Most lung abscesses are caused by infectious agents, including bacteria, fungi, parasites, and mycobacteria. However, most cases involve a mixed bacterial flora that includes anaerobes up to 90% of the time. Aerobic bacilli may be present in up to 50% of patients, but in most cases they coexist with anaerobes. The proposed pathogenesis is a combination of infective orolingival material in a host who has a predisposition to aspirate this material into a lung that cannot adequately clear the infectious challenge. The first pathogenetic factor, aspiration, is more likely to occur in patients who have altered consciousness or oropharyngeal/esophageal dysfunction. This includes patients with alcoholism, seizure disorders, drug overdose, general anesthesia, protracted vomiting, or neurologic disorders such as cerebrovascular accident, myasthenia gravis, amyotrophic lateral sclerosis, and other bulbar processes. As the second required factor, the material aspirated must contain a large concentration of potentially pathogenic bacteria. Aspiration of gastric contents may not always lead to infection, especially if the aspirate is only acid, in which case a chemical pneumonitis will result. On the other hand, orolingival material often contains a large bacterial inoculum and can lead to lung abscess, especially if the inoculum size is enhanced by the presence of poor dentition or gingival disease.

Bartlett and Finegold found that about 73% of patients with lung abscess had at least one predisposing factor for aspiration, and many had gingival disease found after careful dental evaluation. Obviously, not all patients with risk factors develop abscesses, and other factors, particularly underlying comorbidities and impaired host defenses, also play a key role in the development of lung abscess. In patients with HIV infection, the risk factors for lung abscess include advanced illness (CD4 cell count less than 50 per cubic millimeter), prior pulmonary infection, and other opportunistic infections, but gingivitis is not common in this population and therefore anaerobic abscess is uncommon in this group.

According to animal and some human data, the development of a lung abscess occurs 7 to 14 days after aspiration of infectious orolingival material into the terminal bronchioles. When aspirated in large amounts, a single species of anaerobic bacteria, or a combination of multiple organisms, can cause a necrotizing pneumonitis that, if progressive, can become a lung abscess. The location of the abscess is determined by gravity and body position at the time of aspiration. As most patients aspirate while upright or supine, a lung abscess is typically located in the basal segments of the lower lobes, the superior segment of the lower lobe, or the posterior segments of the upper lobes. With these pathogenetic principles in mind, it is clear that an abscess arising in an edentulous patient (without oral anaerobes) or in a location other than the ones mentioned should raise suspicion of another pathogenic process, involving either a nonanaerobic infection or an endobronchial obstructive lesion.

MICROBIOLOGY AND CLASSIFICATION

About 90% of lung abscesses are associated with anaerobic bacteria, either as the primary pathogens or in combination with aerobic bacterial agents. This observation may be explained by the fact that anaerobic bacteria commonly cause necrotizing infection, but other bacteria that can cause lung abscess include *Staphylococcus aureus*, *Escherichia coli*, *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*, other gram-negative bacilli, *Streptococcus pyogenes*, *Pseudomonas pseudomallei* (melioidosis), *Haemophilus influenzae* (especially type b), *Legionella pneumophila*, *Nocardia asteroides*, *Actinomyces* species, and, rarely, *Pneumococcus*. Parasites (*Paragonimus westermani*, *Entamoeba histolytica*), fungi, and mycobacteria may also cause lung abscess.

In infections caused only by anaerobes, the average number of different organisms isolated is three; thus, most lung abscesses are polymicrobial infections, involving either strictly anaerobes or a combination of aerobic and anaerobic bacteria. In only 10% of lung abscesses are anaerobes not involved; these are caused by aerobes only. Although the bacteria involved in this process have not changed much in recent years, the taxonomy of the bacteria has changed, and the current names of the most clinically relevant organisms are *Peptostreptococcus* species (anaerobic gram-negative cocci), *Fusobacterium nucleatum*, *Fusobacterium necrophorum*, *Porphyromonia* species (formerly classified in the genus *Bacteroides*), and *Prevotella melanogenicus* (also formerly classified in the genus *Bacteroides*).

The bacteria involved in lung abscess may differ in the HIV-infected patient. In this population, anaerobes do not play an important role, and the infection often involves a mix of aerobic bacteria. However, 25% of this population can have a lung abscess involving fungi and protozoa. In one series of lung abscess patients with HIV infection, the most commonly identified pathogen was *P. aeruginosa*, but other pathogens included other gram-negatives, *Pneumocystis carinii*, and fungi such as *Aspergillus* species and *Cryptococcus neoformans*.

Lung abscesses have been categorized using several methods, but the separation between acute and chronic has the most clinical utility. This distinction is not absolute but can aid the clinician by helping in the planning of treatment regimens and by identifying patients who may need further diagnostic evaluation, such as bronchoscopy. A patient with an acute lung abscess presents with symptoms of less than 2 weeks' duration; he or she is less likely to have an underlying neoplastic process and is more likely to have infection caused by a virulent aerobic bacterial agent such as *S. aureus* or *K. pneumoniae*. A patient with a chronic lung abscess (symptoms lasting more than 4 to 6 weeks) has an underlying cancer or an infection with a less virulent anaerobic agent. There may be some overlap in this classification scheme, as it does not take into account host defense factors or serious comorbidities. However, this scheme can be useful during the initial patient evaluation to help plan a diagnostic and therapeutic approach.

CLINICAL FEATURES

SIGNS AND SYMPTOMS

Most patients with lung abscess have an insidious presentation, with symptoms lasting at least 2 weeks before evaluation. Signs and symptoms include cough, foul-smelling sputum that forms layers on standing, hemoptysis (in 25% of patients), fever, chills, night sweats, anorexia, pleuritic chest pain (in 60% of patients), weight loss, and clubbing. Patients with HIV infection have the same constellation of symptoms with lung abscess as other populations. Although most of these signs and symptoms are sensitive, their specificity is extremely low. However, foul-smelling or putrid sputum is a highly specific sign that is pathognomonic for anaerobic infection, although it is found in only 50% to 60% of patients. A history of weight loss is also common, occurring in 60% of patients, with an average loss of between 15 and 20 pounds. As described earlier, historical data may also include risk factors for aspiration such as alcoholism, drug overdose, seizures, head injury, or stroke,

and the absence of such risk factors should prompt a search for a diagnosis other than primary lung abscess.

PHYSICAL EXAMINATION

Physical examination may reveal fever, altered sensorium, poor dental hygiene, and clubbing. Fever is found in about 60% to 90% of patients with lung abscess, with an average maximal temperature of 39.1°C. Clubbing is present in about 20% of patients but, like other findings, it lacks sensitivity and specificity.

LABORATORY DATA

Laboratory data are also nonspecific, showing an elevated erythrocyte sedimentation rate, anemia of chronic inflammation, and leukocytosis. Culture and microbiologic information are generally not helpful unless the abscess is caused by nonanaerobic agents such as mycobacteria, fungi, or aerobic bacteria. Sputum examination is useful only in helping to diagnose nonanaerobic pulmonary infections because sputum can pick up anaerobes as it is expectorated through the oral cavity; thus, the finding of these organisms is not specific. More invasive methods are available for microbiologic diagnosis (transtracheal aspiration and bronchoscopy) but are rarely used because most patients are treated empirically and invasive diagnostic procedures are usually not justified. If the patient presents in an atypical way or is not responding to therapy, then invasive techniques are justified to look for an endobronchial obstructive lesion. If the abscess is associated with an empyema, as is the case 30% of the time, then culture of the empyema fluid may yield reliable bacteriologic data.

RADIOLOGIC DATA

Although certain historical information may suggest the presence of a lung abscess, a radiograph is needed to define the presence of a cavitary lung lesion ([Table 367.1](#)). The typical chest radiograph reveals a solitary cavitary lesion measuring about 4 cm in diameter with an air-fluid level. Some studies reported that the size of the cavity is helpful in distinguishing neoplastic versus non-neoplastic lung abscesses, but others have not found such a correlation. Instead, the amount of inflammation, seen radiographically surrounding the abscess, can help to identify patients more likely to have an underlying nonmalignant abscess. In contrast to an infectious abscess, neoplasms tend to have less surrounding radiographic infiltrate.

Infectious	Neoplastic
Anaerobic abscess	Bronchogenic carcinoma
Aerobic abscess	Squamous cell
Infected bulla	Metastatic carcinoma
Infected pulmonary infarct	Colorectal
Empyema	Renal
Tuberculosis	Lymphoma
Actinomycosis	Hodgkin's disease
Fungi	Inflammatory
Coccidioidomycosis	Wegener's granulomatosis
Histoplasmosis	Sarcoidosis
Blastomycosis	
Aspergillosis	
Cryptococcus	
Parasitic	
Echinococcus	
Amebiasis	

TABLE 367.1. DIFFERENTIAL DIAGNOSIS OF CAVITRY LESION ON CHEST RADIOGRAPH

Radiographically, empyema and lung abscess are sometimes difficult to distinguish from one another. An empyema is a purulent infection usually confined to the pleural space, although it can develop as a complication of or serve as a cause of a lung abscess. Both entities can have air-fluid levels, but one is intraparenchymal (lung abscess) and the other is extraparenchymal (empyema). If an empyema contains an air-fluid level, then a bronchopleural fistula is usually present.

When the chest radiograph cannot distinguish these entities, a computed tomography scan should be performed. On the computed tomography scan, a lung abscess usually appears as a thick, irregular-walled cavity with no associated lung compression; an empyema has a thin, smooth wall with compression of the uninvolved lung. The real difficulty arises when one tries to differentiate a lung abscess from an empyema with a bronchopleural fistula, as both may be radiographically similar. The radiographic characteristics that help identify an empyema with a bronchopleural fistula are listed in [Table 367.2](#).

