serous discharge indicates NGU, but this distinction is not highly reliable. In men with a visible discharge, secretions at the tip of the penis are collected with a cotton or Dacron swab and evaluated by Gram's stain for the presence of leukocytes and intracellular gram-negative diplococci. If intracellular diplococci are seen, gonococcal urethritis is indicated; if not, the condition is considered to be NGU. The sensitivity and specificity of Gram's stain for gonococcal infection in symptomatic men are each more than 95% (compared with about 50% in infected men who have no symptoms).

In men without a visible discharge (even after stripping the urethra), a thin urethral swab should be inserted 2 to 3 cm to obtain secretions; this technique is particularly helpful in evaluating patients who report symptoms but who have no apparent sign of discharge at the time of examination. If urethritis is not confirmed at the initial visit of a patient who reports symptoms, the patient should return for another examination the following morning, before urinating. Although the urethral smear is useful for distinguishing men who have gonococcal urethritis from those who do not, men with a smear suggestive of gonococcal infection should also be tested by culture for *N. gonorrhoeae*, in part for medicolegal reasons. Symptomatic men with NGU should be tested for *C. trachomatis*, because finding *C. trachomatis* is important for appropriate treatment of sexual partners.

For screening asymptomatic men for gonococcal and chlamydial infection, polymerase chain reaction and ligase chain reaction tests, which can be performed on urine, have higher sensitivities than other nonculture tests. An inexpensive option for detecting urethritis in asymptomatic individuals is the leukocyte esterase test, which can be performed on the initial 15 to 20 mL of voided urine. This technique has been best evaluated in adolescent boys, in whom the sensitivity of detecting *N. gonorrhoeae* and *C. trachomatis* ranges from 50% to 100%, and the specificity ranges from 80% to 100%.

Initial treatment of patients with urethritis should be based on the results of Gram's stain. (In the symptomatic patient, if a Gram's stain of urethral secretions is not immediately available, treatment for both gonococcal and nongonococcal urethritis is advised.) Tetracycline-resistant *U. urealyticum* and other sources of NGU should be considered in patients with persistent NGU who have completed therapy and have not been reexposed to an untreated sex partner.

VAGINAL DISCHARGE

Vaginal discharge is most often the result of bacterial vaginosis, vulvovaginal candidiasis, or trichomoniasis. The prevalence of these conditions varies according to the population of patients; bacterial vaginosis is usually the most common. Severe cervicitis caused by *N. gonorrhoeae*, *C. trachomatis*, or HSV infrequently results in vaginal discharge. Abundant vaginal secretions are occasionally physiologic and do not necessarily indicate the presence of infection. Treatment regimens for common causes of vaginal discharge are listed in [Table 272.5](#).

Disease	Recommended Regimens	Alternative Regimens
Bacterial vaginosis	Metronidazole, 500 mg orally twice daily for 7 days ^a Clindamycin cream, 2% (one full application QD) or intravaginally at bedtime for 7 days ^b Metronidazole gel, 0.75%, one full application QD intravaginally four times a day for 5 days	Metronidazole, 2 g orally in a single dose Clindamycin, 300 mg orally four times a day for 7 days
Heterologous vaginitis	Metronidazole, 250 mg, 1 g intravaginally for 3 days Clindamycin, 1% cream, 1 g for 7-10 days Clindamycin, 100 mg vaginal tablets, four for 3 days Clindamycin, 100 mg vaginal tablets, one tablet in a single application Metronidazole, 250 mg, 1 g intravaginally for 7 days Metronidazole, 500 mg vaginal suppositories, one for 3 days Metronidazole, 500 mg vaginal suppositories, one for 7 days Nystatin, 100,000-unit vaginal tablet, one for 14 days Terconazole, 0.4% cream, 1 g intravaginally in a single application Terconazole, 0.4% cream, 1 g intravaginally for 7 days Terconazole, 0.4% cream, 1 g intravaginally for 7 days Nystatin, 400 mg suppositories, one suppository for 14 days or Nystatin, 100 mg orally in a single dose ^c Metronidazole, 2 g orally in a single dose ^d	Metronidazole, 500 mg orally daily for 7 days

^aDuring pregnancy, the recommended regimen for bacterial vaginosis is metronidazole, 500 mg orally twice daily for 7 days. Metronidazole may be treated during pregnancy with metronidazole, 2 g orally in a single dose. ^bContraindicated during pregnancy.

TABLE 272.5. TREATMENT REGIMENS FOR COMMON CAUSES OF VAGINAL DISCHARGE

The typical discharge of bacterial vaginosis is white or gray, homogeneous, and adherent to the walls of the vagina. Vulvovaginal candidiasis is characterized by a white, often curdlike discharge sometimes accompanied by vulvitis. Trichomoniasis produces a profuse yellowish discharge, and the vaginal walls may appear inflamed; a *strawberry cervix* with petechial lesions may be seen. It is often difficult to distinguish these conditions based on history and physical examination alone; the conditions may exist without symptoms, and co-infections are common. Frequent douching may also affect the appearance of vaginal secretions that are normally associated with these pathogens. It is important not only to perform diagnostic testing on the vaginal discharge but also to examine every patient with vaginal discharge for cervicitis and to test for gonorrhea and chlamydia, especially women with an STD risk factor.

In evaluating the possibility of vaginitis, a specimen of vaginal secretions should be collected from the posterior fornix of the vagina using a cotton or Dacron swab. Apply the swab to two microscope slides. One or two drops of 0.9% saline may be added to one slide for wet-mount examination for motile trichomonads and for the clue cells typical of bacterial vaginosis. A 10% potassium hydroxide (KOH) solution added to the second slide improves the examination for yeast or pseudohyphae.

Bacterial vaginosis results from an alteration in vaginal flora that is characterized by replacement of the normally dominant *Lactobacillus* species with an overgrowth of *Gardnerella vaginalis*, *Mycoplasma hominis*, and anaerobic bacteria, including *Bacteroides* and *Mobiluncus* species. The typical clue cells seen in the 0.9% saline preparation are vaginal epithelial cells with a granular appearance and indistinct margins caused by adherent bacteria. The Amsel criteria for diagnosis of bacterial vaginosis require that the vaginal discharge have at least three of these four characteristics: typical vaginal discharge, clue cells present on wet mount, a typical fishy amine odor (often produced or enhanced when mixed with 10% KOH), or a vaginal pH of more than 4.5. New tests for bacterial vaginosis include a rapid test of vaginal secretions for elevated pH and amines and a nucleic acid probe assay for *G. vaginalis* antigens. Tests for *G. vaginalis* are not specific for bacterial vaginosis, however, because this organism is found in a high proportion of women with no signs or symptoms. In the absence of symptoms in nonpregnant women, a finding of bacterial vaginosis is not sufficient indication for treatment. Some experts recommend screening and treatment of asymptomatic pregnant women (particularly those with a history of premature delivery) or asymptomatic women about to undergo invasive gynecologic surgery, in light of evidence that treatment may help prevent premature births and postoperative infections. Bacterial vaginosis is associated with sexual intercourse, but no counterpart of this disease is found in men; treatment of men does not prevent recurrence of this syndrome in their sex partners.

Vulvovaginal candidiasis most often is caused by *Candida albicans* and less frequently by *Torulopsis* species and other *Candida* species. Diagnosis usually is made on clinical grounds and by examining the KOH preparation by microscopy. Vulvovaginal candidiasis is not sexually transmitted. The primary goal of therapy is alleviation of symptoms; *Candida* species often can be detected in vaginal secretions by culture, even in the absence of vaginal discharge. Patients with acute or recurrent vulvovaginal candidiasis (usually defined as three or more episodes annually) may have predisposing risk factors, such as antibiotic or glucocorticoid use, diabetes, immunosuppression, or HIV infection, though such factors are identified in a minority of cases. Many topical azole preparations are available for treatment of vulvovaginal candidiasis. Oral azole therapy is another option, but it should not be used during pregnancy. Over-the-counter topical preparations are available, but they should be used only by women in whom vulvovaginal candidiasis has been diagnosed previously and who experience symptoms similar to their previous episode; recurrences within 2 months of treatment should be reevaluated thoroughly.

Trichomonas vaginalis infection is a sexually transmitted protozoal infection that should be treated even when it is detected in patients with minimal or no symptoms. In patients with a typical vaginal discharge, the sensitivity of wet-mount examination is high, but in patients with milder symptoms, wet mount is less sensitive; culture or nucleic acid probe assay may assist in making the diagnosis. Sex partners of patients with *T. vaginalis* should be treated. Infections can be resistant to the standard doses of metronidazole; such infections may respond to retreatment or to treatment with higher doses of the same drug (2 g of metronidazole taken orally in a single dose for 3 to 5 days). Infections that persist even after treatment with this higher dose should be evaluated for susceptibility to metronidazole and referred to an expert.

CERVICITIS

Mucopurulent cervicitis (MPC) is characterized by the presence of a yellowish, mucopurulent, endocervical secretion present at the cervical os or on a white endocervical swab. MPC is often associated with cervical friability (bleeding that occurs with insertion of the first endocervical swab used for specimen collection) and with an edematous zone of cervical ectopy. The presence of increased numbers of white blood cells (more than 30) on an endocervical Gram's stain also supports the diagnosis, but this sign is too nonspecific to be diagnostically useful. Although the source of MPC is identified in a minority of cases, it is typically found in association with chlamydial infection, sometimes with gonococcal infection, and occasionally with HSV.

All patients with MPC should be tested for *C. trachomatis* and *N. gonorrhoeae*. To assess the possibility of MPC and endocervical infection, first wipe away with a swab any vaginal secretions obscuring the cervical ostium. If endocervical specimens are to be collected, a swab for the gonorrhea test should be inserted 1 to 2 cm into the endocervix and left in place for 10 to 15 seconds to absorb secretions. When using an endocervical swab to collect a specimen for examination for *C. trachomatis*, at least one full rotation of the swab or Cytobrush should be made; in sampling for chlamydia, it is optimal to obtain columnar epithelial cells present on the endocervix, because chlamydia preferentially infect these cells. Urine tests for gonococcal and chlamydial infections using nucleic acid amplification methods can be performed in lieu of tests on endocervical specimens.

An endocervical Gram's stain for gram-negative intracellular diplococci has a sensitivity of no more than about 60% for *N. gonorrhoeae*, even in experienced laboratories, and is therefore not an adequate test. In patients with MPC who have a high likelihood of having both gonorrhea and chlamydia, the clinician should treat empirically for both diseases. If the likelihood of infection with *N. gonorrhoeae* is low but that of *C. trachomatis* is appreciable, the clinician should treat for chlamydial infection and await the gonorrhea test results. If neither infection is considered likely, the clinician should await the results of both diagnostic tests before prescribing therapy.

PELVIC INFLAMMATORY DISEASE

PID, a syndrome that includes endometritis, salpingitis, tuboovarian abscess, and, in severe cases, peritonitis and pelvic abscess, can be initiated by gonococcal or chlamydial infection and possibly by bacterial vaginosis. In many instances, however, none of these sources can be confirmed. In a substantial proportion of cases of PID, there is anaerobic infection of the upper genital tract, and some experts recommend providing all women with PID with comprehensive treatment for anaerobic infection in addition to therapy for gonorrhea and chlamydial infection. Because many patients with acute PID have no symptoms or only mild symptoms, it is difficult

to make a clinical diagnosis of acute PID, and many cases go unrecognized. Severity of symptoms has not been shown to correlate with severity of tubal damage or related effects of PID; for this reason, the physician should have a low threshold for instituting therapy. PID should be suspected and treatment initiated when lower abdominal tenderness, adnexal tenderness, and cervical motion tenderness are present, if other causes have been excluded. More comprehensive evaluation should be undertaken if the symptoms and signs are more severe (a discussion is beyond the scope of this chapter). Hospitalization for PID is often indicated ([Table 272.6](#)).

Surgical emergencies, such as appendicitis, cannot be excluded.
 The patient is pregnant.
 The patient does not respond clinically to oral antimicrobial therapy.
 The patient is unable to follow or tolerate an outpatient oral regimen.
 The patient has severe illness, nausea and vomiting, or high fever.
 Patient has a tuboovarian abscess.
 The patient is immunodeficient (i.e., has HIV infection with low CD4 count, is taking immunosuppressive therapy, or has another disease).

TABLE 272.6. CIRCUMSTANCES UNDER WHICH HOSPITALIZATION FOR TREATMENT OF PID IS ESPECIALLY RECOMMENDED

STRATEGIES FOR OPTIMAL CARE

MANAGEMENT

In deciding on STD diagnostic and treatment services for a particular practice setting, consideration should be given to the risk profile of the patients served, the disease prevalence rates in the clinic population, and the likelihood that patients will comply with requests for a return visit. In settings providing services to many adolescents and young adults, it is essential to make available screening examinations for gonorrhea and chlamydia. Nucleic acid amplification assays for these agents, using urine specimens, can facilitate testing in places where gynecologic examinations are not routinely performed. In facilities where patients with urethritis and cervicitis are seen relatively often, on-site availability of medications for treatment of chlamydial infection and gonorrhea is important. In those primary care settings where patients with bacterial STDs are seen comparatively infrequently, emphasis may be placed on ensuring the availability of confirmatory or repeated testing, to exclude false-positive test results. Clinicians providing prenatal services to a population of patients with a notable prevalence of syphilis morbidity but uncertain follow-up should have on-site RPR card testing and benzathine penicillin G.

When follow-up of patients is uncertain or when continued disease transmission is a concern, immediate treatment (and possibly overtreatment) of curable STDs is preferred to delayed treatment pending the results of laboratory tests. For reasons of acceptability, adherence to treatment, and prevention of disease transmission, single-dose therapy is generally preferable to multidose therapy, and immediate dispensing of medications is preferable to requesting that a patient obtain medications at another site.

Patients diagnosed with one STD should be evaluated for others, including HIV. Practitioners serving populations with STDs should be prepared to perform HIV counseling and testing or to refer for this test. Practitioners serving populations with HIV infection also should be ready to evaluate HIV-infected patients for other STDs. Screening for STDs in HIV-infected patients should include a serologic test for syphilis and, in women, a complete gynecologic examination and tests for endocervical gonococcal and chlamydial infection. Patients with sexually acquired HIV are at increased risk of other STDs, and untreated STDs in these patients raise their risk of transmitting HIV to others.

Patients should be counseled about how to lessen their risk of acquiring STDs; such counseling should include guidance in the consistent and correct use of condoms. Identification, treatment, and counseling of sex partners are essential to prevent reinfection of the patient and further transmission of disease. The physician should assist with this process. In many cases, patients can be encouraged to bring or refer their sex partners for treatment. If patients are unwilling to notify partners, the local health department should be asked to provide confidential partner notification.

COMPLICATIONS AND PITFALLS

The likelihood of surgical emergencies should be considered in persons with possible epididymitis (testicular torsion is part of the differential diagnosis) or PID (ectopic pregnancy and acute abdomen need to be excluded). There are many pitfalls in the treatment of patients with STDs; several are noted in [Table 272.7](#).

Incomplete assessment of a patient's STD risks
 Incomplete physical examination
 Improper specimen collection
 Failure to consider the lack of sensitivity of certain diagnostic tests, leading to possible undertreatment
 Failure to consider the lack of specificity of certain diagnostic tests and the possibility of false-positive results in low-prevalence populations
 Lack of optimal on-site, immediate treatment of high-risk patients
 Underrecognition and undertreatment of PID
 Failure to consider HIV co-infection in patients with STDs and STDs in patients with HIV
 Failure to provide education and counseling in risk reduction
 Failure to prevent transmission or reinfection through identification, notification, and counseling of sex partners

STD, sexually transmitted disease.

TABLE 272.7. COMMON PITFALLS IN THE MANAGEMENT OF PATIENTS WITH STDs

Indications for REFERRAL

Persons who should be referred for further evaluation and treatment may include patients in need of specialized counseling or drug treatment services; patients with nonhealing lesions that may require biopsy; patients with persistent epididymitis, which, in the context of HIV, may be due to fungal or tuberculous infection; and patients with persistent vaginitis, which may be due to metronidazole-resistant trichomoniasis or recurrent vulvovaginal candidiasis.

COST-EFFECTIVENESS

The adverse effects of sexually transmitted infections are responsible for the high human and economic costs associated with these diseases. The annual medical cost of curing STDs (chlamydia, gonorrhea, syphilis, and trichomoniasis) is estimated to be approximately two billion dollars annually; over half of this cost is associated with PID and its effects—infertility, chronic pelvic pain, and ectopic pregnancy. Untreated syphilis during pregnancy results in fetal death in 40% of cases, and the average lifetime cost of care of an infant born with congenital syphilis is more than \$130,000. The costs of non-HIV viral STDs (genital herpes, HPV, hepatitis B) and their side effects also have been estimated to be about two billion dollars annually. Several HPV types, mainly 16, 18, 31, 33, and 35, are associated with the development of cervical dysplasia and carcinoma, and hepatitis B is associated with hepatocellular carcinoma. There is strong evidence that both ulcerative and nonulcerative STDs enhance transmission of HIV, though the extent to which transmission of HIV infection is attributable to other STDs varies locally according to disease prevalence and transmission modes.

Because the economic consequences of STDs place a large burden on the health care system, primary prevention and early detection and treatment of STDs are highly cost-effective measures. The expense and preventability of congenital syphilis have made universal syphilis screening of women during pregnancy a standard preventive measure. Hepatitis A and B are the only STDs for which there are vaccines; the first trials of an HSV vaccine were unsuccessful, and further efforts at vaccine development are under way. When tests are expensive and funds for testing are scarce, selective screening of populations at high risk for STDs may be wise, as described earlier for chlamydial infection. Preventive efforts, including counseling, also should be focused on patients at high risk; a careful risk assessment is a useful cost-effective tool.

CHAPTER 273: SURGICAL INFECTIONS

E. PATCHEN DELLINGER

[Pathophysiology](#)
[Wound Infections](#)
[Preventing Wound Infections](#)
[Necrotizing Soft-Tissue Infections](#)
[Infections in Burn Patients](#)

PATHOPHYSIOLOGY

Surgical infections are different from most medical infections because a mechanical or anatomical barrier to resolution of infection exists. Although the specific pathogens present are susceptible to antimicrobial agents, administration of these agents will not resolve the infection unless the mechanical problem is corrected. Some examples include drainage of an abscess, either superficial or deep; removal of an obstructed and infected appendix; and repair or diversion of an intestinal perforation. Some procedures may not be thought of as “operations” but achieve the same purpose. Thus, opening an infected wound, placing a percutaneous catheter into an intra-abdominal abscess, or draining an obstructed, infected biliary duct system with an endoscopic stent all fulfill this purpose. The key to successful management of a surgical infection is to recognize the “surgical” nature of the infection and to perform the required procedure promptly, in coordination with appropriate antimicrobial administration and other treatment factors.

Infections that follow a surgical procedure are classically considered surgical infections because they occur as a consequence of the procedure; in addition, many of them also require surgical intervention such as opening of the wound, draining of an intra-abdominal abscess, or repair of a leaking anastomosis.

Postoperative fever raises the question of postoperative infection and in many cases serves as the stimulus for the administration of antibiotics. However, most febrile postoperative patients do not have an identifiable infection, and many infected patients do not have a fever in the early stages of infection. Depending on the definition of fever, 20% to 75% of postoperative patients have a fever in the first 5 days after the procedure. More than 75% of fevers noted in the first 2 days are never associated with an identifiable infection. By the fifth postoperative day, the likelihood that a new fever represents a wound infection is about 40% ([Fig. 273.1](#)). Thus, giving empirical antibiotics to a postoperative patient with fever is not a good strategy unless there is a clear presumptive diagnosis of an infection that is expected to respond to antibiotic administration (e.g., pneumonia or urinary tract infection). Other postoperative infections will not respond to antibiotic administration without the appropriate surgical management, and giving antibiotics before the diagnosis is made is likely to delay diagnosis and definitive treatment. Intra-abdominal infections, primary and postoperative, are important examples of such infections.

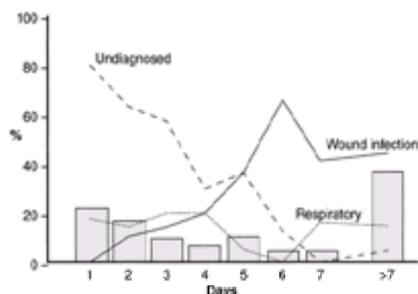

FIGURE 273.1. Bars indicate the percentage of all fevers that appear on each respective day. Lines indicate the percentage of new fevers on each day that are due to wound infection (-----) or respiratory infection (...) or are unexplained (- - -). (Data from Garibaldi RA, Brodine S, Matsumiya S, et al. *Infect Control* 1985;6:273; and Gorbach SL, Bartlett JG, Blacklow NR. *Infectious diseases*. Philadelphia: WB Saunders, 1992:754.

WOUND INFECTIONS

Essentially all surgical incisions are contaminated by some bacteria, but the risk of postoperative wound infection depends on the number and virulence of the bacteria in the wound, the state of underlying host defenses, and the extent to which the operation impairs local and systemic host defenses. Historically, wounds were classified solely by the risk of bacterial contamination during the procedure, as determined largely by entry into the gastrointestinal tract or an area of preexisting inflammation or infection. Currently, the most widely used scoring system, developed by the U.S. Centers for Disease Control and Prevention (CDC), assigns a point for wounds that are contaminated or dirty, a point for an operation that lasts longer than the 75th percentile for that procedure, and a point if the patient is classified as physical status 3 or 4 according to the American Society of Anesthesiology. Using this score, CDC data show a risk of infection of 1.5% for a score of 0, 2.9% for a score of 1, 6.8% for a score of 2, and 13.0% for a score of 3. These data reflect modern surgical and anesthetic practices and current standards for use of perioperative prophylactic antibiotics.

Most wound infections are not evident clinically until after the fifth postoperative day, so with modern practice resulting in shorter hospital stays for most procedures, over half of all wound infections are diagnosed after hospital discharge. The only types of wound infection likely to be diagnosed in the first 48 hours after a procedure are those due either to *β*-hemolytic streptococci or to *Clostridium* species. They are rare, but when they occur they can move rapidly and have devastating consequences. Clostridial infections are noted for the absence of signs of local inflammation due to the leukocidal exotoxins released into the wound. The exudate typically contains gram-positive rods without spores and few or no white blood cells (WBCs). Streptococcal infections do show signs of inflammation, and the Gram smear shows both WBCs and gram-positive cocci. Both streptococcal and clostridial early wound infections are typically accompanied by signs of severe systemic response. Any suspicion of such an infection should cause direct inspection of the wound and a Gram smear of any exudate. If the diagnosis is made, the wound must be opened and debrided, high-dose penicillin should be administered, and vigorous cardiorespiratory stabilization and support should be instituted. Recent *in vitro* and animal data suggest a helpful role for clindamycin administration in such patients due to its action of suppressing toxin production by streptococcal and clostridial species.

The most important treatment for a wound infection is to open the wound. Most wound infections respond promptly and nicely to drainage alone without antibiotics ([Fig. 273.2](#)). Antibiotics are needed for wound infections only if there is evidence of invasive soft-tissue infection beyond the limits of the wound or if there is a systemic response to the infection indicated by elevated temperature (higher than 38°C) and WBC count (more than 12,000 per microliter). If an antibiotic is given, the choice should be guided by the Gram smear of the wound exudate and the type of wound. Antibiotic treatment should be continued only until local signs of inflammation or the systemic response have resolved (usually 2 or 3 days).

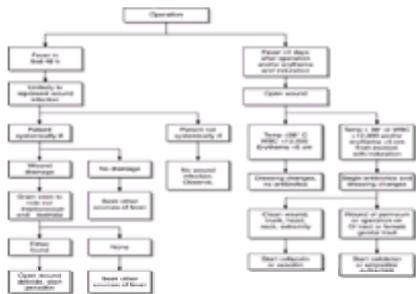

FIGURE 273.2. Diagnosis and treatment of postoperative infection.
EVIDENCE LEVEL: C. Expert Opinion.

Infections following clean operations on the trunk or extremities are most likely to be caused by *Staphylococcus aureus*. Infections that follow operations in the axilla are more likely to involve gram-negative rods, and infections that follow operations on the perineum, the female genital tract, or the large intestine commonly involve a mixture of gram-positive cocci, gram-negative rods, and anaerobes.

PREVENTING WOUND INFECTIONS

Many think first of prophylactic antibiotic administration for preventing postoperative wound infections. However, many elements are important in preventing wound infections ([Table 273.1](#)), and unless these are considered, the use of prophylactic antibiotics will not achieve an acceptable result. In addition, several factors that are not under the surgeon's control increase the risk of infection ([Table 273.2](#)). Knowledge of these can increase the surgeon's awareness of risk and perhaps stimulate additional precautions, including the appropriate use of prophylactic antibiotics for cases that might otherwise not warrant them.

- Do not perform an elective clean operation if there is a distant-site infection (urinary tract, sinusitis, subcutaneous abscess) or an adjacent open wound.
- Do not shave the operative site until just before the time of operation, or at all if possible.
- Perform complete mechanical bowel preparation before an elective colon operation.
- Use good sterile operative technique.
- Avoid tissue trauma during the operation.
- Avoid operative blood loss and minimize operative time.

TABLE 273.1. IMPORTANT ELEMENTS IN PREVENTION OF WOUND INFECTIONS

- Increased age
- Diabetes mellitus
- Obesity
- Malnutrition
- Steroid administration
- Smoking

TABLE 273.2. FACTORS THAT INCREASE THE RISK OF WOUND INFECTION

Principles for the effective use of prophylactic antibiotics have been refined over many years ([Table 273.3](#)). The three most common errors in the use of prophylactic antibiotics are failure to use them at all when indicated; initiating antibiotic administration more than 2 hours before the beginning of the procedure or after the beginning of the procedure; and continuing prophylactic antibiotics for more than 12 hours after the completion of the procedure. Surgeons commonly wish to continue antibiotics for a longer time in high-risk patients or in the presence of a postoperative fever (see above), but there is no evidence that antibiotics administered after the completion of the procedure prevent postoperative infections. Even in trauma patients, where administration of prophylactic antibiotics before the injury is impossible, prospective trials of patients with penetrating intestinal injuries or open fractures have demonstrated that a 12-hour course of antibiotics is not inferior to prolonged administration of the same agents over 5 to 7 days.

- Choose an appropriate agent (see text)
- Use a dose equal to or greater than the usual therapeutic dose for the agent chosen.
- Initiate antibiotic administration intravenously during the 60 min before the surgical incision.
- Discontinue antibiotic prophylaxis preferably at the end of the procedure, but certainly within 12 h.
- During a prolonged operative procedure, repeat doses of antibiotic at intervals of 1–2 times the half-life of the drug.

TABLE 273.3. PRINCIPLES OF PERIOPERATIVE PROPHYLACTIC ANTIBIOTIC USE

Knowledge regarding the specific procedures that benefit from administration of prophylactic antibiotics has evolved over the past 20 years. [Table 273.4](#) lists procedures for which prophylactic antibiotics are effective in reducing the rate of postoperative surgical site infections, and for which the benefit of this reduction is thought to outweigh any complications or costs of the antibiotics used. Prophylactic antibiotics are, however, commonly used in many other situations that have not been proven effective, or where reduction of infection has been demonstrated but the baseline infection rate is low or the consequences of infection are small. In the latter situation, some argue that the costs of the prophylactic use outweigh the benefits. However, there are data indicating that practicing surgeons can recognize

patients who are at higher risk and tend to use prophylactic antibiotics in those settings. Factors such as those listed in [Table 273.2](#) and found in the CDC index may justify the addition of a brief course of perioperative prophylactic antibiotics for procedures that do not have an official recommendation.

- High-risk gastrointestinal procedures (operations for cancer, gastric ulcer, bleeding, or obstruction, and when the patient has received effective acid-reducing therapy or is morbidly obese)
 - High-risk biliary tract procedures (age >60, common duct stones present, bile duct obstruction, recent acute cholecystitis, prior biliary tract operation or instrumentation)
 - Any operation on the colon or distal ileum, including appendectomies
 - Head and neck cancer operations
 - Vascular procedures on the lower extremities or abdominal aorta
 - Hysterectomy
 - Primary cesarean section
 - Joint replacement
 - Placement of other prosthetic devices
 - Cardiac procedures
 - Craniotomy
- Procedures for Which Prophylactic Antibiotic Indications Are Controversial**
- Groin hernia repair without prosthetic mesh
 - Breast mass excision and mastectomy
 - Other clean procedures without prosthetic insertion

TABLE 273.4. PROCEDURES THAT BENEFIT FROM PROPHYLACTIC PERIOPERATIVE ANTIBIOTICS

Many individual antibiotics have been tested and found effective in one or more settings for perioperative prophylaxis. In practical terms, the choice can be determined by whether the planned operation will involve the distal ileum, appendix, or colon. In this case, an agent with activity against enteric facultative and obligate anaerobic bacteria should be chosen. Cefotetan is recommended; cefoxitin is an alternative. For procedures where anaerobic bacteria are unlikely to be involved, the recommended agent is cefazolin. Vancomycin can be used for patients who are allergic to cephalosporins or in settings where methicillin-resistant *S. aureus* are common. However, vancomycin should not be used for prophylaxis unless the indications for it are strong because of its tendency to promote the emergence of vancomycin-resistant enterococci (VRE). Because vancomycin provides no activity against gram-negative rods, an agent such as aztreonam or an aminoglycoside can be added for upper intestinal operations, and metronidazole or clindamycin should be added if anaerobic bacteria will be encountered. For elective colonic procedures, current practice in the United States is to give an oral antibiotic regimen before the operation in addition to parenteral antibiotics at the time of the procedure. The most common regimen with firm support from prospective trials is neomycin 1 g and erythromycin base 1 g orally, given at 19, 18, and 9 hours before the planned procedure.

NECROTIZING SOFT-TISSUE INFECTIONS

These serious infections can be divided into those involving muscle (of which the most severe is clostridial myonecrosis, or gas gangrene) and those not involving muscle. Clostridial myonecrosis is noted for the rapid pace of its spread and the severe systemic reaction associated with it. Signs of inflammation are minimal (as noted in the section on postoperative infections) and the external evidence of infection is less than the underlying tissue involvement. Treatment requires aggressive resuscitation, large doses of penicillin, and aggressive operative debridement, often including extremity amputation. Hyperbaric oxygen probably helps if it is readily available, but the primary treatment must not be delayed by efforts to transfer the patient for its administration. Mortality and morbidity from this infection is high.

The serious nonclostridial infections have been given many names over the years, but the most common label is necrotizing fasciitis. This infection is much more common than serious clostridial infections. The fascia referred to is the superficial fascia, which consists of all tissue between the dermis and the underlying muscle. The difficulty with these infections is that the initial presentation is often misleading, resembling a simple cellulitis that would be expected to resolve with antibiotics alone. The following signs in association with an apparent cellulitis indicate that a necrotizing process is involved and that surgical exploration with probable debridement will be required: skin gangrene, ecchymoses, bullae, crepitus, edema in excess of other local signs of infection and inflammation, and failure to respond to apparently adequate antibiotic therapy. Necrotizing fasciitis can be caused by a synergistic combination of gram-negative rods, gram-positive cocci, and anaerobes, and can also be caused by β -hemolytic streptococci alone. Mixed infections tend to follow traumatic lacerations and operations on the perineum or in the abdomen involving bowel, or to complicate decubitus ulcers. Necrotizing infections that arise in trivial injuries such as varicella lesions, mosquito bites, or superficial scratches or occur with no known injury are almost always due to group A streptococci.

INFECTIONS IN BURN PATIENTS

Infection continues to be one of the primary mechanisms of morbidity and mortality in burn patients. The burn injury itself imposes major trauma with profound metabolic and immune consequences simultaneously with the destruction of the most important bacterial host defense organ, the skin. Bacteria gain access to the devitalized burn wound and previously sterile tissues beneath it at a time of profound depression of systemic host defenses. Therapeutic interventions create the risk of additional nosocomial infections, including pneumonia, urinary tract infection, and intravenous line-associated infection.

Efforts to prevent infection must begin with the initial evaluation of the patient. Tetanus toxoid should be administered. Burn wounds are washed and protected with a topical antimicrobial substance. The ideal agent should penetrate the burn wound, have broad-spectrum antibacterial activity, have little toxicity, and be both easy to apply and painless. Silver sulfadiazine is easy to apply, painless, and effective against most common burn wound pathogens, but it does not penetrate the burn wound. This makes it quite effective in preventing infection but not very effective if infection has already occurred. Mafenide acetate is also broad-spectrum and easy to apply, but it is somewhat painful on application. It penetrates the burn wound and is thus useful for reducing burn wound colonization, but this penetration can also lead to systemic absorption with resulting metabolic acidosis caused by one of the metabolites, which functions as a carbonic anhydrase inhibitor.

A burn wound is rarely sterile, but low levels of bacteria (fewer than 10^3 organisms per gram of tissue) do not cause clinical disease and are referred to as *colonization*. Infection occurs when bacterial overgrowth in the burn wound leads to invasion of adjacent viable tissue. Bacterial numbers associated with burn wound infection are usually more than 10^5 organisms per gram of tissue. Histologic sections of burn wound infection also show bacteria invading beyond the burn wound into viable tissue. Any acute change in the appearance of a burn wound or the surrounding tissues should lead to biopsy for culture and histology to make the diagnosis of invasive infection. Some signs that should stimulate biopsy include an increase in the depth of the burn wound injury, discoloration of adjacent tissue, hemorrhage beneath the burn wound, and greenish discoloration of the burn wound. Typical pathogens in burn wound infections include *S. aureus*, streptococci, *Pseudomonas aeruginosa*, *Proteus* species, *Escherichia coli*, and *Klebsiella* species. Use of parenteral antibiotics should be limited to documented infections, but they are needed for burn wound infection. The best way to prevent infection is through early closure of the burn wound, usually through a combination of excision and grafting.

CHAPTER 274: STAPHYLOCOCCAL INFECTIONS

DENNIS R. SCHABERG

[Epidemiologic Factors](#)
[Etiology and Microbiology](#)
[Pathogenesis](#)
[Clinical Findings](#)
[Laboratory Findings](#)
[Treatment](#)

Infection due to staphylococci is one of the most common problems confronting clinicians in both ambulatory and hospital settings. Staphylococci are conveniently categorized by their ability to coagulate plasma and are referred to as coagulase-positive (*Staphylococcus aureus*) or coagulase-negative. *S. aureus* is a pluripotential pathogen causing a host of clinical syndromes in normal or compromised patients, whereas coagulase-negative staphylococci generally require major host compromise, in particular indwelling devices, in order to produce disease. Other coagulase-negative isolates are limited to selected infections, as is the case for *Staphylococcus saprophyticus*, which usually is restricted to the urinary tract. Despite the availability of very active antimicrobial therapy, staphylococcal infection appears to be on the increase with persistent significant morbidity and mortality.

EPIDEMIOLOGIC FACTORS

Humans are the primary reservoir for staphylococci. Neonates frequently become colonized soon after birth with *S. aureus* at the umbilical stump, perineum, and skin. Later in life, 20% to 40% of the general population become carriers of *S. aureus* with the anterior nasal vestibule as the usual site. Patients who share in common breaks in their skin such as insulin-dependent diabetics, intravenous drug users, hemodialysis patients, and patients receiving allergy injections can have markedly higher rates of carriage. AIDS patients also have very high carriage rates, perhaps related to alteration in integument, as do patients with eczema or psoriasis. Rarely, perineal carriage persists in adults, and approximately 10% of premenopausal women will carry *S. aureus* vaginally with the density of colonization increasing during menses. Coagulase-negative staphylococci are considered to be normal flora of human skin although the particular strains carried can be dynamic.

For *S. aureus*, organisms are transferred from time to time from the site of carriage to intact skin. Normal skin resists persistent colonization, but breaks in the integument provide an opportunity for persistence and further proliferation. This translocation process makes the carrier state very important clinically in that patients with higher carrier rates are at increased risk of infection and the opportunity to eradicate the carrier state presents an opportunity for prevention in high-risk populations. Development of coagulase-negative staphylococcal infection is usually traced to contamination of an implantable prosthetic device or catheter occurring at the time of placement.

Special attention must be made of the growing problem of β -lactam-resistant strains of *S. aureus*, often referred to as methicillin-resistant (MRSA). These organisms have become prominent hospital-acquired pathogens with transmission often occurring via the hands of health care personnel. Outbreaks have also been described in chronic care settings and chronic carriers often serve as reservoirs for the organism in institutional settings. In several urban centers, community-acquired MRSA has been described with major sources of infection arising from intravenous drug users.

Control and interruption of spread of *S. aureus*, especially in institutional environments, is an effective strategy to minimize the impact of this pathogen. Timely identification of isolates, surveillance cultures of potential patient reservoirs, barrier precautions for infected patients, and reinforcement of hand washing are helpful measures in interrupting transmission. Clear identification of patients carrying the organism is also helpful if only to heighten awareness of routine infection control precautions.

ETIOLOGY AND MICROBIOLOGY

Staphylococci are gram-positive cocci that appear as grape-like clusters on Gram stain. These organisms are distinguished by their growth characteristics, colonial morphology, and virulence characteristics. *S. aureus* typically forms yellow colonies, 2 to 3 mm in diameter, with β -hemolysis in blood agar plates.

Staphylococcus epidermidis and *S. saprophyticus* are white and nonhemolytic. The major laboratory feature distinguishing *S. aureus* from the other staphylococci is the ability to produce coagulase. Other tests that may be used include mannitol fermentation and the deoxyribonuclease test, both of which are positive for *S. aureus*, as opposed to coagulase-negative staphylococci. *S. saprophyticus* is further identified by its resistance to novobiocin.

PATHOGENESIS

Infections due to staphylococci are often initiated when a break in the normal barrier of the intact skin or mucosa allows staphylococci access to underlying tissues or to the bloodstream. Multiplication ensues, and whether the infection remains localized or spreads is dependent on the interaction of the virulence determinants of the organism and host defense factors. Risk for infection and dissemination is enhanced by the presence of foreign bodies and devices such as suture material and plastic catheters. A variety of serum and tissue constituents such as fibrinogen, fibronectin, and collagen rapidly coat these materials following implantation. Many *S. aureus* strains produce surface proteins (e.g., fibronectin-binding protein, collagen-binding protein, and elastin-binding protein), which bind to these extracellular matrix molecules enabling the organism to adhere and persist. Opsonophagocytosis is also impaired in the presence of foreign devices tilting the balance against the host.

The specific adherence interactions may help explain the propensity for *S. aureus* to cause endovascular infection and to disseminate widely from a minor skin or soft-tissue focus. The organism binds avidly to endothelial cells and is actually taken up by these cells. This intracellular location protects the organism from more traditional phagocytic cells and from certain classes of antimicrobials with poor cell penetration.

Polymorphonuclear leukocytes (PMNs) are the major defense against *S. aureus*. Anticapsular antibody and C3b complement deposition enhance PMN function. Traditional cellular immunity has a small role. Defects in PMN function or number are often complicated by *S. aureus* infection. The cell wall peptidoglycan of *S. aureus* evokes a brisk inflammatory response mediated via cytokines such as interleukin-1 (IL-1), IL-6, and tumor necrosis factor- α (TNF- α). While markedly increasing the migration of PMNs to the site of inflammation, paradoxically the presence of the cytokines enhances the growth of *S. aureus*.

Staphylococcus aureus is also armed with a variety of exotoxins that affect cell function and host defense. Some of the toxins, such as toxic shock syndrome toxin 1, are pyrogenic toxin superantigens and cause life-threatening disease. They bind directly as superantigens to the invariant region of major histocompatibility complex (MHC) class II molecules, causing an expansion of T cells and a massive release of cytokines. This in turn leads to endothelial injury and shock that is clinically indistinguishable from endotoxic shock. Other toxins are enterotoxins associated with a food poisoning syndrome characterized by sudden onset of nausea and vomiting. These are preformed in the food ingested, odorless, tasteless, and heat-stable. Other secreted toxins, such as α -toxin, probably contribute to pathogenesis mainly by enhancing tissue injury.

CLINICAL FINDINGS

SKIN AND SOFT-TISSUE INFECTIONS

Folliculitis is a pyoderma localized to hair follicles that responds to local care. A furuncle or boil is a more deep-seated infection presenting as a warm, painful, swollen, and indurated area that drains purulent material on excision. If these infections extend into the subcutaneous area, they may form a carbuncle and may be accompanied by systemic findings of fever and chills.

Impetigo is a soft-tissue infection, unrelated to hair follicles, that involves a superficial area of the skin. This disease afflicts mainly children and manifests by an erythematous macule that forms a vesicle of purulent material that ruptures and crusts. Although most cases of impetigo are caused by *S. aureus*, up to 20% are due

to *Streptococcus pyogenes* or a mixed streptococcal and staphylococcal infection.

Staphylococcus aureus is the most common cause of postoperative wound infections; such infections typically occur more than 2 days after surgery and are associated with purulent or hemorrhagic drainage. Antibiotics are only secondary to the adequacy of surgical drainage and assist in local healing and preventing hematogenous spread.

In soft-tissue infections with systemic signs or symptoms, Gram stain, culture of drainage material, and blood cultures should be obtained. In mild cases of infection in the ambulatory setting where systemic symptoms are absent, empiric antistaphylococcal therapy may be prescribed for 7 to 10 days.

OSTEOMYELITIS AND SEPTIC ARTHRITIS

In adults, osteomyelitis most commonly arises from adjacent infections rather than the hematogenous spread common in children. In posttraumatic osteomyelitis, *S. aureus* is the most common organism recovered; in ischemic disease, *S. aureus* is the most common gram-positive organism recovered. The diagnosis of postoperative or traumatic osteomyelitis may be delayed or obscured by changes in plain radiographs and radionuclide scanning attributable to the underlying injury. Postoperative high fever after 2 days and objective evidence of inflammation should lead to the consideration of underlying infection. If drainage occurs, culture and recovery of *S. aureus* suggest a deep-seated infection. If mixed flora are identified, a deep aspirate should be performed for microbiologic confirmation. Adequate surgical drainage of abscesses and removal of devitalized bone and foreign material are important. Adults with *S. aureus* osteomyelitis should receive parenteral antimicrobial therapy for 4 to 6 weeks.

Staphylococcus aureus is the most common cause of septic arthritis in the elderly population and second only to gonococcal disease in persons aged 20 to 40. The patient with septic arthritis presents with a painful, swollen, warm joint; an aspirate yields high bacterial counts (usually more than 50,000 per cubic millimeter) and gram-positive cocci on Gram stain. Therapy for septic arthritis may be confounded by the inability to exclude adjacent osteomyelitis; therefore, parenteral therapy for 4 weeks with an effective antistaphylococcal agent is warranted.

Staphylococcus epidermidis is the most common cause of prosthetic joint infections, which usually occur within 3 months of surgical insertion of the prosthesis. Infections are most often accompanied by pain, joint instability, loosening of the prosthesis, and low-grade fever. Antimicrobial therapy and device removal are required for cure.

ENDOCARDITIS

Staphylococcus aureus is the most common cause of endocarditis associated with intravenous drug use and the second most common organism causing endocarditis not associated with addiction. The diagnosis is clear when the patient has fever, murmur, embolic disease, and persistent bacteremia. In an effort to include cases that have been previously excluded, proposed new criteria include two major criteria, or one major and three minor criteria, or five minor criteria for diagnosing infective endocarditis. Major criteria include positive blood cultures with organisms typical of endocarditis, all positive when drawn 12 hours apart or positive in more than three blood cultures, and evidence of endocardial involvement by echocardiography (oscillating intracardiac mass, abscess, or dehiscence of a prosthetic valve) or clinical evidence of regurgitation. Minor criteria include fever (higher than 38°C), vascular phenomenon, immunologic phenomenon, positive blood cultures not meeting the major criteria, or echocardiogram consistent with endocarditis but not meeting the major criteria.

Careful physical examination is necessary to differentiate endocarditis from nonendocarditis *S. aureus* bacteremia by detecting a new or increasing murmur or new embolic lesions. There are compelling reasons for careful clinical monitoring in the inpatient setting and avoidance of outpatient management of staphylococcal endocarditis with home infusion programs.

Laboratory evidence is generally supportive but not absolute in excluding a diagnosis of staphylococcal endocarditis. Echocardiography can be a useful adjunct, especially transesophageal echocardiography, which can approach sensitivities of 90%.

The diagnostic value of echocardiography in drug users appears to be less because visualization of the tricuspid valve, the most common site for drug use-associated endocarditis, is not significantly improved by an esophageal study over the transthoracic echocardiogram. In one series, 13% of endocarditis in intravenous drug users could not be predicted by clinical or laboratory criteria at presentation.

The mortality of endocarditis varies. The young drug user with right-sided disease has the most favorable outcome, with mortality of about 5%; the elderly hospitalized patient with heart failure or embolic disease has a mortality in excess of 70%.

Patients with *S. aureus* endovascular infection are given a parenteral bactericidal agent for 4 to 6 weeks. The duration of therapy for bacteremia without endocarditis should be 2 weeks. Although some recommend short-course therapy (2 weeks) for right-sided disease, there is limited experience with this approach to support its use on a widespread basis. Short-course therapy must be performed selectively to avoid relapses due to hematogenous seeding from extracardial sites.

The need for cardiac surgery is based on the presence of systemic emboli, cardiac compromise, or microbiologic failure manifest by prolonged persistently positive blood cultures. When a patient has *S. aureus* aortic valve endocarditis, cardiac decompensation should be expected and early surgical intervention considered. Cardiac surgery is seldom justified for right-sided disease.

PNEUMONIA

Staphylococcus aureus as a cause of nosocomial pneumonia is second only to *Pseudomonas aeruginosa*. Risk factors related to *S. aureus* pneumonia in adults include neurosurgical intervention, coma, extremes of age, prior influenza, underlying pulmonary disease, and bacteremic extrapulmonary sites of infection.

Staphylococcus aureus pneumonia also occurs in the community and is especially seen following antecedent viral infection, particularly influenza virus. Radiographs are nonspecific in distinguishing this form of pneumonia from that caused by other pathogens.

Cavities are common in children but relatively rare in adults. The criteria for diagnosis should include pulmonary infiltrate, fever, leukocytosis, and purulent tracheobronchial secretions. Gram stain and culture of the sputum should be obtained to help guide antimicrobial therapy, which usually lasts 2 weeks.

MENINGITIS

Meningitis rarely occurs by itself. Risk factors include central nervous system (CNS) trauma or surgery, intravenous drug use, extra-CNS sites of *S. aureus* infection, and diabetes mellitus. Lumbar puncture shows features typical of bacterial meningitis.

Cerebritis is the presence of microabscesses in the cerebral cortex associated with *S. aureus* bacteremia and usually endocarditis. These patients typically have a predominantly polymorphonuclear pleocytosis with counts lower than those of patients with meningitis and an elevated protein level. Gram stains are usually negative, but occasionally cultures are positive if a microabscess has recently ruptured.

TOXIN-MEDIATED SYNDROMES

Toxic shock syndrome (TSS) is usually but not always caused by *S. aureus*. Menstrual TSS was previously most common, but recently nonmenstrual TSS has become more common. Nonmenstrual TSS may be associated with vaginal colonization by toxin-secreting strains of *S. aureus* involving vaginal infections, contraceptive devices, abortion, childbirth, and the postpartum period. Other TSS-associated conditions include surgical wounds, nasal packing, osteomyelitis, skin and soft-tissue infections, and influenza-associated pneumonia.

The clinical manifestations include multiorgan dysfunction. The criteria established by the U.S. Centers for Disease Control and Prevention include fever (more than 38.9°C), systolic blood pressure below 90 mm Hg, and rash with desquamation on the palms and soles, plus involvement of three or more major organ systems: gastrointestinal (vomiting, diarrhea), muscular (myalgia, increased level of creatine phosphokinase), mucous membranes (hyperemia), renal (elevated creatinine level

with pyuria without infection), hepatic (elevated levels of aspartate transaminase and alanine aminotransferase, bilirubin), blood (thrombocytopenia), and CNS (disorientation without focal neurologic signs). Hypocalcemia without other explanation can be a helpful clue. The patient should have a negative workup for Rocky Mountain spotted fever, leptospirosis, and measles.

Disease management requires aggressive fluid replacement, followed by a careful assessment to define the origin of the toxin-producing strains of *S. aureus*. An antistaphylococcal agent should be administered for 10 to 14 days. Culture of the vaginal flora should be obtained even in the absence of a focus of infection. Once a focus is identified, eradication of the carriage should be documented.

Food poisoning is another disease caused by toxin-producing *S. aureus*. The source is the contamination of food by a carrier. The onset of illness is acute (2 to 6 hours after ingesting the contaminated food), with nausea and vomiting followed by abdominal cramps and diarrhea. The patient with *S. aureus* food poisoning is afebrile. The illness resolves within a day, and antimicrobials are not required.

FOREIGN BODY DEVICES

Staphylococcus epidermidis is the major pathogen of prosthetic devices, leading to dysfunction of the device and often a subacute presentation of infection. For prosthetic heart valves, management usually but not always requires valve replacement; for other prosthetic devices, such as prosthetic joints, shunts, and dialysis access devices, device removal is required for cure of the infection.

LABORATORY FINDINGS

The diagnosis of staphylococcal infection requires confirmation by the microbiology laboratory by culturing material from the suspected site and blood cultures if there are systemic signs and symptoms. Three sets of blood cultures drawn from different sites should be obtained if endocarditis is suspected or possible. Separating collections of each blood culture by 15 to 60 minutes will help in identifying an endovascular infection. *Staphylococcus aureus* grows rapidly in the absence of antibiotics and is usually identified in 1 to 2 days. Obtaining blood cultures 48 hours after the first set can also be helpful in suggesting a possible endovascular focus of origin.

TREATMENT

Therapy for *S. aureus* and *S. epidermidis* depends on antimicrobial susceptibility testing, host tolerance or allergies, and the site of infection. Penicillin is no longer a first-line therapy, as resistance occurs with over 90% of *S. aureus* and *S. epidermidis* pathogens by production of b-lactamase. Since the 1970s, *S. aureus* has demonstrated a gradual increase in resistance to the antistaphylococcal penicillins. These isolates are referred to as methicillin-resistant or b-lactam-resistant, reflecting the cross-resistance to all b-lactams (antistaphylococcal penicillins, cephalosporins, and imipenem). Currently, 5% to 50% of *S. aureus* pathogens are b-lactam-resistant, and up to 65% of cases of *S. epidermidis* are methicillin-resistant.

Familiarity with local susceptibility patterns is critical to selecting empirical therapy. The mechanism for resistance to b-lactams is the production of penicillin-binding protein (PBP-2a), which has a lowered affinity for penicillin binding, thus permitting the peptidoglycan production necessary for cell wall formation to occur uninterrupted.