- Prior pleural fluid on chest radiograph
- Extension of the air-fluid level toward the chest wall
- Extension of the air-fluid level across a fissure
- Tapering of the air-fluid collection

TABLE 367.2. RADIOGRAPHIC CHARACTERISTICS OF AN EMPYEMA WITH A BRONCHOPLEURAL FISTULA

If a lung abscess fails to communicate with a bronchus, the characteristic cavity with an air-fluid level will not be seen radiographically. This often leads to initial misdiagnosis because no clear abscess can be visualized. If no air-fluid level is seen, then the radiographic appearance is one of a focal, ground-glass infiltrate with indistinct borders. Given the history of illness and this radiographic picture, the differential diagnosis includes other chronic pulmonary infections such as postobstructive bacterial pneumonia, nocardiosis, fungal pneumonia, tuberculosis, and actinomycosis. Various noninfectious pulmonary processes can also be confused with a noncavitary lung abscess. These include bronchiolitis obliterans organizing pneumonia, radiation pneumonitis, chronic eosinophilic pneumonia, and allergic bronchopulmonary aspergillosis. When a lung abscess presents in this manner, it is usually necessary to do further diagnostic workup, such as bronchoscopy or lung biopsy.

When the radiograph reveals multiple cavitary lesions, it usually indicates that a necrotizing pneumonitis is present. This type of presentation is usually acute and fulminant, and secondary to virulent aerobic bacteria such as *S. aureus* or *K. pneumoniae*. The presence of multiple bilateral cavities should raise suspicion of a hematogenously disseminated process such as a right-sided endocarditis. Multiple cavities are rarely secondary to an anaerobic process unless the patient is severely immunocompromised or recurrently aspirating, or the anaerobe is virulent, causing a necrotizing pneumonitis, instead of the typical lung abscess.

TREATMENT

In the preantibiotic era, three treatment modalities were available for lung abscesses: supportive care, postural drainage with or without bronchoscopy, and surgery. All three led to the same mortality rate, 30% to 35%. Currently, the mainstay of therapy for lung abscess is antimicrobial therapy that targets orogingival anaerobes, the organisms present in 90% of lung abscesses. The initial antibiotic is usually intravenous penicillin or clindamycin, although in the past oral antibiotics have been used (usually 3 g per day of penicillin V). Penicillin has historically been the first choice of therapy since it was first used in the 1950s, with a cure rate of 95%. With the growing concern over penicillin-resistant anaerobes, two trials compared clindamycin to penicillin in a prospective study design. Both found that clindamycin therapy was associated with fewer treatment failures and a shorter time to symptom resolution. Metronidazole, when evaluated as a single treatment modality, was found to have a 43% rate of treatment failure and hence is not recommended for single-agent therapy. Metronidazole in combination with penicillin is considered an appropriate treatment regimen for lung abscess because the penicillin is active against the aerobic and micro-aerophilic streptococci that are often resistant to

metronidazole.

Many other antibiotics have in vitro activity against orolingival anaerobes but have never been evaluated in clinical trials to gain U.S. Food and Drug Administration approval for use in these infections. These antibiotics include chloramphenicol, imipenem, meropenem, erythromycin, azithromycin, clarithromycin, the new fluoroquinolone trovafloxacin, and b-lactams with a b-lactamase inhibitor (e.g., ampicillin with sulbactam, piperacillin with tazobactam).

After selecting the appropriate antimicrobial agent, the next issue is determining the length of therapy. Although there is controversy in the literature, the approach taken by Bartlett seems the most conservative and appropriate. He recommends treating most patients until the pulmonary infiltrates have resolved or until the residual lesion is small and stable. In the initial stage of treatment, intravenous antibiotics are given until the patient is afebrile and shows clinical improvement (4 to 8 days). This is followed by the use of oral medications, usually for a prolonged time, although the length of time needed varies from patient to patient. Many patients require a total of 6 to 8 weeks of antimicrobial therapy.

In the past, bronchoscopy was part of the standard of care of patients with lung abscess. Its uses included helping to promote drainage and ruling out underlying malignancy. Currently, bronchoscopy is reserved for patients with atypical presentations who are suspected of having an underlying malignancy or an aspirated or obstructing foreign body. Bronchoscopy is no longer routinely used for abscess drainage because most abscesses communicate spontaneously with the airways and drain. There is also a possibility of rupturing an abscess during bronchoscopy and causing contamination of previously uninvolved lung segments. In regard to bronchoscopy's use to rule out underlying malignancy, Sosenko and Glassroth have identified several patient characteristics that correlate with underlying carcinoma. The criteria for bronchoscopy in patients with lung cavities included mean oral temperature below 100°F, absence of systemic symptoms, absence of predisposing factors for aspiration, and a mean leukocyte count below 11,000 per cubic millimeter. If a patient with a lung abscess had more than three of these factors, then an underlying carcinoma was a strong possibility. Other factors that should prompt bronchoscopic evaluation include atypical clinical presentation (noncavitary lesion, fulminant time course), atypical abscess location (especially those located in the anterior half of the lung), abscess formation in an edentulous patient, failure to respond to antibiotics, and lung abscess associated with mediastinal adenopathy, which is not commonly found in anaerobic lung infection.

Complications of lung abscess include empyema formation resulting from a bronchopleural fistula, massive hemoptysis, spontaneous rupture into uninvolved lung segments, and nonresolution of the abscess cavity. Although uncommon, these complications often require prolonged medical therapy as well as surgical intervention, either with tube thoracostomy (in the case of empyema) or lung resection (in the case of massive hemoptysis).

Surgical treatment for lung abscess is usually reserved for complications such as massive hemoptysis, bronchopleural fistula, and empyema. It is also used in the setting of fulminant infection and in patients who fail medical therapy. About 10% of lung abscesses require surgical intervention. Prognostic factors associated with medical treatment failures include recurrent aspiration, large cavity size (more than 6 cm), prolonged symptom complex before presentation, abscess associated with an obstructing lesion, abscesses with thick-walled cavities, and serious comorbidities such as advanced age, neoplasm, and other chronic medical conditions. Patients with HIV infection have a greater than 50% rate of recurrence or death due to lung abscess. Certain organisms are also associated with a high mortality, probably as a reflection of underlying comorbid illness. These include *P. aeruginosa*, *S. aureus*, and *K. pneumoniae*. An alternative to surgical drainage is percutaneous catheter placement into the abscess cavity, which should be reserved for patients who are unresponsive to medical therapy and have lung abscesses located peripherally. This is not a standard therapy, but some investigators have successfully treated patients in this manner, without patients developing a bronchopleural fistula. These patients should also continue to receive intravenous antibiotics during and after percutaneous drainage.

CHAPTER 368: PULMONARY TUBERCULOSIS

CHARLES L. DALEY

[Incidence and Epidemiologic Factors](#)
[Pathogenesis](#)
[Clinical Presentation](#)
[Diagnostic Methods and Laboratory Findings](#)
[Optimal Management](#)
[Role of Public Health in Tuberculosis Control](#)

Tuberculosis (TB) is caused by bacteria of the *Mycobacterium tuberculosis* complex, which includes *M. tuberculosis* (MTB), *M. africanum*, and *M. bovis*. Infection with these organisms occurs primarily through inhalation of infected aerosols that are generated when persons with infectious TB cough. TB may occur shortly after infection or decades later. Clinical manifestations are protean, and although the lungs are most commonly affected, TB may occur at extrapulmonary sites. Persons coinfecting with HIV are at increased risk of developing TB, and coinfection is known to alter the clinical and radiographic presentation of TB. This chapter reviews the epidemiology, pathogenesis, clinical presentation, and treatment of pulmonary TB and latent tuberculous infection.

INCIDENCE AND EPIDEMIOLOGIC FACTORS

An estimated 30% of adults are infected with organisms in the *M. tuberculosis* complex. Worldwide, there are about 9 million cases of TB annually, with over 3 million deaths attributable to the disease. In fact, TB is the leading cause of death from an infectious or parasitic disease worldwide, and it is the number one killer of HIV-infected individuals. High population growth rates and coinfection with HIV are expected to worsen the global morbidity and mortality caused by TB.

In the United States, the TB case rate declined 3% to 5% per year from 1953 to 1984. Between 1986 and 1992, the numbers of TB cases increased by approximately 20%. This increase in the number of cases was the result of at least four major factors: (a) inadequate public-health measures; (b) immigration from countries where TB is prevalent; (c) coinfection with HIV; and (d) the emergence of multidrug-resistant strains of MTB. Fortunately, since 1992 cases are again on the decline.

Certain individuals are at higher risk of developing TB simply because they are more likely to be exposed and thus infected with MTB ([Table 368.1](#)). For example, approximately 40% of reported TB cases in the United States and 70% of cases in California occur in foreign-born individuals who come from areas where the disease is endemic. Other populations with an increased prevalence of tuberculous infection include low-income populations, the homeless, and injection drug users.

High-Prevalence Groups	High-Risk Groups
Persons born in countries with high prevalence of tuberculosis	Persons with HIV coinfection
Low-income populations	Close contacts of persons with infectious tuberculosis
Injection drug users	Persons whose tuberculin skin test results converted to positive within the past 2 years
Persons who live or spend time in some facilities (boarding homes, correctional institutions, homeless shelters, drug treatment centers)	Children <6 years of age
	Persons who have chest radiographs suggestive of old tuberculosis
	Injection drug users
	Persons with certain medical conditions*
	Recent immigrants (<5 years)

* Diabetes mellitus, alcohol, prolonged therapy with corticosteroids, immunosuppressive therapy, leukemia, Hodgkin's disease, head and neck cancer, end-stage renal disease, certain medical conditions, malnutrition.
(From U.S. Centers for Disease Control and Prevention. Core Curriculum on Tuberculosis: What the Clinician Should Know, third edition, 1994.)

TABLE 368.1. HIGH-PREVALENCE AND HIGH-RISK GROUPS

Anyone infected with MTB can develop TB disease, but certain groups have a higher than normal risk for progressing to active disease ([Table 368.1](#)). HIV coinfection is the strongest known risk factor for the development of TB, but there are also other medical conditions associated with an increased risk of developing disease. Persons who were recently infected with MTB are at greater risk of progressing to active disease within the next 1 to 2 years than persons infected in the distant past.

PATHOGENESIS

TB is spread from person to person through the air by droplet nuclei; particles 1 to 5 μm in diameter that contain viable MTB. Droplet nuclei are expelled into the air when patients with infectious TB create an aerosol by talking, coughing, or singing. Three factors determine the likelihood of transmitting TB: the number of bacilli being expelled into the air, the concentration of organisms in the air, and the length of time the contact breathes the infected air. Whether or not an inhaled tubercle bacillus establishes an infection in the contact's lung depends on both the bacterial virulence and the inherent microbicidal ability of the alveolar macrophage that ingests it. If the bacillus survives the initial defenses, it can multiply in the alveolar macrophage.

The tubercle bacillus grows slowly, dividing approximately every 18 to 24 hours. The organisms grow essentially unimpeded until a cellular immune reaction develops after 2 to 8 weeks. However, before the development of cellular immunity, an inflammatory response appears and is associated with the spread of tubercle bacilli through the lymphatics to the hilar lymph nodes or through the bloodstream. Small numbers of MTB organisms are deposited in other organs that act as potential sites for disease.

Once cell-mediated immunity develops, collections of activated T cells and macrophages form granulomas that wall off the MTB organisms. Antibodies against MTB are formed but do not appear to be protective. For most persons with normal immune function, infection with MTB appears to be arrested once cell-mediated immunity develops, even though small numbers of viable bacilli remain in the granuloma. Although a primary complex can sometimes be seen on chest radiograph, most tuberculous infections are inapparent. A positive tuberculin skin test (TST) is the only way to detect latent infection with MTB. Persons with tuberculous infection who do not have active disease are not infectious and thus cannot spread the disease to others.

If cell-mediated immunity cannot contain MTB, the infected person progresses to active disease. Untreated, about 10% of persons with normal immunity develop active TB, 5% within the first 1 to 2 years of infection. In contrast, persons who are coinfecting with HIV have a 5% to 10% annual risk of developing active disease. When active TB develops soon after infection with MTB, the disease is referred to as primary tuberculosis. In contrast, when TB develops years or even decades after the initial tuberculous infection, the disease is referred to as postprimary or reactivation disease. Exogenous reinfection, due to acquisition of a second strain of MTB, appears to be relatively uncommon in immunocompetent individuals but may be more common in HIV-infected persons.

CLINICAL PRESENTATION

The clinical manifestations of TB may vary depending on whether the disease is primary or reactivation in nature. However, it is important to note that the clinical manifestations of active TB are the result of a balance between host defenses and bacterial virulence; therefore, there may be a continuum of disease and the clinical presentation of disease may be altered in severely immunocompromised patients.

PRIMARY TUBERCULOSIS

The initial infection in the lung, referred to as primary infection, may cause an inflammatory infiltrate that may be seen on a chest radiograph: the middle or lower lung zones are often affected. The draining lymph nodes may enlarge and compress adjacent bronchi, particularly in infants and children. Parenchymal disease usually clears as cell-mediated immunity develops, and it tends to clear more rapidly than nodal involvement. If the parenchymal disease persists beyond the development of

cell-mediated immunity, cavitation may occur, although this is uncommon.

Pleural effusions are a common manifestation of primary TB. Presumably this results when a peripheral, caseous focus ruptures into the pleural space. Initially, the pleural fluid has characteristics of acute inflammation, with a predominance of polymorphonuclear cells. Later, the pleural fluid has a predominance of mononuclear cells, including large numbers of TB-specific CD4⁺ T lymphocytes. Pleuritis due to tuberculosis may present as an acute illness characterized by cough, fever, and pleuritic chest pain. Without treatment, the pleuritis resolves, but about half of all patients develop active TB later.

REACTIVATION TUBERCULOSIS

During most initial infections with MTB, small numbers of organisms are disseminated hematogenously and some become seeded in the apexes of the lung. The organisms appear to grow preferentially in this well-oxygenated environment and can progress to active disease months or years after the initial infection. This accounts for the characteristic radiographic location of reactivation disease, which in most cases occurs in the apical or posterior segments of the upper lobes. In areas of chronic infection or areas of caseation, fibrosis may occur. Fibrocaseous lesions may contain live mycobacteria for many years, and these are the lesions that may reactivate years later.

EXTRAPULMONARY TUBERCULOSIS

As tubercle bacilli spread throughout the body during the initial infection, they can lodge in any organ and produce a focus of disease: 17% of patients with TB have an extrapulmonary form of disease only. HIV-infected patients are more likely to develop an extrapulmonary site of infection than HIV-seronegative persons, and the risk increases as the CD4 lymphocyte count decreases. The two most commonly involved extrapulmonary sites are peripheral lymph nodes and the pleura. Other common sites for extrapulmonary TB are those in well-vascularized areas, such as the kidney, the meninges, the spine, and the growing ends of long bones.

MILIARY TUBERCULOSIS

Miliary or disseminated TB occurs when tubercle bacilli spread throughout the body, via the bloodstream, resulting in small (about 2 to 5 mm) granulomatous lesions. Miliary TB is seen more commonly in infants, children under 4 years old, and immunocompromised individuals. Disseminated TB usually develops insidiously with systemic symptoms such as fever, weakness, weight loss, fatigue, and anorexia. Cough and dyspnea may also be prominent symptoms. The mean duration of symptoms approaches 16 weeks, but some patients may go undiagnosed for over 2 years.

DIAGNOSTIC METHODS AND LABORATORY FINDINGS

In order to diagnose TB, the disease must first be suspected. TB should be suspected in certain high-risk groups ([Table 368.1](#)) and when the clinical and/or radiographic presentation is consistent with TB.

MEDICAL HISTORY

The medical history should elicit whether or not the person suspected of having TB has been exposed to MTB or has a previous history of tuberculous infection or disease. Symptoms that are compatible with active TB include fever, chills, night sweats, fatigue, cough, and weight loss occurring over several weeks to a year. Of note, up to 20% of patients with pulmonary disease are asymptomatic. Because patients coinfecting with HIV are at increased risk of developing TB, and the signs and symptoms of active disease may be atypical in this group, TB should be considered when any respiratory infection occurs in these patients or when there is a fever of unknown origin.

TUBERCULIN SKIN TEST

The tuberculin skin test (TST), utilizing purified protein derivative (PPD), is the only way to identify persons with latent tuberculous infection. The intracutaneous Mantoux method is performed by injecting 0.1 mL of PPD containing 5 tuberculin units (TU) into the volar surface of the forearm. The TST is read by noting the transverse diameter of induration (not erythema) at the site of injection at 48 to 72 hours. The sensitivity of tuberculin testing in patients with proven pulmonary tuberculosis is 80% to 95%. Multiple puncture (Tine) PPD skin tests are unreliable and not recommended.

The TST should not be used to screen the general population. Instead, the test should be used to screen populations that have an increased prevalence of tuberculous infection or an increased risk of progressing to TB once infected. Examples of these two categories are listed in [Table 368.1](#).

The TST must be interpreted in the context of a person's risk factors and the prevalence of TB in the community ([Fig. 368.1](#)). False-positive results occur more often in persons living in areas with a high prevalence of nontuberculous mycobacterial infections and in persons recently vaccinated with BCG. False-negative reactions may be due to anergy and often occur in children less than 6 months old and in persons with HIV infection. Up to 20% of patients with active tuberculosis have a negative TST skin test that may convert to positive shortly after initiation of therapy. Thus, the diagnosis of TB should never be excluded because of a negative TST.

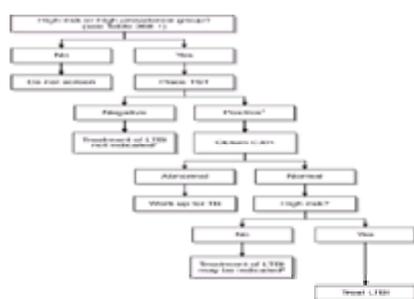

FIGURE 368.1. Management of latent tuberculous infection. TST, tuberculin skin test; CXR, chest radiograph; TB, tuberculosis; LTBI, latent tuberculous infection.

*TST more than or equal to 5 mm is considered positive for persons with HIV infection, close contacts to infectious cases, and persons with an abnormal CXR consistent with old TB. TST more than or equal to 10 mm is considered positive for other high-risk and high prevalence groups. TST more than or equal to 15 mm is considered positive for low-risk reactors (who should not be screened).

†Treatment of LTBI may be indicated for close contacts to infectious persons, even if the initial tuberculin skin test is negative. In persons with symptoms consistent with TB, a CXR should be obtained even if the skin test is negative.

‡Depending on local epidemiologic circumstances, treatment may be indicated.

CHEST RADIOGRAPH

The chest radiograph is useful for determining if there are radiographic findings consistent with TB. However, a chest radiograph alone cannot confirm or exclude the diagnosis of TB. The radiographic manifestations may vary, depending on when the initial infection occurred and whether or not the patient is coinfecting with HIV. Patients coinfecting with HIV may sometimes have a normal chest radiograph but still be coughing up large numbers of tubercle bacilli.

BACTERIOLOGIC EXAMINATION

Sputum specimens, material from fiberoptic bronchoscopy, gastric washings, or other body fluids can be stained for the presence of acid-fast bacillus (AFB) and cultured for MTB. Direct acid-fast smears are generally positive when there are at least 10^5 organisms per milliliter, but fluorescent staining for mycobacteria can detect fewer organisms. Three early-morning sputum specimens are preferred. Because other nontuberculous mycobacteria are also acid-fast, staining with nucleic acid probes specific for MTB complex can be helpful. Nucleic acid amplification tests are more sensitive in detecting small numbers of MTB and offer promise for a more rapid diagnosis of TB. The tests available currently perform best with AFB smear-positive specimens. However, depending on the clinical suspicion of active disease, direct nucleic amplification tests may be useful, even in AFB smear-negative cases.

Culture of MTB remains the only means for confirming the diagnosis of TB. Because of the growth characteristics of MTB, traditional culture methods take 2 to 8 weeks. Radiometric methods using liquid media take less time, but mixed cultures of MTB and nontuberculous mycobacteria are possible. MTB can be identified from cultures and distinguished from other nontuberculous mycobacteria by chemical means or with nucleic acid probes.

DRUG SUSCEPTIBILITY TESTING

Drug susceptibility studies should be performed on all initial isolates and only by laboratories that have experience in culturing mycobacteria and a sufficient volume of such tests. Traditional susceptibility studies involve the proportions method, and careful control is required for meaningful results. Automated radiometric procedures for drug susceptibility testing offer more rapid results. In the near future, nucleic amplification or other molecular techniques may allow for the rapid identification of drug resistance.