If the organism is susceptible to oxacillin, an antistaphylococcal penicillin should be considered such as methicillin, oxacillin, or nafcillin (100 to 200 mg per kilogram per day in six divided doses). Cefazolin, a first-generation agent, is more active than the third-generation cephalosporins (cefotaxime, ceftriaxone, ceftizoxime). Other agents with activity against *S. aureus* include clindamycin, fluoroquinolones, and imipenem cilastatin. With b-lactam-resistant staphylococci, the therapy of choice is vancomycin (15 mg per kilogram every 12 hours). For patients who cannot take vancomycin, sulfamethoxazole–trimethoprim has been shown to be effective against susceptible strains. The report of strains of *S. aureus* requiring markedly increased concentrations of vancomycin for inhibition is a disturbing new development. How widespread these isolates will become and what their clinical significance will be is unclear at present. Currently, it is prudent in particular to perform detailed antimicrobial susceptibilities on isolates from patients failing to improve clinically on vancomycin therapy or patients with end-stage renal disease who may have received vancomycin frequently in the past.

Combination therapy with aminoglycosides (gentamicin or tobramycin) added to the antistaphylococcal penicillin or vancomycin leads to a shortening of the duration of bacteremia. In prosthetic infections, especially cardiac valve prostheses, three-drug combinations (vancomycin, gentamicin, and rifampin) are associated with a more favorable outcome than two-drug regimens.

Treatment of nasal carriage may be considered if a carrier is responsible for recurrent disease or an outbreak of *S. aureus* infections. Successful eradication may occur with topical therapy to the anterior nares with mupirocin twice daily for 5 to 7 days; this agent decreases nasal and hand carriage. As with most other antistaphylococcal agents, resistance to mupirocin has occurred; consequently, indiscriminate use of this agent should be avoided.

CHAPTER 275: STREPTOCOCCAL INFECTIONS

MONICA M. FARLEY AND BENJAMIN SCHWARTZ

[Group A Streptococcus](#)
[Pharyngitis](#)
[Scarlet Fever](#)
[Streptococcal Infections of the Skin and Soft Tissues](#)
[Invasive Group A Streptococcal Infections](#)
[Group B Streptococcal Infections](#)
[Other b-Hemolytic Streptococcal Infections](#)
[Streptococcus Pneumoniae](#)
[Viridans Streptococcus](#)
[Enterococcus and Group D Streptococci](#)

Streptococci are a diverse group of bacteria, including the major human pathogens *Streptococcus pyogenes* (group A streptococci), *Streptococcus agalactiae* (group B streptococci), and *Streptococcus pneumoniae* (pneumococci), that cause a wide range of clinical infections. Streptococci are important pathogens because of their diversity, their significance as common causes of infection in all age groups, and recent developments in the epidemiology and treatment of certain streptococcal infections. These developments include the emergence of antimicrobial resistance in several species, particularly *S. pneumoniae*; the increased awareness of severe infections caused by group A streptococci, including streptococcal toxic shock syndrome (STSS) and necrotizing fasciitis; and the occurrence of clusters of rheumatic fever cases in the United States. The emergence of vancomycin resistance in enterococci (until recently considered to be group D streptococci but now given their own genus designation) poses complicated treatment challenges and creates the potential for spread of vancomycin resistance to more virulent organisms.

Streptococci are gram-positive cocci that form chains in broth media. Most species are facultative anaerobes, although some are strictly anaerobic. Absence of catalase production and the formation of chains distinguish streptococci from most other gram-positive cocci, including staphylococcal species.

A number of classification schemes have been used to differentiate streptococci, and they often must be used in combination to accurately characterize organisms. The Lancefield serogroup is determined based on precipitin reactions of specific antisera to the cell wall carbohydrate antigen. Although over 20 Lancefield groups have been described, groups A, B, C, D, F, or G are the ones most often associated with human disease. The type of hemolysis that occurs when cultured on blood agar can classify strains: a-hemolytic strains partially hemolyze erythrocytes, producing a greenish zone of hemolysis, whereas b-hemolytic strains cause complete hemolysis, leaving a clear zone around a colony. Other strains are nonhemolytic (occasionally referred to as g-hemolytic). Streptococci are assigned to a species group based on metabolic characteristics and molecular techniques, including DNA homology and 16S ribosomal RNA (rRNA) sequencing. [Table 275.1](#) shows the classification of clinically important streptococci based on these three schemas.

Lancefield Group	Species	Hemolysis	Clinical Diseases
A	<i>S. pyogenes</i>	β	Pharyngitis, sepsis, bacteremia, streptococcal shock syndrome, necrotizing fasciitis, acute rheumatic fever, acute glomerulonephritis
B	<i>S. agalactiae</i>	β	Neonatal sepsis, endocarditis, bacteremia, otitis media, meningitis, pneumonia, urinary tract infection, necrotizing fasciitis
C	<i>S. equisimilis</i> , <i>S. anginosus</i>	β	Cellulitis, bacteremia, pharyngitis
D (nonhemolytic)	<i>S. bovis</i>	None	Bacteremia, endocarditis
F (variable)	<i>S. intermedius</i> , <i>S. constellatus</i> , <i>S. anginosus</i> (intermediate or Miller group)	Variable	Neck abscess, abscesses, infections—abdominal cavity, legs, dental abscess
G	<i>S. dysgalactiae</i>	β	Cellulitis, bacteremia, arthritis, pharyngitis
Nongrouped	<i>S. pneumoniae</i>	α	Pneumonia, otitis media, meningitis, bacteremia, meningitis
Nongrouped	Viridans streptococci (Miller group) (<i>S. mitis</i> , <i>S. oralis</i> , <i>S. gordonii</i> , <i>S. salivarius</i> , <i>S. anginosus</i> , <i>S. bovis</i>)	α or none	Endocarditis, bacteremia in immunocompromised patients

TABLE 275.1. CLASSIFICATION OF CLINICALLY IMPORTANT STREPTOCOCCI

GROUP A STREPTOCOCCUS

DEFINITION

Group A *Streptococcus* includes a single species (*S. pyogenes*) and causes a wide array of pyogenic infections including pharyngitis, scarlet fever, skin and soft-tissue infections (e.g., impetigo, cellulitis, necrotizing fasciitis), infection of normally sterile sites (e.g., bacteremia, pneumonia), postpartum infection (puerperal sepsis), and STSS. Nonsuppurative sequelae of group A streptococcal infection include acute rheumatic fever (ARF) and acute glomerulonephritis (AGN).

PATHOGENESIS AND VIRULENCE

Group A streptococcal pathogenicity and virulence are mediated by a variety of cell-associated and extracellular factors ([Table 275.2](#)) and by the host immune response to them. The major virulence factor of group A streptococci is the M protein, which is antigenic and inhibits phagocytosis. More than 80 M protein serotypes and over 100 M protein gene sequence types (*emm* types) have been described. M protein expression is required for invasive infection. Long-term type-specific immunity follows infection, but reinfection with another M serotype is common. In addition, in a susceptible host, cross-reactive antibodies to certain M-protein epitopes may result in the development of nonsuppurative sequelae such as rheumatic fever.

Factor	Activity
Cell-Associated Factors	
M protein	Antiphagocytic, superantigenic in some cases
Hyaluronic acid capsule	Antiphagocytic
Streptolysin S	Leukocyte and erythrocyte cytolysis, promotes spreading
Cla peptidase	Cleaves Cla, decreases neutrophil chemotaxis
Protein F	Mediates attachment to pharyngeal cells
Extracellular Factors	
Streptococcal pyrogenic exotoxins (SpeA, SpeB, SpeC, SpeE)	Superantigenic, responsible for scarlet fever rash, SpeB—cysteine protease precursor
Streptococcal superantigen	Superantigenic
Hyaluronidase	Cleaves hyaluronic acid in connective tissue, promotes spreading
Streptokinase	Cleaves plasminogen, promotes clots
Streptolysin O	Leukocyte and erythrocyte cytolysis, promotes spreading
DNAse	Cleaves DNA and RNA, promotes spreading

TABLE 275.2. VIRULENCE FACTORS AND EXTRACELLULAR TOXINS OF GROUP A STREPTOCOCCI

Streptococcal pyrogenic exotoxins have been implicated in the pathogenesis of serious streptococcal infections. These exotoxins, an extracellular protein known as streptococcal superantigen, and some M-protein fragments act as superantigens, inducing polyclonal T-cell activation and the massive release of inflammatory mediators. The hyaluronic acid capsule of the group A streptococci contributes to virulence by inhibiting phagocytosis, and heavy capsule production has been epidemiologically linked with rheumatic fever-associated isolates.

PHARYNGITIS

EPIDEMIOLOGIC FACTORS

Pharyngitis is the most common clinical manifestation of group A streptococcal infection. Pharyngitis is the fourth leading reason for acute-illness visits to a physician's office in the United States. Although group A streptococci are the most common bacterial cause of pharyngitis, they account for less than half of all pharyngitis episodes. Disease occurs most often in school-age children, but persons of all ages may be affected. Most infections occur during winter and spring. Infection spreads person to person by large respiratory droplets; thus, close contact, such as that in child care settings, crowded households, schools, and military barracks, enhances the spread of infection. In families where a child is infected, 20% of siblings and 5% of adults also develop infection. Asymptomatic pharyngeal carriage is common, affecting 10% to 20% of school-age children during disease outbreaks. However, carriers are less likely to transmit infection, probably due to reduced numbers of organisms and loss of M-protein production in isolates associated with asymptomatic carriage. Foodborne outbreaks of streptococcal pharyngitis have been reported. Fomites and household animals have not been shown to play a role in transmission.

CLINICAL FEATURES

Characteristic symptoms include the acute onset of fever and sore throat; headache, abdominal pain, vomiting, and malaise may also occur, particularly in children. Physical examination typically reveals pharyngeal erythema and edema. Tonsils are enlarged and may have a gray–white exudate. Tender anterior cervical adenopathy is frequently present. Palatal petechiae, while less common, are consistent with a group A streptococcal etiologic process. Signs of upper respiratory infection, such as rhinorrhea, cough, and hoarseness, suggest a nonstreptococcal cause. Despite suggestive clinical findings, overlap with nonstreptococcal pharyngitis is common; thus, accurate diagnosis of group A streptococcal pharyngitis cannot be made with consistency based on clinical findings.

Several other pathogens may cause pharyngitis and can sometimes be differentiated from streptococcal infections, based on clinical and epidemiologic findings (Table 275.3). Respiratory viruses cause most pharyngitis; infection frequently is present in multiple family members and the community, and typical symptoms of upper respiratory congestion and cough are prominent. *Mycoplasma* infections also usually manifest signs of upper respiratory infection, and bullous myringitis may be present. Infections caused by enterovirus and herpes simplex virus are more often stomatitis than pharyngitis. Culture of a throat swab specimen on sheep blood agar remains the gold standard for diagnosis of group A streptococcal pharyngitis. Rapid antigen detection tests, which identify the carbohydrate grouping antigen, offer a highly specific alternative method that allows for immediate diagnosis and initiation of appropriate early therapy. However, because of lower sensitivity, a negative rapid antigen test should be confirmed by conventional culture. Newer tests with greater sensitivity may eliminate the need for backup culture in the future.

Etiology	Clinical/Epidemiologic Characteristics
Group A streptococci	Tonsillar exudate, cervical adenopathy, absence of URI signs
Other β-hemolytic streptococci	Tonsillar exudate, cervical adenopathy, absence of URI signs
<i>Arcanobacterium haemolyticum</i>	Scarlatiniform rash, adolescent age group
<i>Corynebacterium diphtheriae</i>	Gray pseudomembrane, systemic toxicity, nonexacerbation
<i>Neisseria gonorrhoeae</i>	History of sexual activity
Epidemiologic virus	Generalized lymphadenopathy, splenomegaly, atypical lymphocytes
Adenovirus	Signs of URI, conjunctivitis (pharyngoconjunctival fever)
Influenza virus	Signs of URI, occurrence during influenza epidemic
<i>Mycoplasma</i>	Signs of URI, bullous myringitis
Enterovirus	Stomatitis (usually posterior), systemic signs
Herpes simplex virus	Stomatitis (usually anterior)

URI, upper respiratory infection.

TABLE 275.3. ETIOLOGIES OF PHARYNGITIS AND DISTINGUISHING CLINICAL AND EPIDEMIOLOGIC FEATURES

OPTIMAL MANAGEMENT AND PROGNOSIS

Treatment of group A streptococcal pharyngitis reduces spread, prevents suppurative and nonsuppurative complications, and may shorten the duration of illness. Treatment with oral penicillin V (250 mg 3 times a day for 10 days) or intramuscular benzathine penicillin (600,000 units in patients weighing less than 27 kg and 1,200,000 units in patients weighing more than 27 kg) remains the treatment of choice for persons with group A streptococcal pharyngitis. Therapy can be initiated up to 9 days after onset of symptoms and still prevent the occurrence of rheumatic fever. Penicillin resistance among clinical isolates of group A streptococci has not been documented. Erythromycin is recommended for treatment of penicillin-allergic persons; in some countries, resistance to erythromycin may exceed 20%, but in the United States resistance is uncommon. Other b-lactam antibiotics also are effective as therapy when given in a 10-day course. Shorter course treatment options have been proposed (e.g., cefadroxil, cefuroxime, cefpodoxime, azithromycin), but data are limited and must be weighed against the increased cost and broader spectrum of activity of these agents.

Repeat throat culture after therapy to document cure is not recommended in asymptomatic persons. Notable exceptions include when a patient or household member has a history of rheumatic fever; during outbreaks of rheumatic fever or poststreptococcal glomerulonephritis; or during outbreaks of pharyngitis in closed communities. Although some persons will continue to carry group A streptococci, the risk both of disease spread and of developing rheumatic fever are low. Repeat therapy of asymptomatic carriers is not recommended except in special circumstances (e.g., patient or household member with history of rheumatic fever; efforts to terminate large outbreak in closed setting). Clindamycin (children: 20 to 30 mg per kilogram per day for 10 days; adults: 600 mg per day in 2 to 4 equally divided doses for 10 days) or amoxicillin/clavulanate (40 mg per kilogram per day in 3 equal doses for 10 days) have been recommended for symptomatic patients with multiple repeated culture-positive episodes of pharyngitis.

COMPLICATIONS

Suppurative complications of streptococcal pharyngitis include direct extension of infection resulting in peritonsillar or retropharyngeal abscess, sinusitis, otitis media, mastoiditis, or cervical lymphadenitis. Rarely, meningitis, brain abscess, intracranial venous thrombosis, and pneumonia may occur through this mechanism. Bacteremic spread may result in metastatic foci of infection.

ACUTE RHEUMATIC FEVER

Nonsuppurative sequelae of infection include ARF and AGN. ARF occurs after pharyngeal group A streptococcal infection, whereas AGN most often follows cutaneous infection but may also occur after pharyngitis (see Chapter 150 for a discussion of acute glomerulonephritis). The incidence of ARF in the United States is estimated at 0.5 to 1 per 100,000 population. In developing countries, rates several hundred times higher may be observed, and rheumatic heart disease accounts for 25% to 40% of all cardiovascular disease. Although the incidence of rheumatic fever in the United States has declined steadily during the past century, outbreaks in the late 1980s occurred in several communities and military settings, reemphasizing the importance of diagnosing and treating streptococcal pharyngitis. ARF is most common in school-age children and is rare in those under 3 years. Attack rates vary from less than 1% to 3% in persons with untreated streptococcal pharyngitis. In general, ARF has been a disease of lower socioeconomic, minority populations in the United States, probably related to crowded living conditions. However, several outbreaks in the 1980s involved predominantly white, middle-class families in suburban and rural settings.

Although the pathogenesis of ARF is not entirely understood, the importance of tissue cross-reactive epitopes of the group A streptococcal M protein is clear. Antibodies to specific M-protein epitopes may cross-react with myocardial proteins, antigens in the basal ganglia of the human brain, and antigens in articular cartilage. Host factors, including class II HLA antigens (HLA-DR2 in blacks and HLA-DR4 in whites) may contribute to the pathogenesis of rheumatic fever. Certain M-protein types (types 1, 3, 5, 6, 18, and 24) and the mucoid or heavily encapsulated phenotype have been associated with “rheumatogenicity.”

Acute rheumatic fever is defined by a combination of clinical and laboratory findings, occurring in the context of a preceding streptococcal pharyngitis (Table 275.4). In some cases, a history of clinical pharyngitis is absent. Major manifestations include carditis, arthritis, chorea, subcutaneous nodules, and erythema marginatum (a serpiginous, evanescent, erythematous, nontender rash on the trunk or extremities). Minor manifestations include fever, arthralgia, heart block manifested by a

prolonged PR interval, and elevated acute-phase reactants (erythrocyte sedimentation rate or C-reactive protein). Preceding group A streptococcal infection can be ascertained by serologic tests and, less commonly, by culture.

Evidence of Preceding Group A Streptococcal Infection*	
Positive throat culture	Major Manifestations†
Positive rapid antigen detection test	
Elevated or rising streptococcal antibody titer (anti-streptolysin O [ASO], antihyaluronidase, anti-DNAse B, or streptocytin)	Minor Manifestations‡
Carditis	
Polyarthritides	Laboratory
Chorea	
Erythema marginatum	Prolonged PR interval
Subcutaneous nodules	
Edema	Elevated acute phase reactants
Arthralgia	
Fever	

TABLE 275.4. THE MODIFIED JONES CRITERIA: 1992 UPDATE OF GUIDELINES FOR THE DIAGNOSIS OF AN INITIAL ATTACK OF ACUTE RHEUMATIC FEVER^a

Onset of ARF generally occurs 2 to 3 weeks after a preceding streptococcal pharyngitis; however, cases presenting with “pure” chorea may occur several months after a preceding infection. Arthritis is the most common manifestation of disease (47% to 100% of ARF). The ankles, knees, wrists, and elbows are most frequently affected by this migratory polyarthritides. Resolution occurs in several weeks without articular damage. Carditis occurs in 40% to 50% of cases and may vary in severity from pancarditis, resulting in heart failure and death, to subtle myocardial involvement, which can be detected only by echocardiogram. Endocarditis primarily involves the mitral valve and, less commonly, the aortic valve. Although most valvular damage resolves, mitral and aortic valve stenosis may occur. Specific manifestations of ARF vary with age; carditis is more common in children and arthritis more common in adults.

The differential diagnosis of ARF includes other causes of arthritis, carditis, and chorea. Treatment is aimed at reducing inflammation. In less severe disease, high-dose aspirin to achieve a blood level of 20 mg per deciliter is adequate therapy; more severe illness is treated with corticosteroids. Bed rest is recommended, particularly for persons with carditis. Rheumatic heart disease is the only long-term consequence of infection. Patients without carditis during their acute episode are unlikely to develop cardiac disease later.

Recurrences of rheumatic fever may ensue with subsequent group A streptococcal infections. Such recurrences are prevented by continuous antimicrobial prophylaxis. Intramuscular benzathine penicillin given every 4 weeks is recommended and avoids problems with compliance. In settings where the risk of streptococcal infection is high, benzathine penicillin can be given every 3 weeks. Oral sulfadiazine, penicillin, and erythromycin for penicillin-allergic persons are all acceptable alternatives, although none of the oral regimens are as effective as intramuscular penicillin. Prophylaxis should continue until the risk of acquiring group A streptococcal pharyngitis is reduced and at least 5 years after acute illness. In persons with rheumatic carditis, some experts recommend lifelong prophylaxis.

SCARLET FEVER

Scarlet fever presents as a group A streptococcal infection in the presence of a characteristic *scarlatina* rash. It occurs most often in association with pharyngitis but may also present with pyoderma or wound infection (surgical scarlet fever). The epidemiology of infection is similar to that of group A streptococcal pharyngitis, with the exception that scarlet fever is rare in very young children. The cutaneous manifestations of scarlet fever are a result of delayed-type hypersensitivity to streptococcal pyrogenic exotoxins, requiring prior exposure for expression of disease. This probably explains the age distribution in that most infants have not had previous exposure or generated antibodies to the exotoxins.

The hallmark of scarlet fever is a generalized erythematous rash that is noted within 2 days of the onset of pharyngitis symptoms. The rash begins on the upper body and spreads distally, sparing the palms and soles; it is blanching and is composed of fine papules that give the skin the texture of sandpaper. Linear petechial streaks in skin folds are known as Pastia's lines. On the face, the area around the lips is spared, yielding a circumoral pallor. Enlarged papillae on a coated tongue may occur (strawberry tongue), with the tongue later becoming denuded. Nausea and vomiting are common and may be the initial clinical finding. Desquamation may occur during convalescence. The differential diagnosis of scarlet fever includes viral exanthems, Kawasaki's syndrome, and infection with *Arcanobacterium haemolyticus*. Treatment is the same as that for streptococcal pharyngitis.

STREPTOCOCCAL INFECTIONS OF THE SKIN AND SOFT TISSUES

DEFINITION

Group A streptococcal skin and soft-tissue infections differ in their clinical presentation and reflect varying degrees of invasiveness. Impetigo, often referred to as pyoderma, is the most common group A streptococcal skin infection, recognized by shallow ulcers with a honey-colored crust. Cellulitis is a deeper infection involving the subcutaneous tissues and is characterized by erythema, edema, and tenderness, with mild to moderate systemic toxicity. Erysipelas, a characteristic form of group A streptococcal cellulitis, produces lesions that are erythematous and sharply demarcated by a raised edge; the rash is very tender, may involve the face or lower extremities, and is usually accompanied by fever, chills, and leukocytosis ([Fig. 275.1](#)). Deep-tissue infections include necrotizing fasciitis and myositis.

FIGURE 275.1. Erysipelas involving the left malar and preauricular areas of the face. The borders of the infection are clearly demarcated, and the lesions are elevated. Note the impetiginous lesions on the fingers. See [color figure 275.1](#).

EPIDEMIOLOGIC FACTORS

Impetigo is the second most common manifestation of group A streptococcal infection. It occurs primarily in pre-school-age and school-age children in late summer or fall. Group A streptococcal colonization of intact skin may lead to impetigo following minor trauma or insect bites. Crowded conditions and poor sanitation enhance spread of streptococci from skin sites. As with pharyngitis, fomites are unlikely to have a major role in transmission.

Other group A streptococcal skin and soft-tissue infections, such as cellulitis, erysipelas, and necrotizing fasciitis, occur more frequently in adults. Infection may be associated with local trauma, surgical wounds, or chronic skin disorders such as eczema and psoriasis. Individuals with impaired lymphatic drainage may have

recurrent episodes of cellulitis in the affected area. Intravenous drug use has been associated with acute cellulitis, at times associated with bacteremia, due to groups A, B, C, or G streptococci. Varicella infection can predispose to severe streptococcal skin and soft-tissue infection, including necrotizing fasciitis. Anecdotal reports and small case series have linked development of necrotizing fasciitis to the use of nonsteroidal anti-inflammatory drugs; however, an association has not been proved in a controlled study. Most cases of streptococcal necrotizing fasciitis occur in older adults, and the rates increase with age.

ETIOLOGIC FACTORS

In addition to group A streptococci, *Staphylococcus aureus* can frequently be isolated from impetigo lesions, but its relative clinical importance is not entirely clear. Streptococcal strains associated with impetigo differ in M-protein types from those associated with pharyngitis and include some highly nephritogenic M types that have been linked to community outbreaks of post-streptococcal glomerulonephritis.

Erysipelas is almost always caused by group A streptococci, occasionally by group C or G streptococci. In contrast, acute cellulitis may be associated with a number of organisms, most often β -hemolytic streptococci and *S. aureus*. *Streptococcus pneumoniae*, gram-negative organisms such as aeromonads and pseudomonads, vibrios, and clostridia may also be considered in certain epidemiologic settings. Many forms of necrotizing soft-tissue infections have been described and associated with a variety of etiologic agents including *Clostridium perfringens* and other clostridial species, *S. aureus*, mixed aerobes and anaerobes, and group A and rarely group B streptococci. Group A streptococcal necrotizing fasciitis may be distinguished from other forms of necrotizing fasciitis by the severity of pain and systemic toxicity, the rapid progression of necrosis, and association with multiorgan failure.

CLINICAL FEATURES

Impetigo lesions usually begin as papules that evolve to vesicles and pustules, which over several days break down, leaving shallow ulcerated lesions with a honey-colored crust. Regional lymphadenopathy may occur, and systemic signs are rare. In contrast to these lesions, staphylococcal pyoderma (bullous impetigo) presents with large bullae that rupture, leaving a nonpurulent, thin, shiny crust. Impetigo lesions occur most commonly on the face and extremities.

Streptococcal cellulitis occurs most often at the site of skin disruption, trauma, or in an area of impaired lymphatic drainage. Lesions are tender, erythematous, and edematous; lymphangitis is common. Systemic manifestations such as fever and leukocytosis often accompany the local findings. Differentiating streptococcal cellulitis from other causes, such as *S. aureus*, is not usually possible on clinical grounds. In contrast, the clinical appearance of erysipelas is characteristic. Lesions generally occur on the face or extremities and are characterized by a well-demarcated, raised, advancing edge. The affected area is tender and there is marked systemic toxicity. Blood cultures are usually negative in both erysipelas and streptococcal cellulitis.

Initial clinical signs of necrotizing fasciitis are similar to those of cellulitis, except that the degree of pain is severe and, at least at first, appears disproportionate to the appearance of the lesion. Skin lesions may become bullous, turning violaceous in color and then necrotic ([Fig. 275.2](#)). Infection advances rapidly with progressive necrosis of subcutaneous fascia and fat, prompting the lay press to refer to it as the “flesh-eating” infection ([Fig. 275.3](#)). When the diagnosis is in question, magnetic resonance imaging and examination of frozen section biopsies may be useful in determining the extent of tissue involvement. Fever and systemic toxicity, at times progressing to multiorgan failure, are common. Approximately 50% of patients with necrotizing fasciitis are also diagnosed with STSS.

FIGURE 275.2. Group A streptococcal necrotizing fasciitis in a child with preceding varicella infection. Note the large bullous lesions with surrounding violaceous discoloration of skin. (Courtesy of Dr. Larry Slack, Vanderbilt University.) See [color figure 275.2](#).

FIGURE 275.3. Group A streptococcal necrotizing fasciitis. See [color figure 275.3](#).

OPTIMAL MANAGEMENT

Penicillinase-resistant oral antibiotics are effective therapy for impetigo. Erythromycin therapy has proven effective in the past, but erythromycin resistance among *S. aureus* may compromise use of this agent in the future. Topical therapy with mupirocin also is very effective.

Cellulitis and erysipelas may require parenteral antibiotics. If the cause of the cellulitis is unknown, a semisynthetic, penicillinase-resistant penicillin or first-generation cephalosporin should be used. In necrotizing fasciitis, surgery is required to remove necrotic tissue or to relieve increased compartment pressure. The large inoculum of organisms with the propensity to be in a phase of growth during which expression of penicillin-binding proteins (PBPs) may be reduced results in reduced efficacy of penicillin in streptococcal necrotizing fasciitis (the Eagle effect). Clindamycin therapy has been shown to be superior to penicillin and unaffected by the inoculum size in experimental streptococcal myositis. Most experts currently recommend the administration of clindamycin and penicillin. Intravenous immune globulin (IVIG) has been used when necrotizing fasciitis occurs in association with streptococcal toxic shock (see discussion of management of STSS below).

INVASIVE GROUP A STREPTOCOCCAL INFECTIONS

DEFINITION

Invasive group A streptococcal infections can be defined by the isolation of the organism from normally sterile sites and may be associated with skin and soft-tissue infections, respiratory tract infections, or, in some cases, bacteremia with no identified septic focus. STSS, which was first recognized in 1987, is characterized by hypotension and multiorgan failure ([Table 275.5](#)).

- I. Laboratory isolation of group A streptococci
 - A. From a normally sterile site
 - B. From a non-sterile site
- II. Clinical findings occurring within 48 h of hospitalization or 48 h of illness for a nosocomial case
 - A. Hypotension
 - B. Multiorgan involvement defined by two or more of the following
 1. Renal impairment
 2. Coagulopathy (thrombocytopenia or disseminated)
 3. Liver involvement
 4. Adult respiratory distress syndrome or evidence of diffuse capillary leak
 5. Generalized erythematous macular rash that may desquamate
 6. Soft-tissue necrosis, including necrotizing fasciitis or myositis, or gangrene

^a An illness that meets criteria IA and II (both A and B) is defined as a definite case. An illness that meets criteria IB and II is defined as a probable case if no other etiology is identified. Adapted from Working Group on Severe Streptococcal Infections. Defining the group A streptococcal toxic shock syndrome. *JAMA* 1993;269:376.

TABLE 275.5. DEFINITION OF STSS^a

INCIDENCE AND EPIDEMIOLOGIC FACTORS

The incidence and severity of invasive group A streptococcal infections have increased since the mid-1980s. Incidence of disease ranges from 1.5 to 5 cases per 100,000 population. Rates of disease are highest among infants, the elderly, African Americans, and Native Americans. Rates of invasive group A streptococcal infection also are significantly increased in persons with chronic illness, malignancy, diabetes mellitus, varicella infection, HIV infection, and alcohol abuse. A number of outbreaks of invasive group A streptococcal disease in nursing homes have been reported.

More than 10% of invasive group A streptococcal infections occur in a nosocomial setting. Most common syndromes include postpartum endometritis and sepsis, surgical wound infections, and catheter-related sepsis. Health care workers with asymptomatic skin, pharyngeal, vaginal, and anal carriage have been implicated in nosocomial outbreaks.

Streptococcal toxic shock syndrome accounts for 15% of invasive infections. Although younger, previously healthy individuals are emphasized in case reports of this syndrome, population-based surveillance reveals that the elderly and those with underlying illness are at greatest risk.

ETIOLOGIC FACTORS

Changes in the epidemiologic factors associated with invasive group A streptococcal infection and the emergence of STSS correspond to an increase in infections caused by M types 1 and 3 and an increase in the proportion of strains producing pyrogenic exotoxin A (SpeA). In the United States, statistically significant associations have been shown between these serotypes and SpeA production and STSS, whereas European investigators have associated pyrogenic exotoxin B (SpeB) production with disease severity. Although M types 1 and 3 are most common, many other M types have been associated with invasive disease, and geographic variation has been observed. M-protein genotyping (*emm* typing), based on sequencing of the variable region of the M-protein gene, is now available and will be useful in monitoring trends in M-protein prevalence.

CLINICAL FEATURES

Half of invasive group A streptococcal infections occur in association with skin and soft-tissue infection, followed by bacteremia without a defined source and respiratory tract infection. Clinical presentations and severity vary with the site of infection and the health status of the host. Overall mortality is 15% and it increases with advancing age.

Streptococcal toxic shock syndrome frequently begins with nonspecific, flulike symptoms, including fever, malaise, and myalgia. Although diagnosis at this early stage may be difficult, one should maintain an increased index of suspicion when evaluating patients in high-risk groups, particularly outside of the flu season, and in the setting of ongoing community outbreaks. Within 24 to 48 hours of onset, however, hypotension occurs accompanied by organ system impairment or acute respiratory distress syndrome. A generalized erythematous rash occurs in 10% to 20% of patients, and necrotizing fasciitis is observed in a similar proportion. Desquamation may occur during convalescence. Mortality ranges from 30% to 65%.

OPTIMAL MANAGEMENT

Parenteral therapy with a β -lactam agent or clindamycin is appropriate for invasive group A streptococcal infections. As with necrotizing fasciitis, a combination of clindamycin and penicillin is recommended for severe infections such as STSS. Inhibition of synthesis of streptococcal proteins such as M protein and pyrogenic exotoxins is an added benefit of clindamycin therapy. Supportive care and surgical intervention in the case of associated tissue necrosis or endometritis are also important. There is increasing evidence to suggest that high-dose IVIG may improve survival in persons with STSS. IVIG has been shown to contain neutralizing activity against streptococcal superantigens, although significant variation has been noted between IVIG preparations. Given the extremely high case fatality rates for STSS, the available data, though not based on randomized trials, support the use of IVIG in treatment of STSS. The recommended dosage is 1 to 2 g per kilogram given once and repeated if needed.

When an episode of postoperative or postpartum group A streptococcal infection is identified, health care workers involved in direct patient care during delivery, operative procedure, or wound care should be screened for asymptomatic carriage. Screening should include nares, throat, vagina, rectum, and skin. Medical and laboratory records should be reviewed to identify additional cases and efforts made to retrieve and subtype isolates to determine relatedness. Secondary cases of invasive group A streptococcal disease have been reported among household contacts of an index case. However, the magnitude of the risk of subsequent cases and optimal chemoprophylaxis regimens have not been adequately determined. Until such data are available, decisions regarding chemoprophylaxis should be based on individual assessment of risk in each case.

GROUP B STREPTOCOCCAL INFECTIONS

INCIDENCE AND EPIDEMIOLOGIC FACTORS

Group B streptococci (*S. agalactiae*) cause infection primarily in newborns, pregnant women, and adults with underlying medical conditions. Over the past several decades, group B streptococci (GBS) have emerged as the leading cause of sepsis, meningitis, and pneumonia in newborn infants in the United States; the incidence of invasive neonatal disease is about 1.0 case per 1,000 live births (approximately 3,900 cases in the United States per year). This represents a substantial recent decline likely related to implementation of new prevention guidelines. Epidemiologic risk factors for neonatal infection include African American background, low socioeconomic status, teenage pregnancy, and previous delivery of a GBS-infected infant. Risk is also increased in preterm delivery and in the presence of intrapartum risk factors such as maternal fever (38°C or above), prolonged rupture of membranes (18 hours or longer), and maternal colonization with GBS. The GBS are estimated to account for 15% to 25% of maternal infections.

In nonpregnant adults, the risk of invasive GBS infections increases with age and is higher among African Americans. The incidence of invasive GBS infections in adults is approximately 5 cases per 100,000 persons and has been noted to be increasing in recent years. Conditions that predispose nonpregnant adults to serious GBS infections include diabetes mellitus, malignancies in young and middle-aged adults, cirrhosis, presence of decubitus ulcers, and a neurogenic bladder. Nosocomial infection is relatively common (20% of invasive cases) and has been associated with placement of central venous catheters.

ETIOLOGIC FACTORS AND PATHOGENESIS

At least ten GBS serotypes have been identified; types Ia, Ib/c, Ia/c, II, III, and V are most common in the United States. Immunity is mediated by antibody to the capsular polysaccharide and is serotype-specific. Several studies have shown that susceptibility to neonatal infection is increased in infants born to mothers with low

levels of anticapsular antibody. GBS are a common inhabitant of the gastrointestinal tract and lower genital tract. Rectal and vaginal carriage can be identified in 25% to 30% of pregnant women. Newborns may become infected from ascending infection after rupture of membranes while still in utero or during vaginal delivery.

Little is known about immunity to GBS infections in adults. The diverse group of underlying conditions among nonpregnant adults with GBS disease suggests that susceptibility to infection may be complex and include waning antibody levels, impaired immune response, and local factors such as skin breakdown, aspiration, and structural abnormalities in the urinary tract.

CLINICAL FEATURES

Pneumonia and bacteremia are the most common presentation of early-onset neonatal GBS disease. Meningitis is the most common presentation of late-onset infection in neonates; bacteremia, pneumonia, and bone and joint infection may also occur. The case fatality rate of neonatal infection is approximately 5%. Neurologic sequelae occur in up to one-third of infants who survive GBS meningitis.

Postpartum endometritis, wound infections (often associated with cesarean section), and bacteriuria are the most common presentations of maternal GBS infection. Signs of endometritis generally begin within 48 hours of delivery and include fever and uterine tenderness. Polymicrobial infection is common. The severity of GBS urinary tract infection ranges from asymptomatic bacteriuria to pyelonephritis.

In nonpregnant adults, the most common clinical diagnoses are skin, soft-tissue, or bone infection; bacteremia with no identified source; urosepsis; and pneumonia. Typical skin or soft-tissue infections include cellulitis, wound infection, and infection of foot ulcers or decubitus ulcers. More than half of patients with such infections have diabetes mellitus. Endocarditis and meningitis are uncommon manifestations of invasive GBS disease. There are rare reports of GBS associated with STSS and necrotizing fasciitis. Clinical findings vary with the site of infection. Overall mortality for invasive GBS in adults is approximately 25%; risk of death is higher in the elderly and in those with pneumonia.

The gold standard for diagnosis of GBS infection is culture. Optimal sensitivity of vaginal and rectal cultures from pregnant women requires inoculation of a selective broth medium rather than direct plating of the specimen. GBS antigen detection tests are thus far insufficiently sensitive to be used for prenatal or intrapartum screening. Invasive GBS disease may present as a polymicrobial bacteremia in nonpregnant adults, most often involving mixed infection with staphylococci.

OPTIMAL MANAGEMENT

Parenteral antibiotic therapy and supportive care are the mainstays of therapy. All GBS strains are susceptible to penicillin. The combination of a b-lactam and aminoglycoside is recommended for severe neonatal infections. Erythromycin resistance is increasing and compromises the use of this agent in penicillin-allergic individuals. Use of clindamycin is preferred in this setting. Surgical debridement may also be important in the treatment of certain skin and soft-tissue infections.

PREVENTION

Many neonatal GBS infections can be prevented by intrapartum antimicrobial prophylaxis. Chemoprophylaxis with penicillin or ampicillin significantly reduces the incidence of neonatal infection and of postpartum maternal febrile illness. The approach recommended by the U.S. Centers for Disease Control and Prevention (CDC) includes prenatal screening cultures at 35 to 37 weeks' gestation; and intrapartum antibiotics for preterm deliveries (less than 37 weeks' gestation), GBS carriers, and mothers with intrapartum risk factors and unknown colonization status. Vaccines for the prevention of GBS infection in newborns are in development.

OTHER b-HEMOLYTIC STREPTOCOCCAL INFECTIONS

INCIDENCE AND EPIDEMIOLOGIC FACTORS

Group C and G streptococci have been implicated as causes of endemic and epidemic pharyngitis and of invasive infection. Because many group C streptococci are also bacitracin-sensitive, they may be misidentified as group A streptococci when this technique is used to identify positive throat cultures.

In one hospital-based case series, group G and C streptococci accounted for 11% and 5% of all bacteremic b-hemolytic streptococcal infections. Group G streptococcal infection, however, represented only 0.3% of all positive blood cultures. Populations at high risk for invasive group C and G streptococcal infections are similar to those populations at high risk for group B streptococci.

ETIOLOGIC FACTORS AND PATHOGENESIS

Most group C streptococcal infections in humans are caused by *Streptococcus equisimilis*. *Streptococcus zooepidemicus* is primarily an animal pathogen and rarely infects humans; outbreaks associated with unpasteurized dairy products have been reported. Only one case of bacteremic infection with *Streptococcus equi* has been reported. Group G streptococci generally are not characterized by species.

Both group C and G streptococci make streptolysin O, and *S. equisimilis* produces the streptokinase that is used for human thrombolytic therapy. Group G streptococci have M proteins that are antiphagocytic. Pyrogenic exotoxins have not been documented in either group C or G.

CLINICAL FEATURES

The clinical presentation of group C and G pharyngitis is similar to that of group A streptococcal infection. Both endemic disease and epidemics of foodborne infection can occur. A variety of suppurative infections due to group C and G streptococci have been reported. Bacteremic group C and G streptococcal infection presents most commonly with skin and soft-tissue infection, pulmonary infection (pneumonia and empyema), or with no defined focus. Endocarditis, puerperal sepsis, bone and joint infection, and peritonitis have also been reported.

TREATMENT

Penicillin is the treatment of choice for these infections. For severe infections (e.g., endocarditis), an aminoglycoside may be added for synergy. Similar to GBS infections, 26% of invasive group G streptococcal infections were polymicrobial, *S. aureus* being identified in half of the infections; thus, broader spectrum antimicrobial coverage may be indicated until culture results are known.

STREPTOCOCCUS PNEUMONIAE

INCIDENCE AND EPIDEMIOLOGIC FACTORS

Streptococcus pneumoniae (pneumococcus), an a-hemolytic streptococcus, is the leading cause of bacterial meningitis, community-acquired bacteremia, and bacterial pneumonia in the United States. The annual incidence of pneumococcal bacteremia is 23 cases per 100,000 persons. Rates are highest at the extremes of age. The pneumococcus also accounts for 30% to 40% of otitis media cases—approximately 7 million cases per year in the United States. Risk factors for pneumococcal infection include chronic and immunosuppressive illness, particularly hematologic malignancies, HIV infection, anatomical and functional asplenia, cerebrospinal fluid leaks, and very young or older age. Rates of pneumococcal disease are increased in African Americans and certain Native American populations in the southwestern United States. Cigarette smoking and passive exposure to cigarette smoke have both been shown to increase the risk of invasive pneumococcal disease in nonelderly adults. Children with underlying diseases and those who attend day care are at increased risk for invasive pneumococcal disease.

Pneumococcal infection is transmitted person to person by direct contact with respiratory secretions. Although outbreaks of pneumococcal disease are uncommon, recent occurrences of clusters in an overcrowded jail, among military trainees, and in day care and nursing home settings emphasize the role of crowding as a risk factor for transmission. Pneumococcal infections usually occur during the winter and early spring, and may complicate infections caused by influenza and respiratory

syncytial virus.

ETIOLOGIC FACTORS AND PATHOGENESIS

More than 80 capsular types of *S. pneumoniae* have been identified. Most infections are caused by relatively few of these types: the seven most common serotypes account for over 70% of infections in the United States. As with other streptococcal species, the capsule inhibits phagocytosis, and anticapsular antibody provides type-specific protection. The immune response to infection and to nasopharyngeal carriage varies with serotype and age.

Although several pneumococcal toxins have been identified, their pathogenic role remains unclear. Pneumolysin activity may be important in the development of pneumococcal pneumonia. Cell wall teichoic acid of *S. pneumoniae* elicits a potent inflammatory response. Peroxide production by the organism may also contribute to pathogenesis.

Pneumococcal upper respiratory infections, otitis media, and sinusitis occur following direct extension from the nasopharynx, and pneumonia occurs following aspiration of the organism. Host factors that promote aspiration or inhibit mechanical or immunologic defense mechanisms, such as alcohol abuse or smoking, increase the risk of pneumonia.

CLINICAL FEATURES

Pneumococcal otitis media and sinusitis present with findings typical of infection at those sites and cannot be distinguished clinically from other etiologies of infection. Pneumococcal pneumonia often presents with abrupt onset of fever and chills. Cough is productive of purulent to blood-tinged sputum. Pleuritic chest pain, tachypnea, and tachycardia are common. Hypoxemia and cyanosis may occur. On examination, the patient appears acutely ill. Rales and signs of consolidation are usually present. A pleural rub or signs of an effusion may occur. The abdomen may be distended and abdominal pain may occur with lower lobe pneumonia. Laboratory evaluation reveals leukocytosis with an increased proportion of neutrophils and band forms. The most common radiographic finding is lobar consolidation, usually involving a single lobe; however, multilobar disease or bronchopneumonia may also occur. Blood culture may be positive in 20% of patients. Examination of sputum specimens often reveals gram-positive, intracellular, lancet-shaped diplococci.

Pneumococcal bacteremia may occur in association with pneumonia or with no evidence of a primary focus. Up to half of all pneumococcal bacteremia in children occurs in those presenting to the emergency department with fever and no localizing signs; most children are clinically well and culture-negative on reevaluation at 24 to 48 hours, regardless of whether antimicrobial therapy was begun. In contrast, pneumococcal bacteremia in adults is generally associated with significant systemic toxicity and most patients are hospitalized for treatment of their disease. Metastatic focal infections including meningitis, osteomyelitis, septic arthritis, and peritonitis may occur following bacteremia in children and adults.

OPTIMAL MANAGEMENT

The emergence of antimicrobial resistance among pneumococci has had a major impact on therapy for these infections. Resistance to penicillin and other β -lactam antibiotics occurs through changes in the PBPs, which decrease their affinity for these agents. Resistance occurs along a continuum that depends on the number of changes within the PBPs. These changes occur following exchange of genetic material with other pneumococci or other streptococcal species. Resistance is unrelated to β -lactamase production and thus inhibitors of β -lactamase add nothing to the treatment of penicillin-resistant pneumococcal infections. Penicillin-resistant strains frequently have decreased susceptibility or resistance to the cephalosporins, including third-generation cephalosporins, which also rely on binding to PBPs for their activity. Penicillin-resistant pneumococci are also more likely to be resistant to erythromycin and trimethoprim–sulfamethoxazole, although by completely different mechanisms. Currently, most resistance is clustered within several serotypes, including 6A and B, 9V, 14, 19A, and 23F. Rates of resistance vary widely among geographic areas but have now reached significant levels in most areas of the United States.

Although penicillin resistance is defined by a minimum inhibitory concentration (MIC) of greater than 1 μg per milliliter and intermediate susceptibility by an MIC between 0.1 and 1 μg per milliliter, the clinical response to therapy depends on the antibiotic concentration that can be achieved at the site of infection. Pneumonia and bacteremia caused by intermediate strains may be successfully treated with high-dose penicillin. Fully resistant infections at these sites may still respond to penicillin or can usually be treated with a parenteral third-generation cephalosporin because achievable blood levels of the antibiotic are many times higher than the MIC. Recent trends toward ever higher MIC levels among pneumococci may compromise treatment with β -lactams in the future. Expanded spectrum fluoroquinolones have good activity against β -lactam-resistant pneumococci at this writing. However, use of such agents is not currently approved in children, and judicious use in adults is recommended to avoid rapid emergence of resistance.

Because of decreased penetration of penicillin across the blood–brain barrier and decreased opsonophagocytosis in the central nervous system, pneumococcal meningitis caused by intermediate or resistant strains cannot be treated with penicillin. In addition, the increasing prevalence of third-generation cephalosporin resistance makes reliance on these agents for empirical treatment of pneumococcal meningitis no longer acceptable. Treatment with a parenteral third-generation cephalosporin (cefotaxime or ceftriaxone) *in combination with* vancomycin is now recommended. The addition of rifampin has been advocated by some in difficult cases. All pneumococci remain susceptible to vancomycin. Amoxicillin remains the drug of choice as first-line empirical therapy for children with otitis media, although an increase in the dosage to 80 or 90 mg per kilogram per day is recommended.

PREVENTION

A 23-valent pneumococcal polysaccharide vaccine is recommended for persons over 2 years of age in high-risk groups and for all persons over 65. Approximately 90% of invasive pneumococcal infections are caused by a type included in the vaccine or a related type with cross-protection. Vaccine efficacy for bacteremic disease is about 70% and varies with underlying disease and age. Efficacy has not been demonstrated in persons with sickle cell anemia, Hodgkin's disease, and other hematologic malignancies. Penicillin prophylaxis has been effective in decreasing invasive pneumococcal infections in patients with sickle cell disease. Seven-, nine-, and eleven-valent polysaccharide/protein conjugate vaccines will soon be available for use in infants and young children. Indications for use of the conjugate vaccines in adults have yet to be determined.

VIRIDANS STREPTOCOCCUS

DEFINITION

Viridans streptococci are a heterogeneous group of organisms that are not uniformly classified by either blood agar hemolysis or Lancefield serogroup classification systems. The Latin word *viridans*, meaning “green,” was chosen because many of the species in this group are α -hemolytic; however, other species in this group are nonhemolytic and a few are β -hemolytic. The viridans streptococcal species do not have predictable, characteristic Lancefield serotypes, although an individual isolate may react with one or more Lancefield sera. In general, then, the viridans streptococci are a group defined more by exclusion than inclusion; they must be distinguished from pneumococci, enterococci, group D streptococci, and other groupable streptococci.

The nomenclature and number of species in the viridans streptococci group have changed several times over the past two decades. Clinically significant viridans streptococci include *S. mitis*, *S. oralis*, *S. sanguis*, *S. gordonii*, *S. cristii*, *S. salivarius*, *S. mutans*, and the Intermedius or Milleri group that includes *S. intermedius*, *S. constellatus*, and *S. anginosus*. Nutritionally variant streptococci were formerly classified as viridans streptococci and now form a separate group. They require pyridoxal or vitamin B₆ for growth. Although they will grow in broth blood culture media, which contains the necessary nutrients, they will not grow when subcultured onto agar unless the media is supplemented. Two nutritionally variant streptococcal species are proposed: *S. adjacens* and *S. defectivus*. Because the clinical features of nutritionally variant streptococcal disease are similar to those of the viridans streptococci, they are included in this section.

INCIDENCE AND EPIDEMIOLOGIC FACTORS

Because of changes in patient populations and underlying cardiac diseases, viridans streptococci are now responsible for about 35% of all cases of native valve endocarditis, whereas in the past they constituted a much greater proportion of cases. Most patients with endocarditis due to viridans streptococci have congenital or acquired valvular heart disease (rheumatic disease, congenital disease, mitral valve prolapse, and degenerative valve disease) or prosthetic valves. Although many

species of viridans streptococci produce endocarditis, they are not distinguishable by clinical manifestations.

PATHOGENESIS AND CLINICAL FEATURES

Viridans streptococci are common commensals of the oral pharynx, gastrointestinal tract, and female genital tract. Viridans streptococci are organisms of low virulence, in part because they lack the usual repertoire of pathogenic mechanisms such as production of endotoxins, exotoxins, or pyogenic factors. The important characteristic that they do possess is the ability to adhere to and propagate on endocardial surfaces. This characteristic is mediated in part by production of extracellular dextran, a compound produced unpredictably by certain isolates, and by the production of lipoteichoic acid, which mediates binding to fibronectin on cardiac valves. Dextran not only mediates adherence to valvular surfaces but also decreases the ability of penicillin to kill organisms, resulting in enhanced vegetation size in dextran-producing strains.

Endocarditis is the major clinical disease caused by the viridans streptococci. The course of endocarditis caused by viridans streptococci is typically indolent, resulting in delayed diagnosis, often 2 to 5 weeks following the onset of symptoms (see [Chapter 270](#)).

The clinical significance of the growth of viridans streptococci from blood cultures is frequently questioned. However, viridans streptococci are well-established causes of significant bacteremia without endocarditis in immunocompromised hosts, particularly patients undergoing bone marrow transplant or chemotherapy for malignancy. In some centers, it is the most common cause of bacteremia in such patients. Bacteremia has been associated with neutropenia, the presence of mucositis, and prophylactic use of trimethoprim–sulfamethoxazole. *S. mitis* is the most frequently reported species. It typically occurs within 15 days of bone marrow transplant and is more common in children than adults. While the majority of patients have an uncomplicated febrile illness, up to one-fourth develop a fulminant shock syndrome characterized by vascular collapse, rash, adult respiratory distress syndrome, and subsequent desquamation.

Viridans streptococci can also cause meningitis, albeit rarely. Isolation of viridans streptococci from the cerebrospinal fluid poses a challenge of interpretation because only a single preantibiotic specimen is usually available. In the face of signs, symptoms, or other laboratory data indicating true meningitis, viridans streptococci must be considered in the list of causative agents and not summarily disregarded as a contaminant. Viridans streptococcal meningitis and bacteremia have been described among all age groups, including neonates. The Intermedius or Milleri group is well known for the propensity to cause pyogenic infections such as intra-abdominal and visceral abscesses, brain abscesses, and endocarditis complicated by myocardial or perivalvular abscesses.