OPTIMAL MANAGEMENT

TREATMENT OF TUBERCULOSIS DISEASE

Identifying and treating patients with TB is the most effective way of preventing transmission in the community. TB must be treated with at least two drugs to which the organism is susceptible to prevent the emergence of drug resistance. Dosages of commonly used drugs are shown in [Table 368.2](#). A regimen containing isoniazid (INH) and rifampin for 6 months, plus pyrazinamide for the initial 2 months, is considered standard short-course therapy. Ethambutol or streptomycin should be added to the initial regimen if drug resistance is suspected or the patient comes from an area or population in which the prevalence of INH resistance is 4% or higher. In most urban areas of the country, levels of INH resistance are above 4%.

Drug	Dose in weight			Reference Dose (mg)	Reference Dose (mg/kg)	Comments
	5	10	15			
Isoniazid	100 mg	200 mg	300 mg	300 mg	6 mg/kg	Significant interactions with rifampin, phenytoin, and carbamazepine. Significant interactions with rifampin, phenytoin, and carbamazepine. Significant interactions with rifampin, phenytoin, and carbamazepine.
Rifampin	150 mg	300 mg	450 mg	450 mg	9 mg/kg	Significant interactions with rifampin, phenytoin, and carbamazepine. Significant interactions with rifampin, phenytoin, and carbamazepine.
Ethambutol	150 mg	300 mg	450 mg	450 mg	9 mg/kg	Significant interactions with rifampin, phenytoin, and carbamazepine. Significant interactions with rifampin, phenytoin, and carbamazepine.
Pyrazinamide	1500 mg	3000 mg	4500 mg	4500 mg	90 mg/kg	Significant interactions with rifampin, phenytoin, and carbamazepine. Significant interactions with rifampin, phenytoin, and carbamazepine.
Streptomycin	750 mg	1500 mg	2250 mg	2250 mg	45 mg/kg	Significant interactions with rifampin, phenytoin, and carbamazepine. Significant interactions with rifampin, phenytoin, and carbamazepine.

TABLE 368.2. DOSAGE RECOMMENDATIONS FOR THE TREATMENT OF TUBERCULOSIS IN ADULTS

Other treatment regimens require at least 9 to 24 months of therapy, depending on the drugs used. In addition to the first-line agents noted in [Table 368.2](#), there are other drugs available for the treatment of TB that are needed to treat patients with multidrug-resistant disease. These medications include the quinolones, *para*-aminosalicylic acid, ethionamide, cycloserine, clofazamine, and injectables such as kanamycin, capreomycin, and amikacin. A review of the treatment of multidrug-resistant disease is beyond the scope of this chapter. However, if any drug is stopped due to underlying drug resistance or drug toxicity, expert consultation should be obtained to determine the appropriate duration of therapy.

In order to prevent acquired drug resistance, clinicians must prescribe an adequate regimen and ensure that patients adhere to therapy. Directly observed therapy (DOT) should be used whenever possible. If DOT is not available, combined preparations that include INH and rifampin (Rifamate), or INH, rifampin, and pyrazinamide (Rifater), should be considered.

Persons with active untreated pulmonary TB are infectious, particularly those who have AFB identified in a sputum specimen. Treatment of TB rapidly renders these patients noninfectious. According to the U.S. Centers for Disease Control and Prevention (CDC), patients are not considered infectious if they have been receiving adequate therapy for 2 weeks or longer, have a favorable clinical response to therapy, and have three consecutive negative sputum smear results from sputum collected on different days.

Special Circumstances

HIV Coinfection

Despite being immunocompromised, HIV-infected individuals with TB respond well to regimens containing INH and rifampin (see [Chapter 294](#)). Thus, the current recommendations are to begin the same antituberculosis regimens as used in HIV-seronegative cases. Therapy should be initiated as soon as TB is suspected because delays in treatment have been associated with a high mortality rate.

Recently, the treatment of TB in HIV-infected individuals has become more complicated because of the availability of highly effective antiretroviral agents, such as the protease inhibitors (PIs) and non-nucleoside reverse transcriptase inhibitors (NNRTIs). These drug have bidirectional pharmacokinetic interactions with rifamycin derivatives, such as rifampin, rifapentine, and rifabutin. Some combinations of these drugs are contraindicated, and for other combinations dosages must be adjusted. Therefore, consultation with an expert in the field is necessary to determine the best treatment regimens for HIV-infected patients with TB.

Children

Children should be treated with the same regimens as those recommended for adults, but doses should be adjusted appropriately. Some experts do not recommend the use of ethambutol until the child can be monitored accurately for optic neuritis (the primary drug toxicity associated with this drug). Additionally, some experts recommend increasing the duration of therapy to 12 months in children with disseminated, meningial, or bone and joint disease.

Pregnancy

Pregnant women with active TB must be treated because the risk of transmitting TB to the fetus is always greater than any small risks of therapy. However, streptomycin and the quinolones should be avoided if possible because of potential fetal toxicity. Pyrazinamide is not recommended currently by the U.S. Food and Drug Administration in the setting of pregnancy because of a lack of data regarding teratogenicity.

Monitoring For Adverse Reactions

All patients receiving antituberculosis therapy must be educated about possible drug-related adverse reactions. The patients should be warned about insignificant side effects, such as the orange discoloration of urine from rifampin, as well as the symptoms of potentially serious side effects ([Table 368.2](#)). Patients must be instructed to seek medical attention immediately if they have symptoms of a serious side effect. Baseline measurements of hepatic enzymes, bilirubin, serum creatinine, and blood urea nitrogen, as well as a complete blood cell count including platelets, are obtained before drug therapy is begun. A serum uric acid level is obtained if pyrazinamide is included in the drug regimen. Visual acuity and red/green color discrimination are monitored in patients receiving ethambutol. Although routine laboratory monitoring for drug toxicity may not be necessary, many centers repeat liver function tests after a month of therapy and thereafter if symptoms develop or the liver function tests are elevated significantly.

Evaluating Response to Therapy

Sputum examinations at monthly intervals are important to monitor response to therapy. Smears and cultures should be negative after 3 months of therapy. If the sputum remains positive after 3 months, the patient must be reevaluated; special attention is given to monitoring adherence and ruling out acquired drug resistance. Drug susceptibility tests are repeated, and the appropriateness of the drug regimen is reassessed. Most patients with HIV coinfection respond well to treatment. However, the duration of therapy is extended if response is delayed or incomplete. These patients must be carefully monitored after completing therapy for possible recurrence of disease.

TREATMENT OF LATENT TUBERCULOUS INFECTION (PREVENTIVE THERAPY)

Persons who are infected with MTB but do not have active disease should be considered for treatment of their latent infection. However, treatment is not recommended for all persons with a positive TST. Instead, therapy should be provided to those persons at higher risk for tuberculous infection and/or TB ([Fig. 368.1](#)). For persons who are at increased risk of progressing to disease, treatment of latent infection is indicated, regardless of age. However, for persons who have a positive TST but who are not at increased risk of developing TB, therapy is generally reserved for younger individuals. Everyone being considered for therapy should receive a clinical and radiographic evaluation to exclude the possibility of active disease

Historically, the primary treatment regimen for latent tuberculous infection has been INH 300 mg given daily (or 900 mg per day given twice a week) for 6 to 12 months. Recently, other options have become available as well ([Table 368.3](#)). The CDC currently recommends 9 months of INH, 2 months of rifampin and pyrazinamide, or 4 months of rifampin for all persons with evidence of tuberculous infection, regardless of HIV status. Patients with parenchymal abnormalities on the chest radiograph due to prior inadequately treated TB should be given 9 to 12 months of INH, 4 months of rifampin (with or without INH), or 2 months of rifampin and pyrazinamide, once active disease has been ruled out. For persons exposed to an INH-resistant patient, rifampin alone for 4 months or rifampin and pyrazinamide for 2 months may be used.

Drug	Frequency and Duration	Comments
Isoniazid	Daily or twice weekly* for 6–9 mo	Nine months is the preferred duration
Rifampin plus pyrazinamide	Daily or twice weekly* for 2 mo	Rifabutin may be substituted in patients receiving PIs or NNRTIs*
Rifampin	Daily for 4 mo	For persons who cannot tolerate pyrazinamide

* DDT must be used for twice-weekly regimens.
 * Rifabutin may be used with certain PIs or NNRTIs, dose adjustment of rifabutin and/or the PI may be necessary.
 DDT, directly observed therapy; PI, protease inhibitor; NNRTI, non-nucleoside reverse transcriptase inhibitor.

TABLE 368.3. RECOMMENDED REGIMENS FOR TREATMENT OF LATENT TUBERCULOUS INFECTION IN ADULTS

Monitoring for Adverse Effects

Patients should be informed of the possible drug-related toxicities and told to return to the clinic as soon as any of these symptoms develop. Most persons taking INH do not require routine laboratory monitoring of liver function tests. Persons who have other risk factors of hepatotoxicity (e.g., HIV infection, pregnant or post-partum, taking concurrent hepatotoxic medications, significant alcohol use, chronic or acute liver disease) should have baseline liver function tests measured. These tests should be repeated periodically in particularly high-risk individuals or if the baseline liver function tests are abnormal. Whether or not regimens containing rifampin and pyrazinamide require more intensive monitoring is not yet known. Routine chest radiographs are not recommended as follow-up for persons with a positive TST; rather, periodic review of symptoms is indicated.

ROLE OF PUBLIC HEALTH IN TUBERCULOSIS CONTROL

Control of TB transmission is possible only with the coordinated efforts of the private medical community and public health departments. All patients with suspected TB must be reported to the local department of public health as soon as possible (exact reporting requirements vary from jurisdiction to jurisdiction). Outpatient management of TB and the timely identification and treatment of contacts of patients with TB need to be coordinated with appropriate public health personnel. The local health department often has resources that are not available to the private medical community, such as the ability to provide DOT. In some jurisdictions, incentives and enablers such as housing, food, and transportation may be provided to help ensure completion of therapy. In addition, most jurisdictions have laws that can assist with the management of cases involving nonadherent infectious persons.

CHAPTER 369: BRONCHOPULMONARY ASPERGILLOSIS

ALAN F. BARKER

[Definitions and Incidence](#)
[Pathogenesis](#)
[Clinical Findings](#)
[Differential Diagnosis](#)
[Optimal Management and Prognosis](#)

DEFINITIONS AND INCIDENCE

Bronchopulmonary aspergillosis (BPA) occurs in persons with damaged airways, as found in those with asthma and cystic fibrosis. In North America, an estimated 5% to 10% of steroid-dependent asthmatic patients have BPA, whereas in Great Britain the percentage approaches 20% or higher. Because wheezing, cough with phlegm, and dyspnea are typical features of patients with asthma, a heightened awareness or different diagnostic criteria may partly explain differences in prevalence. Debate is ongoing regarding whether the entity is strictly a hypersensitivity reaction to fungal (*Aspergillus*) spores or is an actual infection due to *Aspergillus*.

Immune features include the setting of usually atopic asthma, peripheral and airway eosinophilia, very high IgE levels, type I skin test positivity to *Aspergillus* protein, and minimal airway mucosal damage in the early stages. Features favoring an infectious component include viscid airway secretions containing fungal hyphae and spores, airway mycotoxins and lysosomal enzymes such as elastase, and cytokines such as interleukins 4 and 5. In addition, in later stages neutrophilic airway damage occurs and is sometimes accompanied by invasion of the organism into the mucosa leading to the entity of semi-invasive or limited invasive aspergillosis. The major hallmarks of BPA are listed in the [Table 369.1](#) and include an appropriate clinical setting, chest imaging, blood laboratory testing, and a single skin-prick test.

History of asthma or cystic fibrosis
Migratory pulmonary infiltrates on chest radiographs
Type I wheal-and-flare reaction to *Aspergillus* antigen
Serum precipitins against *Aspergillus* antigen
Blood eosinophilia
Very high serum concentrations of total IgE^a
Central bronchiectasis^a

^a Most specific laboratory features.

TABLE 369.1. DIAGNOSTIC FEATURES OF BRONCHOPULMONARY ASPERGILLOSIS

PATHOGENESIS

Bronchopulmonary aspergillosis is most commonly caused by a reaction to the fungus *Aspergillus fumigatus* (but other species of *Aspergillus* have been noted), although rarely other fungi such as *Candida* and *Penicillium* have been implicated. *Aspergillus* is a ubiquitous aeroallergen. When inhaled in persons with normal airways, it is cleared rapidly from the upper and lower airways by mechanical defense mechanisms. In those individuals with damaged airways or excessive mucus such as with asthma, spores are retained, resulting in prolonged exposure to phagocytic cells and bronchus associated lymphoid tissue. In atopic individuals an intense IgE and a lesser IgG antibody response are elicited, triggering mast cell degranulation in migration of eosinophils with subsequent discharge of inflammatory mediators and cytotoxic proteins. Recent experimental work suggests incremental involvement of the T-helper type 2 lymphocyte capable of releasing interleukins 4 and 5 into airway secretions. Finally the fungi themselves release mycotoxins and proteolytic enzymes. The combination of these potent inflammatory mediators causes sustained mucous gland hypersecretion and mucosal epithelial damage releasing debris that becomes inspissated. This causes blocking of small and sometimes large airways and contributes to the mucous plugs and parenchymal infiltrates seen on chest imaging. Although *Aspergillus* may be cultured from sputum in patients with BPA, it is not a required because airway secretions are not uniform and the intense inflammatory reaction is not related to the quantity of fungal organisms.

CLINICAL FINDINGS

Specific clinical clues include expectoration of viscid brown phlegm, sometimes with hardened mucous plugs. Patients may report frequent episodes of decompensation simulating a respiratory tract infection. These may be accompanied by reduced peak flow recordings, increased use of stabilizing aerosol corticosteroids or bronchodilators, increased use of rescue medication such as albuterol, or increased need for systemic prednisone. No single or combination of physical findings, including chest auscultation, indicates BPA in an asthmatic patient. Gross examination of phlegm for mucous plugs should raise suspicion that laboratory analysis can be performed for infectious pathogens (*Aspergillus*) and eosinophils and their breakdown products such as Curschmann's spirals or Charcot–Leyden crystals.

LABORATORY FINDINGS

Judicious use of laboratory testing as outlined in [Table 369.1](#) establishes or refines the diagnosis. Although the leukocyte count is normal or slightly elevated, eosinophils are almost always high. In asthmatic patients without BPA the eosinophil percentage is often 4% to 9%, and the absolute number is 400 to 900 per cubic millimeter. In patients with BPA the eosinophil percentage is often 10% to 20%, with an absolute number of 1,000 to 2,000 per cubic millimeter. A unique feature of BPA is an extremely high total IgE. The normal range for IgE is 0 to 100 ng per milliliter. In asthmatic patients values of 100 to 400 ng per milliliter may be seen. Almost all patients with BPA have values greater than 1,000 ng per milliliter, with values of 3,000 to 5,000 ng per milliliter often noted. Serum immunoglobulins IgG, IgM, and IgA are normal. Specific IgE and IgG antibodies against *Aspergillus* are elevated in those with BPA, but assays are not routinely available. Serum precipitins to *Aspergillus* are present in about 10% of asthmatic patients and in most patients with BPA. The immediate cutaneous reactivity to *Aspergillus* antigen is positive in up to 4% of the general population, 10% to 40% of an asthmatic population, and almost 100% of patients with BPA. The eosinophilia, high IgE, and precipitins reaction all are reduced in the presence of corticosteroids at the time of suspected diagnosis or during therapy with corticosteroids. Other tests of immune function, such as antinuclear antibody (ANA), rheumatoid factor, and antinuclear cytoplasmic antibody (ANCA) have not been studied in proven cases of BPA.

IMAGING

Chest imaging plays a key role in confirming the diagnosis of BPA. The chest radiograph is usually normal without infiltrates in asthma. The presence of patchy infiltrates, atelectasis, thickened airway (tram lines or ring shadows) are certainly nonspecific but should raise suspicion of BPA or bronchiectasis. Infiltrates, focal consolidations, and subsegmental atelectasis raise the suspicion of proximal airways obstruction by mucous plugging. Broad or tubular (2 to 7 mm wide) infiltrates may be seen representing actual mucous plugs that appear and disappear with coughing and expectoration. High-resolution computed tomography (HRCT) without contrast has become the standard imaging test for bronchiectasis. The characteristic distribution of bronchiectasis in BPA is usually central or proximal airway, but review of large numbers of patients with bronchiectasis has shown the central distribution to be neither sensitive nor specific. On HRCT, bronchial wall thickening can be seen in asthmatic patients, reflecting mucosal edema and inflammation. In BPA patients, other changes are seen on HRCT, such as airway dilatation detected by the finding of parallel (tram) lines or end-on ring shadows. Cysts off the bronchial wall are a more destructive feature of bronchiectasis. Mucous plugs may be observed as on chest radiographs with proximal tapering from the periphery like an arrow.

CULTURES AND PULMONARY FUNCTION TESTS

Positive fungal cultures for *A. fumigatus* are not a cardinal feature of the diagnosis. The usefulness of cultures is in looking for bacterial and nontuberculous mycobacterial pathogens that may be seen in a similar clinical setting. A patient with asthma and an infiltrate may have bacterial pneumonia. In patients with bronchiectasis, *Mycobacterium avium* complex may be a colonizing or even infecting organism.

Pulmonary function tests are normal or show obstructive impairment persons with asthma. Decrements in spirometry should raise an alarm that complications such as BPA are present. Spirometry can be a useful adjunct as therapy is administered.

In summary, the most characteristic confirmatory laboratory features are very high serum IgE, positive skin-prick tests to *Aspergillus*, and HRCT evidence of central bronchiectasis.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of a patient with asthma and deteriorating function is often triggered when a complete blood cell count shows eosinophilia, or there is an abnormal chest radiograph. Other confounding diseases include eosinophilic pneumonia, extrinsic allergic alveolitis (e.g. bird fancier's lung or farmer's lung), Churg–Strauss vasculitis, particularly in the setting of leukotriene modifier use or corticosteroid tapering, other drug-induced pulmonary eosinophilia (methotrexate, nitrofurantoin), mucoid impaction, bronchocentric granulomatosis, and parasitic infection. Testing for specific bird antigens or thermophilic fungi assists the diagnosis of extrinsic allergic alveolitis. Churg–Strauss vasculitis is often accompanied by neuropathy, skin lesions, or cardiomyopathy, and patients have a positive perinuclear ANCA. Mucoid impaction and bronchocentric granulomatosis have many features of BPA but lack high IgE. Airway or lung biopsy may be needed to confirm bronchocentric granulomatosis. Confirming parasite infection of the lung requires sputum or bronchoscopic lavage with wet mount preparation.

BPA occurs in patients with cystic fibrosis. BPA should be suspected when a patient fails to respond to seemingly appropriate antibacterial therapy (for *Pseudomonas*), develops a new chest radiographic infiltrate, or has *Aspergillus* in the sputum. Tests for BPA should be considered to include *Aspergillus precipitins* and IgE levels with the same diagnostic criteria as for asthmatics. Making the diagnosis of BPA is important because corticosteroids will be helpful in treatment.

OPTIMAL MANAGEMENT AND PROGNOSIS

Treatment for BPA requires reducing the intense inflammatory airway response and the mucous viscosity of the secretions and plugs. With the multifaceted inflammatory response in BPA, broad and systemic anti-inflammatory therapy is the mainstay. Although there has always been a hypothetical concern that aerosol corticosteroids might promote lower airway fungal colonization and predispose to BPA, this has never been proved. Nevertheless, prednisone at 0.75 to 1.0 mg per kilogram per day is the beginning recommended treatment of choice to be continued for 2 to 6 weeks. If the patient is already taking prednisone, higher doses may be needed initially. Dosage reductions are guided by improved symptoms and peak flows, reductions in IgE levels, and decreasing chest radiograph opacities. Tapering over 3 to 6 months is recommended. Although some clinicians recommend early switch to every-other-day dosing to reduce side effects, the off-steroid day is often accompanied by increased symptoms such that slow daily reductions are more effective. There are no large studies of the use of nonsteroid immune-altering agents such as azathioprine and cyclophosphamide. Because *Aspergillus* may be an infectious pathogen as well as an intense immune modifier, itraconazole has been reported as an adjunctive agent to reduce the colonizing load of *Aspergillus*.