OPTIMAL MANAGEMENT AND PROGNOSIS

Most but not all viridans streptococci remain very sensitive to penicillin G. Resistance to penicillin is mediated by alteration of the PBPs and not by β -lactamase production, similar to pneumococci. Strains with an MIC between 0.1 and 0.5 μg per milliliter are defined as relatively resistant or intermediate, and those with an MIC of 0.5 μg per milliliter or more are defined as resistant. The American Heart Association recommends treatment with a combination of high-dose parenteral penicillin (20 to 30 million units per day) with gentamicin or vancomycin with gentamicin for resistant (MIC 0.5 μg per milliliter or greater) infections. Cephalosporins should be used with caution in penicillin-resistant viridans streptococcal infections; because cephalosporins also bind to PBPs, alterations may cause some degree of cephalosporin resistance in addition to penicillin resistance.

No vancomycin resistance among viridans streptococci has been reported; however, this drug should be considered only in cases in which no other therapy can be used, such as serious β -lactam allergy. A variety of other antibiotics may have activity against penicillin-resistant infections. These include chloramphenicol, imipenem, and teicoplanin. Sensitivity to these antibiotics is not uniformly predictable; therefore, MIC testing of the isolate should be done.

ENTEROCOCCUS AND GROUP D STREPTOCOCCI

DEFINITION

Enterococci are gram-positive, variably hemolytic cocci that usually react with Lancefield group D antisera but now form a separate genus. Two species, *Enterococcus faecalis* and *Enterococcus faecium*, account for 80% to 90% and 5% to 10% of human enterococcal disease, respectively. Enterococci are ubiquitous, hardy organisms, which are part of the normal human gastrointestinal flora and sometimes are found as part of the genital and skin flora. They are also found in the gastrointestinal tracts of other animals and in environmental sources such as soil and water. The remarkable capacity of enterococci to manifest antimicrobial resistance, most notably vancomycin resistance, makes this otherwise low-level pathogen a major clinical challenge.

INCIDENCE AND EPIDEMIOLOGIC FACTORS

Enterococci now rank as the second or third most prevalent cause of hospital-acquired infection. Although *E. faecalis* and *E. faecium* are responsible for the majority of human enterococcal disease, other *Enterococcus* species that are rarely encountered as human pathogens include *E. gallinarum*, *E. casseliflavus*, *E. durans*, *E. hirae*, *E. avium*, and *E. raffinosus*. Colonization with *Enterococcus* organisms is far more common than clinically relevant disease. The enterococcus is of low virulence in humans and most patients with serious enterococcal infection have significant underlying diseases.

Although enterococci are normal inhabitants of the gastrointestinal tract, studies have demonstrated that disease-causing isolates are frequently acquired exogenously. Such acquisition highlights the potential preventability of nosocomial infections and the importance of limiting the spread of resistant organisms from one patient to another. Health care workers whose hands become contaminated with vancomycin-resistant enterococci (VRE) may contribute to nosocomial transmission. Risk factors for nosocomial enterococcal disease include prolonged hospitalization, intensive care unit location, antibiotic therapy (particularly with cephalosporins or aminoglycosides), and use of vascular or urinary catheters. Critically ill patients in intensive care, oncology, and transplant units are at greatest risk of acquiring multidrug-resistant enterococci, particularly VRE.

CLINICAL FEATURES

The most common enterococcal infections involve the urinary tract and are often associated with structural abnormalities or recent instrumentation. Enterococci cause a variety of other clinical diseases, including wound and tissue infections, bacteremia, meningitis, endocarditis, intra-abdominal infections, and pelvic infections. Enterococci account for 5% to 10% of bacterial endocarditis cases. Underlying valvular damage or heart disease is not a prerequisite for infection. Enterococcal bacteremia is more common than endocarditis and is often identified in the setting of polymicrobial disease. A source of bacteremia may be identified in the abdomen, pelvis, biliary tract, urinary tract, or a wound. Patients with enterococcal bacteremia have a mortality rate in the range of 30% to 50%; host underlying illness and immunocompromised states contribute to this high case fatality rate.

Enterococcus is an unusual but well-known cause of meningitis, particularly among neonates. As with other enterococcal infections, meningitis occurs among patients with underlying disease, including structural abnormalities or trauma, previous procedures to the central nervous system, or previous antibiotic use or immunocompromised state. Enterococci are frequently isolated from polymicrobial intra-abdominal and pelvic abscesses; however, their role may be more synergistic than directly pathogenic. The need for specific antienterococcal therapy in this setting is not fully defined because resolution of many mixed infections is achieved through combinations of antibiotics that are not effective therapy for *Enterococcus*. Pure enterococcal pelvic and abdominal infections are described most notably among peritoneal dialysis patients, cirrhosis patients, and women following cesarean section. Mixed aerobic and anaerobic wound and tissue infections may include *Enterococcus*; however, as with abdominal infections, the precise pathogenic role of this organism is difficult to establish.

OPTIMAL MANAGEMENT

All enterococci exhibit low-level intrinsic antibiotic resistance to a variety of agents, including penicillin, cephalosporins, clindamycin, and aminoglycosides. Most enterococci have also acquired “tolerance” to cell wall–active agents such as β -lactams and vancomycin. High-level β -lactam resistance is most often seen in *E. faecium*. Penicillin resistance is generally due to decreased PBP affinity but β -lactamase production is occasionally detected. Synergistic activity occurs between cell wall–active agents, such as ampicillin, and aminoglycosides; combination therapy is standard for serious enterococcal infections. Unfortunately, high-level aminoglycoside resistance, now seen with increasing frequency, eliminates the synergistic benefit.

A striking increase in the prevalence of VRE has occurred in the last decade. VRE account for almost 15% of enterococcal infections in intensive care units, and their

prevalence in other hospital locations is increasing. The vanA, vanB, vanC, or vanD resistance phenotypes that result in variably decreased glycopeptide antibiotic binding affinity mediate resistance to vancomycin. The vanA phenotype, inducible high-level vancomycin and teicoplanin resistance, is present in approximately 70% of VRE in the United States; the vanB phenotype, variable vancomycin resistance and teicoplanin susceptibility, is present in about 25% of VRE.

The treatment of choice for susceptible infections that do not require bactericidal activity, such as urinary tract infections, remains ampicillin or penicillin. Use of vancomycin should be reserved for penicillin-allergic patients or in patients with *E. faecium* infections that show high-level penicillin resistance. For infections that require bactericidal therapy such as endocarditis, meningitis, and life-threatening bacteremia, a combination of a cell wall-active agent (e.g., penicillin, ampicillin, or vancomycin) and an aminoglycoside (e.g., gentamicin or streptomycin) is recommended. Clinical failures and relapses occur more often in persons infected with strains with high-level aminoglycoside resistance, when synergy cannot be achieved. Isolates with high-level gentamicin resistance should also be tested for streptomycin resistance, as streptomycin may occasionally remain active in this setting. Treatment options for high-level gentamicin- and streptomycin-resistant enterococci include therapy with higher doses or prolonged courses of ampicillin or vancomycin (e.g., ampicillin 12 to 16 g per day for 8 to 12 weeks for endocarditis).

Optimal treatment for VRE infections has not been established. VRE urinary tract infections can be successfully treated with nitrofurantoin. In many *E. faecalis* VRE infections, penicillin or ampicillin remains active and can be used for treatment. Teicoplanin may be useful in the subgroup of VRE infections with the vanB resistance phenotype, but emergence of teicoplanin resistance on therapy has been noted. VRE infections due to *E. faecium* are particularly problematic due to the common association with high-level penicillin resistance and resistance to most other available agents. Combinations of agents, including some fluoroquinolones, doxycycline, rifampin, novobiocin, and chloramphenicol, have been proposed; the bacteriostatic nature of these agents limits their use in endocarditis and meningitis. Quinupristin/dalfopristin offers another option for treatment of *E. faecium* VRE infections but it is not active against *E. faecalis*. The investigational drug linezolid, the first synthetic oxazolidinone, has shown good in vitro activity against both *E. faecalis* and *E. faecium* VRE.

Because most resistant enterococcal infections are hospital-acquired, strategies to prevent the spread of these strains are vital. These include prudent vancomycin use by clinicians and appropriate infection control measures to prevent person-to-person transmission.

GROUP D STREPTOCOCCI

Streptococcus bovis, a group D streptococcus, is a common colonizer of the gastrointestinal tract and relatively uncommon cause of endocarditis and bacteremia. *S. bovis* is responsible for approximately 15% of cases of infective endocarditis and the presentation is clinically indistinguishable from that caused by viridans streptococci. Invasive disease due to *S. bovis* has been associated with underlying gastrointestinal pathology, particularly colon cancer. As a result, most experts recommend that patients who have *S. bovis* isolated from blood be evaluated for colonic malignancies. Penicillin is the drug of choice for treatment of *S. bovis* infections; other antibiotics active against these bacteria include cephalothin, vancomycin, erythromycin, and clindamycin.

CHAPTER 276: ANTHRAX

RAYMOND A. SMEGO, Jr.

[Incidence and Epidemiologic Factors](#)
[Microbiology](#)
[Pathogenesis](#)
[Clinical Features](#)
[Diagnosis](#)
[Treatment](#)
[Prevention and Control](#)

Anthrax is a zoonotic infection, affecting domestic livestock that acquire infection by grazing on spore-contaminated fields. It causes human disease by way of direct animal contact or through exposure to contaminated animal hides, meat, or other products. No human-to-human transmission has been demonstrated. *Bacillus anthracis*, the causative organism of anthrax, is an aerobic, nonmotile, gram-positive bacillus that can exist as a spore, thus allowing the organism to withstand adverse environmental conditions and persist in the soil for up to 60 years. The disease is the result of a virulence capsule and necrotizing toxin that are produced by the organism once it has invaded the host and reverted to its vegetative form.

INCIDENCE AND EPIDEMIOLOGIC FACTORS

With its name derived from the Greek derivative for “coal,” anthrax has had an important place in human history. The disease was one of the plagues of the Middle Ages. Known as the “Black Bane,” it swept through Europe during the seventeenth century. Rayor in 1850 described filiform bodies in the blood of dying livestock, and in 1863 Davaine transmitted anthrax to experimental animals by subcutaneous injection of infected blood. Robert Koch later recognized the sporulation of *B. anthracis* and its importance in the life cycle and environmental perpetuation of the organism. Anthrax has a place of importance in early immunization history as well; in 1881 Pasteur successfully administered a heat-attenuated anthrax vaccine to sheep.

Anthrax is rarely seen in industrialized countries, with sporadic cases occurring in individuals exposed to contaminated animal hides, hair, wool, bone, or other animal products. Cases of oropharyngeal and gastrointestinal anthrax are associated with ingestion of contaminated meat. The disease is endemic in parts of the Middle East, Africa, Asia, and Haiti. Recent large-scale outbreaks occurred during the 1970s to 1990s in Zimbabwe, Tanzania, and Haiti. In 1979, in Sverdlovsk in the former Soviet Union, the largest known epidemic of inhalational anthrax occurred; it was later found to have been the result of an accidental release of anthrax spores from a military research facility. This outbreak demonstrated the potential suitability of *B. anthracis* as a weapon of biologic warfare.

MICROBIOLOGY

Bacillus anthracis grows aerobically on 5% sheep blood agar without hemolysis. This gram-positive rod-shaped bacterium produces oval spores that are centrally or paracentrally located and produce no swelling of the bacillus. In tissues or discharges, the organisms appear in short chains (less than three bacilli). Lysis of specific g-bacteriophage confirms identification.

PATHOGENESIS

The virulence of *B. anthracis* is due to an antiphagocytic poly-D-glutamic acid capsule and a three-component exotoxin consisting of protective antigen, edema factor, and lethal factor. After inoculation through the skin or mucous membranes, spores germinate in macrophages and grow at the local site to produce capsule and toxin, resulting in characteristic extensive tissue edema and a paucity of neutrophils. Edema factor has adenyl cyclase activity and raises cyclic adenosine monophosphate (cAMP) levels up to 200-fold, and is responsible for the edema and impaired neutrophil function. Spread of bacilli to regional nodes with further production of toxin gives rise to the hemorrhagic, necrotic, and edematous lymphadenitis characteristic of anthrax.

CLINICAL FEATURES

Clinical forms of anthrax include cutaneous (more than 90% to 95% of cases), inhalational, oropharyngeal, gastrointestinal, sepsis, and meningeal disease. Typical cutaneous anthrax evolves through a range of local changes, even after initiation of antimicrobial therapy, beginning as a nonspecific, erythematous, painless, pruritic papule or macule that appears after an incubation period of 3 to 4 days. The lesion subsequently develops into a vesicle from which the organism can be isolated. The formation of the vesicle is accompanied by a mild to moderate ring of gelatinous edema that is usually more severe on the neck or face than on the trunk or extremities. The vesicle subsequently ulcerates and forms a characteristic centrally depressed black chancre (or malignant pustule) ([Fig. 276.1](#)). Other features of cutaneous anthrax include edema out of proportion to the size of the lesion, typical lack of pain, location on the face or extremities ([Fig. 276.2](#)), regional lymphadenitis, and rarity of neutrophils of Gram stain of lesion specimens. Approximately 80% of cutaneous lesions contain localized and resolve spontaneously within a few weeks. Cutaneous lesions that may mimic the early stages of anthrax include staphylococcal infections, plague, and tularemia. However, these diseases seldom lead to the severe skin necrosis seen in patients with anthrax.

FIGURE 276.1. Typical anthrax eschar on the right shoulder of a 12-year-old boy.

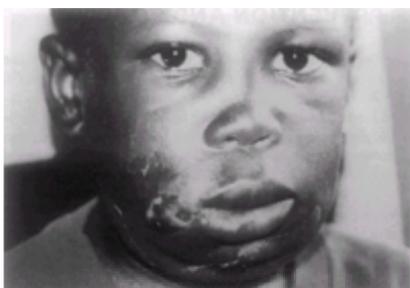

FIGURE 276.2. Cutaneous anthrax with eschar on the lip commissure and facial edema (day 3).

Inhalational anthrax (or wool sorter's disease) begins with an influenza-like prodrome that lasts for 1 to 6 days, followed by sudden deterioration with dyspnea, stridor, cyanosis, and hypoxemia. The key diagnostic feature is widening of the mediastinum due to hilar adenopathy; pleural effusions may be seen but pneumonia is uncommon. Inhalational disease is usually diagnosed late in its course and, like the extremely rare oropharyngeal and gastrointestinal forms, is usually fatal despite antibiotic therapy, often the result of sepsis or meningitis.

DIAGNOSIS

Worldwide most cases of animal and human anthrax are diagnosed on clinical and epidemiologic grounds, especially in developing countries where laboratory facilities and personnel are not readily accessible or available. Laboratory confirmation can be made by demonstration of the causative organism in blood, tissue fluids, and exudates by direct microscopic examination and culture, or by animal inoculation. Enzyme-linked immunosorbent assay (ELISA) or fluorescent antibody serologies are available but are rarely used or helpful ante mortem, especially in fulminant systemic disease. Polymerase chain reaction techniques can detect as few as three spores per clinical specimen, and a rapid hand-held immunochromatographic assay has recently been developed and made suitable for field use.

TREATMENT

Penicillin is the drug of choice for all clinical forms of disease. A daily dose of 1.2 to 8 million units of penicillin G (or V) for 7 to 10 days virtually eliminates the spread of cutaneous anthrax and essentially reduces the mortality rate to zero. Antibiotic therapy, however, will not prevent or retard the natural progression of the anthrax lesion. Penicillin has no effect on necrotizing toxin already secreted in the host tissue. It is also ineffective against *B. anthracis* spores but will stop further multiplication of the vegetative form of the organism, consequently preventing further spread of the disease. For serious systemic disease, high-dose penicillin (24 million units per day) is recommended. Tetracycline, erythromycin, chloramphenicol, and ciprofloxacin are suitable alternatives for penicillin-allergic patients. One uncontrolled study suggested a benefit of corticosteroids for serious systemic infection. Specific anthrax antiserum seems to be of value in toxic patients but it is not commercially available in most countries.

PREVENTION AND CONTROL

Effective agricultural regulations that reduce or eliminate the incidence of anthrax include vaccination of domestic livestock, prohibition of the slaughter of unvaccinated animals, and burning of animals suspected of having anthrax. Recently, in a number of developing countries, political instability and disruption of economic infrastructures have led to a lack of enforcement of these effective public health measures, thus creating a significant potential for an increase in the number of outbreaks of anthrax as occurred in Zimbabwe following the 1978–1980 civil war, and in Haiti in 1994 after the ousting of the dictatorial government. Newer human anthrax vaccines are under development. Clinicians and public health officials must be capable of recognizing this uncommon but epidemic-prone disease.

CHAPTER 277: LISTERIA AND ERYSIPELOID INFECTIONS

BARRY ZELUFF, MARCIA KIELHOFNER AND SUSAN J. BURGERT

[Listeriosis](#)
[Erysipelothrix Rhusiopathiae](#)

LISTERIOSIS

INCIDENCE AND EPIDEMIOLOGY

Listeria monocytogenes is a b-hemolytic, facultative intracellular, gram-positive coccobacillus with a characteristic tumbling motility. This organism may be mistaken for a contaminant in the laboratory due to its similar appearance to diphtheroids. *Listeria* strains may be readily recovered from soil, water, and decaying vegetation, and have been isolated from sheep and cattle (where epizootics have been described) as well as other wild and domestic mammals and avian species. Despite this widespread distribution, invasive disease occurs in only 3.6 to 7.1 per million population in the United States, accounting for approximately 1,700 cases annually. The disease has an increasing incidence with age, and a slight male predominance (1.4:1) has been noted. The vast majority of patients with invasive listeriosis are immunocompromised; the disease has been associated with solid and hematologic malignancies, liver disease, systemic lupus erythematosus, steroid and other immunosuppressive therapies, renal failure, alcoholism, pregnancy, and transplantation (often in the context of treatment for allograft rejection). Although an uncommon infection in patients with AIDS, the frequency is reportedly up to 300 times that seen in the general population, most commonly occurring in patients with CD4 counts of less than 100.

The importance of foodborne transmission has been underscored by several outbreaks over the past two decades. Implicated vehicles include raw vegetables, processed undercooked meats, unpasteurized milk and soft cheeses. Other reported methods of transmission include transplacental spread, direct transmission to veterinarians delivering infected calves, and nosocomial outbreaks involving contaminated rectal thermometers and resuscitation equipment.

PATHOGENESIS

The development of invasive listeriosis is dependent on host susceptibility, bacterial virulence, and inoculum. The importance of T-cell-mediated immunity against this pathogen is exemplified by the populations at highest risk for disease. There may also be a role for humoral immunity, as low levels of IgM and decreased classic complement pathway activity have been correlated with neonatal disease. Gastric acidity is an important local defense against listeriosis.

Several important virulence factors have been identified: internalin, a protein that promotes entry into cells; listeriolysin O, which enables the organism to escape from phagolysosomes and evade intracellular killing; and Act A, a surface protein that induces actin filament assembly and facilitates cell-to-cell spread of the organism.

CLINICAL FEATURES

Listeria monocytogenes infections can exhibit a myriad of clinical presentations. These can be divided into categories to include central nervous system (CNS) infections, sepsis of unknown origin, focal infections, infections associated with pregnancy, and neonatal infections.

CENTRAL NERVOUS SYSTEM INFECTIONS

Two-thirds of adult infections involve the CNS, as either meningitis or meningoencephalitis. Unlike other common causes of bacterial meningitis, *L. monocytogenes* has a tropism for the brain (particularly the brain stem) as well as the meninges, and many patients present with altered levels of consciousness, movement disorders, or seizures that are more suggestive of a meningoencephalitis than pure meningitis. In a recent review of community-acquired bacterial meningitis at a large referral hospital, *L. monocytogenes* was the third most frequent cause of meningitis. It is second only to *Pneumococcus* as the leading cause of bacterial meningitis in adults older than 50 years. It is the leading cause of bacterial meningitis in organ transplantation patients, lymphoma patients, and any patient receiving corticosteroid therapy.

Meningitis due to *L. monocytogenes* usually resembles other forms of bacterial meningitis but may have a more subacute presentation akin to tuberculous meningitis. Nuchal rigidity is uncommon, with less than 50% of patients displaying meningismus on presentation. Movement disorders (ataxia, tremors, myoclonus) and seizures are common. Two-thirds of patients present with an altered sensorium, and a fluctuating mental status is common. The cerebral spinal fluid (CSF) findings are generally indistinguishable from other causes of bacterial meningitis. The white blood cell count is usually between 100 and 5,000 cells, and the majority of cells are neutrophils. Mononuclear cells predominate in one-third of patients. The CSF glucose is typically normal in two-thirds of patients. The CSF Gram stain is negative in two-thirds of patients and may be misleading as it is often misread as a "diphtheroid."

An unusual form of CNS infection involves primarily the brain stem and is termed *rhombencephalitis*. This syndrome is distinct from other forms of *Listeria* CNS infections in that the normal host appears more susceptible to this form of infection. The typical illness presents with a prodrome of fever, headache, nausea, and vomiting that lasts for approximately 4 days. This is followed by the abrupt onset of cerebellar signs, cranial nerve defects, and long-tract motor and/or sensory signs. Asymmetry of neurologic signs is characteristic of this syndrome. Nuchal rigidity is present in only 50% of the cases. Respiratory failure or arrest occurs in 40% of patients. The CSF findings are typically minimally abnormal, with the Gram stain positive in less than 10% of patients. The CSF cultures are positive in 40% whereas the blood cultures are positive in 60% of patients. Overall mortality is high, and serious neurologic sequelae are common in the survivors.

Brain abscesses are an unusual presentation of *Listeria* CNS infections occurring in less than 10% of cases. One-fourth of patients will have associated meningoencephalitis as manifested by positive CSF cultures. Bacteremia is present in the majority of cases, distinguishing *L. monocytogenes* from other causes of brain abscesses. Brain abscesses occur most commonly in persons at high risk for listerial infections. Unlike other causes of brain abscesses, involvement in the thalamus, pons, and medulla is common with *Listeria*. With appropriate antibiotic therapy, prognosis is generally favorable, although residual neurologic sequelae are not uncommon ([Fig. 277.1](#)).

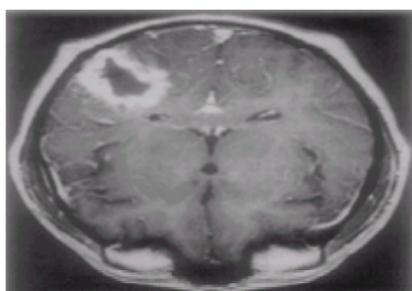

FIGURE 277.1. *Listeria* brain abscess in a patient taking corticosteroids.

SEPSIS OF UNKNOWN ORIGIN

The second most common clinical presentation of *L. monocytogenes* infections is sepsis of unknown origin. The clinical picture may vary from a mild febrile illness to complicated septic shock. The pregnant woman often has a mild flulike illness with *Listeria* bacteremia, whereas her infant may develop overwhelming sepsis. The majority of adults with sepsis of unknown origin are immunosuppressed. The clinical presentation is indistinguishable from other causes of sepsis due to both gram-positive and gram-negative bacteremia.

Listeria monocytogenes endocarditis has been reported on both native and prosthetic valves. It usually presents as a subacute form of endocarditis that is indistinguishable from other causes of endocarditis, such as viridans streptococci. Multiple blood cultures are usually positive. Mortality with *Listeria* infection is high in both forms of endocarditis.

FOCAL INFECTIONS

Focal infections can be the result of hematogenous seeding or direct inoculation of *Listeria*-infected material. Veterinarians in direct contact with infected animals have reported a pustular rash. Purulent conjunctivitis has also been reported due to direct inoculation. *Listeria* pneumonia may be seen in neonates who aspirate infected amniotic fluid or adults who aspirate contaminated food. The pneumonia is lobar and is usually diagnosed by positive blood cultures for *Listeria*. Other focal infections reported include peritonitis, hepatitis and hepatic abscesses, cholecystitis, arteritis of both native and synthetic grafts, osteomyelitis, septic arthritis, and endophthalmitis.

LISTERIOSIS IN PREGNANCY

The cell-mediated immune defect that occurs during pregnancy places the pregnant woman at risk for listerial infection. In addition, the placenta appears to provide a protected site for proliferation of the organism. Bacteremia is the most common manifestation of infection and is seen most often in the third trimester. Symptoms are of a nonspecific, febrile, flulike illness. Perinatal infection is rarely life threatening to the mother; however, amnionitis may result, and premature labor is common with stillbirth or neonatal death in 22% of cases. Mortality is highest when infection occurs early in gestation. Early diagnosis and treatment improve outcome. For unclear reasons, listerial meningitis is uncommon in the pregnant woman.

LISTERIOSIS IN THE NEONATE

Infection in utero can result in spontaneous abortion, stillbirth, early disseminated disease known as granulomatosis infantiseptica, or early-onset sepsis. The most serious of these illnesses is granulomatosis infantiseptica, the hallmark of which is abscess and granuloma formation in multiple organs. The infant may have respiratory or hemodynamic compromise, pharyngitis, conjunctivitis, or meningitis. A rash may be present, with ulcerating papules on the trunk and extremities. The mortality in this syndrome may approach 100%. When infection occurs during vaginal delivery, the neonate more commonly presents with a late-onset meningitis 2 weeks post partum. This form of late infection may also be acquired by horizontal or nosocomial acquisition.

DIAGNOSTIC MODALITIES

Listerial infection is diagnosed by the isolation of the organism from a normally sterile site and identification by microbiological techniques. Routine culture methods are typically adequate to identify *Listeria* species, although cold enrichment techniques and the use of selective media may be employed when suspicion of listeriosis is high. Serologic tests are not useful in establishing this diagnosis.

OPTIMAL MANAGEMENT

Recommendations for antibiotic management of listeriosis are based on in vitro susceptibility data, animal studies, and clinical experience ([Table 277.1](#)). Large comparative trials evaluating antibiotic efficacy are lacking. Ampicillin is regarded as the drug of choice for *Listeria* species, although the data that support ampicillin use over penicillin use are controversial. Both drugs appear very active, while other b-lactam antibiotics are less active. Penicillin and ampicillin are, however, considered bacteriostatic for *Listeria* species. Although there are no comparative clinical data that clearly support combination therapy, the aminoglycosides demonstrate synergy with penicillin and ampicillin, and the addition of an aminoglycoside is thus recommended in some circumstances (i.e., in the treatment of meningitis, brain abscess, endocarditis, and in the immunocompromised host). Whether intrathecal aminoglycoside administration is necessary in the treatment of meningitis is unclear.

Site of Infection	First-Line Therapy	Second-Line Therapy	Duration
Primary bacteremia	Ampicillin 6–10 g/d	TMP-SMX 20 mg/kg/d	2 wk
Meningitis	Ampicillin 6–10 g/d + Gentamicin 6 mg/kg/d ^a	TMP-SMX 20 mg/kg/d	2 wk
Brain abscess	Ampicillin 10 g/d + Gentamicin 6 mg/kg/d ^a	TMP-SMX 20 mg/kg/d	4–6 wk
Endocarditis	Ampicillin 6–10 g/d + Gentamicin 6 mg/kg/d ^a	TMP-SMX 20 mg/kg/d	4–6 wk
Bacteremia in pregnancy	Ampicillin 6–10 g/d	Erythromycin 4 g/d	2 wk

^aDosing based on trimethoprim component.
^bNo data regarding oral vs. intravenous dosing.
 TMP-SMX, trimethoprim-sulfamethoxazole.

TABLE 277.1. MANAGEMENT OF LISTERIOSIS IN THE ADULT^a

In penicillin-allergic patients, trimethoprim–sulfamethoxazole (TMP-SMX) is the preferred alternative. It is suitable for the treatment of both meningeal and nonmeningeal infection as it has excellent CNS penetration. In the pregnant patient, in whom sulfa drugs may be contraindicated, erythromycin appears to be effective for nonmeningeal infection if allergy precludes ampicillin use. There is limited clinical information regarding the newer macrolides in the treatment of listeriosis, although clarithromycin may show promise. Imipenem and meropenem also show good in vitro activity versus *Listeria* species, but supportive clinical data are awaited.

Drugs thought to have insufficient activity for reliable use in listeriosis include chloramphenicol, rifampin, tetracycline, currently available quinolones, and the cephalosporins. Variable success has been reported with vancomycin, but considering its poor CSF penetration, vancomycin likewise may not be a reliable agent—especially when CNS involvement is suspected. The inadequate activity of the cephalosporins is notable as these agents are frequently used in the initial empirical coverage for meningitis. In any patient with meningitis and a risk factor for listerial infection, ampicillin or TMP-SMX should be included in initial coverage unless there is Gram stain evidence supporting another bacterial etiologic process. The role of steroids in the treatment of listerial meningitis is unknown.

PREVENTION

Both isolated cases and outbreak cases of listeriosis have been associated with ingestion of contaminated foods. Persons at risk for infection with this organism should be counseled to avoid dietary habits associated with listeriosis. Recommendations are to avoid soft cheeses, unheated leftover foods, ready-to-eat foods (hot dogs), and unheated delicatessen foods. All persons should be mindful of ways to decrease acquisition of foodborne organisms: by cooking animal products thoroughly, washing raw vegetables, keeping uncooked meats separate from other foods, avoiding raw milk and milk products, and washing hands and utensils carefully after handling uncooked foods.

ERYSIPELOTHRIX RHUSIOPATHIAE

EPIDEMIOLOGY

Erysipelothrix rhusiopathiae is a nonsporulating, nonmotile, a-hemolytic, pleomorphic, gram-positive bacillus that was first established as a human pathogen by Rosenbach in 1909. The organism is known to produce both neuraminidase and hyaluronidase, the activity of which may correlate with virulence. The organism is distributed worldwide in decaying organic matter, where it can survive for weeks to months. Domestic swine, which are susceptible to infection with this organism, are the major reservoir of human infection. Sheep, horses, fowl, fish, shellfish, and many other wild and domestic animals may also be reservoirs of disease. Infection with *Erysipelothrix* is most commonly related to occupational exposure, particularly among veterinarians, butchers, fish handlers, and other persons in occupations involving possible trauma (typically puncture wounds) coupled with animal exposure. No human-to-human transmission has been documented.

CLINICAL FINDINGS

The most common manifestation of infection with *Erysipelothrix* is a nonsuppurative cellulitis of the upper extremity. Patients typically present 2 to 7 days following a cut or abrasion with severe pain and pruritus, swelling, and violaceous, well-defined areas of cellulitis. The central area often fades as the cellulitis spreads peripherally. Adenopathy and lymphangitis are seen in approximately one-third of patients, and low-grade fever and arthralgias in only 10%. This so-called "erysipeloid of Rosenbach" is typically self-limited over 3 to 4 weeks.

Occasionally, the cellulitis progresses proximally from the area of inoculation or appears at remote areas. In this setting, fever and arthralgias are common. Blood cultures are invariably negative with this form of disease. Recurrence of this more severe form of cellulitis is common and the course more protracted.

Bacteremic infection with *Erysipelothrix* is associated with infective endocarditis in 90% of cases. History of cutaneous lesions is elicited from more than one-third of these patients. The disease is more prevalent in males (likely reflecting occupational exposure to the pathogen). Underlying structural cardiac valve disease is noted in over 40% of cases of *Erysipelothrix* endocarditis, and the aortic valve is most commonly affected. Although a subacute presentation is common, the organism is often highly virulent, resulting in marked valve destruction with a high need for valve replacement (more than 33%) and high mortality (38%). Bacteremia without associated endocarditis may be more common in immunocompromised patients. Brain abscess, osteomyelitis, and chronic arthritis have also been caused by this agent.

OPTIMAL MANAGEMENT

Most strains of *Erysipelothrix* are susceptible to penicillins, cephalosporins, carbapenems, clindamycin, and ciprofloxacin. The in vitro activity of chloramphenicol, erythromycin, and tetracycline is variable. Notably, the organism is uniformly resistant to sulfonamides, aminoglycosides, and vancomycin (an agent commonly used empirically for the treatment of infective endocarditis). The regimen of choice for infective endocarditis is 12 to 18 million units of aqueous penicillin G daily for 2 to 4 weeks. While cutaneous disease may be self-limiting, antibiotic therapy may shorten the duration of symptoms.

Preventive measures against *Erysipelothrix* infection include the wearing of protective gloves among persons involved in occupations associated with this disease. A live attenuated vaccine is available for veterinary use.

CHAPTER 278: CORYNEBACTERIAL INFECTIONS

ROBERT T. CHEN AND CHARLES R. VITEK

[Diphtheria](#)
[Other Corynebacteria](#)

DIPHTHERIA

The genus *Corynebacterium* contains pleomorphic gram-positive rods, of which *Corynebacterium diphtheriae* is the most important human pathogen. Other corynebacterial species (diphtheroids) are ubiquitous and generally innocuous except in immunocompromised hosts. Diphtheria is an acute communicable disease of humans caused by infection with *C. diphtheriae*. The respiratory form of diphtheria is classically characterized by an adherent pseudomembrane covering the tonsils or pharynx, whereas cutaneous diphtheria is classically characterized by the presence of nonhealing skin ulcers. Complications of diphtheria, such as myocarditis, neuritis, shock, and death, may occur due to an exotoxin elaborated by toxigenic strains. Immunization with diphtheria toxoid is highly effective in preventing diphtheria. Boosters throughout adulthood are needed to maintain immunity.

INCIDENCE AND EPIDEMIOLOGIC FACTORS

Humans are the only natural host of *C. diphtheriae*. Transmission is generally person to person through close respiratory and physical contact (important in cutaneous diphtheria). Because the vaccine protects against the toxin and not the bacterial infection, immune persons can become asymptomatic carriers of toxigenic *C. diphtheriae*. Patients are usually infectious for 2 to 4 weeks if untreated, less if treated with antibiotics. Chronic nasal carriage for more than 6 months may occur despite treatment.

Despite modest declines in incidence associated with improved living conditions, respiratory diphtheria was a leading cause of child mortality in the first decades of the twentieth century, with a marked winter seasonality in temperate zones. The introduction of diphtheria toxoid vaccine in the 1920s and routine childhood vaccination in the 1940s led to rapid declines in incidence and eventually to virtual elimination of indigenous respiratory diphtheria in most developed countries. Five or fewer cases have been reported annually in the United States since 1980, mostly among adults. The last large outbreak—1,100 cases, 86% of which involved cutaneous diphtheria—occurred in 1972 to 1982 among Seattle's "skid row" population. In tropical countries, cutaneous diphtheria is the most common form of the disease and is an important mechanism of natural immunity.

Due to the decline in the circulation of toxigenic strains of *C. diphtheriae* and the waning of vaccine-induced immunity in the absence of regular booster immunizations, a substantial proportion of adults in most developed countries have become susceptible to diphtheria. Diphtheria outbreaks can recur when toxigenic strains are reintroduced into a susceptible population, especially if hygienic and social conditions facilitate spread. Adult susceptibility, reintroduction of toxigenic strains, and poor socioeconomic conditions have led to a massive epidemic of diphtheria in the former Soviet Union, with more than 150,000 reported cases and over 5,000 deaths from diphtheria from 1990 through 1997. Most reported patients in this outbreak have been 15 to 50 years old. Although this outbreak is coming under control, travelers to these and other countries where diphtheria remains endemic may import the organism.

ETIOLOGIC FACTORS

Corynebacterium diphtheriae is an aerobic, unencapsulated, nonmotile, nonsporulating, gram-positive rod. It is destroyed by heat, light, and most disinfectants, but survives freezing and prolonged desiccation. In nutritionally deficient Löffler's medium, it develops a characteristic club shape arranged like Chinese characters. Recovery is selective on tellurite-containing media, on which corynebacteria form distinctive grayish black colonies. The three biotypes of *C. diphtheriae* (*gravis*, *mitis*, and *intermedius*) are distinguished by colonial morphology and fermentation reactions. The severity of disease is not correlated with biotype but depends on whether the strain produces toxin (toxigenic) or not (nontoxigenic).

The gene coding for toxin production, *tox*, resides in several closely related B phages that can lysogenize nontoxigenic diphtheria organisms, converting them to toxigenic strains. Diphtheria toxin is an extremely potent inhibitor of protein synthesis. Toxin expression requires low-iron conditions in vitro, but the clinical significance of this is unknown.

PATHOGENESIS

The upper respiratory tract is the most common portal of entry for *C. diphtheriae*. The organism remains localized on the mucosal epithelium. After an incubation period of 2 to 5 days, toxigenic strains elaborate toxin, killing local epithelial cells and eliciting a severe inflammatory response. The resultant enmeshed fibrin, necrotic epithelium, leukocytes, and bacterial organisms form a 1- to 3-mm-thick pseudomembrane, which is adherent to the underlying tissue and becomes a fertile site for further bacterial growth and toxin production. Extension of the pseudomembrane is associated with greater toxin absorption and a grave prognosis. Mechanical obstruction of the bronchi may occur. Absorbed toxin is disseminated by the circulation. All tissues are vulnerable, especially the heart, peripheral nerves, and kidneys.

In addition to the toxin, the pathogenesis of diphtheria is also mediated by its cell wall antigens and other enzymes. Nontoxigenic strains can produce mild localized disease without systemic complications.

CLINICAL FINDINGS

The clinical course is determined by the patient's preexisting immunity against diphtheria toxin, the virulence and toxigenicity of the infecting organism, other coexisting disease, and the anatomical location of the infection.

In the most common form, pharyngotonsillar diphtheria, onset occurs insidiously over several days (versus the acute course of streptococcal pharyngitis). Early symptoms are nonspecific. Fever is low (under 102°F) throughout the illness. The pharynx appears injected. The membrane begins as small, white patches on the tonsil(s); as it coalesces, it may spread to cover the pharynx, uvula, palate, and larynx. The membrane may become thicker and gray, with green or black necrotic patches. It is adherent to underlying tissue, and removal causes bleeding. Some patients may complain of sore throat, dysphagia, nausea, vomiting, and headache. Older membrane may become necrotic and odorous. Anterior cervical nodes are usually soft, swollen, and tender. In severe cases, marked edema of adjacent tissue results in a "bull's neck" appearance. In the laryngeal form, there may be difficult and noisy breathing, hoarseness, stridor, and cough. Anterior nasal diphtheria is mild. A membrane may form on the nasal septum, but toxins are poorly absorbed from this site.

In mild cases, the membrane generally sloughs off in about a week with a proportional decrease in systemic symptoms. Patients with severe disease appear toxic, with a racing pulse; they may develop stupor, coma, and death from circulatory or respiratory failure within 10 days. Myocarditis is detectable in half of patients, beginning 1 to 6 weeks after the onset of illness, with the mortality rate proportional to the rapidity of appearance. Clinical findings may include tachycardia, muffled S₁, dysrhythmias, and failure. Peripheral neuropathy, mainly bilateral, motor, and reversible, appears 3 to 7 weeks after onset in 20% of cases, resulting in paralysis of the soft palate, posterior pharynx, cranial nerves, and respiratory muscles. The effects may range from mild debilitation to sudden death. Other internal organs may suffer nonspecific damage from the toxin.

Cutaneous diphtheria classically manifests as punched-out ulcers; however, any skin lesion can be superinfected with *C. diphtheriae*. The clinical course tends to be mild, but skin lesions may be an important source of infection to others. Rarely, the eye, genitalia, and middle ear can be infected.

The death-to-case ratio for respiratory diphtheria was 35% before the availability of antitoxin therapy and as high as 90% for laryngeal diphtheria. The fatality rate with antitoxin therapy has remained around 5% to 10% and is associated with delays in the initiation of antitoxin therapy.

Antitoxin should be given if diphtheria is clinically suspected, as therapy cannot await culture confirmation. Diphtheria should be considered whenever a patient

presents with a membrane in the throat. The differential diagnosis includes group A streptococcal or viral tonsillopharyngitis, infectious mononucleosis, candidiasis, and Vincent's angina. Diagnosis based on smears of lesions alone is unreliable.

Cultures should be obtained from the nose and throat and from any other lesions. Part of the membrane or the material underneath should be obtained using a swab. The laboratory should be alerted to the possibility of diphtheria so that they can inoculate the specimen onto a Löffler or Pai slant, a tellurite-containing medium, and a blood agar plate. Silica gel is recommended if transport requires more than 24 hours. Rapid presumptive diagnosis may be obtained after incubation of the slant overnight and examination for characteristic morphology under methylene blue staining. Cultures may be negative if obtained after the initiation of antibiotic therapy. Culturing of close contacts may also be helpful. All isolates of *C. diphtheriae* should be tested for toxigenicity using the in vivo guinea pig lethality test or the in vitro Elek immunodiffusion test. Toxigenic and nontoxigenic strains can coexist, so that multiple colonies should be tested. In addition to culture, a polymerase chain reaction assay for diphtheria toxin is available through the U.S. Centers for Disease Control and Prevention (CDC). Serology can occasionally be useful; a low pretreatment antitoxin titer is consistent with but does not prove the diagnosis, whereas a high titer makes diphtheria unlikely.

LABORATORY FINDINGS

Laboratory findings are nonspecific and may include moderate leukocytosis and transient albuminuria and thrombocytopenia. Serial electrocardiograms and cardiac enzyme assays are needed for early detection of myocarditis; when present, patients should be transferred to units with adequate monitoring and therapy for serious dysrhythmias and conduction defects.

OPTIMAL MANAGEMENT

After ensuring airway patency, the only specific therapy is diphtheria antitoxin. Equine antitoxin should be administered after conjunctival or intradermal testing for hypersensitivity. Antitoxin should be administered as early as possible, as it can neutralize only toxin not already bound to cells. The recommended antitoxin dosage varies from 20,000 to 120,000 units (see package insert), depending on the anatomical site and the severity and duration of illness. Antitoxin is available from the CDC at (404)639-2888.

Antibiotics do not alter the course or outcome of disease or the incidence of complications but are used to eliminate the organism from the patient. This prevents further toxin production and transmission of the organism. Erythromycin (1 to 2 g per day orally for adults, 40 to 50 mg per kilogram orally for children) or penicillin (intramuscularly or intravenously in age-appropriate doses) should be administered for 14 days. Patients should be isolated until two successive cultures, taken at 24-hour intervals after completion of therapy, are negative. General supportive care includes strict bed rest and observation and treatment for cardiac and respiratory complications. Intubation to maintain the airway or bronchoscopy to remove obstructing membrane may be necessary. Steroids do not appear to prevent myocarditis or neuritis. Age-appropriate doses of diphtheria toxoid should be administered during convalescence, as disease may not induce immunity. Without antitoxin therapy, mortality may reach 30% to 50%. Even with antitoxin therapy, mortality of 5% to 10% may be observed, probably due to delays in diagnosis and therapy. The rapid onset of cardiac complications portends a poor prognosis.

For children less than 7 years old, active immunization is with diphtheria toxoid [6.7 to 12.5 Lf (limits flocculation units)/dose] combined with tetanus toxoid (DT), or also with acellular pertussis vaccine (DTaP). A primary series of three doses at 2, 4, and 6 months of age, followed by boosters at 12 to 18 months of age and 4 to 6 years of age, is recommended in the United States. Older persons should receive adult tetanus and diphtheria (2 Lf) toxoids (Td) to complete their primary series. A Td booster every 10 years is recommended to prevent waning immunity.

Control efforts after the diagnosis of an index case should be directed to the early diagnosis, isolation, and treatment of patients. The health department should be notified. Close contacts (e.g., household, school) should receive an age-appropriate booster dose of diphtheria-containing vaccine if they have not completed a primary series or received a booster dose within 5 years. All such contacts should also be cultured, started on antibiotic prophylaxis with either erythromycin or penicillin, and observed for symptoms for 7 days.

OTHER CORYNEBACTERIA

Corynebacteria are ubiquitous and are frequent contaminants of cultures. Many are known pathogens of animals; some may also produce an exotoxin and infect humans. *Corynebacterium ulcerans*, *C. haemolyticum*, and *C. pyogenes* organisms can cause pharyngitis. *C. ovis* organisms cause a granulomatous lymphadenitis in sheep handlers. Opportunistic pathogens in severely compromised hosts, frequently related to indwelling catheters and prosthetic heart valves, have been reported with *C. xerosis*, *C. pseudodiphtheriticum*, *C. equi*, *C. matruchotii*, and a group called JK. The organisms can be differentiated based on their morphologic, biochemical, and genetic features. Erythromycin is the drug of choice for all except group JK, for which vancomycin is preferred.

CHAPTER 279: MENINGOCOCCAL INFECTIONS

PETER DENSEN

[Incidence and Epidemiologic Factors](#)
[Bacteriologic Studies](#)
[Pathogenesis](#)
[Clinical Features and Laboratory Findings](#)
[Treatment](#)

Meningococcal disease takes the form of several well-described syndromes, ranging from chronic relapsing bacteremia to focal meningitis to full-blown sepsis and shock. But it is the epidemic potential of this organism combined with its ability to strike suddenly, causing rapidly fatal disease that imparts a healthy respect, if not dread, in physicians and lay persons alike. Recent excellent clinical investigations have clarified fundamental epidemiologic and immunologic details, and in so doing have served to elucidate the pathogenesis of endotoxic shock in general.

INCIDENCE AND EPIDEMIOLOGIC FACTORS

Globally, the incidence of meningococcal disease (cases per 100,000 population) varies over several orders of magnitude: from about 0.1 case in Japan (hypoendemic), to one in the United States (endemic), to approximately 10 in recent group B epidemics in South America and Norway, to approximately 100 in the group A and C hyperepidemics in Africa and China. Crowding, low socioeconomic status, poor public hygiene, and the level of immunity in a population clearly constitute major risk factors for meningococcal disease in general, but they provide an incomplete understanding of the epidemic potential of this organism.

The incidence of meningococcal disease also varies with age, being highest (10 to 15 cases per 100,000 population, i.e., epidemic levels) between 2 months and 2 years of age. About 70% of U.S. cases occur before 10 years of age. For unknown reasons, perhaps related to intimate socialization, epidemic disease is associated with a shift in the median age of infected individuals from childhood to the mid-teens.

Although 13 meningococcal serogroups have been described, serogroup A, B, C, Y, and W135 strains cause over 99% of all meningococcal infections. Group A meningococci are responsible for epidemic disease in Africa, the Middle East, and China, whereas group B, C, W135, and Y disease predominates in the United States, Europe, and South America. Epidemic disease has not occurred in the United States since the late 1940s. Rather, clusters of disease activity are reported yearly, group B disease predominating in children less than 2 years of age and group C disease in older individuals, especially college students in association with dormitory living and alcohol-related socialization.

BACTERIOLOGIC STUDIES

In clinical specimens, *Neisseria meningitidis* appear as asymmetrical gram-negative cocci that resemble kidney beans. They tend to occur in pairs, with the poles of paired cocci touching one another. They typically engender a polymorphonuclear inflammatory response and are often seen extracellularly because of the antiphagocytic properties of their capsule. On primary isolation they grow best when incubated at 37°C in a 5% CO₂ atmosphere on chocolate agar. Meningococci are oxidase-positive and metabolize both glucose and maltose.

Like other gram-negative bacteria, meningococci have a trilaminar cell wall consisting of an inner cytoplasmic membrane, a periplasmic space, and an outer membrane composed of a lipid bilayer containing lipopolysaccharide and outer membrane proteins. External to the cell wall lies a polysaccharide capsule, which is pierced by hairlike protein filaments called pili.

Classically, meningococci are serogrouped according to their capsular polysaccharides and subdivided further into serotypes on the basis of 5 classes of major outer membrane proteins and 12 different lipopolysaccharides (LOSs). As a consequence, meningococci differing in their serogroup may nevertheless share the same serotype or partial serotype.

Genetic mechanisms enable the meningococcus to rapidly and independently shift its display of outer membrane molecules. Organisms expressing a “new” protein or LOS molecule appear with a frequency of 10⁻³ to 10⁻⁵. The factors that promote the emergence of these new strains are poorly understood but are clearly important clinically and epidemiologically.

Since genetic shifts also occur rapidly upon subculture, the accuracy of serologic techniques in tracking the relatedness of disease strains becomes a limitation. Consequently, new techniques have been developed that classify meningococci on the basis of either several “housekeeping” gene products [multilocus enzyme electrophoresis (MEE)] or the pattern of genomic DNA generated by cutting with splicing enzymes [pulsed-field gel electrophoresis (PFGE)]. The electrophoretic types (ET) generated by MEE can be grouped into electrophoretic complexes that have proven particularly useful in tracking meningococcal disease both locally and globally. The ET-5 complex has been responsible for the group B epidemics in Norway and Cuba, whereas the clusters of group C disease that have occurred in recent years in the United States and Canada are caused by meningococci belonging to the ET-37 complex.

PATHOGENESIS

Humans are the unique reservoir for *Meningococcus*. Organisms are spread via large respiratory droplets during close contact between the 2% to 15% of the population who carry them in the oropharynx and noninfected persons. On inhalation, meningococci attach to respiratory epithelial cells, but only in a tiny proportion of infected individuals (less than 1%) does this acquisition progress to invasive disease. The ratio of carriage to cases of invasive disease varies among the serogroups, ranging from around 400:1 for ET-37 complex C strains to more than 12,000:1 for group Y strains, respectively. Invasion, when it does occur, appears to do so shortly (2 to 10 days) after acquisition. Viral respiratory infections, by altering ciliary function, mucus secretion, exposure of respiratory epithelium, or the expression of glycoproteins and lipids on these cells, are well-described antecedent events that can affect whether an encounter with the meningococci results in invasive disease rather than carriage of the organism.

A current model of the acquisition event proposes that pili are the primary meningococcal structures mediating initial adhesion to host cells. Attachment is promoted further by the class 5 outer-membrane proteins interacting with the glucose moiety on host cell glycoproteins and lipids, and by host cell proteins binding to the oligosaccharide moiety of meningococcal LOSs. On the other side of the coin, the meningococcal capsule and/or LOS sialylation inhibit attachment. Thus, intimate contact and internalization of meningococci by respiratory mucosal epithelial cells is favored by the acquisition of acapsulate, unsialylated strains—precisely those commonly identified in culture surveys.

Genetic shifts in the expression of meningococcal class 5 and LOS allotypes select for those mutations within an infecting strain that are best matched with the corresponding ligands on host epithelial cells to promote optimal attachment between the two entities. Following internalization, some meningococci remain within intracellular vacuoles, whereas others are discharged into the submucosal space. Subsequent uptake by vascular endothelial cells and breach of this barrier leads to bloodstream invasion by a single meningococcal clone that is heavily pilated and possesses a capsule and sialylated LOSs. These structural differences compared to those on the initially acquired strain speak to the critical role of dynamic genetic plasticity of these surface molecules in the pathogenesis of meningococcal disease.

In most instances, bloodstream invasion results in low-level bacteremia. Most circulating meningococci are cleared by the spleen, but a few adhere to and migrate through endothelial cells at other sites, most typically the choroid plexus, where they cause local infection. Low concentrations of antibody, complement, and neutrophils in cerebrospinal fluid contribute to the predilection of meningococci to cause meningitis. As local infection progresses, meningococci may reinvade the bloodstream, causing secondary bacteremia in addition to local infection.