Mechanical measures as used in bronchiectasis to loosen viscid secretions may be helpful. Examples are maintaining systemic and airway hydration with bland aerosols, chest physical therapy with postural drainage, and positive expiratory pressure or flutter valve maneuvers.

The prognosis of patients with BPA varies widely. Some patients worsen in spite of high-dose prednisone or as corticosteroids are lowered. Other *Aspergillus*-complicating diseases may develop, such as mycetoma or even the semi-invasive aspergillosis. A rising IgE level is probably the best index to deterioration and may precede clinical or radiographic worsening.

CHAPTER 370: CYSTIC FIBROSIS

MOIRA L. AITKEN

[Definition](#)
[Incidence and Epidemiologic Factors](#)
[Etiologic Factors](#)
[Pathogenesis](#)
[Clinical Findings and Management](#)
[Laboratory Findings](#)

DEFINITION

DIAGNOSIS

The diagnosis of cystic fibrosis (CF) is based on a positive sweat test (greater than 60 mEq per liter) or genetic testing demonstrating two CF alleles and symptoms compatible with CF. When performed correctly, the sweat test is highly sensitive (96% of adults) and specific for CF. False-positive sweat tests can be seen in hypoadrenalism, hypothyroidism, or renal diabetes insipidus.

GENETICS

The *CF* gene is located on the long arm of chromosome 7. The deletion of three base pairs (ΔF508) accounts for approximately 70% of all the *CF* alleles. There are over 700 other alleles, none of which is found on more than 5% of CF chromosomes. Clinical laboratories can screen for up to 70 alleles, accounting for 87% of abnormal genes; thus, a negative screening test does not exclude carrier status. The high prevalence of CF suggests a survival advantage of carrying one copy of this gene, which may be protection against chloride-secreting diarrheas, such as cholera.

INCIDENCE AND EPIDEMIOLOGIC FACTORS

Cystic fibrosis is an autosomal recessive disorder and approximately 1 in 30 persons of European descent are carriers. It affects 1 in 3,000 whites, 1 in 15,000 blacks, and 1 in 90,000 Asians.

ETIOLOGIC FACTORS

The *CF* gene product is expressed in cells of epithelial origin with disease manifest in the lungs, sinuses, pancreas, gastrointestinal (GI) tract, hepatobiliary system, sweat glands, and reproductive tract. The term cystic fibrosis refers to the original description of the pathologic appearance of disease in the pancreas.

PATHOGENESIS

The *CF* gene encodes for the cystic fibrosis transmembrane conductance regulator (CFTR), a membrane glycoprotein that is a chloride ion channel. In CF, one of the chloride ion channels present on the apical membrane of the epithelial cells either is absent or does not open under appropriate stimuli. The apical membrane of the airway epithelial cells also shows increased sodium ion absorption. The pathophysiologic mechanism by which these ion channel defects lead to organ disease is incompletely understood. In the lung, increased sodium absorption and decreased chloride secretion reduce the water content of the periciliary fluid. The osmolality of the periciliary fluid in CF has not been measured, but hyperosmolar periciliary fluid would lead to unhydrated mucin and increased mucus viscosity. This in turn may slow mucociliary transport, but slowed mucociliary transport per se is probably not the only abnormal process involved in the disease process. Another mechanism postulated is that CFTR may also be expressed in the intracellular organelles by the production of many abnormal proteins, such as epithelial cell receptors that have a predilection for *Pseudomonas* attachment. This phenomenon may be the explanation for the increased sulfation of CF mucin, leading to increased viscosity of the mucus, and for increased bacterial adherence to the altered mucin. More recently, a third mechanism has been postulated. Airway epithelial cells secrete antimicrobial peptides (defensins) that are capable of killing bacteria at low salt concentrations. Human b-defensin-1 is salt-sensitive and may be inactivated in CF. Human b-defensin-2 is also expressed in the airway and may contribute to the pathogenesis of CF disease.

CLINICAL FINDINGS AND MANAGEMENT

SWEAT DEFECT

The sweat duct ion-channel dysfunction is different from that of respiratory epithelia. Like the respiratory epithelia, the sweat duct has a reduced chloride ion permeability, but sodium ion transport across the CF sweat duct is not raised. In the secretory coil of the sweat gland, sweat is isotonic or slightly hypertonic. As it moves through the duct, sodium is conserved by being pumped out of the fluid, and chloride passively follows sodium. In CF, impermeability to the chloride ion prevents chloride from leaving the duct and results in an elevated concentration of chloride in the sweat. Electro-neutrality causes a greater amount of sodium concentration in the sweat.

PULMONARY DISEASE

Over 95% of CF patients die from respiratory failure. Histologically the lung is normal at birth. The earliest pathologic change is plugging of submucosal gland ducts in the large airways. Recent evidence from bronchoalveolar lavage fluid in infants suggests that infection is preceded by an inflammatory response with neutrophil influx to the airways. Once infection is present, the chronic presence of potent neutrophil chemoattractants leads to a self-perpetuating destructive inflammatory reaction in the CF lung. Neutrophils release chemoattractants and elastase, which cause tissue destruction directly; interfere with phagocytosis as well as complement and immunoglobulin function; and perpetuate airway infection. Disease can progress rapidly, causing bronchiolitis and bronchitis, with some degree of bronchiectasis usually demonstrated by 6 to 24 months. Although the severity of pathologic changes often varies greatly within each lobe or segment, the upper lobes (and particularly the right upper lobe) tend to be the earliest and most severely affected.

PULMONARY COMPLICATIONS

Acute Exacerbation

A diagnosis of acute exacerbation is made on the basis of subjective symptoms: increased cough, sputum production, and shortness of breath, sometimes associated with anorexia and weight loss. Fever or leukocytosis may be seen (but not invariably) in the adult population. An objective way to assess an exacerbation is by improvement in spirometric values with treatment for the exacerbation. Sputum quantitative cultures and DNA concentration are not precise in the individual patient.

Infection

Global T-cell and B-cell function, complement function, and phagocytosis is normal in CF. Infection is predominantly caused by *Staphylococcus aureus*, *Haemophilus influenzae*, and *Pseudomonas aeruginosa*. *S. aureus* and *H. influenzae* are often recovered from respiratory secretions of children with CF. *P. aeruginosa* eventually becomes the dominant organism in at least 90% of CF patients. Colonization of the respiratory tract with *P. aeruginosa* almost always begins with the morphologically classic (nonmucoid) strain. Onset of *P. aeruginosa* colonization often begins while *S. aureus* is still present. A variety of morphologic variants can occasionally be detected thereafter; however, eventually a smooth mucoid strain appears, and it is this strain that ultimately dominates or totally replaces the other *P. aeruginosa* variants and, often, all other pathogens as well. *B. cepacia* is not an inevitable colonizer, but in some patients it can become the dominant pathogen, replacing all others, including *P. aeruginosa*. Infection with *B. cepacia* can be associated with a rapid decline in pulmonary status. There is also strong epidemiologic evidence of

person-to-person transmission of *B. cepacia*; clinical isolation between those infected with *B. cepacia* and those not infected is advocated.

Colonization with nontuberculous mycobacteria has been reported in up to 20% of patients with CF. Rarely does nontuberculous mycobacteria cause disease that requires chemotherapy.

Aspergillus, usually *Aspergillus fumigatus*, is frequently recovered from CF respiratory secretions. Allergic bronchopulmonary aspergillosis occurs in 2% of patients with CF. Invasive aspergillosis has been reported in CF but is quite rare.

Common respiratory viruses, including respiratory syncytial virus and influenza, and measles can be associated with pulmonary exacerbations.

Hemoptysis

Blood streaking of the sputum is very common in CF patients over 10 years of age, and massive hemoptysis occurs in up to 10% of adults, leading to death in 1% of that population. Mild streaking hemoptysis is caused by mucosal irritation in the airway and is often associated with an acute pulmonary exacerbation. Streaking hemoptysis should prompt a check of coagulation. Massive hemoptysis is due to bleeding from the bronchial circulation, which becomes tortuous and enlarged with the chronic infection of CF. Patients should be warned of the potential of massive hemoptysis and urged to seek emergency treatment if it occurs. (See [Chapter 353](#) for a discussion of the management of massive hemoptysis.)

Pneumothorax

Pneumothorax occurs in 8% to 23% of older CF patients who have more severe pulmonary disease. The incidence in men and women is equal, and appearance is as common on the right as the left. Because of a 50% to 70% chance of recurrence in pneumothorax, obliteration of the pleural space is the treatment of choice but may depend on whether the patient is a candidate for lung transplantation. If the patient is a lung transplantation candidate, intercostal drainage, chemical pleurodesis, ligation of bullae, or limited surgical pleurodesis should be performed in preference to pleurectomy. The majority of CF patients develop pleural adhesions spontaneously, presumably because of air or bacterial leakage into the pleural space.

Clubbing and Hypertrophic Osteoarthropathy

Clubbing of the fingers and toes is eventually a universal finding in CF patients with pulmonary disease, but the severity is variable. Hypertrophic osteoarthropathy is occasionally seen in older patients.

Respiratory Failure and Cor Pulmonale

Secondary pulmonary hypertension leading to cor pulmonale occurs late in the course of disease, with a mean survival of 8 months once right heart failure develops. The indications for oxygen therapy are primarily extrapolated from the Nocturnal Oxygen Therapy Trial group in the chronic obstructive pulmonary disease population, which suggested that oxygen reduced mortality, preserved exercise capacity, and improved neuropsychologic function. In small studies, no improvement in these parameters has been shown in CF patients, but improved quality of life has been demonstrated.

Patients can very rarely be weaned from mechanical ventilation instituted for end-stage disease. A handful of CF patients have successfully undergone lung transplantation from mechanical ventilation, but only a minority of transplantation centers perform transplantation on patients receiving mechanical ventilation. BiPAP has been shown to improve ventilation and oxygenation, and can be a bridge for patients awaiting transplantation.

TREATMENT OF PULMONARY DISEASE

Antibiotics

The mainstay of treatment for pulmonary disease in CF has been chest physical therapy and antibiotics, although the bacterial pathogen is rarely eradicated from the airway. Antibiotics are usually given for 2 weeks for exacerbation of disease, but no trials have been conducted to ascertain the optimum duration of treatment. Several studies have shown that intravenous antibiotic therapy in the home may be as effective as hospitalization. The advantages of cost savings and reduced psychosocial disruption are weighed against more intensive chest physical therapy and more rest in the hospital.

There is no consensus as to whether prophylactic antibiotics should be used in CF. A 5-year multicenter study of prophylactic continuous antistaphylococcal therapy showed no benefit. Prophylactic aerosolized antibiotics (penicillin, carbenicillin, aminoglycosides, colistin, neomycin, and ceftazidime) have also been used in studies. Collectively, these studies showed an initial improvement in spirometry lasting up to 6 months and a decreased number of acute exacerbations over several months. The disadvantage of prophylactic treatment is the emergence of drug-resistant organisms.

Chest Physical Therapy

The results of pulmonary function tests (PFTs) improve following treatment of an exacerbation with chest physical therapy alone. Postural drainage usually accompanied by percussion, deep breathing exercises, directed cough, forced-expiration technique, positive expiratory pressure, flutter and vest devices, as well as exercise have all been used in clinical practice. The optimal chest physical therapy is somewhat controversial and should be the one with which the patient is most compliant.

Bronchodilators

Airway hyperreactivity with a positive methacholine challenge test is present in 50% to 60% of CF patients. β -Agonists may be indicated for those who are clinically wheezy or demonstrate a significant bronchodilator response; it must be recognized that reversible airway obstruction caused by secretions and edema in the airway wall is a universal finding in CF patients with pulmonary disease. Ipratropium bromide may be equally efficacious to β -agonists in this population. There are variable reports on the benefit of theophylline on pulmonary function in CF patients. Theophylline improves diaphragmatic contractility and may assist patients with air trapping and hyperexpansion.

Cromolyn

Small studies suggest that cromolyn sodium is not an effective treatment in cystic fibrosis, which appears counterintuitive as there is a high prevalence of atopy and airway hyperresponsiveness.

Airway Clearance Agents

N-Acetylcysteine, taken by inhalation, may cause bronchospasm, and iodinated therapy and glyceryl guaiacolate are unproven in CF. Recombinant human DNase alters the rheologic properties of sputum by cutting the size of DNA molecules in sputum. Clinical trials have shown a sustained 5% improvement in pulmonary function with this drug.

Anti-inflammatory Drugs

Anti-inflammatory agents, including corticosteroids, ibuprofen, and antiprotease, have been examined in CF. High-dose corticosteroids (1 to 2 mg per kilogram 4 times a day) have been shown to ameliorate the decline in PFTs over a 4-year period, but not without significant side effects. Whether a lower dose would be beneficial has not been studied. Large randomized trials of inhaled steroids in CF have not been completed, but inhaling steroids seems reasonable in patients with an asthmatic component to their disease. The administration of high doses of ibuprofen has shown a more modest decline in PFTs compared to placebo over a 4-year period in a small clinical trial.

Therapeutic options being developed for CF are those meant to correct the basic defect of CF by increasing gene expression or by activating abnormal CFTR.

Lung Transplantation

A final therapeutic option for a few CF patients may be lung transplantation. As of 1998, more than 700 CF patients in the United States had received a heart–lung or double-lung transplant. The 3-year survival is 60%. There is no CF pulmonary disease recurrence as demonstrated by a normal transepithelial potential difference in the transplanted lung. In a very small number of cases, transplantation of unilateral lower lobes has been performed for CF, necessitating two living donors (see [Chapter 391](#) for further discussion of this procedure).

SINUS COMPLICATIONS

The pathophysiologic factors involved in sinus disease are similar to those involved in pulmonary disease. Alteration in mucus, impaired mucociliary transport, and mechanical obstruction of the sinus ostia occur. Obstruction is followed by bacterial infection. Pan-opacification of the paranasal sinuses is present on the sinus radiographs in 90% to 100% of patients. The frontal sinuses rarely develop in CF patients. It is believed that the early onset of sinusitis prevents pneumatization. Nasal polyposis is found in up to 30% of patients, more commonly seen in the pediatric group. Surgical removal of polyps is associated with a 50% to 90% recurrence rate. Acute symptoms of sinusitis are far less common than the radiologic appearance. Treatment is with antibiotics, nasal irrigation, and nasal steroids, and, if necessary, surgical drainage. Whether the organisms giving rise to sinusitis are the same as those in the sputum is controversial but may not correlate.

PANCREATIC DISEASE

Exocrine Pancreatic Insufficiency

Up to 90% of CF patients have exocrine pancreatic insufficiency, and failure to thrive is a common presenting symptom of the disease. The pancreatic lesion appears to be the result of obstruction of the pancreatic ducts with eosinophilic inspissated secretions. Intraluminal calcifications may develop but are rarely large enough to be seen on plain abdominal films. The diagnosis of pancreatic dysfunction is made by clinical symptoms of malabsorption and measurements of the serum levels of fat-soluble vitamins and sometimes of fecal fat. The quantity of enzymes used with each meal varies from patient to patient and is based on the number of calories consumed; the number, volume, and quality of the stools; and the presence of cramping abdominal pain.

Pancreatitis

Acute pancreatitis occurs in up to 10% of patients. Cholelithiasis should be sought as a precipitating factor. The clinical course of pancreatitis in CF patients appears more benign than in the general population, possibly because the pancreas is scarred and replaced with fatty tissue and because development of a pseudocyst is rare.

Diabetes Mellitus

Diabetes mellitus occurs in up to 15% of CF patients and glucose intolerance in up to 75% of CF patients, contributing to malnutrition in this population. The clinical course and metabolic patterns seen in diabetes associated with CF is distinct from those associated with type I or type II diabetes. This diabetes differs from type I in that it is of slow onset and nonketotic, some insulin secretion persists, intermittent episodes of hyperglycemia occur between prolonged episodes of euglycemia, and markers for islet cell autoimmunity are absent. It differs from type II in that patients are underweight and hypoinsulinemic, and its onset is early in life. It differs from both type I and type II in that glucagon secretion varies, ranging from hypoglucagonemia to hyperglucagonemia. Although the complications of diabetes have not frequently been reported in CF diabetes, typical complications of diabetes are expected to occur over time in a group of patients whose median survival is rising. Treatment is with diet and insulin. The only controversy over treatment is about the use of oral hypoglycemic agents and whether they have any role in CF-associated diabetes control.

GASTROINTESTINAL DISEASE

Meconium Ileus and Meconium Ileus Equivalent

Meconium ileus, present in up to 10% of CF neonates at birth, is diagnostic of CF. Meconium ileus is caused by meconium plugging the lumen of the small intestine, usually near the ileocecal valve. Meconium ileus equivalent and distal intestinal obstruction syndrome are the terms used to describe partial or complete intestinal obstruction beyond the neonatal period. It occurs in 10% to 20% of adult CF patients. The cause of meconium ileus is multifactorial. Intestinal mucoproteins may be more viscous; the increased acid in the small intestine may precipitate proteins; undigested fat stimulates enteroglucagon release, which may further slow intestinal transit. Meconium ileus equivalent can present as an acute intestinal obstruction. Often there are recurrent episodes of colicky abdominal pain, with some distention and relative constipation. A soft, mobile, nontender mass in the right iliac fossa is sometimes present. Patients with chronic symptoms often recognize the precipitating events and alter their behavior to avoid them. Precipitating causes include abrupt cessation of pancreatic enzymes, pulmonary exacerbation, dehydration, or change in diet. Acute episodes are treated with rehydration and hyperosmolar enemas, e.g., diatrizoate meglumine (Gastrografin) and nasogastric suction. If partial obstruction is present, oral hyperosmolar solutions (GoLyteLy), 5% *N*-acetylcysteine, and pancreatic supplement may be given orally. Surgery is rarely required.

Gastroesophageal Reflux

Clinically apparent reflux is present in up to 14% of patients. The predominant reflux mechanism is a transient inappropriate lower esophageal sphincter relaxation. Gastroesophageal reflux may contribute to poor pulmonary function because of recurrent aspiration. Patients respond well to cisapride and antireflux therapy.

Peptic Ulceration

Peptic ulcers are found in up to 13% of CF patients. The increased incidence of peptic ulcer disease is related to the decreased pH of the luminal contents secondary to decreased pancreatic bicarbonate secretion. Endoscopic evaluation is the procedure of choice in CF patients with peptic ulcer disease. Contrast radiography is inaccurate because the duodenal mucosa typically appears nodular and distorted with poor definition of the mucosal folds. The ulcers heal well (90%) with H₂ receptor antagonists.

Crohn's Disease and Bowel Strictures

The incidence of Crohn's disease is higher in this population than in the general population. Large quantities of high-strength enteric-coated pancreatic enzymes appear to be associated with nongranulomatous bowel strictures. Currently, no pathophysiologic explanations exist for either of these clinical observations. Concomitant use of H₂ blockers to increase gastric pH allows release of enteric-coated enzyme preparations and thus decreases the total amount of enzymes used.

Intussusception and Rectal Prolapse

Intussusception occurs in 1% of pediatric CF patients, and rectal prolapse is seen in up to 20% of pediatric patients 6 to 36 months of age.

HEPATOBIILIARY DISEASE

Hepatomegaly, splenomegaly, or both are found in 1% to 5% of CF patients. The pathogenesis of multilobular cirrhosis is thought to be a response to the accumulation of thickened secretions in the bile ductules, leading to plugging, ductular proliferation, inflammation, and, finally, fibrosis. Patients with overt liver disease often have stricture of the distal common bile duct. Abnormal liver function tests (transaminases two to three times normal values) are frequently found in CF patients with no clinically apparent disease. There is no specific regimen to prevent progression of the hepatic lesions, although treatment with ursodeoxycholic acid has shown improvement in liver function tests and weight gain. Cholelithiasis is found in up to 12% of CF patients; symptomatic presentation is rare before

adolescence.

OSTEOPOROSIS

Patients with CF are susceptible to osteopenia and osteoporosis because of malabsorption of vitamin D, calcium, and other nutrients, possible hypogonadism, corticosteroid use, physical inactivity, and circulating cytokines from chronic pulmonary infection. Management includes giving adequate nutritional support, implementing vitamin D and calcium replacement, ensuring appropriate gonadal hormonal levels, encouraging exercise, and using corticosteroids only when necessary. It remains unclear as to when to initiate screening with a DEXA scan. Certainly CF patients being assessed for lung transplantation and those who fall below ideal body weight should have a DEXA scan.