During multiplication, either locally or within the vasculature, the meningococcus releases outer membrane blebs that elicit local and systemic inflammatory responses. LOSs within blebs stimulate the release of various mediators, e.g., tumor necrosis factor (TNF), interleukins, interferon- γ , platelet-activating factor, from professional and nonprofessional immune cells, as well as the activation of various cascade systems (e.g., complement, clotting, fibrinolysis arachidonate). The

interaction of blebs or intact meningococci with microvascular endothelial cells and the activation of the cascade systems at the blood–endothelial cell interface impair vascular integrity throughout the body, producing the petechial–purpuric rash that typifies clinical meningococcal disease. Thus the distribution and concentration of LOSs is the major organism-based determinant of the extent and compartmentalization of the inflammatory response, clinical findings, and outcome in meningococcal disease.

From the standpoint of the host, the outcome of its interaction with the meningococcus is affected primarily by the presence and concentration of specific antibodies, as well as the complement system. The fact that the highest age-specific incidence of meningococcal disease (2 months to 5 years) is inversely related to the presence of serum bactericidal activity for the meningococcus underscores the extreme importance of specific antibody in determining the outcome of the encounter of the host with the meningococcus in the general population. Antibody to capsular polysaccharide, which is protective by virtue of its ability to promote bactericidal and opsonophagocytic activity, is particularly important. Antibodies to subcapsular antigens are also bactericidal, and because they cross-react with epitopes shared across distinct serogroups, they play a significant role in natural immunity to meningococcal disease. This is especially true for group B disease because humans have limited capacity to synthesize antibody to the homopolymeric sialic acid that constitutes its capsule. Antibodies to subcapsular antigens are generated during the carrier state, during colonization with related organisms (e.g., *Neisseria lactamica*), and as a result of exposure to epitopes shared with enteric organisms.

Serum bactericidal activity arises from the ability of specific antibody to activate the complement cascade. Thus, persons with either acquired (e.g., systemic lupus erythematosus, C3 nephritic factor) or inherited complement deficiencies who are unable to generate complement-dependent bactericidal activity experience about a 1,000-fold increased risk of acquiring meningococcal disease. The probability that a given person with meningococcal disease has a complement deficiency is inversely proportional to the incidence of the disease in the general population (or age group); it is between 5% and 10% in countries with endemic disease and even higher in countries with hypoendemic disease.

Acquired or genetic antibody or complement deficiencies increase the risk of invasive meningococcal disease. In contrast, the severity and prognosis of the disease are modulated by genetic polymorphisms that affect the intensity of the inflammatory response. For example, a polymorphism (B2) in the promoter region of the TNF- α gene results in higher concentrations of TNF- α , more severe disease and a worse prognosis in patients with meningococcal disease. Similarly, the Fc γ R IIa R131 polymorphism, which results in impaired phagocytic efficiency, is associated with more severe meningococcal disease. In contrast, complement deficiencies, though they increase the probability of invasive disease, are associated with less severe disease, presumably because complement-dependent amplification of the inflammatory response is blunted.

CLINICAL FEATURES AND LABORATORY FINDINGS

Meningococcal disease occurs year-round, but most cases occur between November and March, coincident with the peak in respiratory viral illnesses; about 50% of diseased patients have a several-day history of antecedent upper respiratory illness. There are four distinct patterns of meningococcal disease. Meningitis and meningococcemia account for 65% to 80% and 20% to 35%, respectively, of the total burden of meningococcal infections. Chronic meningococcemia and focal infection (e.g., pneumonia, suppurative arthritis, urethritis) are uncommon and account for less than 5% of all meningococcal disease.

Meningococcal meningitis is the second most common cause of acute bacterial meningitis in most developed countries. Most incidents (70%) occur in children between ages 2 months and 10 years. Patients typically appear quite ill and describe the relatively sudden onset of fever, headache, and stiff neck. The illness progresses rapidly: the median time from the onset of symptoms until presentation is 26 hours. A rash is present in 75% of patients when they are first seen. In most cases, it consists of petechiae or 2- to 5-mm purpuric lesions. Lesions may develop rapidly and involve the mucosal membranes, a consideration that necessitates repeated careful examination. The cerebrospinal fluid typically demonstrates an elevated white count (more than 1,000 neutrophils per microliter), a markedly depressed glucose level, and an elevated protein level (more than 150 mg %). Gram stain of the cerebrospinal fluid is positive in 50% to 70% of patients, and the culture is positive 80% to 90% of the time. Blood cultures are positive in 20% to 35% of infected patients. With prompt recognition and institution of appropriate antibiotic therapy, the prognosis is good, with a mortality of 5% to 10% in most developed countries.

The clinical syndrome of meningococcemia represents bacteremia without evidence of infection elsewhere. It reflects primary invasion of the bloodstream and uncontrolled, often explosive organism growth within the vascular tree, and a clinical picture that ranges from simple bacteremia to fulminant sepsis and shock. The disease progresses extremely rapidly, with the median time from the onset of illness to presentation being just 12 hours. Patients are typically restless or extremely anxious, have a very high temperature, and complain of severe myalgia. The absence of a rash in 25% of patients and the absence of meningeal symptoms or signs makes the specific diagnosis difficult. However, orthostatic changes in the blood pressure and pulse, or frank hypotension, are present in most patients and should point to a diagnosis of sepsis. The presence of a petechial or purpuric rash strongly supports a clinical diagnosis of meningococcemia. Laboratory data reveal an elevated white blood cell count with a neutrophilic predominance, but some patients exhibit leukopenia; in either setting, a marked left shift is usually present. The patient frequently exhibits some degree of thrombocytopenia. Elevated prothrombin and partial thromboplastin times are often observed, and frank disseminated intravascular coagulopathy occurs about 10% of the time. In this setting, consideration should be given to the possibility of accompanying adrenal hemorrhage (Waterhouse–Friderichsen syndrome), and appropriate diagnostic and therapeutic intervention instituted. Patients with meningococcemia usually have very high levels of bacteremia; consequently, blood cultures are positive in 90% of infected patients. In contrast, the cerebrospinal fluid usually contains few or no cells, and most cerebrospinal fluid cultures fail to grow meningococci. Prompt institution of antibiotic therapy and appropriate supportive care have reduced mortality to 15% to 20%. Acute renal failure, myocarditis, extensive dermal infarction, and autoamputation of distal digits result in significant morbidity in an additional 10% to 15% of survivors.

As discussed above, the outcome in meningococcal infections is directly related to the number of meningococci, the concentration of meningococcal endotoxin, and the resulting high levels of inflammatory cytokines at the site of infection. In meningococcal meningitis, with or without accompanying bacteremia, the primary infection is largely contained within the subarachnoid space, and the concentration of both microbial and host inflammatory mediators is high within the cerebrospinal fluid but low or undetectable in the systemic circulation. Consequently, organ damage is largely confined to the brain, and most patients survive. In contrast, in patients with meningococcemia, the concentration of these mediators is low or undetectable in the cerebrospinal fluid but high in the systemic circulation. The highest levels of these mediators are seen in fulminant meningococcemia (LOS concentration greater than 700 ng per milliliter); as such, this form of the disease represents an extreme example of the systemic inflammatory response syndrome, and resultant mortality is high.

Several prognostic scores have been developed to predict patient outcome. The simplest, the Glasgow Meningococcal Septicemia Prognostic Score, assigns points for hypotension (3), skin/rectal temperature difference more than 3 (3), coma score less than 8 (3), lack of meningismus (2), deterioration in past hour (2), base deficit more than 8 mmol per liter (1), and extending or widespread ecchymoses (1). Scores greater than 8 to 10 progressively predict mortality exceeding 36% to 45%. Chronic meningococcemia is an uncommon infection characterized by recurrent episodes of low-grade fever, scattered petechial lesions, arthritis, and low-grade intermittent bacteremia. Often patients do not appear acutely ill and recover spontaneously only to experience a recurrence days to weeks later. Blood cultures are often negative, and the diagnosis is often missed or mistaken for the gonococcal dermatitis/arthritis syndrome.

Focal meningococcal infection is also uncommon, but pneumonia, arthritis, and urethritis are well described. Given the frequency with which the organism colonizes the upper respiratory tract, the diagnosis of meningococcal pneumonia requires both a compatible clinical picture and a positive blood culture. Genital meningococcal infection has been reported in persons practicing oral sex.

Complement deficiency should be suspected in persons who have a family history of meningococcal disease, who have recurrent meningococcal infection, whose first infection occurs at 15 to 17 years of age or older, and whose infection is caused by serogroup Y, W135, or X.

TREATMENT

Meningococcal disease is a medical emergency. Outcome is directly related to the interval from presentation to diagnosis and institution of therapy. Delays in treatment are due to the failure of parents, referring doctors, and hospital physicians to recognize specific aspects of the disease. Treatment should be initiated in the emergency department or before transfer, even if diagnostic cultures have not been completed. Because the disease can progress extremely rapidly, patients should be admitted to an intensive care unit for appropriate treatment and supportive therapy. Intravenous penicillin (10 to 20 million units per day) remains the standard treatment for meningococcal disease. However, the desirability of achieving antibiotic concentrations 10-fold greater than the minimal inhibitory concentration for the organism and cost considerations have prompted regular use of third-generation cephalosporins, particularly ceftriaxone (1 to 2 g per day intravenously). Chloramphenicol (50 mg per kilogram to a maximum of 4 g per day in divided doses every 6 to 8 hours) is used in penicillin-allergic patients and for treatment of penicillin-resistant strains. Therapy is administered for 2 weeks, contingent on the clinical response, although small case series support 5 days of treatment.

Patients should be placed in respiratory isolation and the disease reported to public health officials. Family members living with the patient have a 3500-fold increase in the risk of developing meningococcal disease. This degree of risk also applies to dormitory roommates or medical personnel involved in the resuscitation, but not routine care, of infected patients. These close personal contacts should receive chemoprophylaxis. Oral rifampin (10 mg per kilogram, to a maximum of 600 mg, every 12 hours for 2 days) remains the standard antibiotic treatment for the elimination of the carrier state in exposed persons. However, single-dose therapy with intramuscular ceftriaxone (250 mg) or oral ciprofloxacin (500 mg) appears even more effective. Administration of the tetravalent meningococcal capsular polysaccharide vaccine (serogroups A, C, Y, and W135) is recommended when the respective serogroups have caused disease because up to 50% of secondary infections occur 2 to 4 weeks after the index case—a period sufficient to permit a protective immune response. Policy decisions regarding administration of the vaccine and/or chemoprophylaxis to control cluster outbreaks in schools are best made in conjunction with public health authorities.

A number of additional therapeutic interventions have been tried in patients with severe meningococcal disease; however, controlled trials supporting their utility are generally lacking. Clearly, corticosteroid administration is essential in documented adrenal failure. Dexamethasone is commonly administered for the first 2 days of treatment for meningococcal meningitis. Heparin can be useful in the treatment of disseminated intravascular coagulopathy but is clearly secondary to treatment of the infection itself. Infusion of fresh frozen plasma to replace protein C may improve outcome. The utility of plasmapheresis and treatment with monoclonal antibody to lipid A remain uncertain but probably are not beneficial.

CHAPTER 280: GONOCOCCAL INFECTIONS

GEORGE F. BROOKS

[Incidence and Epidemiologic Factors](#)
[Etiology](#)
[Pathogenesis](#)
[Clinical Features](#)
[Laboratory Findings](#)
[Optimal Management](#)
[Prognosis](#)

Gonococcal infections are caused by the gram-negative diplococcal bacteria *Neisseria gonorrhoeae*. The most common form of gonococcal infection in men is urethritis. In women, endocervicitis is most common, but the complication of uterine tube infection [pelvic inflammatory disease (PID)] is most important.

INCIDENCE AND EPIDEMIOLOGIC FACTORS

Gonorrhea remains a major public health problem worldwide. In the United States, the incidence of gonorrhea began to increase in the mid-1950s, and by 1975 nearly 500 cases per 100,000 population or about 1 million cases were reported; the actual incidence may have been twice that because of unreported cases. In recent years, the incidence of reported gonorrhea has declined significantly to less than 125 cases per 100,000 population ([Fig. 280.1](#)). This decline reflects changes in sexual behavior and safe-sex practices in response to AIDS.

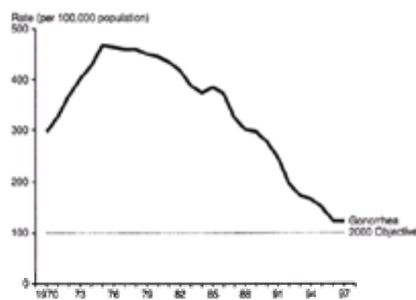

FIGURE 280.1. Reported rates of gonorrhea for the United States, 1970–1997. The incidence of gonococcal infections in the United States peaked at nearly 500 cases per 100,000 population in 1975. By 1996 the rate had fallen below 125 cases per 100,000 population. (From Division of STD Prevention. *Sexually Transmitted Disease Surveillance, 1997*. U.S. Department of Health and Human Services. Atlanta: Centers for Disease Control and Prevention, September 1998; <http://www.cdc.gov>.)

In the United States, the incidence of gonorrhea is highest in adolescents and young adults (15 to 24 years old), particularly the urban poor and minority ethnic groups. In developing countries and in the military, where male contact with prostitutes is more common, the male/female ratio approaches 10:1. In civilian populations of Western countries, the ratio is about 1.5:1. Gonococcal infection in a child often indicates sexual abuse of the child.

Neisseria gonorrhoeae is transmitted by sexual contact. Inoculation of infected genital secretions by hand sometimes occurs, yielding secondary sites of infection and, rarely, infection of another person.

ETIOLOGY

Neisseria gonorrhoeae is a member of the genus *Neisseria*. *Neisseria meningitidis* is the other important pathogen in the genus and is closely related to *N. gonorrhoeae*. Gonococci ferment glucose but not maltose, lactose, or other sugars, which differentiates them from other *Neisseria* species. Fluorescence microscopy, coagglutination tests, enzyme immunoassays, and DNA probes can also be used to separate the species. All gonococci require cysteine for growth. Gonococcal strains can be typed by determining nutritional requirements (auxotyping) and by determining the porin protein serovar.

GROWTH CONDITIONS

Gonococci grow on agar containing hemin and additional supplements, and do not routinely grow on standard nutrient or sheep blood agar. Modified Thayer–Martin medium with hemin, IsoVitalX, and antibiotics is the selective medium used in the United States for clinical cultures to diagnose gonococcal infections. Gonococci grow best at 35°C to 37°C in a humid environment with 5% to 10% CO₂; often a candle extinction jar is used to grow them. Gonococci do not grow in ambient air. Cultures of clinical specimens on selective medium should be examined after overnight incubation and again after 48 hours before discarding. Typical colonies are small (0.5 to 2 mm), grayish, convex, and shiny. When grown on translucent agar, large and small colonies that are opaque or transparent can be seen, depending on the expression or nonexpression of pili and opacity-associated proteins.

STRUCTURE

Knowledge of the surface or outer-membrane structures has been the key to understanding the pathogenesis of and immunologic factors involved in gonococcal infection, as well as infections by other mucosal pathogens.

PILI

Pili (fimbriae) are the hairlike appendages that extend from the gonococcal cell surface. Piliation is required to yield infection in human volunteers. Pili are made of repeating units of pilin protein. Pili function in the adherence of gonococci to host cells on the mucosal surface. Pilin antigenic variation aids the gonococci in evading the immune system. Each strain of *N. gonorrhoeae* has a series of genes that code for antigenically different pilin, and these are variably expressed during growth. Also, nearly every strain of gonococci expresses pilin molecules that are antigenically different from every other strain. Thus, there are hundreds or thousands of antigenically different gonococcal pili.

PORIN PROTEIN

The porin protein (Por) occurs in trimers and extends through the gonococcal outer membrane to form channels through which some nutrients enter the cell. Only one antigenic type of Por is expressed by each strain of gonococci, but different strains have distinct Por types. There are two major Por types, A and B, and more than 40 subtypes, based on monoclonal antibody typing systems. Serotyping of Por is a major tool used in epidemiologic studies but is not available for routine clinical use. Monoclonal antibodies against Por are routinely used to identify gonococci in fluorescent antibody tests.

OPACITY-ASSOCIATED PROTEIN

Opacity-associated proteins (Opas) are named because gonococci in opaque colonies on agar have an Opa in the outer membrane. Opas are variably expressed

outer-membrane proteins that function in gonococcal attachment to and invasion of host cells, and in evasion of the immune system. Each strain of gonococcus has 10 to 12 *opa* genes that code for six to eight antigenically different Opas. Clinical isolates of *N. gonorrhoeae* typically have one to four Opas on their surface. There are hundreds of antigenically different Opas.

LIPOLIGOSACCHARIDE

Lipoligosaccharide (LOS) is the toxic substance of the outer membrane. Gonococci can simultaneously and variably express several antigenically different forms of the LOS carbohydrate chains. Gonococci make LOS molecules that structurally resemble human glycosphingolipids, a form of molecular mimicry. The gonococcal LOS and the human glycosphingolipid of the same class react with the same monoclonal antibodies, indicating their structural similarities. One conserved LOS structure has the same lacto-*N*-neotetraose glucose moiety as the human glycosphingolipid paragloboside series. Other LOS glucose structures are shared with those of the globoside, ganglioside, and lactoside series. This molecular mimicry helps the gonococci evade the immune system.

ANTIGENIC VARIATION

Clinical isolates of *N. gonorrhoeae* have pili and Opa. In the laboratory, these proteins show phase variation—expression or nonexpression. Pili, Opa, and LOS each have a high frequency of antigenic variation: they switch expression from one antigenic form to another at a frequency of about 1 in every 10^3 gonococci (mutation rates for bacteria are one in 10^8 or 10^9). The variation for each of these antigens is independent of the others. Thus, every strain of *Gonococcus* may have different surface antigens from other strains, and each strain changes its surface antigens at a high frequency.

Gonococci also have several outer-membrane proteins that are antigenically similar in all strains, including Rmp (reduction-modifiable protein), Lip, and iron-regulated proteins.

GENETICS

Gonococci take up and integrate naked DNA (transformation); piliated gonococci do this much better than nonpiliated gonococci. Gonococci in contact can mate (conjugation) and exchange genetic information. Transduction does not occur in gonococci.

Gonococci have three types of plasmids (circular nonchromosomal DNA). The smallest plasmid is about 2.5 MD in size, occurs in 95% of gonococci, and has no known function. The second type of plasmid is 3.4 to 4.7 Md, carries the genes for penicillinase (b-lactamase) and other antibiotic resistance, and is found in 10% to 50% or more of gonococci, with geographic variation. The 24.5-Md plasmid controls gonococcal conjugation; this plasmid occurs with high frequency in areas where the 3.4- to 4.7-Md plasmids and resistance to penicillin G are common. The conjugative plasmid promotes the transfer of the plasmids that code for antibiotic resistance.

PATHOGENESIS

ADHERENCE, MUCOSAL COLONIZATION, AND INVASION

Pili appear to mediate the initial adherence of gonococci to mucosal epithelial cells; Opa is a secondary adherence effector. Por has been shown to insert and translocate across plasma membranes and, during the adherence process, may be inserted into the host cell membrane.

In over 95% of newly infected men, attachment and colonization of the urethra by gonococci results in an inflammatory response, predominantly of polymorphonuclear leukocytes. Asymptomatic infection occurs in 3% to 5% of new infections but may be of high prevalence because it is of long duration and not treated. About 25% of female patients have endocervical inflammation or urethral infection with sufficient signs and symptoms for them to seek medical care. Other women have asymptomatic infection of the endocervix or urethra. Asymptomatic endocervical infection is, then, an important reservoir of *N. gonorrhoeae*, leading to transmission during sexual intercourse. Pharyngeal carriage and rectal carriage also are often asymptomatic or only mildly symptomatic.

A few gonococci survive within polymorphonuclear leukocytes, which may also provide a reservoir for transmission of infection. In the female genital tract, gonococci may gain access to the fallopian tube by attaching to spermatozoa, by propulsion by coital contractions, or by migration during menses.

Gonococcal invasion of mucosal cells has been studied in in vitro human genital epithelial cell and fallopian tube models of infection. Once inoculated onto the genital epithelial cell surface, the gonococci adhere to the microvilli; pili and Opa may both be required for this process. In the fallopian tube model, the gonococci adhere primarily to the microvilli of nonciliated epithelial cells. The gonococcal LOS destroys the ciliated cells, causing them to slough. The gonococci enter the nonciliated epithelial cells by a poorly understood engulfment mechanism, multiply in the cells, pass through and destroy them, and enter the submucosal space. The result is major damage to the epithelial surface, which can yield ectopic pregnancy or infertility.

Gonococci enter the bloodstream from sites of active inflammation or, more commonly, from sites of asymptomatic infection (e.g., the endocervix at menstruation). Gonococci isolated from the blood are resistant to killing by antibodies and complement in normal human serum; gonococci isolated from uncomplicated mucosal infections are often serum-sensitive. Resistance to antibody- and complement-mediated killing is an important virulence factor for dissemination in patients with normal complement systems.

IMMUNITY

Humans infected with gonococci often have high levels of serum IgG and IgM that are reactive with outer-membrane structures; serum IgA is less important. The primary genital antibodies are IgA and IgG, which react predominantly with pili, Opa, and LOS.

Gonococci and other pathogens that reside on human mucosa (e.g., *N. meningitidis*, *Haemophilus influenzae*, *Streptococcus pneumoniae*) make the enzyme IgA₁ protease. IgA₁ is the major IgA subclass present on mucosal surfaces. The enzyme splits IgA₁, inactivating it.

There is no known protective immunity for uncomplicated gonococcal infection; a person can have repeated infections. The highly variable surface antigens help gonococci to evade antibodies and repeatedly infect humans. Longitudinal studies in high-risk women have shown that antibodies against Rmp correlate with increased risk for infection, especially PID. Antibodies against Opa correlate with decreased risk for PID but do not change the risk for uncomplicated infection.

Persons with congenital deficiency of one of the late-acting components of complement (C5, C6, C7, or C8) are at high risk for systemic gonococcal or meningococcal infection because the circulating antibody- and complement-mediated bactericidal system will not kill the *Neisseria* organisms. As many as 20% of patients with meningococcal bacteremia or meningitis have one of these complement deficiencies. The incidence of complement deficiency is lower in gonococcal bacteremia because gonococci that cause bacteremia are commonly resistant to killing by antibody and complement.

Pili, Por, and whole-killed gonococci have been studied as vaccines for gonorrhea, but all have failed.

CLINICAL FEATURES

INFECTIONS OF WOMEN

Lower Genital Tract

Symptoms of endocervical infection are recognized by only 20% to 25% of infected women. Typically, they have an unusual or purulent vaginal discharge, and may have irregular or abnormal periods. Infection of Bartholin's or Skene's glands can yield swelling and formation of pus. Gonococcal urethritis is not routinely diagnosed in women, but dysuria and a urethral discharge are often present. Positive urethral cultures can often be obtained from women with acute uncomplicated gonorrhea.

Gonococci are one of the causes of the acute urethral syndrome, in which a woman presents with acute dysuria suggestive of a bladder infection.

Pelvic Inflammatory Disease

In about 20% of women with endocervical gonorrhea, the infection spreads to involve the endometrium, fallopian tubes, and peritoneum, causing PID. This is the most important consequence of gonococcal infection. In the United States, gonococci cause 30% to 50% of cases of PID; *Chlamydia trachomatis* and mixed infections with anaerobes and aerobes are the other major causes. Mixed infections with anaerobes and aerobes cause the most severe symptoms in acute PID, including fever, adnexal masses, and pyosalpinx. Gonococcal PID is intermediate in clinical symptoms. *C. trachomatis* PID often has relatively few symptoms, but it may have the worst prognosis in terms of subsequent infertility and ectopic pregnancy.

Patients with PID present with lower abdominal pain, increased vaginal discharge, and fever, usually around the time of menstruation. Physical findings are limited to the lower abdomen and pelvis; the most common findings are adnexal tenderness, pain on cervical motion, and a palpable adnexal mass. A wide range of symptoms and physical findings in patients with PID make clinical diagnosis imprecise, short of laparoscopy. The differential diagnosis of PID includes ectopic pregnancy, appendicitis, and other intra-abdominal conditions.

Gonococcal PID predisposes to recurrent episodes of PID, which may be nongonococcal. The probability of sterility or ectopic pregnancy increases with each recurrence.

Perihepatitis (Fitz-Hugh–Curtis Syndrome)

Perihepatitis in women can occur with gonococcal or *C. trachomatis* infection after retrograde spread of infection from a pelvic focus. It rarely follows bacteremia. Right upper quadrant tenderness is common, and there may be an associated friction rub and elevated liver enzyme levels. If laparoscopy is done, adhesions between the hepatic capsule and the parietal peritoneum are evident. Response to antibiotic therapy is rapid.

INFECTIONS OF MEN

Urethritis

The likelihood of a man acquiring urethral gonococcal infection after a single exposure to an infected woman is about 25%. The incubation period is 3 to 5 days to the development of symptoms, typically consisting of urethral discharge, dysuria, or both. Between 5% and 40% of men have asymptomatic infection, and this can last for months. Asymptomatic infection is most likely to be found in men whose female consorts have disseminated gonococcal infection, PID, or positive screening cultures.

Epididymitis

Neisseria gonorrhoeae and *C. trachomatis* are the common causes of epididymitis in men under age 35. Acute epididymitis develops in men with untreated gonococcal infection. Pain and swelling of the epididymis occur. The diagnosis is made clinically and by culturing *N. gonorrhoeae* from an epididymal aspirate; a presumptive diagnosis is made by culturing the bacteria from a urethral swab specimen.

INFECTIONS OF WOMEN AND MEN

Conjunctivitis

Ophthalmia Neonatorum

Gonococcal ophthalmia neonatorum is an important cause of blindness in children in developing countries. It is uncommon in the United States because of antenatal screening and the widespread use of prophylaxis with antibiotic eye drops. Ophthalmia neonatorum usually presents after an incubation period of 2 to 3 days. Signs are bilateral conjunctival inflammation and chemosis, followed by purulent discharge. Dissemination can occur from the conjunctivae, leading to septic arthritis.

Adult Gonococcal Conjunctivitis

Gonococci can be inoculated into the conjunctivae on fingers contaminated with infected genital secretions and, rarely, by bacteremia. The infection presents as an acute purulent conjunctivitis, often unilateral.

Pharynx

Pharyngeal gonococcal infection is acquired by oral–genital sex, most commonly fellatio. Transmission by kissing or oral secretions is rare. Disseminated gonococcal infection may result from pharyngeal carriage. Symptomatic infection with a mild to severe sore throat occurs in only about 5% of persons with pharyngeal infection. A purulent exudate may be present. The differential diagnosis of severe gonococcal pharyngitis includes group A b-hemolytic streptococcal disease, infectious mononucleosis, diphtheria (very rare in the United States), and various viruses that occasionally cause severe sore throats. Gonococcal pharyngitis is diagnosed by culture. The indication for a pharyngeal culture for gonococci is a history of oral sex.

Rectum

Isolation of *N. gonorrhoeae* from the anal canal is common in women who have endocervical gonococcal infection and may be due to contamination by vaginal secretions or anal intercourse. Anorectal gonococcal infection in men occurs in those who engage in receptive anal intercourse with an infected partner. Symptomatic rectal infection (gonococcal proctitis) occurs in a few infected persons; symptoms include pruritus, tenesmus, purulent discharge, and bloody diarrhea. On proctoscopy, a mucopurulent discharge or a friable mucosa is noted. The differential diagnosis of such findings in a male homosexual includes proctitis due to *C. trachomatis* or herpes simplex virus. Rectal cultures for gonococci should be done routinely for persons who practice rectal intercourse and are suggested for routine cultures of women, where anatomical proximity leads to rectal infection.

Disseminated Gonococcal Infection

Probably less than 1% of genital gonococcal infections lead to disseminated gonococcal infection (DGI). The rate appears to be decreasing because the auxotype associated with DGI is less common in the United States. About 75% of cases of DGI occur in women, often in association with menstruation. The symptoms variably include fever, skin rash, joint or tendon pain, and a migratory polyarthritis. The skin rash occurs on the distal parts of the arms and legs, including the hands and feet. It starts as small red papules and evolves into pustules a few millimeters in diameter ([Fig. 280.2](#)). Other infectious diseases can yield similar rashes (e.g., meningococemia, staphylococcal endocarditis). The arthritis usually stops with one joint, often a major joint such as the knee, with swelling and redness. The gonococcus is the most common cause of septic arthritis in young adults. Pus can be aspirated from the joint. When promptly treated, gonococcal arthritis rarely yields joint damage.

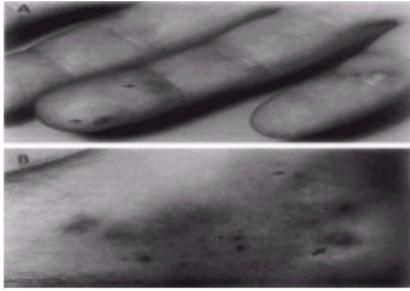

FIGURE 280.2. Petechial and small pustular lesions (*small arrows*) on the fingers (**A**) and foot (**B**) of a patient with disseminated gonococcal infection. The large arrow indicates a hemorrhagic bullous lesion on the foot.

A presumptive diagnosis of DGI can be made in a young adult with typical clinical findings who has *N. gonorrhoeae* isolated from a mucosal surface and responds rapidly to antibiotic therapy directed at the gonococcus.

Gonococcal endocarditis is rare in the antibiotic era but can result in rapid valve destruction. Gonococcal meningitis cannot be distinguished clinically from meningococcal meningitis.

LABORATORY FINDINGS

GRAM STAIN AND OTHER RAPID DIAGNOSTIC TECHNIQUES

In men with symptomatic urethritis, the diagnosis of gonorrhea can be made by a Gram stain of the urethral discharge and the finding of polymorphonuclear cell-associated (intracellular) gram-negative diplococci ([Fig. 280.3](#)). The sensitivity of the Gram stain for symptomatic men exceeds 90%, and the specificity is 98% to 99%. The predictive value of a positive Gram stain is very high and cultures for gonococci are not indicated if the stain is positive. Gram stain of the exudate from the endocervical canal in women is less sensitive (about 50%). In women (and at nongenital anatomical sites), the normal mucosal bacterial flora can obscure or mimic gonococci, and the stain is not a sensitive diagnostic tool. Gram stain may be helpful in the initial diagnosis of conjunctivitis but does not indicate the species of bacteria.

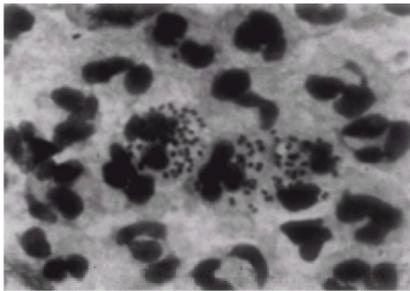

FIGURE 280.3. Gram stain of urethral exudate from a male patient with gonococcal urethritis showing gram-negative intracellular diplococci. (Courtesy of U.S. Centers for Disease Control and Prevention.)

CULTURE AND OTHER DIRECT DIAGNOSTIC LABORATORY METHODS

The diagnosis of gonococcal infection in women and at all anatomical sites except the male urethra is best made by culture. Modified Thayer–Martin or other selective medium should be used for culture of specimens from mucosal sites. Enriched chocolate agar without antibiotics can be used for joint fluid specimens.

Urethral cultures are obtained by inserting a small sterile swab about 0.50 in. into the anterior urethra. Anal cultures are obtained by inserting a swab 1 in. into the anal canal, avoiding contact with feces. In women, a swab is inserted in the endocervical canal and rotated. The specimen should be placed directly onto the culture medium when possible, or put in transport medium and sent directly to the laboratory.

In DGI, blood cultures are positive in only 25% of cases and joint fluid cultures in about 10% of cases. Gonococci do not grow well in liquid media and are often susceptible to sodium polyanethol sulfonate, an anticoagulant and antiphagocytic factor commonly included in blood culture media. Early subculturing of blood cultures or the use of the lysis–centrifugation system may increase the yield for gonococci.

When genital Thayer–Martin medium cultures of sexually transmitted disease clinic patients are positive, a simple and inexpensive laboratory identification (e.g., fluorescent antibody test) is sufficient. Positive cultures of any other patients or from any anatomical site outside the genital tract require more extensive laboratory confirmation tests, preferably by two separate methods, because other *Neisseria* or other gram-negative cocci that do not cause gonorrhea can be isolated. Careful laboratory confirmation of gonococcal infection is especially important if the patient is a child and there is a possibility of sexual abuse.

An enzyme immunoassay is available to diagnose genital gonococcal infections in men and women. The assay is equivalent to the Gram stain for men but is much more expensive, and it is less sensitive and specific than culture to diagnose endocervical infections.

Another direct method to detect gonococci in genital tract specimens uses a nonisotopic probe to hybridize with gonococcal ribosomal RNA in a 2-hour test. The sensitivity of the test is 90% to 95% compared with culture. The specificity after discrepant analysis is 97% to 100%.

Nucleic acid amplification in the form of the ligase chain reaction can be used to diagnose gonococcal infection. In this test a sequence in the *N. gonorrhoeae opa1* gene is amplified. The sensitivity of this test is 90% to 100% and the specificity after discrepant analysis is 99% to 100%. Nucleic acid amplification in the form of the polymerase chain reaction also can be used to diagnose gonococcal infection.

OPTIMAL MANAGEMENT

ANTIBIOTIC RESISTANCE

Neisseria gonorrhoeae strains that are resistant to penicillin, tetracycline, or both are common in the United States ([Fig. 280.4](#)) and worldwide. Gonococci resistant to ciprofloxacin also have been isolated but are relatively uncommon; spectinomycin resistance has been reported as well. All gonococci are susceptible to the third-generation cephalosporins; they are the mainstay of therapy in developed countries but may be too costly for use in developing areas.

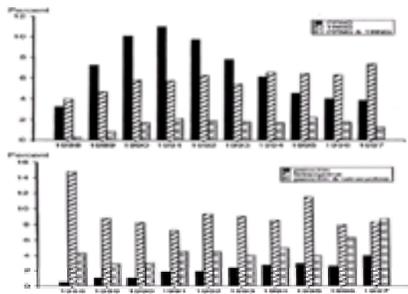

FIGURE 280.4. Trends in gonococcal resistance to penicillin and tetracycline, 1988–1997, from the Gonococcal Isolate Surveillance Project. **A:** Plasmid-mediated resistance. PPNG, penicillinase-producing *Neisseria gonorrhoeae*; TRNG, tetracycline-resistant *N. gonorrhoeae*. **B:** Chromosomally mediated resistance; resistant is a minimum inhibitory concentration of penicillin (b-lactamase-negative) or tetracycline of $\leq 2 \mu\text{g/mL}$. (From Division of STD Prevention. *Sexually Transmitted Disease Surveillance, 1997*. U.S. Department of Health and Human Services. Atlanta: Centers for Disease Control and Prevention, September 1998; <http://www.cdc.gov>)

Penicillinase-producing *N. gonorrhoeae* (PPNG) are resistant to penicillin G because they produce a *TEM-1* b-lactamase that inactivates penicillin. The plasmids of *N. gonorrhoeae* that code for penicillinase are related to similar plasmids in *Haemophilus* species. The incidence of PPNG in the United States is 6% to 10% of all *N. gonorrhoeae* strains with some year-to-year variation (Fig. 280.4). PPNG are common in many other places in the world. PPNG also are often resistant to tetracycline.

Tetracycline resistance in gonococci may also be plasmid-mediated. Insertion of the streptococcal *tet-M* gene into the gonococcal conjugative plasmid (25.2 Md) yields the high-level tetracycline resistance (minimal inhibitory concentration 16 μg per milliliter or more).

A second type of resistance to penicillin is mediated by gene(s) on the chromosome and is not related to penicillinase production. Gonococci with chromosomally mediated penicillin resistance are increasingly common worldwide. Chromosomally mediated resistance to tetracycline also is common.

ANTIBIOTIC THERAPY

Guidelines for treatment of uncomplicated and complicated gonococcal infections reflect the emergence of antibiotic-resistant *N. gonorrhoeae*, the high frequency of coexisting chlamydial infections in patients with gonorrhea, and the potential serious complications of these infections (Table 280.1 and Table 280.2). Cephalosporins (e.g., ceftriaxone, cefixime), quinolones (e.g., ciprofloxacin, ofloxacin), and spectinomycin are active against antibiotic-resistant gonococci. A complete set of recommended therapies and options are presented in the *Guidelines for Treatment of Sexually Transmitted Diseases* published by the U.S. Centers for Disease Control and Prevention.

Site	Therapy
Cervix, urethra, and rectum	Cefixime 400 mg orally in a single dose, or ceftriaxone 125 mg IM in a single dose, or ciprofloxacin 500 mg orally in a single dose, or ofloxacin 400 mg orally in a single dose, plus a regimen effective against possible coinfection with <i>Chlamydia trachomatis</i> such as azithromycin 1 g orally in a single dose, or doxycycline 100 mg orally b.i.d. for 7 d
Pharynx	Ceftriaxone, or ciprofloxacin, or ofloxacin, plus azithromycin, or doxycycline as above

TABLE 280.1. THERAPY FOR UNCOMPLICATED GONOCOCCAL INFECTIONS

Infection	Therapy
Pharyngeal inflammatory disease	Treatments regimens* should include agents active against <i>N. gonorrhoeae</i> , <i>Chlamydia trachomatis</i> , gram-negative bacilli (<i>Haemophilus</i> , <i>Moraxella</i> , and <i>Neisseria</i>), and anaerobes. Ceftriaxone, 1 g IM or IV every 24 h
Disseminated gonococcal infection†	Ceftriaxone, 1 g IV every 12 h for 7 d

TABLE 280.2. THERAPY FOR COMPLICATED GONOCOCCAL INFECTIONS

All gonorrhea patients should have serologic tests for syphilis and should be offered counseling and testing for HIV infection. Ceftriaxone therapy for gonorrhea cures incubating syphilis, but spectinomycin and quinolones may not.

PROGNOSIS

Untreated gonococcal urethritis may cure spontaneously, or a less purulent urethral discharge or asymptomatic carriage may result. Effective antibiotic therapy eradicates gonococcal infection, and resolution of symptoms indicates cure. Follow-up cultures are not needed. Gonococcal salpingitis may lead to infertility, ectopic pregnancy, or recurrent PID. Treated gonococcal arthritis usually has no sequelae.

[Optimal Management](#)
[Prevention](#)

DEFINITION

Salmonellosis is one of the most common bacterial infections in the United States. The various types of the *Salmonella* bacteria cause a variety of clinical syndromes, including enterocolitis, bacteremia, enteric fever, and severe focal infections. Persons with AIDS are particularly susceptible to invasive infections.

INCIDENCE AND EPIDEMIOLOGIC FACTORS

Between 1970 and 1985, the incidence of reported *Salmonella* infections in the United States increased from 11 per 100,000 to 28 per 100,000, after which it declined slightly (Fig. 281.1). Because of marked underdiagnosis and underreporting, it is likely that the true number of incidents is approximately 1.4 million each year. The emergence of nontyphoidal salmonellosis is related to changes in food animal production and slaughter practices that make contamination of fresh meat likely, and to the increasing number of highly susceptible persons in the population.

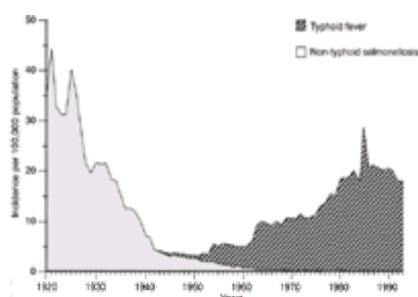

FIGURE 281.1. The annual incidence of reported typhoid fever and nontyphoidal salmonellosis in the United States, 1920–1997.

The incidence of salmonellosis is highest among children under 1 year of age and is particularly likely if the infant is bottle-fed. Incidence is also higher among the elderly. Infections can occur year-round but are more likely to occur in the summer and early fall. About 10% of cases are linked to recognized outbreaks, but most occur sporadically.

With the exception of *S. typhi*, which is found almost exclusively in humans, most nontyphoidal *Salmonella* infections in humans are related directly or indirectly to infected animals, including birds, mammals, and reptiles. Most human infections result from the ingestion of contaminated food, particularly foods of animal origin contaminated by *Salmonella* from the animals themselves. More recently, fresh fruits and vegetables have been implicated in an increasing number of outbreaks. Waterborne transmission has occasionally occurred, and direct person-to-person transmission has been demonstrated in newborn nurseries. *Salmonella* organisms can also be easily transmitted from pet reptile to child. Pet iguanas are an increasingly common source. Most typhoid fever cases are associated with travel to the developing world and consumption of contaminated food or water there.

Nontyphoid *Salmonella* organisms are commonly isolated from raw foods of animal origin, including unpasteurized milk, raw eggs, and raw meat. They are readily killed by heating to 74°C (165°F), but multiply rapidly on food held at ambient temperature. Most outbreaks and sporadic infections result from food handling practices that allow the organisms to survive and multiply in food. Common food vehicles include beef, chicken, and turkey, and grade A shell eggs, which have emerged as a particularly common source of *S. enteritidis* in most of the industrialized world. Large outbreaks occur when salmonellae contaminate a mass-produced food; in 1985, one outbreak caused by *S. typhimurium* in pasteurized milk produced more than 200,000 cases. Salmonellosis outbreaks have also been traced to many other vehicles, including raw milk, precooked roast beef, homemade and commercial ice cream, marijuana, sprouts, orange juice, tomatoes, cantaloupe, and pharmaceutical agents such as carmine dye and pooled platelets.

ETIOLOGIC FACTORS

Salmonellae are gram-negative, flagellated, nonsporulating aerobic bacilli. They are serotyped using the schema developed by Kauffman and White using somatic (O) and flagellar (H) antigens; more than 2,000 serotypes have been identified. Current convention refers to the serotype as a serovar of the species *S. enterica*, for example: *Salmonella* serotype *typhimurium*, *S. dublin*, or *S. enteritidis*. Most clinical laboratories use only the O antigen to group salmonellae into broad serogroups A through G. Complete serotyping is available through state public health laboratories and can be clinically and epidemiologically useful. Ten serotypes account for the majority of infections (Table 281.1). Many serotypes have specific animal reservoirs and exhibit unique patterns of age specificity, invasiveness, antibiotic resistance, and geographic distribution.

Serotype	1980		1990		1997			
	No. of Isolates	Percentage	No. of Isolates	Percentage	No. of Isolates	Percentage

TABLE 281.1. THE 10 MOST COMMON SEROTYPES IDENTIFIED AMONG HUMAN SALMONELLA INFECTIONS IN 1980, 1990, AND 1997^a

PATHOGENESIS

The pathogenesis of *Salmonella* infections remains incompletely understood. The clinical expression of infection depends on the serotype and strain of the organism, the underlying health and gut flora of the host, and the dose and vehicle of infection. In normal volunteers, the presence of 10^5 to 10^9 organisms is usually necessary to produce symptomatic infection. Highly susceptible hosts or foods that protect the bacteria from gastric acid may lead to infection at much lower doses. After ingestion, salmonellae must survive gastric acid and successfully colonize the small intestine. Disruption of the normal intestinal flora by antimicrobial agents decreases the dose needed to produce illness.

The bacteria attach to and penetrate the intestinal mucosa. In most infections, salmonellae may cause diarrhea simply by direct damage to the mucosa or by local action of bacterial toxins. However, salmonellae can invade the gut-associated lymphoid tissues, multiply within macrophages, and reach the bloodstream. Some serotypes are particularly invasive and more likely to result in bacteremia, enteric fever, and distant focal infections.

Persons at the extremes of age, those with reduced gastric acidity, and those who have recently taken an antibiotic are more susceptible to *Salmonella* infection following exposure. Persons silently infected with a resistant strain of *Salmonella* may develop clinical illness if they take an antibiotic to which the infecting strain is resistant. Disorders of reticuloendothelial cell function, such as sickle cell anemia, and defects in cellular immunity, such as those associated with AIDS, lymphoma, leukemia, or antineoplastic therapy, predispose to bacteremia and invasive disease.

CLINICAL FINDINGS

Salmonella infections can manifest as five syndromes.

ASYMPTOMATIC CARRIAGE

Transient asymptomatic infection is common in normal hosts exposed to low doses of salmonellae. Following symptomatic nontyphoidal salmonellosis, half of patients still shed the organism in their stool after 4 weeks, but only 0.5% continue to shed for more than a year. Chronic asymptomatic biliary carriage (carriage lasting for more than a year) may follow up to 3% of *S. typhi* infections, particularly in patients with gallstones or biliary scarring. Typhoid carriers may intermittently shed large numbers of organism for many years.

ENTEROCOLITIS

Acute enterocolitis or gastroenteritis is the most common illness caused by nontyphoid salmonellae. The incubation period is typically 8 to 48 hours. The initial symptoms include nausea and vomiting, followed by abdominal cramps and diarrhea, which is occasionally bloody. About half of patients have fever and headache. The severity of diarrhea may vary from a few loose stools per day to profuse watery or bloody diarrhea. Diarrhea typically subsides in 3 to 5 days but may persist for 2 weeks. Acute infection with nontyphoidal salmonellae can trigger the reactive postinfectious syndrome of Reiter's arthropathy in persons with a susceptible genotype.

ENTERIC FEVER

The enteric fever syndrome is typically seen with *S. typhi* infection but may occur with other strains, particularly *S. paratyphi* type A and B. The incubation period is usually 1 to 3 weeks, depending on the dose ingested. Early symptoms are nonspecific and include cough, sore throat, myalgia, and abdominal pain. The patient may experience constipation or mild diarrhea. Within a week, a pronounced and sustained fever develops, and headache, anorexia, lethargy, and a characteristically clouded mental state become prominent. Physical examination often reveals relative bradycardia, hepatosplenomegaly, and abdominal tenderness. Rose spots (clusters of delicate pink, irregular macules 2 to 4 mm in diameter that blanch with pressure) may be seen on the trunk. Complications of enteric fever include myocarditis, bone marrow depression, and intestinal perforation and hemorrhage.

BACTEREMIA

Sustained bacteremia, characterized by high fevers and leukocytosis but without other clinical features of enteric fever or diarrhea, can occur with a variety of serotypes, but is most typical for *S. choleraesuis*. Recurrent *Salmonella* bacteremia, usually with *S. typhimurium* or *S. enteritidis*, is an important problem among patients with AIDS; relapse may follow prolonged courses of antibiotics.

FOCAL INFECTIONS

Focal *Salmonella* infections have been reported in many sites, including the brain, meninges, lung, pleural space, pericardium, kidney, bone, liver, spleen, bladder, heart valve, and endarterial lesions. Such infections follow an initial bacteremia, which may be silent. *Salmonella* meningitis occurs almost exclusively in young infants. Salmonellae appear to have a predilection for infecting atherosclerotic lesions, particularly atherosclerotic aortic aneurysms.

LABORATORY FINDINGS

Definitive diagnosis depends on identification of *Salmonella* organisms. Unless antibiotic treatment has already been given, routine bacteriologic techniques will readily yield salmonellae from stool, blood, cerebrospinal fluid, or other clinical specimen. No specific serologic tests are available. Typhoid fever can present a particular diagnostic challenge, as stool cultures are often negative early in the illness and blood cultures may be negative in some patients, particularly those who have been partially treated. Cultures of bone marrow, bile obtained by duodenal string test, and, in the future, polymerase chain reaction–based diagnostic tools may be helpful in such cases. The Widal serologic test is fraught with problems. False-positive test results may be caused by other infections or previous vaccine administration, and some typhoid fever patients may never mount an antibody response.

ANTIMICROBIAL RESISTANCE

Salmonellae have become increasingly resistant to antimicrobial agents. Although treatment is not indicated for uncomplicated gastroenteritis, resistance can lead to treatment failure in severe infections. To monitor trends in resistance, a national surveillance system was recently implemented. In 1997, more than 1,300 nontyphoidal *Salmonella* isolates from 15 states and local health departments were tested for antimicrobial resistance to 17 agents; 34% of strains were resistant to at least one antimicrobial agent and 27% were resistant to multiple agents—a substantial increase from earlier surveys. Similar resistance is found in salmonellae isolated from meats and is a direct consequence of the use of antimicrobial agents in animal husbandry. Multiply-resistant *S. typhi* and nontyphoidal salmonellae are now being identified in many developing countries.

OPTIMAL MANAGEMENT

The treatment of salmonellosis depends on the type of infection. Antimicrobial agents are not indicated for uncomplicated enterocolitis since they do not shorten the illness and actually prolong bacterial shedding. Fluid and electrolyte losses should be replaced and antimotility agents avoided. Convalescent carriage of nontyphoidal salmonellae is not shortened by antimicrobial therapy, and treatment of convalescent carriers is not indicated. Because chronic carriers of *S. typhi* represent a major reservoir for that organism and are excluded from some jobs, elimination of carriage is desirable. Prolonged high doses are required, with the most encouraging results reported for either norfloxacin 400 mg twice a day or ciprofloxacin 750 mg twice a day for 4 weeks.

Chloramphenicol, ampicillin or amoxicillin, or trimethoprim–sulfamethoxazole have long been the treatments of choice for enteric fever. However, increasing antimicrobial resistance limits the current usefulness of these agents. Third-generation cephalosporins, including ceftriaxone, cefotaxime, and cefoperazone, and fluoroquinolones, including norfloxacin and ciprofloxacin, have demonstrated efficacy in treating typhoid fever. Although in vitro sensitivity may be reported, tetracyclines and first- and second-generation cephalosporins are not effective for *Salmonella* infections, including typhoid fever.

Bacteremia and focal infections have also traditionally been treated with chloramphenicol, ampicillin, and trimethoprim–sulfamethoxazole, and more recently with fluoroquinolones. For meningitis and osteomyelitis, ceftriaxone and cefotaxime offer excellent in vitro activity, achieve good levels in tissue, and are bactericidal. Prolonged therapy of 2 to 4 weeks should be given. Localized abscesses, infected aneurysms, and infected heart valves usually require surgical management. Because of the frequency of recurrence, long-term suppressive therapy with an oral antimicrobial agent should be considered for AIDS patients with *Salmonella*

bacteremia.

PREVENTION

Salmonellosis can be prevented by simple measures that caregivers can encourage. Particular care is warranted to avoid salmonellosis in infants, the elderly, and the immunocompromised, among whom severe outcomes are most likely. Breast-feeding is strongly protective against this and other diarrheal diseases in infants. Unpasteurized milk and raw eggs should be avoided. Care in handling meat, eggs, and other foods of animal origin will prevent many cases, if the foods are cooked thoroughly, and if hands, knives, and work surfaces are immediately washed with soap. Most reptiles carry salmonellae and are not appropriate pets for households with infants or HIV-infected persons. The risk of salmonellosis in institutions such as hospitals and nursing homes can be further decreased by use of pasteurized eggs rather than shell eggs, and by standard food safety measures. Salmonellosis outbreaks in hospital nurseries have been curtailed by infection control, hand washing, and cohorting. The risk of acquiring salmonellosis from fresh fruits and vegetables can be reduced by the use of chlorinated water in all postharvest product handling.

New measures to reduce the risk of *Salmonella* infection through foodborne transmission include cleaner slaughter practices on the farm and, in the future, irradiation of meat and poultry products. Judicious use of antibiotics in all arenas, especially animal husbandry, will help to prevent the development of antibiotic-resistant strains of *Salmonella*. It is important for clinicians to culture all specimens from persons suspected of having *Salmonella* infection and for laboratories to serotype all isolates; all suspected outbreaks should be reported to local or state health departments.

Typhoid fever in the United States has been controlled by improvements in water and sewage treatment. Travelers to developing countries can lower their risk by careful selection of food and drink. Vaccination is recommended for people living in or visiting areas of endemic disease for extended periods or under conditions of poor hygiene, for family members of chronic typhoid carriers, and for microbiology personnel who are likely to be exposed to *S. typhi*. Three licensed typhoid vaccines are available in the United States. One is a heat- and phenol-inactivated preparation that has been shown to provide 65% to 70% protective efficacy after two initial doses one month apart. Adverse reactions are common (25% to 45%) and include local pain, fever, myalgia, and headache. The second vaccine is a live attenuated oral one made from the Ty21a strain, taken in four oral doses at 48-hour intervals. In field trials, efficacy of a three-dose regimen was 66%, and the vaccine was virtually free of side effects. Finally, a parenteral vaccine containing purified Vi polysaccharide antigen from *S. typhi* provides 55% to 74% efficacy after a single dose and is associated with only mild local reactions. All require boosting at intervals. In the future, Vi polysaccharide conjugated to carrier proteins may increase immunogenicity in young children.

CHAPTER 282: SHIGELLOSIS

KAREN KOTLOFF AND MYRON M. LEVINE

[Definition](#)
[Etiology](#)
[Incidence and Epidemiologic Factors](#)
[Pathogenesis](#)
[Clinical Findings](#)
[Approach to Laboratory Diagnosis](#)
[Optimal Management](#)

DEFINITION

Shigellosis is the clinical syndrome that occurs when bacteria of the genus *Shigella* invade the human terminal ileum and colon. The spectrum of symptoms may include asymptomatic infection, mild watery diarrhea, or severe dysentery characterized by high fever, toxemia, cramps, and tenesmus. The term *shigellosis* is commonly used to describe prototypic bacillary dysentery (the passage of frequent scanty stools containing blood and mucus).

ETIOLOGY

Shigella are gram-negative, non-lactose-fermenting, nonmotile bacilli of the family Enterobacteriaceae. Four species or groups of *Shigella* are recognized: *S. dysenteriae* (group A), *S. flexneri* (group B), *S. boydii* (group C), and *S. sonnei* (group D). Groups A, B, and C have multiple serotypes and subtypes, whereas group D has only a single serotype.

There is geographic variation in the predominant serogroup of *Shigella* that appears to be related to the local standard of sanitation and hygiene. *S. sonnei* is by far the most common type found in industrialized countries, accounting for more than 70% of isolates reported in the United States. *S. flexneri* predominates in developing countries but constitutes only about 20% of isolates in the United States. *S. dysenteriae* occurs in the least developed areas of the world where it causes a small proportion (about 6%) of endemic disease. In addition, the *S. dysenteriae* type 1 serotype, also known as the Shiga bacillus, elaborates Shiga toxin and is uniquely capable of forming pandemics of severe disease that spread in waves from country to country. In the United States, *S. dysenteriae* type 1 has been eliminated except when introduced by travelers. *S. boydii* is an uncommon serogroup in both developing and industrialized countries.

INCIDENCE AND EPIDEMIOLOGIC FACTORS

The predominant mode of transmission is by fecal–oral contact, and a low infectious inoculum (as few as 10 organisms can cause illness) renders *Shigella* highly contagious for humans, the only natural host. Sustained person-to-person transmission from symptomatic individuals is largely responsible for persistence of this pathogen. Spread by ingestion of fecally contaminated food or water is less common (*Shigella* causes about 3% of bacterial foodborne outbreaks in the United States) since the organism survives poorly in the environment, but individual outbreaks can be extensive. Salad is the most common vehicle; contamination is usually related to a breach in hygienic practices by an infected food handler. Transmission subsequent to swimming in fecally contaminated water occasionally occurs. In certain settings where disposal of human feces is inadequate, houseflies may transmit infection. Among homosexuals, transmission via anal–oral contact has been reported.

Shigella infections occur worldwide but are most prevalent in settings where crowding, poor sanitation, inadequate water supplies, and primitive personal hygiene coexist. Seasonal peaks appear in the late summer and fall in temperate climates. Throughout the world, the incidence of shigellosis is highest among children 1 to 4 years of age. Infants and young children who are breast-fed have fewer episodes of shigellosis, and when an episode occurs, it is less severe compared to that in children who are not breast-fed.

In the United States, endemic foci of shigellosis persist among poor, urban children belonging to ethnic minorities, and in some Native American communities. An elevated risk of shigellosis is also found among young children in day care centers, residents of custodial institutions, travelers to less developed countries, and soldiers in field conditions. The incidence of shigellosis in the United States has been estimated based on national laboratory surveillance data collected by the U.S. Centers for Disease Control and Prevention (CDC). Since the 1960s, periodic peaks and troughs have been observed, ranging from 5.4 to 10.1 isolations per 100,000 population. Since only about 15% of cases are reported, this figure is believed to markedly underestimate the actual rate of *Shigella* infection in the United States. Nonetheless, *Shigella* remains a relatively uncommon enteropathogen in the United States, causing fewer than 5% of diarrheal episodes among children younger than 5 years. Data on case fatality are limited, but it has been estimated at about 0.4%, resulting in approximately 60 deaths per year in the United States.

Two notable demographic trends were reported in the United States in recent years. Since the late 1970s, marked increases have been observed in the rate of infection reported among women of childbearing age. Presumed to reflect transmission from infected children to their mothers (rates of secondary transmission of *S. sonnei* in households with small children often exceeds 50%), this trend could be explained by a steady increase in the use of day care facilities whose role in disseminating shigellosis in the community is well recognized. Increases in isolation of *S. flexneri* from adult men in the 1980s were attributed to transmission among homosexual men.

The burden of disease from *Shigella* infection is greatest in developing countries, where endemic *Shigella* (mainly *S. flexneri* serotypes) is responsible for about 1% to 15% of diarrheal episodes among young children. Overall it is estimated that *Shigella* causes 163 million cases of diarrhea in developing countries and 1.1 million deaths annually. In addition, pandemic Shiga dysentery has appeared in Central America, South and Southeast Asia, and sub-Saharan Africa since the late 1960s, primarily affecting populations in areas of political upheaval and natural disaster. The pandemic strains are notoriously multiply antibiotic-resistant and cause high attack rates and mortality in all age groups. The ravaging effects of *S. dysenteriae* among refugee populations in pandemic areas was observed when approximately 800,000 Rwandans fled to Democratic Republic of Congo in 1994. During the first month of the crisis alone, approximately 20,000 persons died from dysentery caused by a multiply antibiotic-resistant strain of *S. dysenteriae* type 1.

PATHOGENESIS

In response to certain environmental signals, shigellae can exhibit remarkable acid resistance. This apparently enables the bacteria to survive transit through the gastric acid defense barrier following oral ingestion. Ultimately, shigellae reach the terminal ileum and colon, where they invade and proliferate within enterocytes, produce cell death, and incite an intense inflammatory reaction.

The cardinal pathogenic feature is invasion of intestinal epithelial cells that involves a bacteria–host cell interaction wherein shigellae secrete invasins that induce ruffling of the enterocyte membrane. Fusion of these flowerlike membrane projections leads to bacterial internalization via macropinocytosis. Within minutes of entry, the bacteria escape the membrane-bound pinocytotic vacuole to reach nutrients within the cytosol that are required for the next phase of intense bacterial replication. These nonmotile bacteria then acquire the ability to undergo directed intracellular movements, navigating via reorganization of the host cell cytoskeleton to form a unipolar actin comet tail. Some bacteria are propelled toward the cell surface, leading to the development of long protrusions that penetrate adjacent epithelial cells. As contiguous enterocytes become infected and die, areas of ulceration and hemorrhage are formed.

Invasion of the intestine by shigellae elicits a potent inflammatory response characterized by polymorphonuclear leukocyte (PMN) chemotaxis, edema, infiltration of the lamina propria with PMNs and mononuclear cells, and formation of mucosal microabscesses. Shigellae induce apoptotic death of macrophages, their own front-line predator in subepithelial tissues. Apoptotic killing of macrophages confers two distinct advantages: it allows bacterial survival, and it releases cytokines that trigger inflammation and render the epithelial barrier more permeable to *Shigella* invasion. Integrity of the epithelial lining is disrupted as PMNs migrate through the intercellular space to reach luminal organisms, opening additional pathways for invasive organisms to access enterocytes.

Until recently, the pathogenesis of the watery diarrhea that typically precedes dysentery and that is often the sole clinical manifestation of mild infection remained enigmatic. Then two novel *Shigella* enterotoxins, designated ShET1 and ShET2, were incriminated as the likely mediators of the watery diarrhea seen early in the

clinical course. Transudation and decreased absorption of water by an inflamed colon may also play a role.

The *S. dysenteriae* type 1 serotype uniquely produces a highly potent exotoxin called Shiga toxin. Shiga toxin is a powerful inhibitor of protein synthesis; however, its precise role in the pathogenesis of Shiga dysentery is still not entirely clear. Mutants of *S. dysenteriae* type 1 that are invasive but do not express Shiga toxin nevertheless have caused typical Shiga diarrhea and dysentery when fed to monkeys and volunteers, although less endothelial damage to intestinal microvasculature was evident.

Hemolytic–uremic syndrome is a well-recognized, life-endangering complication of *S. dysenteriae* type 1 infection in children, which manifests as thrombotic thrombocytopenic purpura in adults. The central pathophysiologic process is believed to be vascular endothelial cell death induced by systemically absorbed Shiga toxin. Whereas the inciting agent is usually *S. dysenteriae* type 1 in developing countries, most cases in the United States and other industrialized countries follow infection with enterohemorrhagic *Escherichia coli*, a category of diarrheagenic *E. coli* (most commonly serotypes O157:H7 and O26:H11) that elaborates Shiga toxin (or the related Shiga toxin 2).

CLINICAL FINDINGS

The incubation period is usually 1 to 4 days but may be as long as 8 days with *S. dysenteriae* type 1. Shigellosis often progresses through several phases. Typically the illness begins with fever and other constitutional symptoms such as headache, malaise, anorexia, and, occasionally vomiting, followed by several hours of watery diarrhea (Table 282.1). Most cases in the United States are limited to these milder manifestations. However, progression to frank dysentery may occur with frequent scanty stools containing blood and mucus, accompanied by lower abdominal cramps and tenesmus. Disease is most severe in young children and in the elderly, whereas many adults have asymptomatic or mild illness.

Acute Manifestations	Complications	
	Intestinal	Extraintestinal
Fever	Toxic megacolon	Dehydration
Headache	Rectal prolapse	Electrolyte abnormalities
Malaise	Intestinal perforation	Hypoglycemia
Anorexia	Persistent diarrhea	Hypoproteinemia
Vomiting	Protein-losing enteropathy	Malnutrition
Watery diarrhea		Bacteremia
Dysentery		Extraintestinal infection
Abdominal cramps		Hemolytic-uremic syndrome
Rectal tenesmus		Thrombotic thrombocytopenia purpura
		Reactive arthritis
		Reiter's syndrome

TABLE 282.1. CLINICAL MANIFESTATIONS OF SHIGELLOSIS

Most cases of shigellosis in otherwise healthy individuals are self-limited and resolve within 5 to 7 days. Acute, life-threatening complications occur most frequently among infants and young children living in developing countries, and among people infected with *S. dysenteriae* type 1, although in endemic areas any species of *Shigella* can cause severe illness or death. Intestinal complications include toxic megacolon, rectal prolapse from tenesmus, and intestinal perforation (Table 282.1). Extensive damage to the intestinal mucosa of young children can cause marked exudation of proteins, leading to hypoproteinemia and acute kwashiorkor. Dehydration, hyponatremia, hyperkalemia, and hypoglycemia are acute metabolic derangements requiring immediate therapeutic intervention. *Shigella* sepsis, seen most often in young, malnourished children, occurs uncommonly but is a leading cause of death during shigellosis. In the United States, bacteremia has occasionally been reported among HIV-infected and other immunocompromised patients. Rarely, *Shigella* organisms cause focal infections such as meningitis, osteomyelitis, arthritis, and splenic abscess.

A variety of unusual extraintestinal manifestations can occur (Table 282.1). The most common is seizures, which are reported in 5% to 45% of children hospitalized with shigellosis. They usually occur in children younger than 5 years who have fever or metabolic derangements known to precipitate seizures. Rarely encephalopathy is encountered. Hemolytic–uremic syndrome, manifesting as microangiopathic hemolytic anemia in association with thrombocytopenia and renal insufficiency, can follow infection with Shiga toxin–producing organisms. Another hematologic complication encountered with *S. dysenteriae* type 1 infection is a leukemoid reaction with PMN counts exceeding 50,000 to 100,000 per cubic millimeter.

An uncommon late sequela seen primarily in adults is reactive arthritis, alone or as part of a constellation of arthritis, conjunctivitis, and urethritis known as Reiter's syndrome. Arthritis has an acute onset usually 2 to 4 weeks after the intestinal illness and most often follows infection with *S. flexneri* serotypes. Joint symptoms can range from mild arthralgia to severe polyarthritis, which becomes chronic in about 10% of cases. Individuals with the HLA–B27 histocompatibility antigen are predisposed, accounting for approximately half of cases. It has been suggested that there are “arthritogenic” *Shigella* strains that carry a small plasmid encoding a cross-reactive peptide.

APPROACH TO LABORATORY DIAGNOSIS

There is no commercially available serologic assay indicating acute infection. Leukocytosis is often present, sometimes with marked bandemia in the peripheral blood smear. Measurement of serum electrolytes, glucose, blood urea nitrogen, creatinine, and protein is indicated in patients who appear dehydrated, malnourished, or have changes in mental status.

STOOL MICROSCOPY

If *Shigella* infection is suspected, fresh stool should be examined for the presence of fecal leukocytes. The observation of large numbers of fecal leukocytes in a patient with acute diarrheal illness provides evidence that a bacterial pathogen has invaded the colonic mucosa and produced inflammation. *Campylobacter jejuni*, enteroinvasive *E. coli*, *Yersinia enterocolitica*, and nontyphoidal *Salmonella* species are bacterial pathogens aside from *Shigella* that cause dysentery accompanied by abundant fecal leukocytes. Stool microscopy also differentiates other infectious causes of bloody diarrhea from enteroinvasive bacterial infection. Notably, amebic dysentery and enterohemorrhagic *E. coli* do not induce abundant fecal leukocytes.

STOOL CULTURE

A specific diagnosis can usually be made within 48 hours by bacteriologic culture. When feces are acidic, bacteria remain viable for only a few hours; therefore, culture of a fresh stool is optimal. If this is not feasible, buffered glycerol saline makes the best transport medium. Differential, moderately selective media such as xylose–lysine deoxycholate (XLD) agar and *Salmonella–Shigella* (SS) should be used. Culture of two or more stool specimens increases the likelihood of isolating *Shigella* organisms. If *S. dysenteriae* is suspected, Tergitol-7 agar is particularly useful, but XLD agar can also isolate this fastidious bacterium. Susceptibility testing of isolates should be performed.

OPTIMAL MANAGEMENT

Hygienic behavior such as hand washing is effective in interrupting transmission. Segregation of ill persons is important in controlling infection in settings where hygienic practices are difficult to enforce, such as outbreaks occurring in institutions for the mentally handicapped. Antibiotics should not be given to prevent infection.

Correction of fluid and electrolyte deficits and replacement of ongoing losses is a central feature of management. The clinician should be alerted to other possible complications of shigellosis that may require specific therapy, such as seizures and intestinal perforation.

No evidence suggests that common antidiarrheal preparations, such as kaolin–pectin formulas, lactobacilli, or bismuth salicylate, have a significant beneficial effect,

nor does evidence suggest that these agents are deleterious and therefore contraindicated. Agents that suppress intestinal motility, such as diphenoxylate, loperamide, and tincture of opium, have generally been avoided in known or suspected shigellosis because they may prolong or exacerbate the clinical and bacteriologic course of the disease, particularly in young children. Nonetheless, a randomized, double-blind, placebo-controlled trial demonstrated that adults with dysentery due to *Shigella* (predominantly *S. flexneri*), or the closely related enteroinvasive *E. coli*, who were treated with loperamide plus ciprofloxacin had significantly fewer diarrheal stools (median 2.0 stools) than subjects who were treated with ciprofloxacin alone (median 6.5 stools), and a significantly shorter duration of diarrhea (19 hours versus 42 hours, respectively). Adverse effects from loperamide were not detected. These findings suggest that loperamide may offer additional benefit to ciprofloxacin in adults with *Shigella* dysentery. However, loperamide should not be given to children, to debilitated or immunocompromised patients, to patients who may be infected with ciprofloxacin-resistant strains, or to those infected with *S. dysenteriae*.

Many controlled clinical trials have shown that appropriate antibiotics significantly decrease the duration of fever, diarrhea, and excretion of the pathogen in shigellosis. Most patients in these studies were infected with either *S. flexneri* or *S. dysenteriae*. The advantages of treating *S. sonnei*, which is usually self-limited, are less clear; benefit is likely to be greatest when therapy is initiated early in the course of illness. Nonetheless, this cumulative experience, in conjunction with the fact that treatment of ill persons may interrupt transmission, provides the rationale for treating patients with shigellosis with antibiotics.

The decision to treat must be reconciled with the reality that only a few antibiotics have proven to be clinically efficacious and that resistant *Shigella* strains eventually emerge from widespread use of these antibiotics. In 1997, nearly 20% of *Shigella* isolates reported to the CDC were resistant to both ampicillin and trimethoprim-sulfamethoxazole (TMP-SMX). *Shigella* isolates in Oregon between 1993 and 1998 demonstrated high-level (greater than 60%) resistance to either ampicillin or TMP-SMX. Resistance is more likely to be encountered if there is a history of recent foreign travel in the patient or in a household member with diarrhea. In Asia and Africa, nearly all *S. dysenteriae* type 1 strains are now resistant to tetracycline, ampicillin, TMP-SMX, and nalidixic acid (the drugs previously used to treat this infection), and other *Shigella* species are commonly resistant to these agents.

If the strain is susceptible, then inexpensive and highly effective antibiotics for adults include ampicillin (but not amoxicillin), tetracycline, TMP-SMX, and nalidixic acid (Table 282.2). Fluoroquinolones (e.g., ciprofloxacin, norfloxacin) are a highly effective albeit more expensive choice. A recent trial demonstrated that azithromycin was therapeutically equivalent to ciprofloxacin and may be considered as a second-line agent. Infections with strains having unknown susceptibility can be empirically treated with a fluoroquinolone; the increasing levels of TMP-SMX resistance suggest that this is no longer appropriate empiric therapy for shigellosis in many areas. Some antibiotics should be avoided because they lack clinical efficacy even though shigellae appear to be susceptible in vitro; these include nitrofurans, aminoglycosides, and first- and second-generation cephalosporins.

Antibiotic	Route	Adult Dose	Pediatric Dose ¹
Ampicillin	PO, IV	500 mg q.i.d. for 5 days	25 mg/kg q.i.d. for 5 days
TMP-SMX	PO, IV	160 mg TMP/800 mg SMX b.i.d. for 5 days	5 mg/kg TMP/25 mg/kg SMX b.i.d. for 5 days
Quinolones			
Ciprofloxacin	PO, IV	500 mg b.i.d. for 5 days ²	15 mg/kg b.i.d. for 5 days ³
Norfloxacin	PO	400 mg b.i.d. for 5 days ²	See text ³
Nalidixic acid	PO	1.0 g q.i.d. for 5 days	15 mg/kg q.i.d. for 5 days
Azithromycin	PO	500 mg on day 1, followed by 250 mg q.d. on days 2-5	Efficacy not evaluated in children

¹Maximum dose not to exceed adult dose.
²In settings such as developing countries where the expense and practicality of a 5-day course of therapy are problematic, shigellosis caused by serotypes other than *S. dysenteriae* type 1 can be successfully treated with a 1-3-day regimen.
³These quinolones have not yet been approved for use in children younger than 18 years. However, there is growing evidence that they are safe and effective for use in multiply resistant childhood infections.
 TMP-SMX, trimethoprim-sulfamethoxazole.

TABLE 282.2. TREATMENT OF SHIGELLOSIS

Therapy for children is similar to that for adults, with the following four exceptions. For one, despite growing evidence that they are safe and effective, fluoroquinolones have been used cautiously in children younger than 18 years because they cause arthropathy in young animals. Nonetheless, limited use of fluoroquinolones in children has shown that standard doses do not cause arthropathy. Similar experimental toxicity is observed with the quinolone nalidixic acid, but it was approved for use in children before this toxic effect was known and it has been used extensively without associated joint damage. Second, tetracycline should be avoided in children younger than 9 years because it may cause tooth enamel hypoplasia and discoloration. Third, data on the efficacy of azithromycin in treating children with shigellosis are insufficient to formulate recommendations. Finally, whereas oral cefixime was not efficacious in adults, both oral cefixime and parenteral ceftriaxone have appeared to be beneficial in children.

Antibiotics are usually given for 3 to 5 days. In developing countries where costs of therapy constitute a critical consideration, short (1- to 3-day) courses of oral quinolones have been shown to be effective for milder illness caused by serotypes other than *S. dysenteriae* type 1; however, a 5-day course of therapy should be administered for severe illness or for suspected Shiga dysentery. With the exception of severely ill patients, therapy can be administered orally.

There is a pressing need for more effective control measures, such as improved hygiene and sanitation, and vaccination. In the 1960s, attenuated mutant strains of *Shigella* (in particular streptomycin-dependent mutants) were shown to be safe and protective when used as live oral vaccines. However, these vaccines had drawbacks and never gained widespread popularity. Research in this area has continued and has resulted in newer candidate vaccines, some of which have entered clinical trial. The objective is safe vaccines that provide broad-spectrum, long-lived immunity after administration of only one or two oral doses.

CHAPTER 283: INFECTIONS CAUSED BY VIBRIO AND CAMPYLOBACTER SPECIES

J. GLENN MORRIS, JR AND MARTIN J. BLASER

[Microbiology](#)
[Cholera](#)
[Vibrio Cholerae in O Groups Other than O1 and O139](#)
[Vibrio Parahaemolyticus](#)
[Vibrio Vulnificus](#)
[Other Vibrios](#)
[Aeromonas](#)
[Plesiomonas Shigelloides](#)
[Campylobacter Jejuni](#)
[Campylobacter Fetus](#)

The pathogenic genera *Vibrio*, *Aeromonas*, *Plesiomonas*, and *Campylobacter* represent a diverse collection of gram-negative bacteria. *Vibrio cholerae* strains in O groups 1 and 139 cause cholera; patients with cholera have profuse, watery diarrhea that in the absence of treatment can rapidly lead to dehydration, shock, and death. Diarrhea is the most common clinical manifestation seen in association with other *V. cholerae* serogroups and other disease-causing species and strains in these genera. Some species also cause wound infections or septicemia. Septicemia, when it occurs, is usually limited to impaired hosts. [Table 283.1](#) summarizes the principal features of the agents reviewed.

TABLE 283.1. CLINICAL AND EPIDEMIOLOGIC FEATURES OF INFECTIONS CAUSED BY VIBRIO AND CAMPYLOBACTER SPECIES

MICROBIOLOGY

Essentially all thin, curved, motile, gram-negative bacteria were originally considered to be vibrios, but closer examination has indicated that several distinct genera can be justified, including *Vibrio*, *Aeromonas*, *Plesiomonas*, *Campylobacter*, and *Helicobacter*. *Campylobacter* species were segregated because they are microaerophilic, whereas the true *Vibrio* species are facultative aerobes. All pathogenic *Vibrio* species other than *V. cholerae* require salt for growth. Isolation of *Vibrio* species from a stool specimen may be done by direct plating on thiosulfate citrate bile salt sucrose (TCBS) medium. After overnight incubation, suspect colonies can be identified; pre-enrichment in alkaline peptone water may increase the yield of culture. For *V. cholerae*, a reference microbiology laboratory (such as a state health department laboratory) can differentiate between cholera-associated strains (strains in O groups 1 and 139), and strains in other O groups, which may or may not be pathogenic. *V. cholerae* in O group 1 (*V. cholerae* O1) may be further classified by biotype (El Tor or classical) and serotype (Inaba or Ogawa).

Aeromonas and *Plesiomonas* species are rod-shaped bacteria of the family Vibrionaceae. Species considered to be pathogenic for human beings include *Aeromonas hydrophila*, *Aeromonas caviae*, *Aeromonas sobria*, and *Plesiomonas shigelloides*. These organisms may be differentiated from the Enterobacteriaceae because most are oxidase-positive, non-lactose fermenters. Blood agar that contains ampicillin is a selective medium for fecal isolation.

Campylobacter species were not isolated from fecal specimens until selective methods were used; these include a microaerobic atmosphere (5% oxygen) and use of either an antibiotic-containing plate medium or filtration for selective enrichment. A wide variety of *Campylobacter* and closely related *Helicobacter* species have been associated with human diarrheal illnesses. These include *Campylobacter coli*, *Campylobacter fetus*, *Campylobacter lari*, *Helicobacter cinaedi*, *Helicobacter fennelliae*, *Campylobacter upsaliensis*, and *Campylobacter hyointestinalis*; however, *Campylobacter jejuni* remains the most important and the prototype for the other organisms. A related organism, *Helicobacter pylori*, has been isolated from the gastric mucosa from patients with gastritis. Several diagnostic methods are based on its highly conserved urease enzyme.

CHOLERA

EPIDEMIOLOGIC FACTORS

Cholera has been recognized in the Indian subcontinent for hundreds of years. Seven cholera pandemics have occurred since 1817, involving spread of cholera from endemic areas in India and Asia through much of the rest of the world. The seventh pandemic (caused by *V. cholerae* O1 strains with an El Tor biotype) started in Indonesia in the early 1960s and, in the intervening three decades, has spread through Asia, parts of southern Europe, Africa, Oceania, and, beginning in 1991, South America. In the fall of 1992, a new cholera strain, *V. cholerae* O139 Bengal, was identified as the cause of epidemic cholera in Madras, India. This new strain subsequently spread through much of Asia, and in the Indian subcontinent is now as common, if not more common, than seventh-pandemic *V. cholerae* O1 El Tor strains.

Vibrio cholerae is a free-living organism in estuarine and other aquatic environments. Strains in this environmental reservoir may proliferate with seasonal increases in water temperature or other stimuli, and may be introduced into human populations through contaminated seafood, food, or water. In areas with poor sanitation, fecal material from ill persons further contaminates water or food sources, leading to additional cases and initiating cycles of epidemic disease. In areas in which the disease has become established, epidemics of this type usually occur once or twice a year, at very predictable times ("cholera season"). In such areas, illness is most common among children; adults are thought to have some degree of immunity because of prior exposure to the organism. In contrast, when *V. cholerae* is introduced into populations without prior exposure to cholera (or when there are major modifications in the antigenic structure of the strain, as occurred with the emergence of *V. cholerae* O139 Bengal strains), attack rates are equal in all age groups.

PATHOGENESIS

The primary mechanism for disease is the production of a potent enterotoxin, *cholera toxin*, that, through stimulation of adenyl cyclase on the membrane of small intestinal crypt cells, results in a net secretion of salt and water into the intestinal lumen. This augmentation of normal physiologic mechanisms, not actual damage to tissue, produces the often severe diarrhea for which cholera is known.

Recent studies indicate that the cholera toxin gene is carried by a filamentous phage, which is capable of integration into the bacterial chromosome. The receptor for this phage appears to be encoded by a gene in the *Vibrio* pathogenicity island (VPI), which is carried by a second phage. Genes responsible for expression of critical surface antigens also appear to be capable of transfer among strains. These findings underscore the genetic plasticity of cholera strains, a plasticity that may have contributed to the ability of the microorganism to "reinvent" itself in a series of pandemics.

CLINICAL FINDINGS

The manifestations of infection with O1 *V. cholerae* range from asymptomatic carriage to a rapidly fatal, fulminating illness. In severe cases, the sequence is massive diarrhea, volume depletion, hypotension, shock, and death. Without fluid replacement, death can occur within hours of onset of symptoms. Initially, stools may be loose, but the classic “rice-water” appearance then develops. Because the manifestations of disease result from a noncytolytic intoxication, fever and abdominal cramping are uncommon. The most common other symptoms—thirst, anxiety, muscle cramps, and light-headedness—are related to the rate and extent of fluid and electrolyte loss. Vomiting may contribute to fluid loss and impair the use of oral rehydration regimens. Dulled sensorium or convulsions, especially in children, may be caused by hypoglycemia. Hypokalemia may result in ileus that disguises the extent of fluid loss (cholera sicca), weakness, or arrhythmia.

DIAGNOSIS

Clinical diagnosis depends on the presence of massive watery stools, the absence of fever or abdominal cramping, and, usually, an exposure history. Volume replacement therapy for depleted patients should be begun before information on the specific etiologic agent is available. Dark-field or phase contrast microscopic examination of stools may show the typical *Vibrio* forms with darting motility. Definitive diagnosis is based on isolation of the organism on plate media. Isolation is facilitated by use of TCBS, although the organism will grow on MacConkey agar.

OPTIMAL MANAGEMENT

Cholera is a medical emergency. The treatment of all diarrheal diseases, and especially cholera, is the adequate replacement of fluid and electrolyte losses. In most cases, oral rehydration is sufficient, and the most favorable outcome is associated with its early institution. Oral rehydration packets of electrolytes and sugar to be mixed with water are available in most areas of the world in which cholera is endemic. If they are unavailable, the following should be added to each liter of boiled drinking water: NaCl, 3.5 g; NaHCO₃, 2.5 g; KCl, 1.5 g; glucose, 20 g. In an emergency, only NaCl and glucose are necessary. For patients already in shock or unable to take oral fluids, intravenous therapy is necessary and should be begun immediately. Lactated Ringer's solution or normal saline containing NaHCO₃, 4 g per liter, and KCl, 1 g per liter, in volumes to replace stool losses should be given. After initial stabilization by either intravenous or oral fluids, ongoing fluid loss in adults should be counterbalanced by oral rehydration solution at a ratio of 1.5:1 (150 mL of oral rehydration solution for every 100 mL of diarrheal stool). For children, losses should be replaced at a ratio of 1.1:1.

Antibiotics can shorten the duration of cholera diarrhea and the period of excretion of *V. cholerae*. However, antimicrobial therapy is clearly secondary in importance to fluid replacement: patients recover without difficulty in the absence of antimicrobial therapy but die without volume repletion. Tetracycline is the drug of choice, administered as 500 mg 4 times a day for 3 days; a single dose of 300 mg of doxycycline is also effective. Resistance to tetracycline is becoming increasingly widespread, particularly in sub-Saharan Africa. For tetracycline-resistant strains, alternative agents include ciprofloxacin, erythromycin, trimethoprim–sulfamethoxazole, and furazolidone.

PREVENTION

In endemic areas, prevention ultimately must be based on improving the quality of the water supply for drinking and cooking as well as for bathing and washing. The simple expedient of hand washing during outbreaks may diminish intrafamilial transmission. In epidemic situations, the widespread availability of oral hydration solutions is life saving. The use of older, parenteral, killed, whole-cell cholera vaccines is currently not recommended; protection with these vaccines was minimal, and they were associated with substantial side effects. Live attenuated and killed oral vaccines are currently undergoing evaluation and should become commercially available in the near future.

VIBRIO CHOLERAЕ IN O GROUPS OTHER THAN O1 AND O139

EPIDEMIOLOGIC FACTORS

As noted earlier, *V. cholerae* is common in estuarine and other aquatic environments. Non-O1/non-O139 strains of *V. cholerae* are particularly common environmental isolates, and are often present in shellfish, such as oysters, which are filter feeders. In the United States, cases of gastroenteritis caused by these strains are almost always associated with eating raw oysters. Outside of the United States, non-O1/non-O139 *V. cholerae* strains are recognized as a cause of travelers' diarrhea.

PATHOGENESIS

Most non-O1/non-O139 *V. cholerae* strains do not produce cholera toxin. Diarrheal illness has been reported in association with a subset of strains that produce a heat-stable enterotoxin called NAG-ST; the association between other enterotoxins and cytotoxins and illness remains unclear. Strains which are heavily encapsulated are more likely to cause septicemia.

CLINICAL FINDINGS

Gastrointestinal infections manifest with diarrhea and abdominal cramps in most cases. In contrast to O1/O139 *V. cholerae*, infections with non-O1/non-O139 strains frequently result in fever or bloody diarrhea. The incubation period is usually less than a day, and illness lasts less than a week and often for 48 hours or less. Non-O1/non-O139 *V. cholerae* strains can cause otitis externa and wound infections in people bathing in estuarine or other water containing the organism. People who have liver disease or who are immunosuppressed are at risk for bacteremia. Mortality rates for patients with bacteremia exceed 60%.

DIAGNOSIS

Diagnosis is based on isolation of the organism from stool, wound, or blood cultures. Isolation from stool is facilitated by use of TCBS medium.

OPTIMAL MANAGEMENT

Therapy of diarrhea should focus on appropriate fluid replacement. Although no data on efficacy are available, it would appear reasonable to treat patients with severe or prolonged gastroenteritis with tetracycline or ciprofloxacin. Patients with bacteremia require aggressive antimicrobial therapy (with tetracycline or ciprofloxacin) and good supportive care ([Table 283.2](#)).

Infection	Agent of Choice	Alternative
<i>V. cholerae</i>	Tetracycline, 500 mg PO qid for 3 d or single 200-mg dose of doxycycline (q ciprofloxacin for bacteremia)	Furazolidone, 100 mg PO t.i.d. Ciprofloxacin, 500 mg PO b.i.d.
<i>V. parahaemolyticus</i>	Tetracycline, 500 mg PO q.i.d. for 3 d	Ciprofloxacin, 500 mg PO b.i.d.
<i>V. vulnificus</i>	Minocycline 100 mg q12h PO, and rifampin 300 mg q12h IV	Tetracycline, ciprofloxacin, chloramphenicol
<i>Aeromonas</i> species	Trimethoprim–sulfamethoxazole	Ciprofloxacin
<i>Acinetobacter baumannii</i>	Trimethoprim–sulfamethoxazole	Tetracycline
<i>C. jejuni</i>	Doxycycline, 200 mg PO q.i.d. for 3 d	Tetracycline, 500 mg PO q.i.d. for 3 d Azithromycin, 1000 mg PO t.i.d. for 3 d or ciprofloxacin, 500 mg b.i.d. for 5 d
<i>C. fetus</i>	Clindamycin for systemic infection; erythromycin, 250 mg PO q.i.d. for 3 d for diarrhea	Chloramphenicol for systemic infection

TABLE 283.2. RECOMMENDED AGENTS FOR ANTIMICROBIAL TREATMENT OF INFECTIONS WITH *VIBRIO* AND *CAMPYLOBACTER* SPECIES

VIBRIO PARAHAEMOLYTICUS

EPIDEMIOLOGIC FACTORS

Vibrio parahaemolyticus may frequently be isolated from seawater, sediment, fish, and shellfish; however, only a minority of these environmental strains are pathogenic for human beings. Illness is usually associated with the eating of raw or undercooked seafood, or the cross-contamination of cooked food by raw seafood. In Japan, *V. parahaemolyticus* is the most commonly reported bacterial cause of acute enteritis. Illness occurs year round in tropical areas, but in temperate areas it occurs mostly in the summer. The largest North American outbreak of *V. parahaemolyticus* infection reported to date occurred in July–August 1997, in the Pacific Northwest, in association with the eating of raw oysters; increases in seawater temperatures above historic levels were felt to be one factor contributing to occurrence of the outbreak.

PATHOGENESIS

Traditionally, virtually all *V. parahaemolyticus* strains isolated from human beings were b-hemolytic on blood agar (Kanagawa-positive), whereas most environmental isolates were negative. Studies suggest that the thermostable direct hemolysin (TDH), the primary hemolysin responsible for this effect, has a direct role in production of diarrhea; the possible contributions of other factors to pathogenesis remain to be determined. More recently, a subset of isolates that are urease-positive but Kanagawa-negative have been linked with case clusters along the Pacific coast of the United States and in Asia.

CLINICAL FINDINGS

Vibrio parahaemolyticus usually produces a brief, explosive gastroenteritis with watery diarrhea, nausea, vomiting, headache, and low-grade fever. Stools generally are not bloody, although a subset of patients with dysentery-like illness has been reported. The incubation period ranges from 4 to 96 hours. Although diarrhea may occasionally be massive, illness is self-limited to 3 to 5 days in most cases. Wound infections and septicemia may also occur.

DIAGNOSIS

Diagnosis is based on isolation of the organism from culture. As with other *Vibrio* species, isolation from stool is facilitated by use of TCBS medium.

OPTIMAL MANAGEMENT

Specific antimicrobial treatment is not needed in most cases. In severe illness, tetracycline appears to be the treatment of choice ([Table 283.2](#)).

VIBRIO VULNIFICUS

EPIDEMIOLOGIC FACTORS

Vibrio vulnificus is ubiquitous in coastal waters, particularly during the warm summer months when water temperatures exceed 20°C. Oysters harvested from these waters commonly carry *V. vulnificus*. Injuries from shellfish or direct contamination of preexisting wounds with coastal waters may cause wound infections. *V. vulnificus* septicemia may result from a wound infection or follow ingestion of the organism in raw shellfish. Severe illness tends to be restricted to persons with underlying liver disease, hemochromatosis, chronic renal insufficiency, use of immunosuppressive agents, or heavy alcohol consumption.

PATHOGENESIS

Ability to cause either local or systemic infection is associated with the resistance of encapsulated *V. vulnificus* to complement-mediated serum lysis and to phagocytosis. The microorganism also produces a potent cytotoxin and protease, which may contribute to the observed clinical syndrome.

CLINICAL FINDINGS

Wound infections may remain localized or, in persons in the risk groups noted above, may spread rapidly, with formation of bulli. In the most severe cases, the clinical appearance may be similar to that seen with necrotizing fasciitis.

Septicemia may result from a wound infection or follow ingestion of shellfish containing the bacterium. Patients with septicemia usually have the abrupt onset of fever, chills, and hypotension. Characteristic bullous skin lesions develop within the first 24 hours of infection in a majority of cases. Mortality rates for patients with *V. vulnificus* septicemia exceed 50%; mortality is greater than 90% for patients who present in shock or become hypotensive within 24 hours of hospital admission. Even if patients survive the first few days, multiorgan system failure is a common sequela to septicemia, resulting in weeks of hospitalization in an intensive care unit and necessitating prolonged rehabilitation.

DIAGNOSIS

Diagnosis is based on a high index of suspicion among people with seawater or raw shellfish exposure, especially in high-risk patients. The presence of bullous skin lesions in a person with an appropriate history is a sensitive indicator of *V. vulnificus* sepsis. Definitive diagnosis is based on isolation of the causative organism from wound or blood culture.

OPTIMAL MANAGEMENT

Wound infections require rapid surgical debridement and aggressive antibiotic therapy; tetracycline and ciprofloxacin are the drugs of choice. Recent in vitro and animal studies from Taiwan indicate that there is synergism between minocycline and cefotaxime in treatment of serious *V. vulnificus* infections. In light of these latter studies, therapy with minocycline (100 mg q12h PO) and cefotaxime (2.0 g q8h IV), with doses appropriately adjusted for underlying renal or hepatic disease, is recommended for patients with septicemia or serious wound infections. Early initiation of antibiotic therapy has been associated with increased survival for patients with septicemia, and consequently therapy should be started immediately if there is any suspicion of the diagnosis. Patients who are hypotensive require aggressive supportive care in an intensive care unit.

OTHER VIBRIOS

EPIDEMIOLOGIC FACTORS

Other vibrios of medical significance include *V. mimicus*, *V. alginolyticus*, *V. damsela*, *V. hollisae*, *V. fluvialis*, and *V. furnissi*. These organisms have been isolated from estuarine environments, and in some cases illnesses have been associated with consumption of raw or undercooked seafood.

PATHOGENESIS

Although these vibrios have been isolated from patients with diarrheal illnesses or wound infections, their roles as pathogens are not well defined.

CLINICAL FINDINGS

Patients infected with *V. fluvialis* frequently have diarrhea, vomiting, and fever, as well as fecal leukocytes and blood. *V. mimicus* infection has also been associated with bloody diarrhea. *V. damsela* and *V. alginolyticus* are primarily associated with wound or ear infections rather than gastroenteritis.

DIAGNOSIS

Diagnosis of these infections is based on their isolation from stool cultures using selective media or isolation from wound or blood cultures.

OPTIMAL MANAGEMENT

For all diarrheal illnesses, treatment is based on repletion of volume lost in the stools. The role of specific antimicrobial therapy for diarrheal illnesses associated with these agents has not been determined. Wound infections and bacteremia should be treated with tetracycline or ciprofloxacin.

AEROMONAS

EPIDEMIOLOGIC FACTORS

Aeromonas species are widely found in environmental water sources, in highest concentrations in warm water and during the summer months. Potable water, especially if untreated, is usually considered the most important vehicle for this organism. Swimming in fresh or estuarine brackish water is a risk factor for wound infection. People of all ages may be affected with diarrheal disease. Rates of asymptomatic stool excretion of *Aeromonas* are also high in both adults and children, suggesting that not all strains are able to cause diarrhea. Extraintestinal infection occurs chiefly in compromised hosts.

PATHOGENESIS

Although several enterotoxins and cytotoxins have been described, their biologic role is uncertain and it is not known which environmental strains are pathogenic for humans.

CLINICAL FINDINGS

Infection may cause acute, watery diarrhea, dysentery, or a syndrome of chronic diarrhea. Acute, watery diarrhea is most common among children. Illness in these cases is usually self-limited, with a duration of less than 7 days. The dysenteric syndrome resembles shigellosis, with blood and mucus in feces, abdominal cramps, and fever. Chronic or intermittent diarrhea may persist for months to 2 years or more. *Aeromonas* species are associated with wound infections in people with exposure to estuarine and aquatic environments. Extraintestinal infections, including bacteremia, meningitis, endocarditis, and soft tissue, muscle, and bone infections, are also reported; these latter infections usually are limited to compromised hosts.

DIAGNOSIS

Aeromonas infection should be suspected in people who become ill after drinking or swimming in untreated water. Diagnosis is based on isolating organisms from a fecal culture using a selective medium or on isolating organisms from wound or blood cultures.

OPTIMAL MANAGEMENT

For those intestinal infections requiring treatment (those with fever, bloody diarrhea, or chronicity beyond 1 week), trimethoprim-sulfamethoxazole, a quinolone, or tetracycline are the agents of choice (see [Table 283.2](#)). For extraintestinal illness, trimethoprim-sulfamethoxazole is the treatment of choice, with ciprofloxacin a possible alternative.

PLESIOMONAS SHIGELLOIDES

EPIDEMIOLOGIC FACTORS

Water and seafood, especially raw oysters, appear to be the main environmental sources for *Plesiomonas* infection of human beings. Both environmental and human isolates occur more frequently in the summer months. Diarrheal illness occurs chiefly in immunocompetent hosts, whereas extraintestinal infection is most common in compromised hosts. *Plesiomonas* appears to be a cause of traveler's diarrhea.

PATHOGENESIS

The pathogenic mechanisms of *Plesiomonas* are not known, nor has it been determined as to which environmental and fecal isolates are virulent.

CLINICAL FINDINGS

Most patients infected with *Plesiomonas* organisms have bloody, mucus-containing stools with fecal leukocytes. Other patients may have severe abdominal cramps, vomiting, and dehydration. Acute colitis also may be present. Extraintestinal manifestations include cellulitis, meningitis, and septicemia.

DIAGNOSIS

Because the pathogenic potential of *Plesiomonas* strains is not known, by convention, isolation is considered clinically significant when these organisms are found in large numbers from stools using relatively nonselective media, such as MacConkey agar.

OPTIMAL MANAGEMENT

Antimicrobial therapy ([Table 283.2](#)) is indicated for patients with acute toxicity, bloody diarrhea, or long-standing infection; trimethoprim-sulfamethoxazole or tetracycline is considered to be the treatment of choice. Chloramphenicol should be used for septicemia, but self-limited bacteremia also occurs.

CAMPYLOBACTER JEJUNI

EPIDEMIOLOGIC FACTORS

Campylobacter jejuni and closely related organisms in the genera *Campylobacter*, *Helicobacter*, and *Arcobacter* are carried in the intestinal flora of a wide variety of avian and mammalian species, especially those used for food production. Transmission to human beings occurs primarily from undercooked chicken, unpasteurized milk, untreated water, and exposure to infected pets; occasionally, transmission also occurs from young children who are infected. Although infections occur year round, incidence peaks during the summer. In the United States, highest attack rates are in children younger than 1 year of age, but most cases occur in persons 15 to 29 years of age. Persons of any age may be affected, and asymptomatic excretion is uncommon. In developing countries, infection is hyperendemic, but immunity appears to be acquired at a young age; asymptomatic excretion is common.

PATHOGENESIS

The ileum, colon, or both is the usual target of infection, which is manifested as an acute inflammation with neutrophilic infiltration of the lamina propria and destruction of mucous glands. Fecal leukocytes and gross or occult blood are common, but the pathogenic mechanism is unknown. Although both enterotoxins and cytotoxins have been described, whether they are of biologic significance is unknown.

CLINICAL FINDINGS

Most patients infected with *C. jejuni* in the United States have an acute febrile gastroenteritis. Common symptoms are a prodrome lasting for 12 to 48 hours, with fever, myalgia, and other constitutional complaints before the onset of gastrointestinal symptoms. Diarrhea is the most common symptom, and stools may be watery, mucoid, or bloody. At the peak of illness, which usually occurs in the first 48 hours, most patients have 10 or more bowel movements per day. Abdominal cramping is common and may be sufficiently severe to mimic an acute abdomen or acute appendicitis. On occasion, fever and constitutional symptoms may predominate, producing an enteric fever syndrome. Gastrointestinal involvement also may include toxic megacolon or frank lower gastrointestinal hemorrhage, sometimes necessitating colectomy. Extraintestinal manifestations are uncommon but may include bacteremia, cholecystitis, pancreatitis, and pneumonia. Late complications include nonsuppurative arthritis, especially in human leukocyte antigen B27–positive hosts, and the Guillain–Barre(c) syndrome. Altogether, 20% to 50% of all Guillain–Barre(c) syndrome cases follow *Campylobacter* infections.

DIAGNOSIS

The epidemiologic setting may suggest the diagnosis, and it should be remembered that *C. jejuni* is implicated as the cause for acute diarrheal illnesses more frequently than *Salmonella* and *Shigella* species combined. In patients with febrile or bloody diarrhea, microscopic examination of stools may show leukocytes; their presence is an indication for fecal culture and may help identify invasive or cytotoxigenic diarrheal pathogens. Examination of fecal preparations by Gram stain or dark-field microscopy is a rapid technique for diagnosing *Campylobacter* infection; although specificity is close to 100%, sensitivity is about 60%. Definitive identification is made by fecal culture onto *Campylobacter*-specific selective plate media. Most diarrheal illnesses are caused by *C. jejuni*, and less often by *C. coli*, *C. lari*, *C. fetus*, *C. hyointestinalis*, or *C. upsaliensis*, *Helicobacter* species such as *H. cinaedi* and *H. fennelliae*, or *Arcobacter* species. Differentiation must be made by biochemical testing. On occasion, febrile diarrheal disease due to infection with *Campylobacter* species may be diagnosed by blood culture.

OPTIMAL MANAGEMENT

Most gastrointestinal infections due to *Campylobacter* species are self-limited to 5 to 7 days, and specific antimicrobial therapy is not necessary. Treatment ([Table 283.2](#)) is recommended, however, for people with more severe illness that includes bloody diarrhea, continued fever, 10 or more bowel movements a day, persistence of symptoms beyond a week, or underlying immunocompromise.

The agent of choice is erythromycin, 250 mg by mouth 4 times daily for 5 days. Ciprofloxacin also has excellent activity against *Campylobacter* and is an attractive agent for use in patients before culture results are known because of its broad-spectrum activity against a number of bacterial enteric pathogens. However, resistance of *Campylobacter* to ciprofloxacin and other quinolones is increasing globally, with recent rapid increases in resistance in parts of the United States. For resistant organisms, the alternatives are tetracycline, 250 mg orally 4 times daily for 5 days, or furazolidone.

CAMPYLOBACTER FETUS

EPIDEMIOLOGIC FACTORS

Campylobacter fetus is contained in the intestinal flora of cattle, sheep, swine, and reptiles. Transmission to human beings through unpasteurized milk or uncooked meat has been documented, but the source for the organism in most human infections has not been established. Diarrheal illnesses due to *C. fetus* infection may develop in persons of any age, but pregnant women, individuals at the extremes of age, or those debilitated by preexisting illnesses, such as malignancy, liver disease, diabetes, HIV infection, or advanced atherosclerosis, are at risk for development of systemic infection.

PATHOGENESIS

Campylobacter fetus can cause systemic disease because of its resistance to complement-mediated serum lysis and to phagocytosis—properties conferred by a protein capsule. Host defects in reticuloendothelial function or in providing a locus for the organism to multiply also seem important.

CLINICAL FINDINGS

Campylobacter fetus may cause acute diarrheal illnesses with onset and symptoms indistinguishable from those due to *C. jejuni*. For the systemic infections, there may be a prodrome of constitutional symptoms. Fever is the cardinal manifestation; it may be intermittent or continuous, and it may be low grade or part of a syndrome of sepsis. The major types of infection are bacteremia, meningitis, arthritis, abscesses, and endovascular infections, including endocarditis, infected aortic aneurysms, and septic thrombophlebitis. The manifestations of these infections are typical for pyogenic processes at these sites but may persist. Prognosis depends in part on the site of infection, the rapidity with which therapy is begun, and the underlying host status; however, fatal infections are common. Gastrointestinal symptoms may or may not be present.

DIAGNOSIS

Diagnosis is made by isolation of *C. fetus* from cultures of blood or fluid from affected areas. These organisms are fastidious and slow growing, and microbiologic identification may be difficult.

OPTIMAL MANAGEMENT

Diarrheal illnesses, when severe or prolonged, may be treated with erythromycin. Although self-limited bacteremia may occur, extraintestinal *C. fetus* infections usually are severe. Antimicrobial therapy is required in such infections ([Table 283.2](#)); the initial agent of choice is chloramphenicol or an aminoglycoside. Definitive therapy depends on susceptibility of the organism as well as location (e.g., meninges), and the necessity for surgical debridement or drainage of abscesses or other foci of necrosis.

CHAPTER 284: INFECTION CAUSED BY *HELICOBACTER PYLORI*

DAVID Y. GRAHAM

[Microbiology](#)
[Epidemiologic Factors](#)
[Pathogenesis](#)
[Clinical Findings](#)
[Diagnosis](#)
[Optimal Management](#)

Prior to the isolation of *Helicobacter pylori*, a number of diseases were known to be tightly linked to gastritis, including peptic ulcer disease, gastric cancer, and primary gastric lymphoma. The proof that *H. pylori* infection was the major cause of gastritis resulted in a reappraisal of many concepts in gastroenterology and allowed many disparate facts to be linked through the common pathway of a bacterial infection. The identification of a major cause of gastritis also suggested that it might be possible to prevent and to cure the gastritis-associated diseases.

MICROBIOLOGY

Helicobacter pylori bacilli are small (0.5 × 2.5 μm), flagellated, spiral, gram-negative organisms with sheathed unipolar flagella. *H. pylori* are slow growing in vitro, microaerophilic, and require complex media. Three enzymes are uniformly present and useful for laboratory identification: oxidase, catalase, and urease. Urease activity is especially intense in comparison with other urease-producing bacteria and forms the basis of a number of different diagnostic tests.

EPIDEMIOLOGIC FACTORS

Members of the genus *Helicobacter* are widespread in the animal kingdom. *H. pylori* infects humans, although animals, notably other primates, may become infected because of contact with infected humans. *H. pylori* has worldwide distribution. Current evidence is consistent with humans as the major and probably the only important reservoir. The most common mode of transmission is the fecal–oral route but gastro–oral (e.g., exposure to contaminated nasogastric tubes or endoscopes) has also been documented. Risk factors for acquiring *H. pylori* infection include birth in a developing country, low socioeconomic status, crowded living conditions, large family size, unsanitary living conditions, unclean food or water, presence of infants in the home, and exposure to gastric contents of infected individuals.

Current data suggest that, once acquired, *H. pylori* infection is often life-long. The increasing prevalence of infection with age is thought to be the consequence of a birth cohort phenomenon and reflects the fact that older individuals were born in a time when sanitation and standards of living were lower than they are today. *H. pylori* infection is typically acquired in childhood, and the prevalence of the infection at age 20 provides a reasonable estimate of the frequency of symptoms for that birth cohort throughout the remainder of their lives. In adults, the likelihood of acquiring the infection is about 0.5% per year. The natural tendency of the infection is to disappear, and in developed countries the prevalence is falling in every age group probably as a result of the widespread use of antibiotics or other reasons.

PATHOGENESIS

Both urease activity and motility are important for *H. pylori* colonization of the human stomach. *H. pylori* is uniquely adapted to gastric-type epithelium and may colonize the stomach, duodenum, esophagus, or wherever gastric type epithelium is found. The bacteria attach to the epithelium, and there is also evidence for limited invasion of epithelial cells. Attachment is associated with a marked inflammatory response, affecting neutrophils as well as mononuclear cells.

The search for factors that predict virulent versus nonvirulent *H. pylori* has not been rewarding. Nevertheless, strains that contain the *cag* pathogenicity island are associated with more intense acute inflammation and a higher likelihood of symptomatic disease than those that lack that characteristic. This increase in risk is of a low order of magnitude and testing for the presence of any putative virulence has not proven useful.

CLINICAL FINDINGS

The outcome of any infection is closely related to the pattern of gastritis. Although the bacteria are scattered throughout the gastric mucosal surface, the severity of gastritis differs within the stomach. The corpus of the stomach is relatively resistant to developing more than mild gastritis. This resistance can be overcome by any mechanism that reduces acid secretion such as vagotomy or the use of proton pump inhibitors or higher doses of H₂ receptor antagonists, suggesting that it is acid that “protects” this portion of the stomach. Inflammation is typically worse in the non-acid-secreting portions of the stomach, (antrum and cardia). Antral predominant gastritis is typical of duodenal ulcer and is consistent with the old notions and observations that unimpeded acid secretion was a prerequisite of development of duodenal ulcer disease. Corpus gastritis causes a reversible reduction in gastric acid secretion and is associated with a lower frequency of duodenal ulcer disease and also gastroesophageal reflux disease. The pattern of multifocal pangastritis with atrophy and intestinal metaplasia is the phenotype with the highest risk of gastric ulcer and gastric cancer. The fact that *H. pylori* infection may appear to “protect” against gastroesophageal reflux disease is a reflection of the prevalence of multifocal atrophic pangastritis. This has been misinterpreted by some as evidence for the presence of less harmful *H. pylori* organisms.

One outcome of *H. pylori* infection is for there to be a progression from superficial gastritis to pangastritis with atrophy, metaplasia, dysplasia, and, finally, gastric adenocarcinoma. It is currently unknown at which point the cure of *H. pylori* infection halts the progression. Epidemiologic evidence has also linked *H. pylori* infection with low-grade B-cell lymphoma of mucosa-associated lymphoid tissue (MALToma). This lymphoma is of special interest because it appears to be stimulated by the presence of *H. pylori* antigens and regresses when *H. pylori* is treated.

DIAGNOSIS

Diagnostic tests for *H. pylori* can be divided into those performed on gastric biopsy specimens (and therefore requiring upper gastrointestinal endoscopy) and noninvasive tests ([Table 284.1](#)). Noninvasive testing is preferred and should be the approach of choice unless there is another indication for endoscopy such as the presence of features suggesting cancer (e.g., a mass) or an ulcer complication (e.g., bleeding).

Invasive (performed on endoscopic biopsy specimen)
Histology with special stains
Bacterial culture
Biopsy urease test
Noninvasive
Serology
Urea breath test (carbon 13 or 14)

TABLE 284.1. DIAGNOSTIC TESTS FOR *HELICOBACTER PYLORI* INFECTION

The two main noninvasive tests for *H. pylori* are serology and the urea breath test. The urea breath test is the test of choice, especially after treatment. Urea breath testing is inexpensive compared to endoscopy; it is also simple and reliable. The patient ingests isotopically labeled urea, and if *H. pylori* urease is present the urea is

hydrolyzed and labeled carbon dioxide produced can be measured in breath samples. The two isotopes commonly used in the test are carbon 13 and carbon 14, the latter of which is radioactive. As with all tests that require active *H. pylori* infection, false-negative results may occur if the patient had recently taken drugs that reduce the bacterial load such as antibiotics, proton pump inhibitors, or bismuth compounds. H₂ receptor antagonists may also lead to false-negative results with the carbon 14 urea breath test but is not a problem with the carbon 13 urea breath test; this probably relates to the quantity of substrate used in each.

Serologic testing is rapid, convenient, and inexpensive and may be the test of choice for those with active ulcer disease. Unfortunately, serology cannot be used to check early treatment success because reliable falls in antibody levels from the pretreatment baseline may take more than a year. Only IgG-based tests have proven to be clinically useful. There are no IgM or IgA anti-*H. pylori* tests currently approved by the Food and Drug Administration, and those that are available commercially "for research only" are in our experience unreliable and should not be used.

1. Proton pump inhibitor (b.i.d.) or ranitidine bismuth citrate (b.i.d.) plus two of the following:
 - Amoxicillin 1 g b.i.d.
 - Clarithromycin 500 mg b.i.d.
 - Metronidazole 500 mg b.i.d.
2. Bismuth citrate or subsalicylate (2 tablets q.i.d.) plus tetracycline (500 mg q.i.d.) plus one of either
 - Metronidazole 500 mg t.i.d.
 - Clarithromycin 500 mg t.i.d.

TABLE 284.2. RECOMMENDED ANTIBIOTIC REGIMENS FOR TREATMENT OF *H. PYLORI* INFECTION

Endoscopy has an advantage in that it can also establish the diagnosis of peptic ulcer or gastric cancer. Histologic examination of stained gastric biopsy specimen gives information regarding *H. pylori* status as well as the type and severity of gastritis. Hematoxylin and eosin staining alone has repeatedly proven to be unreliable for detection of *H. pylori*, and the clinician should demand that the pathologist examine the tissue with a special stain. We recommend the triple stains of Genta, El-Zimaity, or the combination of a slide stained with hematoxylin and eosin and another stained with Diff-Quik. Bacterial culture is not widely available but is required if antibiotic susceptibility testing is needed (an increasingly common indication). The third commonly used biopsy-based test, the rapid urease test, involves placing a biopsy specimen in a medium containing urea and a pH indicator. A color change occurs if urease is present. These tests are cheap and reliable, and they serve as a good check on the pathologist. Many endoscopists use rapid urease testing as a method to decide which biopsy specimens to send for histologic examination (specimens from patients with negative rapid urease tests are submitted for histologic examination).

OPTIMAL MANAGEMENT

Because of the risks associated with *H. pylori* infection (e.g., one in six patients develop peptic ulcer; lifetime risk for gastric cancer of 1% to 3%) and because the infection is always transmissible, there is general agreement that diagnosis should be followed by treatment. Current discussions concerned whom to test. There is no disagreement about peptic ulcer because cure of *H. pylori* infection cures that disease. Most would test and treat infected patients with dyspepsia based on the premise that the population of otherwise uninvestigated dyspeptics will be enriched for those with peptic ulcer. Most patients with proven nonulcer dyspepsia do not appear to benefit symptomatically from *H. pylori* treatment, but, as there is no method of distinguishing which patients will benefit, many clinicians will test and treat. Other groups that are potential candidates for testing are first-degree relatives of patients with peptic ulcer or with gastric cancer as both groups have markedly increased risk of developing symptomatic *H. pylori* disease. The question about when to refer is addressed in [Fig. 284.1](#)

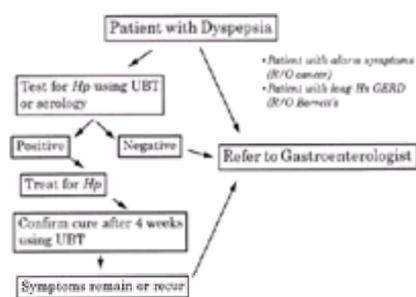

FIGURE 284.1. Clinical pathway for the treatment of patients with suspected peptic ulcer (dyspepsia) to assist in decision making regarding when to refer the patient to a gastroenterologist.

EVIDENCE LEVEL: C. Expert Opinion.

The principle of therapy is to test, treat, and then confirm cure. No patient who does not have an *H. pylori* infection should receive triple antibiotic therapy because they will experience side effects without any possibility of benefit. The actual therapy consists of at least two antibiotics plus a proton pump inhibitor (or a bismuth compound) prescribed in divided doses ([Table 284.1](#)). Which antibiotics? The first question in choosing a specific regimen is, what is the likelihood that resistant organisms are present? For example, resistance to metronidazole or clarithromycin is expected if either of those antibiotics has been used in earlier attempts to cure the infection. Clarithromycin resistance predicts failure with the results of triple antibiotic combinations being reduced to what would be expected with a dual therapy of the remaining drugs (the combination of a proton pump inhibitor, clarithromycin, and amoxicillin would be equivalent to the proton pump inhibitor plus amoxicillin in the face of clarithromycin resistance). In contrast, the deleterious effects of metronidazole resistance can be partially or completely overcome by increasing the dosage of metronidazole and possibly the duration of therapy. Although there has been a tendency to reduce the duration of therapy from 14 days to 10 days or even 7 days, head-to-head comparisons have generally shown that the best results are obtained with a 14-day duration. Four to six weeks after therapy, one should confirm that the therapy was successful. This can easily be done using a urea breath test or possibly an *H. pylori* stool antigen test. Follow-up endoscopy is indicated for those with suspicious histology (e.g., dysplasia) and possibly those with gastric ulcer.

CHAPTER 285: BRUCELLOSIS, TULAREMIA, PASTEURELLOSIS, AND YERSINIOSIS

EDWARD J. YOUNG

[Brucellosis](#)
[Tularemia](#)
[Pasteurellosis](#)
[Yersiniosis \(Including Plague\)](#)

The infections discussed in this chapter share a common feature: they are diseases of animals (zoonoses), and humans are accidental hosts who play no role in maintaining the disease in nature. Man's risk of contracting these infections is principally direct or indirect contact with diseased animals or their products.

BRUCELLOSIS

DEFINITION

Brucellosis is a systemic infection caused by species of the genus *Brucella*.

INCIDENCE AND EPIDEMIOLOGIC FACTORS

Brucellosis exists worldwide, especially in developing countries. As a result of the control and near-elimination of the disease in domestic animals, human brucellosis is now rare in the United States, with less than 0.05 case per 100,000 population being reported in recent years (see [Fig. 285.1](#)). Although occupational exposure (e.g., ranchers, veterinarians, abattoir workers) poses an increased risk of infection, most cases in the United States are now associated with the consumption of unpasteurized dairy products (e.g., milk, cheese) originating in areas where the disease is endemic. No animate vectors are known, and person-to-person transmission is rare.

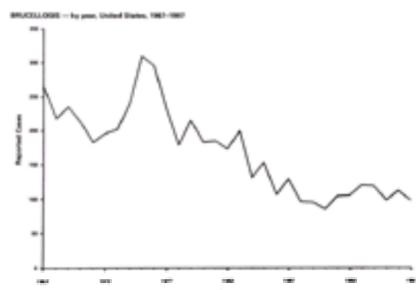

FIGURE 285.1. Number of reported cases of brucellosis by year, 1967–1997. (From U.S. Centers for Disease Control and Prevention. Summary of notifiable diseases, United States, 1997. *MMWR* 1997;46(54):26.)

ETIOLOGIC FACTORS

The brucellae are small, gram-negative coccobacilli that lack capsule, endospores, flagellae, or natural plasmids. Although closely related genetically, *Brucella* species are traditionally classified according to their usual animal hosts (nomen species): *B. abortus* (cattle), *B. melitensis* (goats and sheep), *B. suis* (swine), *B. canis* (dogs), *B. ovis* (sheep), and *B. neotomae* (wood rats). Only the first four species are known to cause human infection. A new species (tentatively termed *B. maris*) has recently been isolated from marine mammals.

PATHOGENESIS

Brucellae are facultative intracellular pathogens that can survive and multiply within phagocytic cells of the host. The major virulence factor appears to be cell wall lipopolysaccharide. Among the nomen species, *B. melitensis* and *B. suis* are the most virulent. During infection the bacteria localize within mononuclear phagocytes of the reticuloendothelial system (e.g., lymph nodes, spleen, liver, and bone marrow), accounting for many of the clinical complications. Localization within cyetic products of some animals may explain their propensity for spontaneous abortions. The activation of macrophages by specifically committed T cells enhances their ability to kill intracellular brucellae. Although humoral antibodies play some role in resistance, recovery from infection depends on cell-mediated immunity.

CLINICAL FINDINGS

Brucellosis is characterized by a multitude of nonspecific complaints (e.g., fever, sweats, fatigue, joint pains, weight loss, and depression), with a paucity of abnormal physical findings other than occasional splenomegaly. The onset can be acute or insidious. Any organ system can be involved, but osteoarticular complications predominate ([Table 285.1](#)). A history of animal exposure or unusual food consumption should be sought. Life-threatening complications include endocarditis and meningitis. Childhood brucellosis is common in areas where *B. melitensis* is endemic. Infection during pregnancy can result in abortion if the disease is untreated. Accidental inoculation of live-attenuated animal vaccines (e.g., *B. abortus* strain 19 or *B. melitensis* strain Rev-1) can result in human infection. The new *B. abortus* vaccine RB51 appears to be less virulent for humans.

Organ System	Complications
Osteoarticular	Sacroiliitis Arthritis (large joints predominates) Spondylitis Chondrolysis Rheumatoid arthritis Pilonidal abscess Pericarditis
Gastrointestinal	Colitis Hepatitis Cholangitis Pancreatitis
Hepatobiliary	Cholecystitis Cholangitis Pancreatitis
Genitourinary	Orchitis Epididymitis Pyelonephritis
Respiratory	Emphysema Lung abscess Rheumatoid arthritis Hypertrophic osteoarthropathy Rheumatoid arthritis Pneumonia Pleuritis Asthma
Cardiovascular	Myocarditis Endocarditis Pericarditis Atherosclerosis
Ophthalmic	Iritis Chorioretinitis Keratitis Scleritis Pachymeningitis
Cutaneous	Cellulitis Vasculitis Abscesses

TABLE 285.1. COMPLICATIONS OF HUMAN BRUCELLOSIS

LABORATORY FINDINGS

Routine tests are of little value for diagnosing brucellosis, although leukopenia is a characteristic finding. A definitive diagnosis is made by isolating brucellae from

blood, bone marrow, or other tissue (Fig. 285.2). Growth of the organism in vitro is slow and prolonged incubation is advised. Differentiation of *Brucella* species is best reserved for specialized facilities since routine handling of cultures poses a risk to personnel and some automated identification systems can result in a misdiagnosis. A presumptive diagnosis is made by showing high or rising titers of specific antibodies in serum (Fig. 285.2). A variety of serologic tests are available, including agglutination and enzyme-linked immunosorbent assay (ELISA). Smooth lipopolysaccharide (SLPS) is the immunodominant epitope, and serologic tests using this antigen can identify the three major nomen species. *Brucella canis* lacks SLPS and tests to diagnose this species require monospecific antigen. With treatment, levels of IgM and IgG antibodies decline slowly over time. Persistent elevation of IgG isotype antibodies presages relapse or chronic infection.

FIGURE 285.2. Number of reported cases of tularemia by year, United States, 1945–1993.

OPTIMAL MANAGEMENT

Hospitalization is usually required to make the diagnosis. Mortality from brucellosis is rare and is usually associated with complications of endocarditis. Chronic infection is uncommon but can result from localized disease that may require surgical intervention. A variety of drugs are active against brucellae, but prolonged treatment (4 to 6 weeks) is necessary owing to the intracellular location of the bacteria. The b-lactam antibiotics are clinically ineffective. Doxycycline (200 mg daily) plus rifampin (600 to 900 mg daily) administered orally for 6 weeks is generally effective therapy. Many authorities still prefer doxycycline for 6 weeks plus streptomycin (1 g daily) administered intramuscularly for the first 3 weeks. Gentamicin is often substituted for streptomycin, but the optimal length of therapy has not been determined. Relapse is common, usually due to inadequate therapy. Since antibiotic resistance is rare, most relapses are treated with a second course of the same agents. Treatment of pregnant women and children younger than 6 years, for whom tetracyclines are contraindicated, remains controversial. Drugs such as trimethoprim–sulfamethoxazole (TMP-SMX) (4 tablets in fixed dosage) for 6 weeks with or without rifampin have been used with some success. Fluoroquinolones administered orally for 6 weeks with rifampin or TMP-SMX have also been used, but monotherapy is never an option. Treatment of complications, such as meningitis or endocarditis, may require even longer courses of therapy, and valve replacement surgery is usually required.

TULAREMIA

DEFINITION

Tularemia is an infection with variable clinical manifestations depending on the route of inoculation caused by *Francisella tularensis*.

INCIDENCE AND EPIDEMIOLOGIC FACTORS

Tularemia is endemic throughout the temperate zone of the Northern Hemisphere except in the British Isles. In the United States, the incidence of human infection is low (approximately 0.05 case per 100,000 population). Human tularemia has been reported from all states except Hawaii, but it is most prevalent in the western and midwestern regions (Fig. 285.3). Rodents and rabbits are the principal animal hosts, although more than 100 wild and domestic animals and birds are susceptible. Cases occurring during the summer are usually related to arthropod bites, whereas direct contact with diseased animals accounts for most cases in the fall and winter. Contaminated water and undercooked meat are rare sources of infection.

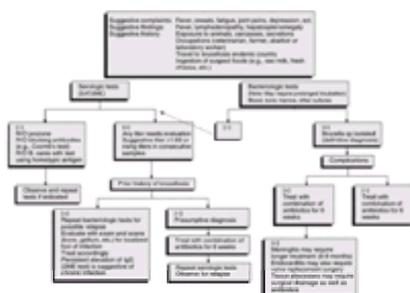

FIGURE 285.3. Approach to the patient with suspected brucellosis.

ETIOLOGIC FACTORS

The genus *Francisella* contains three biovars: *tularensis*, which predominates in North America; *palearctica*, which predominates in Europe and Asia; and *novicida*. *F. tularensis* is a small, nonmotile, nonsporulating, aerobic, gram-negative coccobacillus. It is nutritionally fastidious, requiring glucose–cysteine agar for isolation. It produces no exotoxins but is surrounded by a capsule-like material containing carbohydrate, protein, and large amounts of lipid. It is a hazard to laboratory personnel, and biohazard precautions are necessary when infectious material must be handled.

PATHOGENESIS

Traditionally, tularemia was classified into different types (ulceroglandular, glandular, oculoglandular, typhoidal) depending on the mode of inoculation. Routes of transmission include direct contact with diseased animals, bites of arthropod vectors (ticks, deerflies, mosquitoes), bites from domestic animals (cats) that have ingested infected rodents, inhalation of contaminated aerosols, and, rarely, ingestion of contaminated water or food.

As few as 10 to 50 *F. tularensis* organisms can cause infection when inoculated or inhaled, whereas 10^8 bacteria are required for oral infection. *F. tularensis* is a facultative intracellular pathogen that survives within phagocytic cells of the host apparently by inhibiting phagosome–lysosome fusion. Before the development of immunity, granulocytes may inhibit the spread of tularemia in organs such as the liver by lysing parasitized hepatocytes. Immunospecific protection is afforded by natural infection or by vaccination with live attenuated strains of *F. tularensis*. Cellular immunity is the principal mechanism of recovery and resistance to tularemia.

CLINICAL FINDINGS

Fever, a cutaneous ulcer, and lymphadenopathy are the most commonly reported symptoms of tularemia (Table 285.2). Depending on the location of the tick bite, the most common areas of lymphadenopathy are inguinal, axillary, and cervical chains. Cutaneous ulcers are reported in about 85% of cases, involving the fingers,

hands, legs, head, neck, and buttocks. Patients with pleuropulmonary tularemia present with fever, chest pain, cough, purulent sputum, and patchy alveolar infiltrates. Rarely, foodborne tularemia manifests as an exudative pharyngotonsillitis or mesenteric adenitis. Typhoidal tularemia results from hematogenous spread and can produce cutaneous, pulmonary, and gastrointestinal symptoms. Patients experience fever, chills, confusion, meningismus, vomiting, and diarrhea; cutaneous lesions and lymphadenitis may be absent. Left untreated the typhoidal form is fatal in 30% to 40% of cases.

Clinical Type	Route of Transmission	Findings	Frequency	Mortality
Stenocardiac	Contact with infected animal	Fever Pulso symptom Cutaneous papule (chancroid) Lymphadenitis (glandular)	30%-60%	Low
Disseminated	Same as for stenocardiac	Same as for stenocardiac but lacking cutaneous lesion	10%-15%	Low
Disseminated	Inoculation into the conjunctival sac	Fever Conjunctivitis Periorbital inflammation Lymphadenitis (regional)	10%-15%	Low
Pneumonia	Inhalation of contaminated animal	Fever Pneumonia Pleural effusion	Rare	High
Disseminated	Inhalation of contaminated food or water	Fever Septicemia (systemic) Hemorrhagic diathesis Lymphadenitis (regional)	Rare	High
Typhoidal	Hematogenous spread	Fever Rigors Mucous Hemorrhagic rash Meningismus Diarrhea Vomiting Pneumonia Pericarditis Meningitis	Rare	High

TABLE 285.2. CLINICAL MANIFESTATIONS OF TULAREMIA

LABORATORY FINDINGS

Because *F. tularensis* is rarely seen in Gram-stained specimens and special medium is required for isolation, the diagnosis is usually made by serologic tests. Serum agglutinins are detectable within 10 to 14 days and a fourfold rise in titer is diagnostic. A single titer higher than 1:160 in a patient with compatible clinical findings is also considered diagnostic. Titers can remain elevated for years after an acute infection. Cross-reactions have been reported with other gram-negative bacteria, but usually in low titer. An ELISA and polymerase chain reaction have been used for diagnosis when the agglutination test yields equivocal results.

OPTIMAL MANAGEMENT

Before the introduction of antibiotics, tularemia was fatal in up to 15% of cases. The mortality has declined to about 1%, with typhoidal and pulmonary forms carrying the greatest risk. Streptomycin (7.5 to 10 mg per kilogram twice daily intramuscularly) has long been the recommended drug of choice, although gentamicin, tetracycline, and chloramphenicol are acceptable alternatives. An aminoglycoside is recommended as initial therapy for seriously ill patients, followed by tetracycline (2 g daily by mouth) for 3 to 4 weeks to prevent relapse. Fluoroquinolones have also been used, but their role as primary therapy awaits the results of larger trials. β -Lactam antibiotics including third-generation cephalosporins are not effective therapy.

PASTEURELLOSIS

DEFINITION

Pasteurellosis is an infection caused by members of the genus *Pasteurella*, most commonly *P. multocida*.

INCIDENCE AND EPIDEMIOLOGIC FACTORS

Pasteurella multocida, the species most often isolated from human specimens, is a normal inhabitant of the nasopharynx and intestines of a variety of animals and birds worldwide. Although a history of animal exposure is not always obtained, the majority of human infections are associated with bite or scratch wounds from animals (notably cats and dogs). Occasionally, the organism is recovered from respiratory secretions of healthy persons who have close contact with animals. There is no evidence of foodborne or waterborne spread, nor is there person-to-person transmission. Cases have been reported after contact with inanimate objects soiled by animals.

ETIOLOGIC FACTORS

Pasteurellae are primarily animal pathogens causing diseases such as “shipping fever” in cattle or fowl cholera in birds. Once classified according to host species, in recent years, the taxonomy of pasteurellae has undergone changes based on DNA–DNA hybridization and 16S rRNA sequencing studies. The family *Pasteurellaceae* comprises *Pasteurella* species, *Haemophilus* species, and *Actinobacillus* species. Currently, *Pasteurella sensu stricto* includes 11 species and 3 subspecies of which *P. multocida* subspecies *multocida* and *septica*, *P. canis*, *P. stomatis*, and *P. dogmatis* account for the majority of human isolates. The organisms are small, encapsulated, aerobic, bipolar staining, gram-negative coccobacilli lacking flagella or endospores. They grow on blood, chocolate, and Mueller–Hinton media but not on MacConkey's agar.

PATHOGENESIS

After inoculation through cuts or abrasions in the skin, *P. multocida* multiplies rapidly in the extracellular space, invades the bloodstream, and localizes within the reticuloendothelial system. Little is known about virulence factors except for the capsule that inhibits phagocytosis and the cell wall that contains endotoxin and neuraminidase.

CLINICAL FINDINGS

Soft-tissue infection caused by *P. multocida* cannot be distinguished clinically from infections caused by more common pathogens such as streptococci. Wound infections usually respond to local care plus antibiotics, but patients with underlying liver disease, alcoholism, or immunosuppression are predisposed to hematogenous dissemination.

Infections of sinuses, pharynx, trachea, and lungs have been reported with a clear predilection for the compromised host. Cardiovascular complications include native and prosthetic valve endocarditis. Osteoarticular complications usually follow penetrating animal bites (notably cats) and septic arthritis is common in patients with preexisting inflammatory joint diseases. Central nervous system infections occur in less than 5% of cases, but meningitis, brain abscess, and subdural empyema are reported. Gastrointestinal complications include peritonitis, appendicitis, intra-abdominal abscess, and postoperative infections. Rare genitourinary infections are usually associated with preexisting cancer, ureterostomy, or ureteroileostomy. Ophthalmic manifestations are least common but can occur from direct trauma to the eyes involving animals.

OPTIMAL MANAGEMENT

Pasteurellae are almost universally sensitive to penicillin and ampicillin although rare penicillin-resistant strains are known. Alternative drugs include third-generation cephalosporins, tetracycline, chloramphenicol, and trimethoprim-sulfamethoxazole. Most strains are resistant to aminoglycosides. Experience with quinolones is limited, but ciprofloxacin is active in vitro. The duration of therapy depends on the primary disease process.

YERSINIOSIS (INCLUDING PLAGUE)

Although the *Yersinia* species causing plague (*Y. pestis*) and the nonplague yersinioses (*Y. enterocolitica* and *Y. pseudotuberculosis*) are related, they are traditionally discussed separately because they differ in their epidemiologic factors and clinical manifestations.

DEFINITIONS

Plague is an acute, potentially lethal infection caused by *Yersinia pestis*. Yersiniosis is an infection caused by either of the enteropathogenic *Yersinia* species: *Y. enterocolitica* or *Y. pseudotuberculosis*.

ETIOLOGIC FACTORS

The *Yersinia* species are aerobic, gram-negative coccobacilli belonging to the family Enterobacteriaceae and are therefore lactose-negative. *Y. pestis* is nonmotile at all temperatures, whereas *Y. enterocolitica* and *Y. pseudotuberculosis* are motile at 25°C but not at 37°C. Differentiation of species is based on biochemical reactions, phage lysis patterns, and virulence for animals. A rapid identification of *Y. pestis* can be made using a specific fluorescent antibody.

PATHOGENESIS

The virulence of pathogenic *Yersinia* species appears to be related to a number of factors, some encoded by the bacterial genome, others by plasmids. A plasmid-mediated, capsule-like glycoprotein (fraction 1) of *Y. pestis* interferes with phagocytosis, and antibodies to this substance confer immunity. The ability to synthesize endogenous purines is a characteristic of virulent *Yersinia* species and appears to facilitate intracellular survival. The V and W antigens, closely linked to the expression of free calcium (Ca²⁺) dependence, are encoded by a 75-kb plasmid and are important for intracellular survival. *Y. pestis*, *Y. enterocolitica* serotype 1B, and *Y. pseudotuberculosis* O:1 strains possess a chromosomal determinant that is involved in iron uptake mediated by the siderophore yersiniabactin. This iron acquisition determinant (designated HPI for high-pathogenicity island) is necessary for virulence in mice. A plasmid-mediated bacteriocin (pestin), outer-membrane proteins, a heat-labile exotoxin, and endotoxin are additional virulence factors of *Y. pestis*. Genome-encoded proteins (invasins) of *Yersinia* species mediate endocytosis, which enhances their ability to invade intestinal mucosal cells.

LABORATORY FINDINGS

Yersinia pestis is readily isolated from clinical specimens, whereas special techniques are required for other *Yersinia* species. Bubonic plague can be diagnosed by smear and culture of bubo aspirate. *Y. enterocolitica* and *Y. pseudotuberculosis* can be readily isolated from otherwise sterile sites, such as blood, peritoneal fluid, or mesenteric lymph nodes. Recovery from feces requires selective media, such as cefsulodin–triclosan–novobiocin agar incubated at 25°C for 18 to 20 hours. Cold enrichment (4°C) of stool specimens in phosphate-buffered saline subcultured weekly for 4 weeks has been used to enhance recovery of small numbers of bacteria. Serologic tests can also be used for diagnosis; however, *Y. enterocolitica* O:9 is known to cross-react with *B. abortus* and *Escherichia coli*.

EPIDEMIOLOGY OF PLAGUE

Yersinia pestis exists worldwide, especially in developing countries. It is responsible for four great pandemics of human disease. Factors contributing to pandemic plague are epizootics in nature, poor sanitation, war, and famine. The most important *urban* reservoir of *Y. pestis* is rats. The principal *sylvatic* reservoir of plague in the United States is wild rodents such as ground squirrels and prairie dogs. Humans contract plague from the bite of fleas, from direct contact with diseased animals, or from contaminated aerosols.

Domestic cats and dogs can become infected and on occasion transmit plague to humans via bites, scratches, or aerosols. Person-to-person spread is rare except for cases of pneumonic plague.

CLINICAL FINDINGS IN PLAGUE

Bubonic plague accounts for 80% to 90% of cases of human infection with *Y. pestis*. The disease begins 2 to 8 days after the bite of an infected flea and is characterized by the rapid onset of fever and painful regional lymphadenopathy (buboes). Buboes, usually in the groin, axilla, or neck depending on the location of the bite, are exquisitely painful. Most patients experience transient (often asymptomatic) bacteremia. Bacteremia in the absence of buboes is termed *septicemic* plague, an illness with a grave prognosis. Although similar in presentation to sepsis caused by other bacteria, septicemic plague has a higher mortality, in part due to the high-grade bacteremia. Gastrointestinal symptoms are common, including vomiting, diarrhea, and abdominal pain. Another ominous finding is purpura, associated with disseminated intravascular coagulation. *Pneumonic* plague is a rare but greatly feared complication of hematogenous dissemination or direct inhalation of contaminated aerosols. The sputum usually contains organisms visible by Gram stain and the mortality is high despite antibiotic therapy. Plague *meningitis* is another rare but lethal complication that typically occurs more than a week after inadequately treated bubonic plague.

EPIDEMIOLOGY OF NONPLAGUE YERSINIOSES

Yersinia enterocolitica exists worldwide but appears to be more prevalent in cooler climates. Certain serotypes predominate in different geographic areas, with most human infections caused by types O:3, O:5, O:8, O:9, and O:27. The bacteria are found in the oropharynx and intestines of wild and domestic animals and in shellfish. They have also been recovered from water of lakes and streams and from unpasteurized animal milk. Person-to-person spread is rare, but cases have been traced to transfusions of refrigerated banked blood. *Y. pseudotuberculosis* resides in many of the same animals but is also found extensively in birds.

CLINICAL FINDINGS OF NONPLAGUE YERSINIOSES

The spectrum of disease caused by *Y. enterocolitica* ranges from self-limited infection to potentially fatal septicemia and post-infectious complications. The alimentary tract is the portal of entry in most cases, and enterocolitis is the presenting feature in two thirds of cases. After an incubation period of 4 to 7 days, patients present with fever, abdominal pain, and diarrhea lasting for 1 to 3 weeks. Most patients with enterocolitis are younger than 5 years, whereas older children and adults present with mesenteric adenitis that is indistinguishable from acute appendicitis. Focal extra-intestinal manifestations include pharyngitis; soft-tissue infection; osteomyelitis; and urinary, lung, and eye infections. Bacteremia, with and without seeding of other organs, is reported in patients with underlying diseases, such as alcoholism, cirrhosis, hemochromatosis, malnutrition, and malignancies. Septicemia has a mortality of 30% to 50%. Postinfectious complications include reactive polyarthritis, usually beginning days to a month after the onset of diarrhea and lasting for several months. Arthropathy is more common in patients who have the HLA allele B27 and molecular mimicry is postulated to be the mechanism for this association. The clinical features of *Y. pseudotuberculosis* infection resemble those of *Y. enterocolitica*, except that mesenteric adenitis is more common than enterocolitis.

OPTIMAL MANAGEMENT

The case fatality from untreated plague is at least 50%, especially with septicemic, pneumonic, and meningeal forms. Early diagnosis and treatment significantly reduces mortality. Streptomycin (30 mg per kilogram per day) intramuscularly in two divided doses for 10 days is the treatment of choice. No other drug has been shown to be more efficacious or less toxic. For patients with meningitis, chloramphenicol (75 mg per kilogram per day) intramuscularly in four divided doses for 10 days is recommended. Oral tetracycline (2 g per day) has been used for prophylaxis. A formalin-killed *Y. pestis* vaccine is recommended for laboratory personnel working with plague. The value of antimicrobial therapy for *Y. enterocolitica* and *Y. pseudotuberculosis* enterocolitis and mesenteric adenitis is unproven. Intestinal infections are usually self-limited. For patients with septicemia or other complications, intravenous gentamicin (5 mg per kilogram per day) alone or in combination with a third-generation cephalosporin (ceftriaxone or cefotaxime) has been suggested. Alternatively, TMP-SMX, doxycycline, and ciprofloxacin have been used. For serious infections with *Y. pseudotuberculosis*, intravenous ampicillin (100 to 200 mg per kilogram per day), streptomycin (20 to 30 mg per kilogram per day), or tetracycline (20 to 30 mg per kilogram per day) in divided doses has been used. The mortality from *Y. pseudotuberculosis* septicemia is 75% despite antibiotic therapy.

CHAPTER 286: INFECTIONS CAUSED BY HAEMOPHILUS AND BORDETELLA SPECIES

CHARLES J. SCHLEUPNER AND KENNETH M. SOSNOWSKI

[Haemophilus Infections](#)
[Bordetella Infections](#)

HAEMOPHILUS INFECTIONS

Haemophilus influenzae type B is the major invasive pathogen of this genus, especially in infants and children younger than 2 years of age. However, it also causes disease in adolescents and adults. The nontypable strains of *H. influenzae* are more commonly seen in patients with noninvasive disease and when host defenses are compromised. A biotype of *H. influenzae*, biogroup *aegyptius*, is the causative agent for Brazilian purpuric fever. *Haemophilus ducreyi* is a sexually transmissible pathogen that results in chancroid. The other *Haemophilus* species are less common causes of serious adult infections.

INCIDENCE AND EPIDEMIOLOGY

Haemophilus species are part of the normal flora of the pharynx and, to a lesser extent, the genital tract (excluding *H. ducreyi*). The prevalence of nontypable *H. influenzae* colonization in the pharynx has been reported to be as high as 50% to 80% in healthy adults, whereas encapsulated (50% type B) strains are present in only 5% of healthy individuals. Carriers usually remain healthy. [Table 286.1](#) lists the strains of *H. influenzae* that have been implicated as primary pathogens in both invasive and noninvasive diseases. Type B *H. influenzae* causes 95% of invasive disease in children and bacteremic infection in adults. Meningitis and epiglottitis have accounted for 68% to 80% of all bacteremic *H. influenzae* infections. *H. influenzae* type B was previously the leading cause of bacterial meningitis in children but has dramatically declined over the last 10 years—in some studies by as much as 86%.

Haemophilus Species	Classification	Type
<i>H. influenzae</i> type B	Invasive, often with bacteremia	Meningitis, epiglottitis, endophthalmitis, orbitis, otomastoiditis, septic arthritis, primary bacteremia, pneumonia
<i>H. influenzae</i> , biogroup <i>aegyptius</i>	Invasive, usually bacteremia	Brazilian purpuric fever
<i>H. influenzae</i> , nontypable	Invasive, usually without bacteremia	Pneumonia, neonatal and maternal infections
	Noninvasive	Otitis media, sinusitis, conjunctivitis, bronchitis
<i>H. parainfluenzae</i>	Invasive and noninvasive (occasionally)	Endocarditis, sinusitis, otitis media, conjunctivitis, epiglottitis
<i>H. aphrophilus</i>		Pharyngitis, OSE infections, bone infections, genitourinary infections, hepatobiliary infections
<i>H. paraphrophilus</i>		
<i>H. ducreyi</i>		Chancroid

TABLE 286.1. DISEASES ASSOCIATED WITH HAEMOPHILUS SPECIES

In the past, about 8,000 cases occurred annually in the United States, but because invasive infections due to *H. influenzae* are not reportable to the public health departments in all states, infection rates are not accurate. Overall during 1998, only 1,023 cases of invasive *H. influenzae* disease were reported to the Centers for Disease Control and Prevention (CDC). Serious invasive infections occur more often in male children and adults, blacks, lower socioeconomic families, Alaskan Eskimos, and Navajo and Apache Indians, and during winter months. Children exposed by close contact to children with invasive *H. influenzae* type B disease have high colonization rates (up to 50%) and those younger than 2 years of age have up to a 500 times greater risk of secondary disease if not previously immunized.

The noninvasive diseases due to *H. influenzae* type B (bronchitis, otitis media, conjunctivitis) are more common but less serious overall; they tend to occur in all age groups. Invasive disease due to the nontypable strains of *H. influenzae* is uncommon and usually results from a compromise of the normal host defenses, such as occurs with chronic lung disease, AIDS, asplenia (anatomical or functional), chronic lymphocytic leukemia, multiple myeloma, a cerebrospinal fluid (CSF) leak, or prior head trauma, among other causes. The most common form of invasive infection is pneumonia in the elderly and in patients with chronic bronchitis. The most common forms of noninvasive infection due to the nontypable strains are sinusitis, otitis media, and conjunctivitis.

Other *Haemophilus* species less frequently cause disease and have a low pathogenicity. *Haemophilus parainfluenzae*, *Haemophilus parahaemolyticus*, *Haemophilus aphrophilus*, and others are part of the normal oral and pharyngeal flora of healthy people. Disease results from a lapse in host defenses leading to local or systemic infection. *H. ducreyi* infection is discussed in [Chapter 288](#).

ETIOLOGY

Haemophilus species are small gram-negative, pleomorphic (cocco-) bacilli with specific growth requirements for X factor (hemin) or V factor (a coenzyme, nicotinamide adenine dinucleotide). *Haemophilus* species with the prefix “para” (*H. parainfluenzae*, *H. paraphrophilus*, and *H. parahaemolyticus*) require only the V factor for growth, whereas *H. aphrophilus* and *H. ducreyi* require only the X factor. The remaining clinically significant species, *H. influenzae* and *H. hemolyticus*, require both factors. *Haemophilus* (blood seeking) refers to the original source of its required growth factors. However, *H. influenzae* cannot be grown on standard blood agar because the V factor is available only after being released from erythrocytes by heating the blood (chocolate agar). The phenomenon of “satelliting” refers to the growth of V factor requiring *Haemophilus* species on standard sheep blood agar only in the proximity of colonies of *Staphylococcus aureus*, which may secrete V factor or cause V factor to be released from erythrocytes by hemolysis. Isolation of these organisms is improved by prompt inoculation of clinical specimens and incubation in a humidified environment containing 5% to 10% carbon dioxide. When gram-stained, these organisms may be morphologically confusing, because although they appear coccobacillary in clinical specimens, they may appear filamentous in culture.

H. influenzae isolates can be differentiated into six serotypes (A through F) based on antigenically and biochemically distinct polysaccharide capsules, which are virulence factors. Type B encapsulated organisms are the most pathogenic, although all five other serotypes and nontypable organisms may also be pathogens.

PATHOGENESIS

The determinants of colonization with *H. influenzae* are not well understood. The organism potentially may express four types of fimbriae, one of which mediates epithelial adherence (and hemagglutination by way of the blood group antigen Anton). The role of fimbriae in virulence is unclear, because most nonencapsulated strains are fimbriated; however, this has not correlated with pathogenicity. Furthermore, fimbriae are lost during invasion, and this lack of fimbriae makes organisms less susceptible to phagocytosis. Some strains (encapsulated or unencapsulated) elaborate one or more cilioinhibitory factors that may impair clearance and thus enhance replication of the organism. These effects may ultimately lead to mucus penetration and binding to epithelial receptors. Nontypable *H. influenzae* binds to human buccal and nasopharyngeal epithelial cells better than encapsulated strains.

H. influenzae secretes an IgA1 protease, but its role in virulence is unclear. Synthesis of histamine by *H. influenzae* may contribute to bronchoconstriction in pulmonary infection. The lipopolysaccharide of *H. influenzae* may play a role in damage to the respiratory epithelium, thereby potentiating invasion. The peptidoglycan of *H. influenzae* type B plays a major role in the pathogenesis of meningitis by increasing blood–brain barrier permeability and CSF leukocytosis; the latter is also enhanced by the *H. influenzae* lipopolysaccharide.

The most important virulence factor for encapsulated *H. influenzae* is the polysaccharide capsule, a polymer of ribosyl ribitol phosphate (PRP). Type B capsule impedes phagocytosis in the absence of antibody (or other opsonic factors). Antibody to the PRP capsule enhances complement activation, opsonization,

phagocytosis, and killing of the organism and is the major determinant of immunity in humans. The mechanism for acquisition of antibody to PRP by age 3 to 4 years in unimmunized persons is not well understood. The antibody response to initial type B *H. influenzae* infection in children 12 months of age or younger is poor owing to the limited antibody response of infants to T-cell-independent antigens, thereby allowing for recurrent infections.

The pathogenesis of infection with other *Haemophilus* species is primarily related to a lapse of a host defense. The roles of serum and secretory antibody against nontypable *H. influenzae* and the other *Haemophilus* species remain unclear. The role of mucosal immunity is also not well understood. The complement system plays a major role in the defense against both encapsulated and unencapsulated *Haemophilus* species in both immune and nonimmune hosts. Genetic deficiencies of selected complement components (e.g., C2, C3, C4) enhance the disease potential of *H. influenzae*.

CLINICAL FINDINGS

Meningitis

Meningitis due to type B *H. influenzae* is the most serious manifestation of invasive infection caused by this organism. In neonates, *H. influenzae* meningitis is rare. However, although it was previously the most common cause of meningitis in children from age 6 months to 5 years and was responsible for up to 20% of bacterial meningitis in adults, the incidence of *H. influenzae* meningitis has dramatically declined since 1985 in children older than 6 months. In children, an antecedent upper respiratory infection, commonly otitis media, is usual. In adults, antecedent head trauma, neurosurgery, sinusitis, otitis, or a CSF leak is found in two-thirds of cases. In adults, approximately 50% of cases are caused by nontypable organisms, whereas most episodes in children result from type B strains. The most common signs are fever and an altered mental status. In a child younger than 1 year of age, the disease may be fulminant with death occurring in a few hours; however, acute deterioration usually follows several days of mild upper respiratory illness. In adults, the pathogenesis involves contiguous spread from a primary site of infection, and the illness resembles other forms of acute bacterial meningitis. Associated bacteremia is more common in children than in adults. Coma and bacteremia in adults predict a worse outcome. Mortality rate may be up to 20% to 30% in adults, whereas less than 5% of childhood cases are fatal with therapy. Up to 50% of children even with appropriate antibiotic therapy are left with neurologic sequelae, including hearing and cognitive impairment and seizures. Subdural effusions are also a common complication. Data on the declining incidence of these sequelae are evolving.

Pneumonia and Tracheobronchitis

Primary lung infection due to nontypable *H. influenzae* occurs in adults and in children, especially in infants in developing countries, and has been associated with nosocomial spread resulting in both colonization and respiratory infection. In adults, *H. influenzae* is second only to *Streptococcus pneumoniae* as the most common cause of community-acquired pneumonia. The typical adult patient with invasive *H. influenzae* pneumonia is older than 60 years of age with evidence of chronic pulmonary disease, alcoholism, malignancy, use of steroids, diabetes mellitus, or a recent viral infection, especially influenza. Younger adults with *H. influenzae* pneumonia usually have evidence of alcohol abuse or AIDS, or have an invasive infection associated with other chronic immunocompromising diseases. Type B strains may be responsible only for up to 15% of pneumonia due to *H. influenzae* in adults, and are more frequently associated with bacteremia. Overall, up to 10% to 20% of pneumonias in adults are bacteremic.

The clinical and radiologic findings of *H. influenzae* pneumonia are indistinguishable from those of other bacterial pneumonias. Segmental lobar consolidation occurs frequently, but bronchopneumonia and diffuse interstitial disease have been observed. Cavitory disease and empyema occur; sterile parapneumonic effusions may occur in up to 50% of patients. A form of purulent, febrile tracheobronchitis due to nontypable *H. influenzae* has been reported. The clinical features of patients with a tracheobronchitis are indistinguishable from those with pneumonia; however, the two syndromes can be distinguished by chest radiography.

H. influenzae can be recovered from sputum of most patients with chronic bronchitis, often worsened by prior viral infection. Thus, the presence of the organism in sputum does not necessarily imply a pathogenic role in exacerbations of chronic bronchitis. However, nontypable *H. influenzae* is cultured more frequently during exacerbations of bronchitis than during symptom-free periods. The exact role of these organisms in exacerbations of chronic bronchitis remains controversial. Curiously, tobacco and nicotine have been shown in vitro to stimulate growth of *H. influenzae*.

Other Respiratory Tract Infections

H. influenzae has been isolated from 20% of infants and children with acute otitis media, most commonly from children 6 months to 5 years old. Up to 90% of these strains are nontypable. *H. influenzae* has also been isolated from middle ear aspirates of adults with otitis media, but the prevalence of nontypable organisms in adults is unknown. Nontypable *H. influenzae* is also a common cause of sinusitis in children and adults. Acute epiglottitis (a cellulitis of supraglottic tissue) is a fulminant illness that occurs most often in children 2 to 7 years old, but also has been reported increasingly frequently in adults. In children, the disease typically has an explosive onset, with sore throat, fever, and dyspnea progressing rapidly to acute respiratory obstruction; *H. influenzae* type B is the usual pathogen and is associated with bacteremia in 65% to 90% of cases. Because of use of vaccines since 1985, current data support a declining incidence of epiglottitis in children, with a shift to older ages (from a peak incidence at 36 months to 55 to 80 months) and to nonwhite patients. Since 1985, the incidence of *H. influenzae* type B epiglottitis has not appreciably changed in the adult population. In adults, *H. influenzae* remains the most commonly identified cause of epiglottitis, but bacteremia is less common. The mortality rate in adult cases of epiglottitis has been greater than in pediatric cases, presumably resulting from failure to consider this diagnosis early.

Septic Arthritis

H. influenzae has been the most common cause of infectious arthritis in unimmunized children younger than 2 years. In children, infection usually involves a single, large weight-bearing joint. In adults, *H. influenzae* accounts for less than 1% of all cases of nongonococcal infectious arthritis. About 75% of adult patients with *H. influenzae* arthritis have predisposing conditions, including connective tissue disease, splenectomy, diabetes mellitus, alcoholism, hypogammaglobulinemia, multiple myeloma, lymphoma, or trauma. Up to 50% of affected adults have multiarticular and 65% have extra-articular sites of infection.

Other Infections

Nontypable *H. influenzae* is a cause of genitourinary tract infection, including tubo-ovarian abscess and chronic salpingitis. The association of fetal or neonatal infections with *H. influenzae* genital tract infections in women (endometritis, amnionitis) has been well described, especially after premature rupture of the membranes. Urinary tract infections usually occur in the setting of instrumentation or structural abnormalities of the urinary tract. Facial or neck cellulitis due to *H. influenzae* type B has previously occurred commonly in children between the ages of 6 months and 3 years. Classically, this infection involves one cheek or periorbital area. Immunization of children with conjugated *H. influenzae* type B vaccines has caused a decline of this syndrome. Neck cellulitis has been reported in adults older than 50 years, who present with pharyngitis, high fever, and rapidly progressive anterior neck swelling. The characteristic red-purple hue of the skin described in children with cellulitis may be absent in adults. A number of unusual infections have been attributed to *H. influenzae* in various case reports, including endocarditis, cholecystitis, peritonitis, and epididymo-orchitis.

H. aegyptius (identical with *H. influenzae* biotype 3, the Koch-Weeks bacillus) is associated with a conjunctivitis in children, which may occur in outbreaks. More recently, *H. aegyptius* has been implicated as the causative agent of Brazilian purpuric fever, a fulminant systemic illness first reported in children in Brazil in 1984. This organism has been shown to be toxic to endothelial cells in vitro. The illness has a peak incidence in children 1 to 4 years old, characteristically begins with purulent conjunctivitis, and progresses in a small percentage of patients to a febrile illness with petechial or purpuric skin lesions. If untreated, some patients have experienced overwhelming endotoxemia and fatal shock.

Other *Haemophilus* Species

H. parainfluenzae causes a spectrum of disease similar to *H. influenzae*, including respiratory tract infections, pneumonia, empyema, meningitis, endocarditis, septic arthritis, and hepatobiliary, central nervous system, urinary tract, and genital infections, among others. Over the last decade, *Haemophilus* species (*H. parainfluenzae*, *H. aphrophilus*, *H. paraphrophilus*, and *H. influenzae*) have been recognized as causative agents in about 5% of cases of endocarditis, probably associated with improved microbiologic techniques. These organisms colonize the upper respiratory tract; thus, endocarditis may result from periodontal disease, dental manipulation, or respiratory tract infections. *Haemophilus* species belong to the HACEK group of fastidious gram-negative bacteria associated with the previously termed "culture-negative" endocarditis. The organisms usually cause disease in the setting of previous valvular heart disease, prosthetic valve implants, or intravenous drug abuse in young to middle-aged adults.

Persons with *Haemophilus* endocarditis usually present with subacute onset indistinguishable from endocarditis due to viridans streptococci. The single major distinguishing feature of endocarditis due to *Haemophilus* species is the common occurrence of large valvular vegetations and major arterial embolization, which may occur in up to 60% of cases. Delay in diagnosis and difficulty in isolating and identifying these fastidious organisms may account for the significant morbidity and mortality associated with this form of endocarditis.

LABORATORY FINDINGS

Confirmation of the diagnosis of infection due to *Haemophilus* species should be based on Gram's stain and culture of specific body fluids (e.g., blood, middle ear, sinus, CSF, or aspirates of cellulitis or joint spaces). In the absence of bacteremia, demonstration of the organism by Gram's stain in a sputum screened microscopically for cellular content must be interpreted in the context of an appropriate clinical syndrome. Specimens obtained by transthyroicoid membrane aspiration or bronchoscopy yield more specific (and sensitive) diagnostic information. In addition, the pleomorphic nature of the organism may make Gram's stain interpretation difficult. In cases of meningitis, positive CSF Gram's stains have been reported in only 50% to 70% of cases. Detection of capsular antigen in serum or other body fluids using immunoelectrophoresis, latex agglutination, or enzyme-linked immunosorbent assays (ELISAs) may be an adjunct to diagnosis within the first 72 hours of illness. These methods for detection of capsular antigen may be positive in up to 90% of culture-positive fluids. Other laboratory data (complete blood count, serum electrolytes and chemistries) reflect only specific organ or body system dysfunction related to an ongoing bacterial process and may be nonspecifically abnormal.

A transthoracic or transesophageal echocardiogram may suggest the possibility of *Haemophilus* species as the cause of endocarditis because of the presence of large vegetations on the involved valve. Peripheral arterial embolization also suggests this cause.

OPTIMAL MANAGEMENT

Antibiotics

Without treatment, meningitis and epiglottitis due to *H. influenzae* may be rapidly fatal. Antimicrobial resistance among isolates of *H. influenzae*, and occasionally other *Haemophilus* species, has become an increasingly prevalent problem. Enzymatic resistance to ampicillin mediated by β -lactamases may be present in 24% to 32% of clinical isolates, whereas nonenzymatic resistance (altered outer membrane proteins or decreased affinity of penicillin-binding proteins) may occur in 2% to 4% of isolates. Type b strains are nearly twice as likely as strains other than type b to produce β -lactamase (about 30% and 15%, respectively), whereas the non- β -lactamase resistance to ampicillin is more commonly seen in nontypable strains. Since 1980, the emergence of strains resistant to chloramphenicol has also been described. Although less than 1% of isolates in the United States are chloramphenicol resistant, this phenomenon necessitates sensitivity testing and thoughtful antimicrobial selection. The third-generation cephalosporins, cefotaxime and ceftriaxone, are the preferred agents. They penetrate the CSF and have been shown to be effective in serious *H. influenzae* infections, including meningitis in children and adults.

Dexamethasone therapy to reduce cerebral edema and inflammation in children older than 2 months with meningitis is now accepted. Dexamethasone before or concomitant with the first dose of antibiotics and continued for the first 4 days of therapy of acute *H. influenzae* meningitis in children has been shown to decrease secondary deafness from 17% to 3%. The use of dexamethasone in adult meningitis remains controversial.

Less serious infections, such as otitis and sinusitis, due to β -lactamase-negative strains of *H. influenzae* usually can be managed with amoxicillin. Alternative oral agents for ampicillin-resistant disease include amoxicillin-clavulanic acid, trimethoprim-sulfamethoxazole, cefuroxime axetil, cefpodoxime proxetil, cefixime, ciprofloxacin, ofloxacin, azithromycin, and clarithromycin (Table 286.2). Quinolones should be used with caution in children because of possible toxicities. The typical therapy for endocarditis due to infection with *Haemophilus* species is intravenous ampicillin with or without an aminoglycoside. Ceftriaxone monotherapy may be adequate management of endocarditis due to these organisms. The optimal duration of therapy for endocarditis due to *Haemophilus* organisms is unknown; a minimum of 4 weeks of treatment should be prescribed. Serum inhibitory and bactericidal assays may be used to monitor the potential effectiveness of therapy. Adequate therapy may reduce the previously documented 25% to 50% mortality rate to 10% to 15%.

Antibiotic	% Susceptible According to β -Lactamase Production	
	Positive (n = 479)	Negative (n = 1,209)
Ampicillin	0	99.6
Amoxicillin/clavulanate	100	99.6
Cefaclor	98.8	99.3
Loracarbef	97.9	100
Cefuroxime	100	100
Cefixime	100	100
Ciprofloxacin	100	100
Ofloxacin	100	100
Erythromycin	6.8	3.7
Trimethoprim-sulfamethoxazole	93.7	94.7

(Adapted from Sriver SR, Wainwright SL, Kau CL. Determination of antimicrobial susceptibilities of Canadian isolates of *Haemophilus influenzae* and characterization of their β -lactamase. *Antimicrob Agents Chemother* 1994;38:1678-1680)

TABLE 286.2. ANTIMICROBIAL SUSCEPTIBILITY OF 1,688 ISOLATES OF *HAEMOPHILUS INFLUENZAE* CANADA 1992-1993

Unimmunized young children younger than 2 years old in the same household as an infected person with serious invasive disease due to *H. influenzae* type b have a significantly increased risk of secondary invasive infections due to this organism. Secondary attack rates have been estimated at 2% to 4% in household contacts and 1.3% in day care centers. Rifampin prophylaxis, 20 mg per kilogram with a maximum dose of 600 mg per day given once daily for 4 days, is recommended for both children and adults in homes with children younger than 4 years old. To reduce nasopharyngeal carriage and potential spread, the index case should also be given prophylaxis if he or she is returning to the household of a child younger than 4 years of age.

PREVENTION

The possibility of active immunization against type b *H. influenzae* has become a reality during the 1980s. A vaccine composed of purified type b PRP was shown to give variable results in the United States. Several very effective PRP-conjugate vaccines are now available for children 2 months of age or older, given usually as a series of four injections at 2, 4, 6, and 15 to 18 months of age (Table 286.3). In the United States since 1987, the rate of disease due to *H. influenzae* in children younger than 5 years has decreased by 95%, whereas reported disease in people older than 5 years has remained stable. Conjugated *H. influenzae* vaccines combined with diphtheria-tetanus-acellular pertussis vaccine are now available for children 15 to 18 months. The use of conjugated *H. influenzae* vaccines in immunocompromised adults (i.e., with AIDS) is now being advocated.

FDA-Approved	Vaccine Type	Targeted Population
April 1985	Polysaccharide (PRP) polysaccharide	Children >18 months old
December 1987	PRP-diphtheria toxin conjugate (PRP-D ¹)	Children >18 months old
December 1988	PRP-tetanus meningitis outer membrane protein conjugate (PRP-OMP) ² PRP-polysaccharide diphtheria toxin conjugate (PRP-D ²)	Children >18 months old
December 1989	PRP-DIP HCC	Children >12 months old
March 1991	PRP-tetanus toxin conjugate (PRP-T) ³	Children >12 months old
September 1996	PRP-T recombinant-derived with DIP ⁴	Children >15-18 months old (PRP dose of DIP) ⁵

TABLE 286.3. APPROVED HAEMOPHILUS INFLUENZAE TYPE B VACCINES AND TARGETED POPULATIONS

For children who are receiving immunosuppressive chemicals, children with AIDS, or Native American infants, bacterial polysaccharide immune globulin (BPIG) may be of use in preventing *H. influenzae* disease before such children are able to respond to a PRP-conjugate vaccine. BPIG does not interfere with responses to vaccines (diphtheria–pertussis–tetanus or PRP-conjugate) given concurrently.

BORDETELLA INFECTIONS

Of the seven species within the genus *Bordetella*, only *Bordetella pertussis* and *Bordetella parapertussis* routinely cause disease in humans. *B. pertussis* is the causative agent of whooping cough. Although a mild form of clinical disease has been attributed to *B. parapertussis* in the past, recent studies suggest a frequency of a classic pertussis syndrome due to this organism similar to that caused by *B. pertussis*, especially in children. *Bordetella bronchiseptica* rarely causes whooping cough–like illness in humans and opportunistic infections in compromised hosts. *Bordetella hirci*, *B. holmseii*, and *B. trematum* have rarely been isolated from human infection. *Bordetella avium* is not known to infect humans.

INCIDENCE AND EPIDEMIOLOGY

Pertussis is endemic worldwide, with epidemics occurring every 3 to 5 years. After the whole-cell vaccine (WCV) was introduced in the late 1940s, a marked decline occurred in the annual incidence of pertussis to a nadir of 1,010 cases in the United States in 1976. Because immunity after WCV is usually less than 12 years, most adults are susceptible and have little to no humoral immunity to provide through passive transfer to neonates. Since 1976, there has been a significant resurgence (82% increase) of cases in people 10 years of age or older. This has occurred because of the withholding of booster doses of WCV from adolescents and adults owing to the concern about systemic toxicity.

The attack rate among susceptible people after exposure to *B. pertussis* is 50% to 100%; infection is acquired by exposure to aerosol droplets from a coughing patient at a distance of 5 feet or less. The attack rate, as well as the morbidity and mortality, are higher in female children; the reason for this is unknown.

ETIOLOGY

The human pathogens (*B. pertussis* and *B. parapertussis*) are small, slowly growing, gram-negative, coccobacillary organisms that are nonmotile and require growth medium supplementation with nicotinamide (contained in synthetic medium or in the starch–blood agar medium described by Bordet and Gengou).

PATHOGENESIS

B. pertussis produces several biologically active virulence factors, including a dermonecrotic heat-labile toxin, a tracheal cytotoxin, adenylate cyclase toxin, agglutinogens, and a filamentous hemagglutinin, the last of which is involved in adherence to ciliated respiratory epithelium. The best-characterized virulence factor is pertussis toxin (pertussigen), which promotes epithelial adherence and, as a typical toxin with A and B binding sites, catalyzes the adenosine diphosphate ribosylation of guanine nucleotide-binding regulatory proteins in target cells. Pertussis toxin is also responsible for the lymphocytosis, the sensitization to histamine, and the enhancement of insulin secretion seen in experimental animals and human disease and is the likely cause of the systemic manifestations of disease. Tracheal cytotoxin, dermonecrotic toxin, and adenyl cyclase toxin cause damage to the respiratory epithelium, thereby potentiating infection. Phagocyte function is abrogated by pertussis toxin, adenyl cyclase toxin, and tracheal cytotoxin.

CLINICAL FINDINGS

Classic disease occurs primarily in children 1 to 5 years of age. The limited duration of vaccine immunity and the publicity generated by adverse reactions to the WCV have changed the epidemiology of the illness so that most cases now occur in infants younger than 1 year or adolescents and adults older than 15 years.

Clinical illness presents in three phases: the catarrhal phase, the paroxysmal phase, and the convalescent phase. After an incubation period of less than 1 to 3 weeks, the *catarrhal phase*, indistinguishable from other upper respiratory illnesses, may last for a few days to a week. This phase manifests as rhinorrhea, conjunctival injection, malaise, and low-level fever. The cough paroxysm ensues and consists of a series of short, staccato bursts followed by an inspiratory gasp, resulting in the classic “whoop.” However, the whoop is uncommon among infants and adults with pertussis. The typical laboratory finding of lymphocytosis is noted in the late catarrhal and early paroxysmal phases. Lung consolidation is noted in 20% to 25% of infants and adults. Complications include otitis media, pneumonia, and the sequelae of the severe cough paroxysms, including petechiae, epistaxis, subconjunctival, scleral and central nervous system hemorrhages, and pneumothorax, among others. In children younger than 1 year old, seizures (3%), encephalopathy (0.9%), and death (0.6%) are seen. *B. pertussis* has been recognized as a cause of chronic infection in patients with HIV-1 infection.

LABORATORY FINDINGS

During the late catarrhal and early paroxysmal phases, leukocytosis may be as high as 50,000/mm³, consisting primarily of a T- and B-cell lymphocytosis. The gold standard for diagnosis is culture of *B. pertussis* (or *B. parapertussis*), which may take up to 5 days for growth on specific medium. However, the overall sensitivity of nasopharyngeal culture for disease clinically consistent with pertussis may be as low as 58%. Material for culture should be obtained by calcium alginate swab of nasopharyngeal secretions or by aspiration. Ability to diagnose by culture rapidly diminishes during the paroxysmal phase. Direct fluorescent antibody (DFA) stains of nasopharyngeal specimens or of cultured isolates may aid in more rapid diagnosis, although DFA on direct specimens is less sensitive and specific than culture.

DNA hybridization and polymerase chain reaction (PCR) techniques have been developed for detection of *B. pertussis* in secretions. PCR has been determined to be approximately 98% specific but often less than 50% sensitive when compared with serologic diagnosis. With further refinement, PCR may be a valuable complement to, if not replacement for, culture for the diagnosis of pertussis. Because of these diagnostic limitations, the diagnosis of pertussis in patients with a cough persisting for 2 weeks is often clinical. A retrospective serologic diagnosis of pertussis can be made with ELISA.

OPTIMAL MANAGEMENT

In addition to supportive measures, especially for infants who are at greatest risk for complications, azithromycin, clarithromycin, erythromycin, tetracycline, trimethoprim-sulfamethoxazole, and chloramphenicol eliminate *B. pertussis*. One isolate of *B. pertussis* resistant to erythromycin has been reported. These agents may act by affecting bacterial adherence through protein synthesis inhibition, thereby reducing the severity and duration of infection. However, clinical disease may not be altered by antimicrobial therapy.

PREVENTION

Isolation of cases is ineffective at preventing spread of pertussis because of the nonspecificity of symptoms during early illness. Macrolide prophylaxis may help to control transmission within households and during outbreaks.

Since the late 1940s, the WCV, combined with diphtheria and tetanus toxoids, has been more than 80% efficacious at preventing pertussis in children. The limited duration of immunoprotection is evidenced by the fact that 95% or more of disease occurs 12 or more years after immunization. However, disease is usually less severe in these patients. The WCV is usually given at age 2, 4, 6, and 15 months and at 4 to 6 years. The major limitation of a vaccine containing pertussis WCV is reactogenicity, both local and systemic, in the form of pain, swelling, fever, anorexia, and fretfulness. Encephalopathy and neurologic sequelae, previously associated with pertussis immunization, have been disproved as being caused by the vaccine. However, owing to these concerns, the WCV has been rarely used in older children and adults, except for outbreak control.

Declining immunity in adolescents and adults, despite vaccination levels of 93% in 1994, has led to the resurgence of this disease in many cities and countries since 1976. In 1993, there were 5,457 cases in the United States, representing an 82% increase compared with 1992 and a 540% increase since 1976, primarily in persons older than 5 years.

To avoid vaccine reactions and possibly to enhance the magnitude and duration of immunity, acellular pertussis vaccines combined with diphtheria and tetanus have now been licensed. The acellular pertussis components include from two to four purified or recombinant *B. pertussis* virulence antigens. These vaccines have demonstrated greater immunogenicity and fewer adverse effects. They have been incorporated into three licensed combined diphtheria–tetanus vaccines for administration at ages 2, 4, 6, and 15 to 18 months and at 4 to 6 years. Their potential usefulness for periodic booster immunizations during adult life is likely but not yet advocated.

CHAPTER 287: LEGIONELLOSIS

EMANUEL N. VERGIS AND ROBERT R. MUDER

[Definition and Etiology](#)
[Incidence and Epidemiology](#)
[Pathogenesis](#)
[Clinical Findings](#)
[Laboratory Findings](#)
[Optimal Management](#)
[Prognosis](#)
[Prevention](#)

DEFINITION AND ETIOLOGY

Legionnaires' disease was named after the outbreak of severe pneumonia at the 1976 American Legion Convention in Philadelphia during which over 180 people were afflicted and 34 died. The causative organism, *Legionella pneumophila*, was isolated from postmortem tissue by investigators from the Centers for Disease Control several months after the outbreak. *L. pneumophila* belongs to the family Legionellaceae, which includes a total of 34 described species. Furthermore, more than 50 serogroups are within the individual species of *Legionella*. *L. pneumophila* is the most common species encountered and accounts for approximately 90% of infections caused by the Legionellaceae. Of the 14 serogroups of *L. pneumophila*, serogroups 1, 4, and 6 are responsible for most of the infections among humans. Other *Legionella* species implicated with human infection (pneumonia) include *L. micdadei* (the Pittsburgh pneumonia agent), *L. bozemanii*, *L. dumoffii*, and *L. longbeachae*. These account for approximately 9% of pneumonia due to *Legionella*. Several other non-*pneumophila* species implicated in pneumonia are *L. jordanis*, *L. gormanii*, *L. feeleii*, *L. hackeliae*, *L. maceachernii*, *L. wadsworthii*, *L. birminghamensis*, *L. cincinnatiensis*, *L. oakridgensis*, *L. anisa*, *L. sainthelensi*, *L. tusconensis*, and *L. lansingensis*. Collectively, these less frequently encountered species are responsible for approximately 1% of cases of pneumonia. Another clinical syndrome caused by members of the Legionellaceae family is Pontiac fever, an acute febrile nonpneumonic illness that has been serologically linked to *L. pneumophila* and other *Legionella* species.

Legionellae are widely distributed in both natural and man-made aquatic environments, which include freshwater habitats such as lakes, rivers, streams, thermally polluted waters, cooling towers, evaporative condensers, whirlpool spas, and potable water systems. They are aerobic, gram-negative bacilli, with fastidious growth requirements rendering them incapable of growing on the usual microbiologic media. Their growth is supported by buffered charcoal yeast extract agar supplemented with cysteine, ketoacids, and iron. Legionellae are also considered facultative intracellular pathogens of mononuclear phagocytes, principally monocytes and alveolar macrophages.

INCIDENCE AND EPIDEMIOLOGY

The incidence of legionnaires' disease depends on the extent of contamination of the aquatic reservoir by the organism, the susceptibility of the population exposed to that water, and the intensity of the exposure. In addition, the discovery of this infection also depends on the expertise of the testing laboratory and on the availability of specialized laboratory tests. *L. pneumophila* has been consistently shown to be among the top three most common microbial causes of community-acquired pneumonia. The percentage of community-acquired pneumonia requiring hospitalization due to *L. pneumophila* ranges from 2% to 15% with a median incidence of 5%. Cigarette smoking, advanced age, chronic lung disease, and immunosuppressive therapy are major risk factors for acquisition of legionnaires' disease. Some studies have noted an increased risk among patients with alcoholism and renal failure. Persons with AIDS also appear to have a somewhat increased risk for *Legionella* infection.

Originally, nosocomial legionnaires' disease was believed to be epidemic in institutions. It is now believed that endemic infection is much more common. The incidence of nosocomial pneumonia due to *L. pneumophila* varies and depends largely on the degree of colonization of the hospital hot-water distribution system by the organism and the number of susceptible hosts. As with community-acquired disease, recognition requires availability of specialized testing for *Legionella* within the hospital.

The percentage of nosocomial pneumonia due to *Legionella* varies from less than 1% to 50%. The major predictor of nosocomial infection in susceptible persons is colonization of the hospital hot-water distribution system with *Legionella*. Persons at high risk for nosocomial legionnaires' disease include those who are highly immunocompromised, especially organ transplant recipients. Additional risk factors are recent surgery, endotracheal intubation, and the use of respiratory tract therapy equipment. In addition to *L. pneumophila*, *L. micdadei*, *L. dumoffii* and *L. bozemanii* can cause nosocomial legionnaires' disease provided that the water is colonized by these organisms.

There are many modes of transmission of *L. pneumophila* from a water source to humans. There is evidence of aerosolization, aspiration, and direct instillation into the lung during respiratory tract manipulation. Reports implicating cooling towers as point sources of transmission have gradually disappeared with the recognition that *Legionella* could be pervasive within water distribution systems. Colonization of potable water distribution systems in the home and in the workplace has been implicated in community-acquired cases of legionnaires' disease. Despite the initial isolation of *L. pneumophila* in a hospital from a showerhead, an epidemiologic link between showering and acquisition of disease has never been shown in prospective studies. Aerosols generated by humidifiers, nebulizers, and other respiratory care devices have been linked to infection. Tap water, which is frequently used to rinse respiratory equipment and tubing, may be contaminated by *Legionella*, resulting in infection by direct instillation of the organism into the lung. Aspiration of contaminated water or contaminated oropharyngeal secretions is probably the major mode of transmission. Nasogastric tube placement has been implicated as a risk factor in intubated patients in two prospective studies.

PATHOGENESIS

Legionellae enter the respiratory tract by aerosolization or aspiration of contaminated water. The development of disease subsequently depends on the inoculum and virulence of the organism and the immune competence of the host.

The initial barrier against infection is mechanical clearance of the organism effected by the mucociliary process of the respiratory epithelial cells. Mucociliary action is impaired in patients with chronic pulmonary disease, in cigarette smokers, and in alcoholics—patients in whom there is a consistent epidemiologic association of increased risk of legionnaires' disease. Upon reaching the alveoli, legionellae are phagocytized by alveolar macrophages, where they are capable of replication. The primary host defense mechanism against legionellae appears to be cell-mediated immunity. Evidence for this comes from observation that legionnaires' disease is more common and more severe for patients with cell-mediated immune dysfunction, including transplant recipients, patients receiving corticosteroid therapy, and patients with AIDS. Humoral immunity is a secondary host defense mechanism of limited effectiveness. Antibody does not promote the killing of *L. pneumophila* by complement and causes only a modest amount of killing of *L. pneumophila* by phagocytes. Virulence of *L. pneumophila* varies among different strains. Virulence may be associated with a particular surface epitope that is recognized by a monoclonal antibody (Mab-2). In vivo studies with guinea pigs have shown that a 24-kd protein referred to as *macrophage infectivity potentiator* (Mip) appears to be required for virulence.

CLINICAL FINDINGS

There are two clinical manifestations of *Legionella* infection: Pontiac fever and pneumonia (legionnaires' disease). No clear explanation exists regarding why there are two forms of clinical disease, but different inocula of the organism, different modes of transmission, and host factors are believed to be important. Pontiac fever is an acute, flulike illness without pneumonia, occurring after exposure to heavily contaminated aerosols. The attack rate is over 90%, and the incubation period is 1 to 2 days. Malaise, fatigue, and myalgias are frequently described in 97% of patients. Despite the presence of a nonproductive cough and chest pain, no radiographic evidence of pneumonia is seen. Fever with chills and headache are present in 80% to 90% of patients. Arthralgias, nausea, abdominal pain, and diarrhea are seen in less than 50% of patients. A modest leukocytosis with predominant neutrophils may be seen. The illness is self-limited with full recovery within 1 week without sequelae. *L. pneumophila* serogroups 1 and 6, *L. feeleii*, and *L. micdadei* have been implicated in several outbreaks of Pontiac fever.

Pneumonia is the predominant clinical finding in legionnaires' disease ([Table 287.1](#)). The disease can range from a mild cough and slight fever to bilateral pneumonia with multisystem failure. The incubation period ranges from 2 to 10 days. Nonspecific symptoms such as fever, malaise, myalgia, anorexia, and headache may be

present early in the course of the illness.

Gram's stain of respiratory secretions showing numerous neutrophils, but few, if any, organisms

Hyponatremia

Failure to respond to β -lactam (penicillin or cephalosporin) and aminoglycoside antibiotics

Occurrence in a hospital or environment in which the water supply is known to be contaminated with *Legionella*

TABLE 287.1. CLINICAL CLUES FOR DIAGNOSIS OF LEGIONNAIRES' DISEASE

Initially, the cough is nonproductive or minimally productive of nonpurulent sputum, which on occasion may be blood streaked. Gross hemoptysis is rare. Chest pain, either pleuritic or nonpleuritic, can be a prominent feature for some patients. An incorrect diagnosis of pulmonary embolus may be suggested by the combination of chest pain and hemoptysis. Gastrointestinal symptoms occur in up to 50% of patients. Watery, nonbloody diarrhea is most common. Other gastrointestinal complaints are nausea, vomiting, and abdominal pain. Neurologic symptoms ranging from headache and lethargy to encephalopathy are reported. However, change in mental status is the most common neurologic abnormality.

Examination of the patient with legionnaires' disease shows high fever, and chest findings are typical of bacterial pneumonia. Pulse–temperature dissociation has been unduly stressed as a useful clinical finding, but can occasionally be seen in elderly patients with severe legionnaires' disease. Hypotension and bradycardia are not unusual. However, pneumonia caused by *Legionella* cannot be distinguished from other pneumonias by clinical manifestations alone.

Extrapulmonary manifestations of *Legionella* infection are rare and presumably occur through hematogenous dissemination. Anecdotal reports of cellulitis, sinusitis, pericarditis, myocarditis, prosthetic valve endocarditis, peritonitis, pancreatitis, and acute pyelonephritis with renal abscesses have been reported. Wound infections have resulted from exposure to water containing *L. pneumophila*.

LABORATORY FINDINGS

ROUTINE STUDIES

Polymorphonuclear leukocytosis with immature forms is common in patients with legionellosis. Mild biochemical abnormalities are common, including azotemia, hepatic dysfunction, and hypophosphatemia. Hyponatremia (serum sodium less than 130 mEq per liter) occurs significantly more frequently in patients with legionnaires' disease than in those with pneumonias of other origin.

Gram's stain of sputum showing numerous neutrophils with few or no organisms is a typical finding when specimens are available and should raise clinical suspicion of *Legionella* infection. However, such a stain is also seen with *Mycoplasma*, *Chlamydia*, and viral pneumonia.

CHEST RADIOGRAPHY

The initial common finding on chest radiography is a unilateral alveolar infiltrate that may progress to consolidation. Radiographic evidence of pneumonia is seen by the third day of the illness. Pleural-based rounded opacities may resemble pulmonary infarction. Small to moderate pleural effusions are seen in one-third of patients. Progression of infiltrates may occur, involving multiple lobes even while the patient is on appropriate antibiotic therapy. With apparent clinical response, cavitation is a common feature in the immunocompromised patient receiving corticosteroids or immunosuppressive drugs for legionellosis. Radiographic improvement often lags behind clinical response, and several weeks to months may pass before infiltrates resolve completely.

SPECIALIZED LABORATORY TESTS

Specialized laboratory testing is required to make the diagnosis of legionnaires' disease because it lacks specific findings in its clinical and radiographic presentation. Growth on special media, direct fluorescent antibody (DFA), serologic antibody titers, and urinary antigen detection.

Recovery of *Legionella* from respiratory secretions on buffered charcoal-yeast extract media containing antimicrobial agents to suppress competing microflora and dyes to enhance visibility is the gold standard test for diagnosis of legionnaires' disease. Acid-wash pretreatment of the sputum specimens reduces overgrowth of competing flora and improves sensitivity of the sputum culture. Specimens obtained by bronchoscopy have approximately the same yield as that for sputum samples; bronchoalveolar lavage gives higher yields than bronchial wash specimens. Pleural fluid obtained by thoracentesis should be evaluated by DFA stain and culture. The kit used for detection of *Legionella* antigen in urine has also detected *Legionella* in pleural fluid.

DFA staining is rapid and allows for direct visualization of *Legionella* in specimens. The sensitivity of the DFA stain of sputum ranges from 50% to 80%; organisms are more likely to be seen by DFA when multilobar infiltrates are present on chest radiography. The test is highly specific.

Serologic detection of antibodies is commonly made by either indirect fluorescent antibody or enzyme-linked immunosorbent assays. These techniques have become less useful owing to the availability of culture methods and specialized tests. Serologic diagnosis is made from acute and convalescent sera by documenting a fourfold rise in antibody titer to 1:128. A single titer of 1:256 in the setting of compatible clinical disease is considered presumptive evidence for legionnaires' disease. Maximal sensitivity requires both IgG and IgM tests. The sensitivity of serology is 40% to 60%. The specificity is estimated to be 95% and in cases of infection due to *L. pneumophila* serogroup 1. The usefulness of this test is therefore limited to epidemiologic studies. Specificity in diagnosing infection due to other serogroups or species is uncertain.

A rapid diagnosis of legionnaires' disease can be made by detecting *L. pneumophila* antigenuria. Urinary antigen testing is available only for *L. pneumophila* serogroup 1. The test is easy to perform and is not affected by antibiotics. The sensitivity for urinary antigen detection is 80%. The specificity approaches 100%.

OPTIMAL MANAGEMENT

The new macrolides, especially azithromycin, have replaced erythromycin as the drug of choice. Azithromycin, roxithromycin, clarithromycin, and josamycin have been therapeutically effective in anecdotal reports. These new macrolides have superior lung tissue penetrance and more potent intracellular and in vitro activity than erythromycin. The quinolones also have greater intracellular and in vitro activity than the macrolides. There have been numerous anecdotal successes with the quinolones, especially ciprofloxacin and levofloxacin. Rifampin is highly active in vitro and in vivo against *Legionella*. Tetracycline proved efficacious in the 1976 Philadelphia outbreak, and doxycycline and minocycline have also been efficacious.

Parenteral therapy is preferred initially until there is an objective clinical response, usually within 3 to 5 days. Oral therapy can then be substituted and continued for a total duration of 10 to 14 days, although a 21-day course has been recommended for immunocompromised patients or those with extensive disease seen on chest radiograph. Five to 10 days of azithromycin therapy is sufficient.

We recommend therapy with a newer macrolide, especially for community-acquired pneumonia in the immunocompetent patient. For organ transplant recipients in whom *Legionella* is a possible pathogen, we recommend a quinolone, especially ciprofloxacin or levofloxacin, as the drug of choice. The macrolides (but not

azithromycin) interact with tacrolimus and cyclosporine, which are used as immunosuppressive drugs after organ transplantation. Levels of tacrolimus and cyclosporine increase considerably when macrolides are coadministered, resulting in renal toxicity. The quinolones lack significant interactions with tacrolimus and are therefore recommended in the transplant recipient. The addition of rifampin as adjunctive therapy for legionnaires' disease may be considered in the immunocompromised patient or in the patient with radiographic evidence of multilobar pneumonia. However, rifampin has significant interactions with both tacrolimus and cyclosporine. Coadministration of rifampin with tacrolimus or cyclosporine may result in marked reduction in the levels of the immunosuppressive drugs, which may increase the risk of acute rejection. The dosages of the various antibiotics are shown in [Table 287.2](#).

Antimicrobial Agent	Dosage ^a
Azithromycin	500 mg ^b orally or intravenously every 24 h
Clarithromycin	500 mg orally or intravenously ^c every 12 h
Roxithromycin	500 mg orally every 12 h
Erythromycin	1000 mg intravenously every 6 h
Dicloxacillin	500 mg orally every 6 h
Levofloxacin	500 mg orally or intravenously every 24 h
Ciprofloxacin	400 mg intravenously every 12 h
Ofloxacin	750 mg orally every 12 h
Ofloxacin	400 mg orally or intravenously every 12 h
Doxycycline	100 mg ^b orally or intravenously every 12 h
Tetracycline	100 mg ^b orally or intravenously every 12 h
Tetracycline	500 mg orally or intravenously every 6 h
Trimethoprim/sulfamethoxazole	1600/800 mg intravenously every 6 h
Rifampin	300–600 mg orally or intravenously every 12 h

^a Dosages are based on clinical experience, not on controlled trials.
^b All recommend doubling the first dose.
^c Intermittent form not available in the United States.

TABLE 287.2. ANTIBIOTIC THERAPY FOR *LEGIONELLA* INFECTION

Treatment of Pontiac fever is primarily symptomatic; no antibiotic therapy is required.

PROGNOSIS

Patients treated early with appropriate antibiotics usually have an objective clinical response within 3 to 5 days. Mortality rate from legionnaires' disease in the immunocompetent patient is about 10% and depends primarily on the severity of the underlying illnesses and the timing of initiation of appropriate antibiotics. Mortality may approach 50% in nosocomial *Legionella* infection and reflects the severity of the underlying illnesses. The chest radiograph is not useful for monitoring clinical response.

PREVENTION

Identification of the contaminated environmental water source and subsequent disinfection of the water supply is the ultimate preventive measure. Two methods for disinfection are feasible: superheating the water such that the distal outlet temperature is 70° to 80° C, with flushing of the distal sites (faucets, showerheads) for at least 30 minutes and installing copper–silver ionization systems. Superheating and flushing can be quickly implemented to stop an outbreak, but afford no residual protection for regrowth of *Legionella*. Hyperchlorination is no longer recommended. Copper–silver ionization provides residual protection throughout the water distribution system and has proved cost-effective in hospitals. Based on studies in animals, development of an effective vaccine is feasible, but none is currently available.

CHAPTER 288: CHANCROID AND GRANULOMA INGUINALE

GEORGE P. SCHMID

[Chancroid](#)
[Granuloma Inguinale \(Donovanosis\)](#)

CHANCROID

Chancroid is a sexually transmitted disease characterized by one or more painful genital ulcers, often accompanied by painful inguinal lymphadenopathy.

INCIDENCE AND EPIDEMIOLOGY

Chancroid occurs throughout the world but is most common in developing countries, where it is often the most common of the sexually transmitted diseases characterized by genital ulcers. In the United States, as a result of numerous outbreaks, the number of cases in 1989 (4,714) was the highest since World War II, but for unclear reasons the number of cases declined to 243 in 1997—the lowest since World War II.

The epidemiology of chancroid is characterized by prostitution (often associated with drug use in the United States), poverty, travel, and lack of circumcision. Most cases occur in men, commonly in male:female ratios of 5 to 10:1 in outbreaks. Such ratios have led researchers to look for colonization or asymptomatic infection in women. Colonization has uncommonly been found, although occasionally cervical or vaginal ulcers are found in women who have no symptoms. Most frequently, women have symptomatic vulvar ulcers but continue to have sexual intercourse as a result of need for money or lack of medical care. In locations where chancroid is rare, cases can often be traced to infected people arriving from endemic locations. Uncircumcised men are more likely to acquire chancroid than are circumcised men.

Chancroid, particularly in Africa, has been highly associated with infection by HIV. In one study, 43% of uncircumcised men in whom genital ulcers (most commonly caused by *Haemophilus ducreyi*) developed after intercourse with a prostitute (most, but not all, of whom had HIV) became HIV-infected.

H. ducreyi, first observed by Ducrey in smears of material from ulcers in 1889, is a small, gram-negative bacillus.

PATHOGENESIS AND CLINICAL FINDINGS

The typical incubation period of chancroid is less than 10 days. Many patients first notice a papule or pustule, which ulcerates in 1 or 2 days, leaving an excavated, painful, raw ulcer with irregular erythematous margins. Some ulcers appear to be superficial, but most are deep ([Fig. 288.1](#)). More than 50% of patients have multiple ulcers. The most common location of ulcers is the coronal sulcus in circumcised men and the prepuce in uncircumcised men; ulcers in uncircumcised men may be hidden by a painful phimosis. In women, ulcers occur most commonly on the vulva, but anal, vaginal, and cervical ulcers are also found. Painful inguinal lymphadenopathy, which may become a bubo, occurs in up to 50% of men but in a smaller proportion of women; lymphadenopathy may be bilateral.

FIGURE 288.1. Single chancroid ulcer with unilateral lymphadenopathy.

LABORATORY FINDINGS

Definitive diagnosis of chancroid requires culture of *H. ducreyi*. Isolation is difficult, however, because the organism requires selective, enriched media and microbiologists experienced with the organism. Cultures taken from the cleaned ulcer should be placed directly onto culture media. Gram stains of ulcers, showing gram-negative coccobacilli in chains, suggest the diagnosis.

Other means of diagnosis, such as serologic testing or direct detection of organisms in lesions by immunofluorescence or polymerase chain reaction, are subjects of research.

OPTIMAL MANAGEMENT

Chancroid commonly must be differentiated from syphilis and genital herpes. Syphilis, a curable disease, should always be excluded by serologic testing (and, when possible, by darkfield microscopy). Ideally, a subsequent serologic test for syphilis should be performed; about 10% of patients with chancroid simultaneously have syphilis or genital herpes.

Erythromycin base, 500 mg orally, four times a day for 7 days; ceftriaxone, one dose of 250 mg intramuscularly (IM); ciprofloxacin, 500 mg orally, twice a day for 3 to 5 days; or azithromycin, 1 g orally, are highly effective. Patients with HIV infection do not respond as well as patients without HIV infection; some experts prefer the erythromycin regimen for HIV-infected persons. For ulcers, a subjective response to eventually successful therapy is almost always present by 48 hours, but complete healing usually takes 10 to 11 days. Response of lymph nodes usually parallels that of ulcers, but some nodes progress to fluctuation despite successful therapy. Fluctuant nodes should be aspirated through normal skin or incised. If nodes are aspirated, aspiration may need to be repeated.

Patients should receive an HIV test at the time of diagnosis; if it or the syphilis serologic test is negative, follow-up serology at 3 months is advisable. Cases of chancroid should be reported to health authorities. Sex partners in the 10 days preceding onset should be examined and treated, regardless of the presence of lesions.

GRANULOMA INGUINALE (DONOVANOSIS)

Granuloma inguinale is an indolent disease, sexually transmitted in most cases, characterized by granulomatous ulcers that progressively cause extensive tissue destruction.

INCIDENCE AND EPIDEMIOLOGY

Granuloma inguinale is concentrated in Papua New Guinea, southern India, southern Africa, and the Caribbean; scattered cases are reported elsewhere. In the

United States, fewer than 20 cases are reported annually. The disease is thought to be sexually transmitted because 90% of cases occur in the genital area, but it appears not to be highly contagious because many sex partners of infected persons have no symptoms. Slightly more cases occur in men than in women. Granuloma inguinale has been associated with increased risk of HIV infection.

Calymmatobacterium granulomatis, a gram-negative bacillus, was described by Donovan in 1905.

PATHOGENESIS AND CLINICAL FINDINGS

The typical incubation period is 7 to 30 days. The first manifestation is a papule or nodule, which, after several days, excavates into an ulcer with a beefy base that slowly enlarges over days to months (Fig. 288.2). The skin becomes infiltrated with plasma cells, neutrophils, and histiocytes. Several types of ulcers have been described, the most common being ulcerative (Fig. 288.2) and hypertrophic, with elevated and indurated lesions. Satellite lesions may occur on the genitalia or elsewhere from autoinoculation, and anal lesions are common in homosexual men. About 10% of patients have extragenital lesions only, most commonly in the mouth.

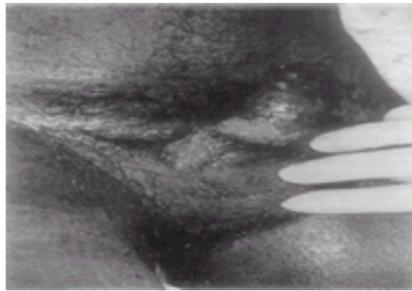

FIGURE 288.2. Granuloma inguinale causing erosion of the base of the penis and inguinal area. (Courtesy of Dr. F. Blais.)

LABORATORY FINDINGS

It is unclear whether *C. granulomatis* can be primarily isolated on artificial media; isolation in eggs and recently on culture using human mononuclear cells have been reported. Consequently, crush preparations of tissue looking for histiocytes with typical intracellular bacilli (Donovan bodies) are considered diagnostic. A small piece of tissue is placed on a slide, crushed with a second slide, air-dried or fixed on the slides with methanol, and stained. Giemsa or Wright stains are most commonly used. The Donovan bodies stain bipolarly, often with a capsule. Many crush preparations may be needed, and silver-stained biopsy specimens may provide an answer if crush preparations do not. Indirect immunofluorescence serology and polymerase chain reaction for detection of *C. granulomatis* in lesions are available on a research basis; skin tests are not available.

OPTIMAL MANAGEMENT

Extensive chancroid, carcinoma, secondary syphilis, and genital warts are the diseases that must usually be differentiated. No clearly preferred drug exists, and tetracycline, 500 mg orally four times a day, trimethoprim-sulfamethoxazole, two tablets orally twice a day, ceftriaxone, 1 g per day intramuscularly, chloramphenicol, 500 mg orally or intravenously three to four times a day, gentamicin, 1 mg per kilogram intramuscularly twice a day, and streptomycin, 1 to 2 g per day intramuscularly, are variously recommended. Therapy should be continued a minimum of 21 days or until lesions have healed.

CHAPTER 289: BARTONELLOSIS

NORBERT J. ROBERTS, JR

[Incidence and Epidemiology](#)
[Etiology](#)
[Pathogenesis](#)
[Clinical Findings](#)
[Laboratory Findings](#)
[Optimal Management](#)

Cutaneous manifestations (verruugas) and the acute form (Oroya fever) of bartonellosis were shown to have a common bacterial cause by Daniel Carrión (hence, Carrión's disease) in 1885. Characteristics of the organism as well as the geographic restriction of infection differentiate bartonellosis from other hemotropic bacterial infections.

INCIDENCE AND EPIDEMIOLOGY

Classically, sandfly vectors transmit this infection in river valleys of the Andes Mountains at altitudes of 2,000 to 8,000 feet in Peru, Ecuador, and Colombia. In those areas, bartonellosis is endemic, and outbreaks of Oroya fever occur even in recent times. Recent studies have reported cases in lowland areas of Ecuador, and several lines of evidence have raised the possibility of a rodent or other reservoir in endemic areas. The absence of detectable organisms on human blood smears or in culture in post- or interepidemic surveys, the infection of humans in otherwise uninhabited areas, and correlations with disease in animals all support the existence of a natural animal reservoir or reservoirs.

ETIOLOGY

The cause of bartonellosis, *Bartonella bacilliformis*, is small, motile, aerobic, and pleomorphic (small bacillary or coccobacillary), with unipolar flagella. It grows best at 28° to 30° C in nutrient agar containing fresh rabbit serum and hemoglobin. The organism stains reddish-purple with Giemsa stain and is gram-negative, but counterstains poorly. Molecular analyses place the organism within the a-2 subgroup of *Proteobacteria*, within a proposed family Bartonellaceae. *B. bacilliformis* has the closest homology (97.9% to 98.8%) to the four *Bartonella* species formerly termed *Rochalimaea*.

PATHOGENESIS

In nonimmune people, infection with *B. bacilliformis* results in Oroya fever. Large numbers of bacteria adhere to erythrocytes and endothelial cells. The infection causes erythrocyte deformation, which is only slowly reversible even in the absence of bacterial internalization. Reticuloendothelial cells destroy infected erythrocytes, whose life span is markedly shortened, and the bone marrow response is acutely depressed. Thus, anemia develops, which can be rapid in onset and severe. Organisms in the blood disappear or decline markedly during recovery, and second episodes of Oroya fever are unusual. In some persons, however, the organism has been reported to persist for up to 1 year or more in the blood. After a variable period, a chronic benign form of infection called *verruuga peruana*, hemangiomatic nodules commonly limited to the skin and subcutaneous tissues, usually develops.

CLINICAL FINDINGS

The incubation period of bartonellosis is about 3 weeks, but marked variability occurs. Blood cultures of apparently healthy people have been found to contain *B. bacilliformis*. In the nonimmune person, onset of the acute Oroya fever form of infection may be insidious or abrupt. Thus, the patient may have an insidious onset of anorexia, headache, malaise, and slight fever over several days. In this period, blood smears may be negative, but cultures may be positive. Alternately, the onset may be sudden with high fever, chills, diaphoresis, headache, and changes in mental function. A generalized, nontender lymphadenopathy may develop, but splenomegaly suggests the possibility of intercurrent infection. Jaundice, combined with an anemic pallor, may be present.

If the patient survives the acute episode, a convalescent phase begins with sudden disappearance of the organisms from the erythrocytes. Intercurrent infection is most common at this stage, with salmonellosis, tuberculosis, enteric bacterial infection, or parasitic infections most common (in more than 40% of cases) significantly affecting prognosis. Recurrence of fever or onset of marked leukocytosis suggests intercurrent infection.

Pain in the bones, joints, and muscles may persist after resolution of Oroya fever. The eruptive form of verruga may follow Oroya fever or may occur without a recent acute episode. The lesions usually appear on exposed parts of the body but may involve mucous membranes and internal organs. They appear in crops, and lesions in stages of growth and regression may coexist. The verrugas may be sessile, nodular, and pedunculated and can have a pustular or ulcerated form with secondary infection. Without complicating infection, they are nontender. The diversity of skin lesions, often appearing after the infected person leaves the endemic area, can make the diagnosis difficult. Epidemiologic data and other physical and microscopic observations aid in eliminating alternate diagnoses such as Kaposi's sarcoma and lymphoproliferative neoplasms. Onset of the cutaneous eruption usually is associated with a decrease in the joint pains and low-grade fever of the preeruptive stage, and anemia is not usually present.

The existence of mild clinical disease, leading to underreporting of bartonellosis has been suggested by serosurveys combined with clinical observations.

LABORATORY FINDINGS

The anemia of the Oroya fever form of bartonellosis is macrocytic, often hypochromic, with abnormal erythrocyte forms. A shift to the left in leukocyte differential, with variable absolute counts, is common. The erythrocyte count may fall rapidly, and numerous organisms can be seen on the blood smear. The most rapid diagnosis of Oroya fever patients, with the proper epidemiologic setting, may be obtained by eosin-thiazine stain (Diff-Quik) of blood smears. In a recently reported outbreak, approximately 60% of the cases had *B. bacilliformis* detectable on blood smears. IgM antibody may be present not only in patients with Oroya fever but in some healthy people, as well as those with verrugas. Crude *Bartonella* antigens, used in enzyme-linked immunosorbent assays, may cross-react with antibodies to other organisms, such as *Chlamydia psittaci*. Several purified *Bartonella* antigens, however, have been shown to be specific in immunoblot assays, and such assays can be used for confirmation when antibody is detected using crude *Bartonella* antigens.

The organism can be demonstrated histologically by electron microscopy and can be cultured from the cutaneous lesions and occasionally from the blood and bone marrow during the verruga peruana stage of the infection.

OPTIMAL MANAGEMENT

Prevention of bartonellosis requires control of the sandfly and insect repellents and bed netting for the individual. A dramatic clinical response in acute bartonellosis has been described with use of chloramphenicol, penicillin, and possibly other antibiotics. Organisms may persist beyond resolution of fever, which can occur within 24 hours. The presence of intercurrent infection may dictate the choice of antibiotics. Thus, chloramphenicol is often the drug of choice (2 g per day or more for 7 or more days) because of the frequency of complicating *Salmonella* infections. Newer antimicrobial agents with anti-*Salmonella* activity have not yet been reported to treat bartonellosis effectively. Severe anemia may require blood transfusions. The cutaneous lesions, if large or secondarily infected, may require surgical excision.

CHAPTER 290: CLOSTRIDIAL INFECTIONS

W. LANCE GEORG

[Incidence and Epidemiology](#)
[Pathogenesis](#)
[Clinical Findings](#)
[Laboratory Findings](#)
[Optimal Management](#)

Clostridia are gram-positive, spore-forming, obligate, anaerobic bacilli that are widely present in soil and the distal gastrointestinal tract of most animal species. They are in the feces of essentially all human beings. At least 40 to 50 different species of clostridia have been detected in studies of human normal fecal flora; these include all the species shown in [Table 290.1](#) except *Clostridium botulinum*.

Clinical Syndrome	Clostridium Species Usually Involved
Botulism	<i>C. botulinum</i>
Tetanus	<i>C. tetani</i>
Food poisoning	<i>C. perfringens</i> , type A
Enteritis necroticans	<i>C. perfringens</i> , type C
Antimicrobial agent-associated diarrhea and pseudomembranous colitis	<i>C. difficile</i>
Myonecrosis or gas gangrene	<i>C. perfringens</i> , <i>C. septicum</i> , <i>C. histolyticum</i>
Metastatic clostridial myonecrosis	<i>C. perfringens</i>
Neuropenic colitis	<i>C. tetani</i> , <i>C. septicum</i> , <i>C. perfringens</i>
Postabortal sepsis/uterine myonecrosis	<i>C. perfringens</i>
Emphysematous cholecystitis	<i>C. perfringens</i> , <i>C. septicum</i>
Suppurative or pyogenic infections (intra-abdominal abscess, fetal foot of the diabetic)	<i>C. ramosum</i> , <i>C. fermentans</i>
Transient (uncomplicated) bacteremia*	<i>C. perfringens</i> , <i>C. septicum</i>

*Twenty-five to 50 other species have also been isolated in low frequency from these infections.

TABLE 290.1. CLOSTRIDIAL DISEASES OF HUMAN BEINGS

Certain clostridial diseases of human beings may present as distinctive clinical syndromes (e.g., botulism, tetanus, and gas gangrene), whereas others (e.g., clostridial wound infection and antimicrobial agent-associated diarrhea) may not be distinguishable clinically from processes that do not involve clostridia. [Table 290.1](#) lists the clinical syndromes or diseases caused by clostridia and the species of *Clostridium* that are usually involved.

INCIDENCE AND EPIDEMIOLOGY

With the exception of mixed anaerobic-aerobic pyogenic infections and *Clostridium difficile*-associated (antimicrobial) diarrhea, clostridial diseases of human beings are relatively rare; unfortunately, the potential for death from these rare processes is substantial. This potential is often exaggerated by the failure of medical personnel to make the correct diagnosis early.

Botulism is a rare disease, although appreciable underreporting probably occurs in all countries. Spores of *C. botulinum* can be found in soil and sediment throughout the world. Most cases are caused by contamination of home-canned food with type A or type B spores; type E disease is usually caused by contaminated canned fish products. Because commercially canned products may be distributed to a large number of people over a large geographical area, the detection of cases may be difficult.

The incidence of tetanus is inversely related to the extent to which the population has been immunized. The number of cases of tetanus reported in the United States is fewer than 100 per year. In other parts of the world, the incidence is much higher. Wound contamination with feces or soil containing *Clostridium tetani* spores is the usual predisposing event; unfortunately, the tetanus-causing wound sometimes appears trivial or even noninfected. Tetanus has also been reported in association with injection drug use, apparently as a consequence of inoculation of spores by needle puncture.

Clostridial food poisoning is a relatively common form of food poisoning and is typically related to preparation of large quantities of food as for banquets and to improper storage after preparation.

C. difficile diarrhea is almost always associated with antimicrobial therapy. Almost all antimicrobial agents that are secreted in bile after parenteral administration or incompletely absorbed after oral administration may reach the colon in appreciable concentrations. High concentrations of these agents produce major changes in the bacterial flora of the colon and thereby permit *C. difficile* (when present) to proliferate and produce its toxins. Nosocomial transmission of the disease has been demonstrated; the spores of *C. difficile* are hardy and may be transferred from one patient to another directly by hospital personnel or by fomites, or both. The most common offending antimicrobial agents are penicillins, cephalosporins, and clindamycin. The incidence of *C. difficile*-induced diarrhea with such agents is probably about 5% of all cases treated. Almost all antimicrobial agents appear capable of causing *C. difficile* diarrhea.

The incidence of clostridial myonecrosis is difficult to estimate. Historically, the disease has been a product of warfare in which traumatic wounds were grossly contaminated with dirt or fecal material and were not debrided promptly. In contrast, an appreciable proportion (perhaps one-third to one-half) of cases of civilian clostridial myonecrosis occur after surgery; the remainder are related to accidental trauma or fetal abortion performed by nonmedical personnel. The usual predisposition is contamination of devitalized tissue, particularly muscle, by *Clostridium perfringens* or other histotoxic clostridia. Although soil may be the source of the organism in some instances, it is becoming increasingly evident that an appreciable number of cases are derived from clostridia in the large bowel. Metastatic clostridial myonecrosis (rather than wound myonecrosis) is a rare disease.

PATHOGENESIS

The pathogenesis of clostridial diseases is varied and depends to a great extent on the specific clinical entity under consideration. In general, clostridial diseases can be divided into those in which production of a toxin is known to be important and those in which a role for toxins has not been shown. Of the clinical entities shown in [Table 290.1](#), toxins are known to be important in all except emphysematous cholecystitis, transient (uncomplicated) bacteremia, and suppurative infections.

Botulism is a paralytic illness caused by *C. botulinum* types A, B, and E and occasionally type F. Each of these strains produces a potent neurotoxin that interferes with release of the neurotransmitter acetylcholine at peripheral cholinergic synapses; disease manifestations are related to this interference with neurotransmission. Minute quantities of the toxin (10^{-8} g) may be lethal. Disease in adults usually occurs as a consequence of ingestion of canned food contaminated with *C. botulinum*; after commercial or home canning, the heat-resistant spores germinate, multiply, and produce toxin. Unfortunately, canned foods that contain *C. botulinum* toxin may have a completely normal odor and appearance. Botulinal toxin is destroyed by boiling for 5 to 10 minutes or by heating to 80° C for 30 minutes. Rarely, an illness that resembles infant botulism occurs in adults; *C. botulinum* autointoxication, adult infectious botulism of unknown source, or “adult infant botulism” is caused by production of the toxin in the gut rather than toxin ingestion. Wound botulism is an uncommon entity that occurs when a traumatic wound is contaminated by soil and becomes infected by *C. botulinum*. Toxin is produced in situ and absorbed from the wound.

Tetanus, in contrast to botulism, is a spastic illness in which the cardinal manifestation is skeletal muscle tetany. The organism is usually introduced into the body through soil or fecal contamination of a traumatic wound; the wound occasionally may be so trivial as to not warrant medical attention. Toxin is elaborated in the soft tissues and in the nonimmune person is absorbed into the bloodstream and disseminated to tissues throughout the body. The toxin is thought to be taken up primarily by the peripheral endings of motor neurons and, to a lesser extent, by sensory and autonomic nerve endings. The toxin then travels along the neuron to the cell body in the central nervous system and then passes across the synapse into the presynaptic terminals of g-aminobutyric acid-releasing spinal inhibitory neurons. The

major activity of the toxin is prevention of neurotransmitter release by these inhibitory neurons; loss of this inhibitory effect leads initially to increased muscle tone and eventually to a sustained contraction (tetany) of both agonist and antagonist muscle groups.

Clostridial food poisoning is a relatively mild illness caused by enterotoxin-producing strains of *C. perfringens*. When foods, particularly meat or meat products, contaminated with *C. perfringens* are stored at ambient temperatures or are allowed to cool slowly after cooking, surviving organisms (usually spores) proliferate to extremely large numbers of vegetative cells. On ingestion, the vegetative cells begin sporulation and during sporulation produce an enterotoxin. In contrast to botulism, the toxin of *C. perfringens* is believed to be produced in vivo rather than being ingested.

Enteritis necroticans (pig-bel) is a severe necrotizing disease of the small intestine that is caused by the b toxin of *C. perfringens* type C. Although the pathophysiology of this disease is complex and unclear, essential factors appear to be reduced trypsin activity in the gut caused by poor nutrition and ingestion of protein-rich foods in conjunction with trypsin inhibitors (such as sweet potatoes). (Trypsin is thought to degrade the toxin.) The classic setting for enteritis necroticans is in the South Pacific islands when pigs are cooked in a manner that results in heavy contamination of the meat by *C. perfringens* type C. Clearly, however, other factors besides pig feasting predispose to enteritis necroticans, as indicated by outbreaks of disease in Europe in the 1940s and in other parts of the world in the 1980s and 1990s.

Antimicrobial agent-associated diarrhea and pseudomembranous colitis are caused by a toxin or toxins of *C. difficile*.

Clostridial myonecrosis (gas gangrene), uterine myonecrosis, and metastatic (or spontaneous) myonecrosis are entities that share the same pathophysiology. The first two processes involve accidental traumatic or surgical introduction of histotoxic clostridia (usually *C. perfringens*) into skeletal or uterine muscle. The process known as metastatic myonecrosis is initiated when a breach of the colonic or cecal mucosa permits *C. perfringens* or *Clostridium septicum* to gain access to the bloodstream. The most common bowel lesion is an unrecognized adenocarcinoma of the cecum, but other solid tumors of the bowel, leukemia, and neutropenia also have been implicated. By mechanisms that are not understood, the organism may lodge in a distant muscle and spontaneously cause myonecrosis. Myonecrosis is produced by local elaboration of a toxin, which is a lecithinase capable of hydrolyzing essential components of mammalian cell membranes. This toxin is therefore thought to be the principal cause of muscle necrosis and intravascular hemolysis.

Gangrenous or emphysematous cholecystitis is a particularly severe form of gallbladder disease that frequently yields *C. perfringens* on culture. Muscle invasion and clostridial toxemia are not features of this entity.

Suppurative or pyogenic infections involving clostridia are the most difficult for the clinician to interpret. Pyogenic infections caused by anaerobes are also likely to yield clostridia because anaerobic infections of the peritoneum, abdominal viscera, female genital tract, and lower extremities are usually derived from fecal flora. Such infections are often associated with soft-tissue (but not muscle) necrosis and may, on culture, yield several species of anaerobes (including clostridia) and several species of aerobic or facultative bacteria. Microscopic examination of infected tissue or exudate may reveal large gram-positive bacilli with square ends or spore-forming bacilli that resemble clostridia. Necrotizing clostridial toxins do not appear to be present in these infections, and many of the species of *Clostridium* that are recovered are not toxigenic.

Clostridial bacteremia in patients with skeletal or uterine myonecrosis is obviously a grave complication and may be associated with intravascular hemolysis. In other patients, however, bacteremia is often a benign clinical event. Frequently, the source of such bacteremia is not clinically evident, and the bacteremia is transient; the presumed source for such a process is the bacterial flora of the colon.

CLINICAL FINDINGS

BOTULISM

The typical incubation period for botulism is about 1 day, but it may range from several hours to 7 or 8 days. Early symptoms may be nausea, vomiting, and generalized lassitude. Extreme dryness of the mouth and throat may cause the patient to complain of sore throat. Ileus, constipation, urinary retention, and systemic hypotension may occur as a consequence of autonomic dysfunction. Neurologic symptoms are usually present early in disease. Symmetrical descending ocular and bulbar dysfunction manifest as diplopia, ptosis, blurred vision, dysphonia, dysarthria, and dysphagia occurs early and is followed by descending weakness of the muscles of respiration and of the extremities. The patient is afebrile, alert, and oriented. The presence of fixed or poorly reactive and dilated pupils in an alert patient is highly suggestive of botulism. The absence of ocular dysfunction does not exclude the disease. Neurologic examination may reveal generalized muscle weakness; sensation is intact; deep tendon reflexes may be present, absent, or depressed; and bowel and urinary bladder atony may be present. Wound botulism is similar clinically, except for the possible presence of fever due to wound infection.

Botulism has had a relatively poor prognosis. Because all aspects of the disease are reversible, the prognosis depends to a great extent on early diagnosis and institution of supportive care. The mortality rate now is 10% to 25%. The major problem in botulism is muscle weakness, which may progress after admission and be severe and protracted. Respiratory arrest has been the usual cause of death. Recovery from botulism is typically gradual over weeks to months.

TETANUS

Tetanus in adults has classically been described as having three clinical forms: cephalic tetanus, in which infection around the head leads to spasm of muscles supplied by the cranial nerves, particularly the facial nerve; local tetanus manifested by tetanic contractions of muscles at the site of infection; and generalized tetanus. Cephalic and local tetanus may progress to generalized tetanus; 75% or more of cases are of the generalized form. The incubation period varies from a few days to a few weeks and is roughly proportional to the distance of the wound from the central nervous system. Clinically, the first signs of tetanus are spasm of the jaw muscles (trismus), neck stiffness, and increased muscle tone and stiffness.

As the disease progresses, the muscle tone may increase to the point of rigidity. Rigidity of facial muscles leads to the facial sneer (*risus sardonicus*); the abdominal muscles and back muscles are tense; and rigidity of the extremity muscles holds the patient in a fixed position of extension. In severe disease, spasm of the powerful extensor muscles of the back may supervene over the spinal flexors to produce the backward arching of the back, termed *opisthotonos*. Muscle rigidity and spasm are extremely painful and can also readily produce bone fracture, particularly of the vertebrae. Spasm of pharyngeal muscles leads to difficulty in swallowing and may result in aspiration of oropharyngeal contents. Spasm of laryngeal muscles may cause airway obstruction, and diaphragmatic and intercostal muscle spasms may cause apnea. Autonomic dysfunction, manifested as fluctuating but sometimes severe hypertension and hypotension, tachycardia, cardiac arrhythmia, profuse diaphoresis, and fever (unrelated to infection) is common in severe cases. The patient's sensorium is not significantly impaired except in severe disease.

Tetanus is a reversible disease. The violent contractions of spasms may lead to respiratory insufficiency (the patient simply cannot ventilate) and to fractures, particularly of vertebrae. Complete recovery may require weeks or months.

OTHER DISEASE FORMS

The incubation period for *clostridial food poisoning* is usually 8 to 12 hours after ingestion of contaminated food. The prominent symptoms are watery diarrhea and moderately severe to severe midepigastic pain. Nausea may be present occasionally, but fever, chills, and emesis are rare, and the stools do not contain either blood or mucus. The disease resolves within 24 hours and is not associated with mortality or prolonged morbidity.

In contrast, *enteritis necroticans* is a serious, life-threatening disease. Illness usually occurs within 24 hours of ingestion of contaminated food and is characterized by vomiting, acute abdominal pain, diarrhea that is often bloody, and shock. Pathologically, inflammation and areas of necrosis are seen in the small intestine. Enteritis necroticans is a rapidly progressive disease. Because bowel necrosis is common, peritonitis may develop rather rapidly. Mortality with this illness has been about 40%.

C. difficile-associated diarrhea may develop during or up to 6 weeks after cessation of antimicrobial therapy. On occasion, it may occur as early as the second or third day of therapy. Occasionally, one or two doses of prophylactic antimicrobial therapy may cause *C. difficile* diarrhea. The course of *C. difficile*-associated diarrhea typically is that of a self-limited illness; resolution may occur in 80% to 90% of cases within 1 or 2 weeks after discontinuation of the offending antimicrobial agent. In a few patients, the illness may be protracted. Complications, including toxic megacolon, bowel perforation, and death, have been reported but are rare. Protein-losing

enteropathy, with significant hypoalbuminemia, may be relatively common.

The incubation period of *clostridial myonecrosis* is variable but typically is 3 or 4 days; it may, however, be as short as 8 to 12 hours. The first sign of myonecrosis is often the sudden onset of severe, unremitting pain at the affected site. The severity of the pain is remarkable because it frequently seems inconsistent with the relatively benign clinical findings at the site of muscle involvement. Moderate fever is typically present. The pain becomes progressively more severe. There is prominent local swelling and blanching of the overlying skin; a thin, but sometimes copious, serous, serosanguineous, or hemorrhagic exudate develops. The wound typically has a sweet odor, but a foul, offensive odor has been noted on occasion. A purple or blue discoloration of the skin may develop, and bullae filled with serosanguineous fluid occur. The sensorium is clear, but the patient is apprehensive and often has a sense of impending doom; toxic delirium, if it occurs, develops late in the course of disease. Other late findings include renal failure and hypotension. Although gas may be present, it is often difficult to detect early in the illness and may become abundant only in the terminal stages of disease.

Uterine myonecrosis lacks the cutaneous features. Jaundice, renal failure, and hemoglobinuria are relatively prominent features of uterine myonecrosis.

Unfortunately, the diagnosis of clostridial myonecrosis can be made definitively only at surgery by inspection of the muscle. Early on, the muscle is pale and edematous; subsequently, contractility disappears, the blood supply is lost, and gas may be detectable. Progressive reddening and purple mottling of the muscle occur and then dark discoloration as the muscle becomes necrotic and liquefies. All these findings may be present simultaneously in various areas of the same muscle, because the changes occur rapidly and the process spreads outward from the initial site of infection.

Emphysematous cholecystitis is an uncommon but severe variant of cholecystitis in which gas is in the gallbladder lumen and later in the surrounding tissues; gangrene and perforation of the gallbladder may develop. Patients with this disease tend to be elderly and have diabetes mellitus.

Suppurative or pyogenic infections that involve clostridia as part of a mixed flora do not appear to be clinically distinct from such infections that do not yield clostridia on culture. These infections are reviewed in [Chapter 291](#).

Bacteremia, which may occur with any of the myonecrosis syndromes, has also been associated with a form of neutropenic colitis; the organisms involved here are *C. septicum*, *C. perfringens*, and *Clostridium tertium*. Transient clostridial bacteremia, by definition, is a benign process that most frequently involves *C. perfringens*; a thorough history and physical examination are necessary and are usually sufficient to exclude potentially life-threatening infection. A second blood culture should be done as a precautionary measure. When *C. septicum* is the cause of transient bacteremia, however, investigation of the large bowel for occult malignancy is prudent.

Clostridial myonecrosis is an extremely rapidly progressive disease that may cause death within hours of onset; therefore, a clinical diagnosis must be established immediately and therapy instituted. The overall mortality rate is about 50%; mortality is lowest when an extremity (that can be amputated, if necessary) is involved and is highest when unresectable paravertebral or abdominal wall muscles are involved or when there is intravascular hemolysis.

LABORATORY FINDINGS

Laboratory findings, other than for selected tests, are not of clinical value and, for most of the important clostridial diseases, the diagnosis must be based on clinical criteria.

With regard to botulism, the cerebrospinal fluid examination is unremarkable. Electromyography, if done specifically as part of an evaluation for botulism, may yield findings consistent with that diagnosis; these findings include enhanced and prolonged post-tetanic facilitation, muscle fibrillation, and small-amplitude polyphasic motor unit potentials. Confirmation of disease by a reference laboratory is an important public health measure to help prevent additional cases. Hence, the suspect food item and the patient's serum, gastric contents, and feces should be tested for *C. botulinum*, toxin, or both, depending on the sample.

Although *C. tetani* may be recovered from the wound of patients with tetanus, it often is not. The diagnosis can be excluded (retrospectively) if protective levels of antitoxin from prior immunization are present in serum obtained before treatment with antitoxin.

Clostridial food poisoning is diagnosed by detecting high counts of enterotoxin-producing *C. perfringens* in the implicated food and by recovery of the same serotype from feces of affected patients.

C. difficile-induced diarrhea is most effectively diagnosed by detection in feces of either the enterotoxin or the cytotoxin, or both produced by the organism; the most sensitive and specific assay available is detection of a cytopathic effect in tissue culture.

Gram's stain of exudate in cases of suspected clostridial myonecrosis may reveal large, gram-positive bacilli with square ends and a paucity of intact leukocytes; culture of exudate or muscle fragments may help to establish the diagnosis retrospectively. For practical purposes, however, the diagnosis must be confirmed by inspection of the involved muscle.

OPTIMAL MANAGEMENT

The more severe clostridial diseases require extensive and aggressive supportive care because of a high incidence of complications, including secondary infection.

Specific therapy for food-borne botulism should include careful observation for signs of respiratory insufficiency and early institution of endotracheal intubation and ventilatory support. Purging of the bowel by gastric lavage, purgatives, and saline enemas is recommended. Trivalent antitoxin should be given as soon as the diagnosis has been established to neutralize toxin that may continue to circulate for prolonged periods. The antitoxin is available from state health departments and the US Centers for Disease Control and Prevention and is an equine preparation directed against *C. botulinum* types A, B, and E.

After hypersensitivity to horse serum has been excluded (or the patient has been desensitized), 2 ampules of the trivalent preparation should be administered and the dose repeated in 2 to 4 hours. Some experts recommend giving half of each dose intramuscularly and half intravenously, whereas others recommend giving the entire dose intravenously. Because the goal is to bind circulating toxin, it seems most appropriate to administer all of each dose intravenously. Hypersensitivity to horse serum occurs in about 20% of patients and anaphylaxis in 3% to 5%. The use of guanidine hydrochloride to promote acetylcholine release is not recommended because there is a lack of convincing scientific data regarding its efficacy. Treatment for wound botulism should also include aggressive debridement of the wound and therapy with penicillin G and other antibiotics as appropriate.

The most crucial aspect of tetanus management is ventilatory support. In full-blown tetanus, the spontaneous spasms prevent effective ventilation. Therefore, tracheostomy, assisted ventilation, and the liberal use of sedating agents, muscle relaxants, and neuromuscular blockade are crucial. Agents that have been used successfully include the shorter-acting barbiturates, benzodiazepines, and, in the case of severe spasms, curare-like agents. The induction of spasms can be decreased by reducing external stimuli; thus, placing the patient in a quiet room and avoiding unnecessary physical stimuli are important. Feeding by means of gastrostomy and parenteral hyperalimentation are preferred to feeding through a nasogastric tube because of the risk of massive and fatal aspiration. Wound debridement and administration of penicillin G (and other antimicrobial agents as indicated) are important to prevent continued toxin production. Passive immunization should be given as soon as the diagnosis is suspected. Passive immunization can be effected by intravenous administration of 3,000 units of human tetanus immune globulin; horse antitoxin should be avoided because of the risk of hypersensitivity reactions. Active immunization should be given using the standard regimen for adsorbed tetanus toxoid, because clinical tetanus does not necessarily confer immunity.

Tetanus can be prevented by active immunization of children and by aggressive surgical management of traumatic wounds and the use of passive and active immunization in these patients ([Table 290.2](#)). Unimmunized adults should receive adsorbed tetanus (and diphtheria) toxoid using a three-dose schedule consisting of an initial dose, a second dose 1 month later, and the last dose 6 months later. Although immunization may be protective for many years, administration of a booster every 10 years is recommended.

Immunization Status	Wound Status	Recommendation
Unimmunized or incompletely immunized	Low-risk wound	Immunization (see text)
	Tetanus-prone wound ^a or any wound neglected for 24 hours	1 dose of TIG ^b and administration of 250 U of HIG; complete immunization later
Fully immunized plus booster in past 10 years	Low-risk wound	None
	Tetanus-prone wound	1 dose of TIG if no booster in past 5 years
	Any wound neglected for 24 hours	1 dose of TIG plus 250 U HIG
Fully immunized but no booster in past 10 years	Low-risk wound	1 dose of TIG
	Tetanus-prone wound	1 dose of TIG
	Any wound neglected for 24 hours	1 dose of TIG plus 250 U HIG

^a A wound that is likely to have been contaminated with soil or feces (e.g., puncture, laceration, burn).

^b A combination of adsorbed tetanus and diphtheria toxoids for administration to adults; diphtheria-pertussis-tetanus vaccine should not be given to adults.

^c Human tetanus immune globulin.

TABLE 290.2. GUIDELINES FOR ACTIVE AND PASSIVE TETANUS PREVENTION

The management of enteritis necroticans is basically surgical and involves resection of necrotic bowel along with antimicrobial treatment of peritonitis when present. Preliminary data suggest that immunization may be useful.

The management of *C. difficile*-induced diarrhea involves discontinuation of the offending antimicrobial agent (or, if further treatment is needed, a change to another agent that is unlikely to cause diarrhea) and consideration of treatment directed against *C. difficile*. If the disease is of mild to moderate severity, removal of the offending antimicrobial agent may suffice. If the disease is severe, if it develops after discontinuation of antimicrobial therapy, or it does not improve within 3 or 4 days after discontinuation of therapy, then treatment directed against *C. difficile* should be instituted. Orally administered vancomycin, metronidazole, and bacitracin have been shown to be effective, and all strains are susceptible to these agents. Based on low cost and worldwide availability, metronidazole, 500 mg orally three or four times per day, is considered to be the drug of choice. Vancomycin, 125 to 250 mg orally four times per day, is as effective as metronidazole but is appreciably more expensive. The dosage of bacitracin is 25,000 units four times per day. Because of recent concerns about the emergence of vancomycin-resistant enterococci, vancomycin is now recommended only in cases of life-threatening or refractory (to other agents) *C. difficile*-induced diarrhea. Therapy with any of these agents should be for 7 to 10 days, and oral administration should be used to ensure adequate gut levels of drug.

Cholestyramine and other binding resins are often used for treatment of *C. difficile*-induced diarrhea; the data, however, suggest that the resins probably do not contribute significantly to patient management. Antimotility agents may exacerbate rather than relieve symptoms in patients with infectious diarrhea and should not be used. A distressing problem in management of *C. difficile*-associated disease is the propensity for relapse of disease after apparent cure with metronidazole, vancomycin, or bacitracin therapy. Such relapse may occur from several days to 6 weeks after treatment. The relapse invariably responds to retreatment with the same drug and is not the result of antimicrobial resistance, but relapse may occur after cessation of treatment. Administration of cholestyramine (but not in association with vancomycin), reconstitution of the fecal flora, and ingestion of *Saccharomyces boulardii* in capsular form have shown limited success in various reports. The most effective means of treating recurring relapsing disease is a prolonged tapering course of oral vancomycin over a 6- to 8-week period or longer.

The mainstay of treatment for clostridial myonecrosis is radical surgical debridement of affected tissues in an emergency setting; many operations are often needed to ensure that all devitalized tissue has been removed. High doses of penicillin G (about 20 million units daily for adults with normal renal function) is considered to be the antimicrobial therapy of choice; concomitant therapy may be indicated to cover resistant anaerobes such as *Bacteroides fragilis* and facultative gram-negative bacilli. Gas gangrene antitoxin has not been shown to be of value; because it is of equine origin, the potential benefit of such antitoxin is outweighed by the risk of adverse reactions. Similarly, hyperbaric oxygen therapy has been promoted for treatment of clostridial myonecrosis, but convincing data are not available. Definitive surgical debridement or amputation certainly should not be delayed to transport the patient to a facility that has a hyperbaric unit.

TABLE 291.3. SPECIFIC CLINICAL SITUATIONS PREDISPOSING TO ANAEROBIC INFECTION

The table content is illegible due to low contrast and small font size. It appears to be a list of clinical scenarios where anaerobic infections are common.

TABLE 291.4. ROLE OF ANAEROBES IN INFECTION

Anaerobes have been recovered from 5% to 15% of all positive blood cultures in various series. The most common isolate, *Propionibacterium acnes*, usually represents a skin contaminant but may be involved in bacteremia in the setting of an implanted prosthetic or intravascular device. The *B. fragilis* group is the anaerobe most commonly encountered. The second most common blood culture isolates of clinical significance are various *Peptostreptococcus* species. Anaerobes are found with some frequency in polymicrobial bacteremia. Distinctive features that are occasionally found and may be suggestive of anaerobic bacteremia include suppurative thrombophlebitis, metastatic infection, and hyperbilirubinemia.

Obligate anaerobes are uncommon causes of endocarditis, but microaerophilic streptococci may be found in up to 5% to 10% of cases. The most common anaerobe encountered is *Peptostreptococcus*. There is a tendency for *Bacteroides*, and perhaps other anaerobes, to produce large vegetations and embolic phenomena in large vessels.

Anaerobic bacteria are the primary cause of brain abscess, accounting for over 90% of cases. Background factors are often sinus, ear, or mastoid infection, oral or dental infection, pulmonary infection, or hematogenous spread from other foci. The anaerobes most commonly involved are *B. fragilis* and other b-lactamase-producing organisms such as *Prevotella* and *Porphyromonas*, along with *Fusobacterium*, *Peptostreptococcus*, *Actinomyces*, and *Clostridium*. Other important organisms include microaerophilic and viridans group streptococci. Anaerobes are not uncommonly involved in subdural empyema and are found occasionally in epidural abscess. They are not at all common in meningitis that has no associated brain abscess or subdural empyema.

Evidence indicates that anaerobes are found in eye infections more frequently than had been appreciated in the past. Anaerobic eye infections are likely to occur in the settings of trauma, surgery, soft contact lens use, topical corticosteroid therapy, and antibacterial therapy. Peptostreptococci are among the most commonly encountered anaerobes in eye infection. *P. acnes* has been recovered a number of times from infection secondary to implantation of artificial lenses. One of the few distinctive clinical syndromes of anaerobic infection of the eye is lacrimal canaliculitis involving *Actinomyces* species, which leads to concretions in the lacrimal canal.

Infections in the head and neck region in which anaerobes may play a role include acute and, more commonly, chronic sinusitis and otitis media, mastoiditis, membranous tonsillitis (Vincent's angina), peritonsillar abscess, deep neck space infections, odontogenic infections, and infection after radical neck dissection or other head and neck surgery. The usual oral anaerobes are the anaerobes most often involved (peptostreptococci, *Prevotella*, *Porphyromonas*, [the *B. fragilis* group may be found in 5% to 20% of certain infections in this area], and fusobacteria). *Fusobacterium necrophorum* is a key pathogen in Vincent's angina and its complications.

Anaerobic bacteria are commonly involved in root canal infection, periapical abscess, osteomyelitis of the jaw, periodontitis and abscess, stomatitis, noma, and other odontogenic infections.

Anaerobes are a major cause of pleuropulmonary infection but are often overlooked because of the difficulty in collecting appropriate specimens. Aspiration pneumonia and lung abscess involve anaerobes in over 90% of cases, and anaerobes are also found commonly in spontaneously occurring thoracic empyema. The most frequently encountered anaerobes are various species of pigmented and nonpigmented *Prevotella*, *Porphyromonas*, *Fusobacterium nucleatum*, and *Peptostreptococcus*. The *B. fragilis* group is found in about 5% of anaerobic pleuropulmonary infections. Viridans streptococci are also common. In hospitalized patients, colonization of the oropharynx with nosocomial pathogens such as staphylococci and various gram-negative bacilli may occur, and such organisms may then be involved in a subsequent aspiration pneumonia, along with the anaerobes.

Mediastinitis related to prior perforation of the esophagus, extension of a retropharyngeal abscess, or extension of cellulitis or abscess of dental origin from the neck commonly involves anaerobes.

In intra-abdominal infection, anaerobes play a prominent role, with the bowel as their point of origin. The *B. fragilis* group is found in most patients because it is the dominant member of the normal colonic flora. Other anaerobes encountered include *Bilophila wadsworthia*, *Peptostreptococcus*, *Sutterella*, and *Clostridium* species. *Escherichia coli* and streptococci, including enterococci, are also commonly found; in patients with prior hospitalization and antimicrobial therapy, more resistant gram-negative bacilli and staphylococci may be found. Wound and other postoperative infections have a similar infecting flora. In biliary tract infection, *Clostridium perfringens* and, less commonly, *B. fragilis* may be found, along with coliforms and enterococci. Anaerobes are probably the predominant pathogens in liver abscess; the most common anaerobic isolates are *Peptostreptococcus*, the *B. fragilis* group, *Prevotella*, *Porphyromonas*, *F. necrophorum*, other fusobacteria, clostridia, and *Actinomyces* species.

Anterior retroperitoneal abscess secondary to appendicitis or diverticulitis typically involves anaerobes. Colonic anaerobes, the *B. fragilis* group in particular, are commonly involved in perineal and perirectal infections.

Anaerobes are frequently involved in female genital tract infections of all types. Peptostreptococci, *Prevotella* (especially *Prevotella bivia* and *Prevotella disiens*, and pigmented species), and *Bacteroides*, including the *B. fragilis* group, are the most common anaerobic isolates, but clostridia, *Actinomyces*, and *Eubacterium* are also important.

Anaerobes are not involved in more than a small percentage of urinary tract infections; data indicate that at least 1.3% of cases of bacteriuria involve anaerobes.

Anaerobic bacteremia after urethral dilatation and other manipulation of the urinary tract has been reported.

Non-spore-forming anaerobes are involved in a wide variety of infections of the skin and underlying soft tissues. Included are such processes as cellulitis, pyoderma, cutaneous and subcutaneous abscesses, hidradenitis suppurativa, infected diabetic and other foot ulcers, infected decubitus ulcers, bite wound infections, burn wound infections, bacterial synergistic gangrene, necrotizing fasciitis, anaerobic streptococcal myositis, muscle abscesses in narcotic addicts, and synergistic nonclostridial anaerobic myonecrosis (synergistic necrotizing cellulitis). Infected decubitus ulcers are an important portal of entry for anaerobic bacteremia.

Evidence exists that non-spore-forming anaerobic bacteria are an important cause of osteomyelitis, particularly chronic bone infection of the lower extremities and pelvis (especially in patients with diabetes mellitus, other causes of vascular insufficiency or neuropathy, or trauma). The anaerobes involved vary with the site of the infection, but peptostreptococci are by far the most common; *B. fragilis* group strains are found in 10% to 15% of cases. Other *Bacteroides* and pigmented *Prevotella* are also important. Purulent arthritis involving anaerobes is uncommon but not rare; the *B. fragilis* group is the most common organism when the source is hematogenous. *F. necrophorum* is much less frequently encountered in bone and joint infections than was true in the preantimicrobial era.

Subareolar and recurrent breast abscesses often involve anaerobic bacteria and, as a result, may present distressing problems, such as chronic draining sinuses with foul-smelling pus. The pathogenesis appears similar to that of hidradenitis suppurativa.

Actinomycosis is a chronic destructive process of soft tissue and bone, and sometimes viscera, caused by various species of *Actinomyces* or by *Propionibacterium propionicum*. Pathologically, there is suppuration or granuloma formation, and fibrosis is common, leading to the woody character that is typical of such lesions on palpation. This has led thoracic surgeons, on occasion, to resect a lung on the mistaken impression that carcinoma was present. Chronic draining sinuses are common. The three classic types of actinomycosis are cervicofacial, thoracic, and abdominal, but any part of the body may be involved. A number of cases have been described in connection with the use of intrauterine devices. Some of these cases, as well as cervicofacial actinomycosis, have yielded *Eubacterium nodatum*, an organism that resembles *Actinomyces* closely.

DIAGNOSIS

Clinical clues to anaerobic infection are noted in [Table 291.5](#). The foul or putrid odor that may be evident is the only clue that is specific; no other organisms causing human infection aside from anaerobes (both clostridia and non-spore formers) lead to such an odor. The absence of such an odor, however, does not rule out the possibility of anaerobic infection. The other clues are nonspecific but are still useful in suggesting the likelihood of infection with anaerobes. The combination of tissue necrosis and gas, along with abscess formation, is highly suggestive of the probability of anaerobic infection, although this may be encountered in other types of infection. The unique morphology on Gram's stain applies particularly to the anaerobic gram-negative bacilli (and certain clostridia); commonly noted are irregular staining and pleomorphism.

Foul odor of lesion or discharge
Location of infection is primarily to a mucosal surface
Classic clinical picture of anaerobic infection (e.g., actinomycosis, lung abscess)
Infection secondary to human or animal bite
Clue in lesions or discharges
Tissue necrosis, gangrene, abscess formation
Septic thrombophlebitis
Infection associated with malignancy (especially colon, uterus, lung)
Previous therapy with aminoglycoside antibiotics (such as neomycin, gentamicin, and amikacin), streptomycin sulfamethoxazole, most other quinolones, tetracyclines, cephalosporins with poor activity against anaerobes (e.g., ceftriaxone)
Black discoloration of blood-containing swabs, these swabs may fluoresce red under ultraviolet light (pigmented <i>Prevotella</i> or <i>Porphyromonas</i> infections)
Presence of "sulfur granules" in discharges (actinomycosis)
Unique morphology on Gram's stain
No growth on routine culture—"sterile pus"
Failure to grow anaerobically, organisms seen on Gram's stain of original material
Growth in anaerobic zone of fluid media or of agar slants
Growth anaerobically on media containing 7% to 10% water of butyryl, mercapton, or polysulfide (or media also containing thiocyanate, in the case of gram-negative anaerobic bacilli)
Characteristic colonies on agar plates anaerobically (e.g., <i>Fusobacterium nucleatum</i>)
Young colonies of pigmented anaerobic gram-negative rods may fluoresce red under ultraviolet light (blood agar plate)

TABLE 291.5. CLUES TO ANAEROBIC INFECTION

Two important considerations for the clinician to remember in documenting the presence of anaerobes in a specimen and in determining the specific cause of an infection are the need for proper specimen collection (to avoid picking up normal flora from a nearby mucosal surface because anaerobes are prevalent in such flora) and the need for transport of the specimen under anaerobic conditions (to avoid die-off related to oxygen exposure). In most situations, proper specimen collection is not difficult. In the case of suspected anaerobic pulmonary infection (e.g., aspiration pneumonia), however, it may be something of a problem.

If pleural fluid is present, it should be tapped. In a true anaerobic pulmonary infection, this is likely to be an empyema, and the microbiology of the empyema fluid will accurately reflect that of the lung parenchyma itself. For less serious degrees of suspected anaerobic pulmonary infection, empiric therapy is reasonable. In a seriously ill patient in whom accurate bacteriologic diagnosis is essential for optimal therapy, if empyema fluid is not available, bronchoalveolar lavage with quantitative culture yields valuable information and may actually be life saving. Specimens obtained properly with a double-lumen, catheter-protected bronchial brush and cultured quantitatively are also satisfactory. A number of commercially available transport devices permit safe transport of delicate anaerobes as well as other organisms.

Results of anaerobic cultures are usually not available for at least a few days because anaerobes grow somewhat more slowly than nonanaerobes and because it may take some time to obtain in pure culture all the different organisms that may be present in a mixed infection. Accordingly, Gram's stain becomes a valuable diagnostic tool because, in a matter of minutes, the clinician may be able to suspect the presence of anaerobic bacteria of specific types and to determine the relative numbers of each of several organisms in a mixed infection.

OPTIMAL MANAGEMENT

The principles of treatment of non-spore-forming anaerobic bacterial infections are modifying the environment so that it is difficult for anaerobes to proliferate and checking the spread of anaerobes into healthy tissues. Measures to control the local environment include debridement of dead tissue, drainage of pus, elimination of obstruction, decompression of swollen tissues restricted by a tight fascia, release of trapped gas, improvement of circulation to the affected part, and improvement of tissue oxygenation. Antimicrobial agents play an important role in limiting the spread of anaerobes into healthy tissues.

The important role of surgical management should be evident from the previous discussion. There are some exceptions, however. Surgery is rarely indicated for lung abscess at present; it is actually contraindicated as a rule because of the hazard of spread of infection. In certain cases of abscess, especially intra-abdominal abscess, drainage may be effected by percutaneous aspiration, with or without catheter drainage, guided by ultrasonography or computed tomography. Hyperbaric oxygen is not beneficial in infection with non-spore-forming anaerobes.

Antimicrobial therapy is important in most anaerobic infections, whether or not surgical treatment has been carried out. Anaerobic bacteria have been manifesting increasing resistance to a number of antimicrobial drugs in recent years. The production of β -lactamases (by many species of anaerobic gram-negative rods and clostridia) is one of the major mechanisms of resistance. Others include plasmid-mediated transferable resistance, transposons, changes in the porin molecules of the outer membrane, and changes in the penicillin-binding proteins. The available agents are listed in [Table 291.6](#) in terms of their in vitro activity against various non-spore-forming anaerobes. The table presents in vitro data, but there are generally comparable clinical data. In vitro results may vary with the test method used (especially with ceftizoxime), strain selection, and other factors. In choosing among several agents, considerations include bactericidal or bacteriostatic activity, penetration of the central nervous system, toxicity, impact on the normal flora, severity of the infection, availability of an orally administered preparation, and cost as well as spectrum of activity against clostridia and nonanaerobes that may be present in a mixed infection.

CHAPTER 292: CAT-SCRATCH DISEASE, BACILLARY ANGIOMATOSIS, AND PELIOSIS HEPATIS

THOMAS H. BELHORN

[Incidence and Epidemiology](#)
[Etiology](#)
[Clinical Findings](#)
[Laboratory Findings](#)
[Optimal Management](#)

Cat-scratch disease (CSD) is a common clinical entity initially described in 1950. The classic disease presentation involves a persistent regional lymphadenopathy in the area of lymphatic drainage from a recent cutaneous cat-scratch lesion. Many subsequent case series have further defined and broadened the clinical presentation and diverse complications associated with CSD.

Since the 1980s, significant advances have been made in defining the causative agent of CSD, *Bartonella henselae*. In addition, several diseases seen primarily in HIV-positive patients, namely, bacillary angiomatosis, bacillary peliosis hepatis, and relapsing febrile bacteremia, are associated with this etiologic agent or closely related *Bartonella* species. Serologic and molecular studies are clarifying the pathogenesis of and relations between these diverse diseases.

INCIDENCE AND EPIDEMIOLOGY

CSD occurs throughout the United States and is estimated to affect approximately 22,000 people and result in 2,000 hospitalizations each year. Most cases are reported in patients 18 years of age or younger, with a slight predominance in boys. However, the disease is seen in all age groups. The increasing number of cases occurring from September through January is thought to reflect either the seasonal variation in acquisition of new family pets or breeding patterns of the reservoir or vector for the pathogen.

In up to 99% of CSD cases, exposure to a cat, usually a kitten, is documented. Symptomatic CSD patients were found to be more likely than a control group to have a pet kitten younger than 12 months of age, to have been scratched or bitten by a kitten, and to have had a kitten with fleas. The domestic cat has been shown to be a major persistent reservoir for the etiologic agent of CSD, with some cats exhibiting prolonged asymptomatic bacteremia. Bites and scratches by other animals, including dogs, may also expose a person to the infectious agent.

Bacillary angiomatosis and peliosis hepatis are most frequently diagnosed in patients with AIDS but are also reported in organ transplantation and cancer patients and rarely in immunocompetent people. Although a recent cat scratch or bite was originally reported in less than 20% of cases of bacillary angiomatosis, further studies have found a strong relation with cat exposure, especially in *B. henselae*-associated disease.

ETIOLOGY

B. henselae (formerly *Rochalimaea henselae*) is the predominant causative agent of CSD as well as of many cases of bacillary angiomatosis and peliosis hepatis. Serologic, epidemiologic, molecular (polymerase chain reaction [PCR]), and culture data have established a convincing link between this organism and the aforementioned diseases. *Afipia felis*, a small, pleomorphic bacillus originally isolated from CSD nodes, may rarely be involved in the pathogenesis of CSD. *Bartonella quintana* (formerly *Rochalimaea quintana*), the causal agent of trench fever, also plays a role in the development of bacillary angiomatosis and peliosis hepatis in HIV-positive patients. Other species of *Bartonella*, *B. clarridgeiae* and *B. elizabethae*, are less commonly associated with these diseases.

CLINICAL FINDINGS

The patient's age, status of the immune system, and mode of transmission influence the clinical presentation. [Table 292.1](#) lists the major characteristics of CSD and selected other diseases associated with *Bartonella* species.

	Cat Scratch Disease	Bacillary Angiomatosis/Bacillary Peliosis Hepatis
Peak age	Children	Young adult
Host immune status	Immunocompetent	Immunosuppressed (HIV, cancer, other), rarely immunocompetent
Predominant clinical manifestations	Lymphadenitis	Cutaneous/visceral lesions
<i>Bartonella</i> species	<i>B. henselae</i>	<i>B. henselae</i> or <i>B. quintana</i>
Antibiotics with possible efficacy	Cephalosporins, rifampin, gentamicin, trimethoprim-sulfamethoxazole, azithromycin	Clarithromycin, doxycycline, rifampin, azithromycin

TABLE 292.1. CHARACTERISTICS OF SELECTED DISEASES ASSOCIATED WITH *BARTONELLA* SPECIES

The initial manifestation of CSD is the appearance of a papule at the site of inoculation, often within the line of a previous cat scratch. This skin lesion, which is noted in 50% to 90% of cases, appears 1 to 2 weeks after contact with the animal. The lesion may evolve from a macule and eventually appear vesicular.

Between 7 to 50 days after the appearance of the cutaneous lesion, the characteristic regional lymphadenopathy ensues. The involved node is enlarged and usually tender. A single node is involved in approximately 50% of the cases, rarely more than three nodes are involved, and the nodes are usually in the distribution of lymphatic drainage from the initial lesion. The nodes affected, in decreasing order of frequency, are axillary, cervical, submandibular, inguinal, preauricular, femoral, and epitrochlear; rarely, postauricular and clavicular nodes and nodes in the chest wall may be involved. Associated fever and mild constitutional symptoms are present in less than one-third of cases, and fever over 39° C is rarely seen. The total duration of symptoms varies from several weeks to several months; suppuration of the node occurs in only 12% of cases.

Unusual manifestations involving different body systems are reported in 10% of CSD cases. Oculoglandular syndrome of Parinaud, first described in the previous century, is a granulomatous conjunctivitis with preauricular adenopathy secondary to inoculation of the agent in the periocular area. Neurologic complications of CSD are reported in more than 2% of patients and include peripheral neuropathy, myelitis, radiculitis, encephalopathy, and retinitis. Patients with encephalopathy can present with headache, seizures, combative behavior, or lethargy; permanent neurologic sequelae are infrequent. A granulomatous hepatitis, occasionally asymptomatic and visualized as hypoechogenic lesions in imaging studies, as well as a granulomatous splenitis, may occur. Immunocompromised patients with CSD may have severe and disseminated disease; renal and liver transplant recipients may present with shock, seizures, and granulomatous hepatitis. Other conditions associated with CSD have included osteomyelitis, pleural effusion, erythema nodosum, erythema annulare, and maculopapular rashes. Prolonged fever without focus has been occasionally described secondary to CSD; enteric acquisition of the agent has been postulated to be responsible for disease without obvious lymphadenopathy.

Bacillary angiomatosis and bacillary peliosis hepatis are distinct pathologic entities occurring almost exclusively in immunocompromised hosts. Cutaneous bacillary angiomatosis presents as single or multiple, red or purple, nodular/papular lesions on the skin or mucosa. These lesions, often described as having a cranberry appearance with occasional crusting or scaling, can reach several centimeters in diameter and ulcerate. Lesions may resemble and must be differentiated from Kaposi's sarcoma. Fever, chills, malaise, headache, weight loss, and other associated constitutional signs and symptoms are not unusual. Extracutaneous

manifestations have been described in such diverse organ systems as the central nervous system, muscles, soft tissue, bone marrow, liver and spleen, heart, and mucosal surfaces of the respiratory and gastrointestinal tract.

Bacillary peliosis hepatitis is a vasoproliferative condition involving the liver of HIV-infected patients, presenting as multiple cystic, blood-filled spaces in the liver. The usual symptoms and signs include fever, abdominal distention, diarrhea, and hepatosplenomegaly. The diagnosis can be made concomitantly with bacillary angiomatosis or bacteremia due to *Bartonella* species. Recurrent bacteremia and endocarditis, including the development of valvular vegetations, may also complicate *Bartonella* infection in the immunocompromised host.

LABORATORY FINDINGS

The diagnosis of CSD has traditionally been based on clinical criteria, mainly the presence of a dermal or conjunctival lesion, regional lymphadenopathy with negative studies for alternative causes, and the history of cat contact. Historically, delayed-type hypersensitivity skin testing with material made from heated purulent lymph node aspirates from CSD patients could be used for confirmation of the diagnosis. However, this test was not standardized or licensed for routine use; serologic testing and alternate methodologies are currently used for confirmation of the diagnosis.

Histopathologic study of CSD lymph nodes characteristically demonstrates granulomas, nonspecific inflammatory infiltrates, and stellate abscesses with central suppurative necrosis and surrounding rims of epithelioid histiocytes. Silver stain impregnation can demonstrate bacilli, especially in nodes examined early in the disease process.

Serologic methods such as an indirect fluorescent antibody assay and an enzyme immunoassay are used for confirmation of *B. henselae* infection and epidemiologic studies. In preliminary studies, the indirect fluorescent antibody assay has shown that 88% of patients with suspected CSD had serum titers of 1:64 or higher to *B. henselae* antigen, whereas healthy control subjects exhibited a low prevalence (3%) of significant titers. A positive serologic test should be interpreted within the clinical context.

Culture of clinical specimens is not routinely performed, because *Bartonella* species are extremely fastidious and require special culture conditions. Varying methods exist for culture of the organisms, but prolonged incubation of lysis centrifugation blood cultures plated onto freshly prepared blood agar plates can be used. PCR has been a useful technique for demonstrating *Bartonella* DNA in clinical specimens and, if available, is considered superior to routine culture for diagnosis.

For diagnosis of bacillary angiomatosis and peliosis hepatitis, lesion biopsy for staining and histologic examination, techniques using immunofluorescent antibody, culture, and PCR may be used. Histologic examination of bacillary angiomatosis lesions shows vascular proliferations with cuboidal "plump" endothelial cells protruding into the lumen. Bacillary forms on Warthin–Starry silver impregnation stain are seen in eosinophilic or basophilic granular material present in the interstitium. Infiltration of polymorphonuclear leukocytes is seen frequently. In addition to blood culture techniques described earlier, the agent can be cultured from tissues by incubation over bovine endothelial cell monolayers with subsequent transfer of supernatants to blood agar. Further optimization of culture and PCR methodologies are likely to enhance the sensitivity of these diagnostic techniques.

OPTIMAL MANAGEMENT

CSD is nonfatal and typically a self-limited disease, usually resolving in 2 to 4 months without specific therapy. Surgical biopsy or excision is not required unless malignancy cannot be excluded as a diagnosis. Routine incision of nodes should be avoided because chronic drainage may occur from the incision site. However, large-needle aspiration or incision and drainage of suppurative, painful nodes is indicated to relieve discomfort and to enhance recovery.

Although antibiotic therapy is unnecessary in patients with mild clinical presentations, patients with significant adenopathy or moderate to severe systemic manifestations may benefit from a course of antibiotics. Few controlled studies on the effectiveness of antibiotics in CSD exist, but various reports have indicated relief of systemic symptoms and a shorter duration of adenopathy with antibiotic therapy. In one prospective study, a 5-day course of azithromycin was found beneficial in decreasing CSD lymph node volume during the first month of observation. Uncontrolled studies have shown that treatment with rifampin, ciprofloxacin, intravenous gentamicin, trimethoprim-sulfamethoxazole, or doxycycline appears to yield the most beneficial results, whereas other antibiotics commonly fail to change the natural course of the disease or effect a decline in the sedimentation rate. The optimum duration of antibiotic therapy is likewise unclear, with courses ranging from 5 days up to 2 months. Some practitioners consider a 10- to 14-day course of ciprofloxacin the treatment of choice for adult CSD patients, although many other therapeutic regimens exist and alternate drugs are mandated in the young pediatric population.

Bacillary angiomatosis, bacillary peliosis hepatitis, and febrile bacteremia associated with *B. henselae* are associated with significant morbidity and mortality if untreated. These diseases often respond relatively well to antibiotic therapy, however, and the response may differ from that seen in typical CSD. Erythromycin or doxycycline have been used with success to resolve systemic symptoms or lesions in these diseases; rifampin may be used in combination with either drug in severely ill patients. Tetracycline, azithromycin, and minocycline have also been used successfully for therapy. The optimum duration of therapy with these agents is unclear, but a minimum course of 2 to 4 months is recommended for immunocompromised patients, depending on the type and extent of disease. Relapses are not infrequent, and lifelong therapy in HIV-infected patients may be necessary to prevent recurrences.

CHAPTER 293: RAT-BITE FEVER

RONALD G. WASHBURN

[Incidence and Epidemiology](#)
[Etiology](#)
[Pathogenesis and Pathology](#)
[Clinical Findings](#)
[Laboratory Findings](#)
[Optimal Management](#)

Rat-bite fever is a rare febrile systemic illness typically transmitted by the bite of a rat or other small rodent. The infection can be caused either by *Streptobacillus moniliformis* or *Spirillum minus*, bacteria commonly found in the oropharynx of rodents. Streptobacillary disease accounts for the majority of cases in the United States, whereas *S. minus* infections occur mainly in Asia. In Japan, the infection caused by *S. minus* is called *sodoku* (so, rat; *doku*, poison). [Table 293.1](#) compares the two different forms of rat-bite fever.

	<i>Streptobacillus moniliformis</i>	<i>Spirillum minus</i>
Organism	Gram-negative bacillus	Gram-negative coiled rod
Geographical distribution	North America, Europe	Asia
Mode of transmission	Rat bite, ingestion	Rat bite
Clinical syndrome		
Relapsing fever	Yes	Yes
Rash	Yes	Yes
Arthritis	Yes	No
Ulceration of initial bite wound	No	Yes
Regional lymphadenopathy	No	Yes
Diagnosis	Culture	Direct visualization, xenodiagnosis
Therapy	Penicillin G	Penicillin G

TABLE 293.1. COMPARISON OF TWO TYPES OF RAT-BITE FEVER

INCIDENCE AND EPIDEMIOLOGY

In the United States, persons at risk for percutaneous inoculation with *S. moniliformis* include animal laboratory workers and persons inhabiting crowded urban dwellings or rural areas infested with wild rats. Rat-bite fever is typically transmitted by the bite or scratch of rats, mice, squirrels, or carnivores that prey on those rodents, including cats, dogs, pigs, ferrets, and weasels. The infection may also be acquired by handling dead rats, with no apparent breach of intact skin. Between 10% and 100% of both wild and laboratory rats harbor *S. moniliformis* in their nasopharyngeal flora. Although healthy laboratory mice generally are not colonized with the organism, they do share with rats the susceptibility to epizootic infection characterized by pneumonia, otitis media, polyarthritis, and septicemia.

Oral ingestion of *S. moniliformis* has caused epidemics of Haverhill fever (erythema arthriticum epidemicum), an illness resembling rat-bite fever. Potential sources of such outbreaks include water or milk contaminated with rat excrement.