MALIGNANCY

The rate of GI cancer is increased in CF. The increased incidence of tumors is found throughout the GI tract. Routine screening for GI malignancy is not recommended because malignancy is rare. There is only speculation as to the pathophysiologic factors involved in the development of these tumors.

REPRODUCTIVE ISSUES

Of men with CF, 98% to 99% have obstructive azospermia. The abnormalities are confined to the derivatives of the embryonic wolffian duct: the vas deferens, seminal vesicles, and body and tail of the epididymis, with absence or atresia of some or all of these structures. Testicular histologic examination is normal and active spermatogenesis occurs, albeit with production of an increased number of abnormal and immature forms. Microscopic epididymal sperm aspiration may offer men with CF the opportunity to father their own genetic children.

Women with CF have anatomically normal reproductive tracts. Fertility rates among CF women have never been documented, but there is no evidence that fertility is decreased in female CF patients. Cervical mucus viscosity is increased but has not been shown to be less permeable for sperm penetration. Oral contraceptives possess a number of potential side effects that could exacerbate preexisting CF-associated conditions, such as diabetes, malabsorption, cholelithiasis, and hepatic dysfunction, but clinical experience with oral contraceptives has been favorable. Women considering pregnancy should undergo formal evaluation. Those women with mild airflow obstruction and good nutritional status usually tolerate pregnancy well. For women with more severe but stable disease, pregnancy may be endorsed, but with the understanding that close medical observation is essential. Pregnancy does not appear to adversely affect long-term prognosis.

Genetic counseling should be offered to all CF patients who are contemplating starting a family. All offspring will be carriers; the risk of having a CF-affected child is 2% if the spouse is of European descent. A final issue to be considered before conception is the shortened life expectancy of the CF parent; patients should make plans as to who will raise the child in the event of their premature death.

ARTHROPATHY

Immune-mediated episodic arthritis most commonly involving the lower limbs and fingers may start in adolescence. This episodic arthritis is usually a nondestructive arthritis, but erosive changes have been reported. A high fever and erythema nodosum may accompany the arthropathy. Attacks last for several days and respond to nonsteroidal anti-inflammatory drugs, although systemic corticosteroids are sometimes necessary. Hypertrophic pulmonary osteoarthropathy is occasionally seen in CF.

PHARMACOKINETICS

Cystic fibrosis patients have altered pharmacokinetics due to a variety of mechanisms. CFTR may alter renal and hepatic cells directly by altering ion channels and by affecting intracellular pH. Loss of bile salts increases hepatic cytochrome P450. The drugs affected range widely from those that are extensively metabolized, such as sulfamethoxazole and theophylline, to those that are excreted unchanged in the urine, such as the penicillins. The increased clearance of sulfamethoxazole is attributable to increased hepatic N-acetylation. The increased clearance of trimethoprim is primarily increased tubular secretion. Aminoglycoside requirement is increased secondary to increased volume of distribution, increased total body clearance, and aminoglycosides binding to DNA in the purulent secretions.

PROGNOSIS

In the United States in 1997, the median survival was 30.6 years ([Fig. 370.1](#)). Prognosis has some correlation to genotype. Patients homozygous for the $\Delta F508$ mutation are diagnosed at an earlier age and die, on average, 3 years earlier than those with other genotypes; however, clinical outcome does not entirely depend on genotype. Other important factors include nutritional status and the number of respiratory viral infections. Prognostic clinical scoring systems that include evaluation of pulmonary function, chest radiograph, and nutritional status have been developed and the forced expiratory volume in 1 second (FEV_1) is the single most sensitive predictor of mortality, with an FEV_1 of less than 30% predicted having a 45% 2-year risk of mortality.

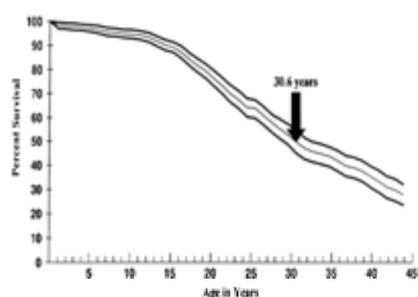

FIGURE 370.1. Chest radiograph of a patient with cystic fibrosis. The lung volumes are increased. The hila are enlarged secondary to lymphadenopathy and are elevated secondary to scarring in the upper lobes. Peribronchial thickening is prominent in the upper and lower lobes. Mucous plugging is most prominent in the upper lobes. A Port-A-Cath accessed with a Huber needle is present

NUTRITIONAL MANAGEMENT

Cystic fibrosis patients often have poor weight gain, growth retardation, delayed puberty; muscle wasting; and vitamin, mineral, essential fatty acid, and taurine deficiencies. Nutrition deficiencies occur because of malabsorption, decreased food intake, and increased metabolic requirements secondary to the disease. Improved nutrition should enhance respiratory muscle strength and immunity, and evidence suggests that it may have important long-term effects on lung function and prognosis.

Management includes a dietary intake history and assessment of malabsorption. A 3-day fecal fat collection may be necessary. Pancreatic enzyme replacement therapy should be given to patients with pancreatic insufficiency before each meal and snack. Most patients require vitamin A and E supplement. Enteral feeding should be offered to patients who lose weight despite aggressive dietary measures. Nasogastric tubes, gastrostomy tubes, and jejunostomy tubes have all been used successfully in patients who have been unable to maintain an adequate calorie intake. Gastrostomy tubes carry the risk of increasing gastroesophageal reflux in this susceptible population.

GENE THERAPY

As of 1999, there have been numerous trials using CFTR vectors trials to the nose, lungs, or sinuses. Vectors used in these clinical trials include adenoviruses, adeno-associated viruses, and liposomes. Outcomes have shown CFTR RNA expression and, rarely, CFTR protein expression by alteration in electrophysiologic measurement across the airway. It is anticipated that it will be many years before any of these vectors are clinically useful.

GENETIC COUNSELING

The American Society of Genetics recommends that patients and their relatives be offered nondirective genetic counseling concerning carrier testing and the risk of having a CF-affected child. A major question is whether population-based screening for CF carriers could or should be implemented at present. The current test detects only approximately 85% to 90% of carriers; therefore, only half of the couples in the general population can be identified. Concern has been expressed about false-negative results that occur in any population screening program. For relatives of CF-affected individuals, accuracy of testing is increased because carrier testing can be performed with linkage analysis in addition to mutation analysis when there is a DNA sample available from an affected person in a family.

LABORATORY FINDINGS

PULMONARY FUNCTION

The newborn with CF probably will have normal pulmonary function until peripheral airways are obstructed by excessive mucus. Infant CF patients often demonstrate increased total respiratory resistance, but as the child grows the airway resistance may again have normal values because with lung growth the relative distribution of resistance between central and peripheral airways changes. As lung disease progresses, initially air trapping is seen (increased residual volume/total lung capacity). Later, airflow obstruction predominates [decreased forced vital capacity (FVC), FEV₁, force expiratory flow (FEF), midexpiratory phase (FEF 25% to 75%), and peak flow]. Finally, a mixed restrictive pattern (decreased total lung capacity) and an obstructive pattern are seen. Spirometric testing should be done during each clinic visit. Changes in spirometric values may be the most objective way to determine whether a patient is having an acute exacerbation of his or her pulmonary disease. Arterial blood gases show progressive widening of the alveolar to arterial oxygen difference with disease progression, and the presence of CO₂ retention is an ominous sign. A P CO₂ greater than 50 torr has a 2-year survival rate of approximately 50%.

MICROBIOLOGIC EXAMINATION

Sputum should be checked during each clinic visit or following a course of antibiotics. The microbiology laboratory should be aware that the sample comes from a CF patient and should have special procedures in the laboratory to deal with the increased viscosity and the organisms found in CF sputum.

RADIOLOGIC EXAMINATION

Overinflation, peribronchial cuffing, and small infiltrates (mucous plugging) are early findings on the chest radiograph. With disease progression, there is bronchiectasis and diffuse fibrosis, most marked in the upper lobes, with scarring and upward retraction of the hila (Fig. 370.2). During an acute exacerbation there may be no obvious changes on chest radiograph. Mucus plugging and increased peribronchial thickening may inconsistently be found. Pneumothorax, pneumomediastinum, lobar and segmental atelectasis, pleural fluid, and large cysts or blebs (particularly in the apices) may be present. Hilar and mediastinal adenopathy secondary to chronic infection and enlargement of the pulmonary arteries is present later in the disease course. Bronchiectasis is observed at a much earlier stage with computer tomography scanning; airway structure is demonstrated to the level of the subsegmental bronchi. It is also sensitive for small cysts (3 mm), bullae, peribronchial thickening, fibrosis, and early infiltrates.

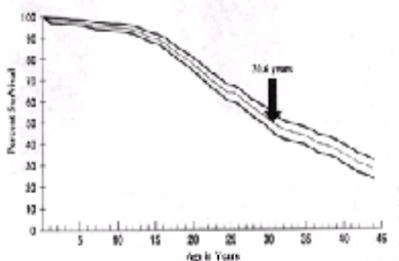

FIGURE 370.2. Median survival of patients with cystic fibrosis in the United States in 1997. Thirty-six percent of patients are 18 years of age or older. (Data from National Cystic Fibrosis Patient Registry, Cystic Fibrosis Foundation, Baltimore, MD, 1998.)

NUTRITIONAL ASSESSMENT

The Cystic Fibrosis Foundation Clinical Practice Guidelines recommend that complete blood count and liver function testing be performed at least annually. It is not uncommon for adult patients with CF to have anemia of chronic disease. It is also common for them to have a hepatic enzyme rise of two to three times normal values. Vitamin A and vitamin E levels should be monitored at least annually. This may monitor both adequate pancreatic enzyme and vitamin supplementation.

DIABETES SCREENING

The Cystic Fibrosis Foundation consensus statement recommends that a random blood sugar be done annually and, if it is above 126 mg per liter, that a fasting blood sugar follow. A confirmed fasting blood sugar above 126 mg per liter indicates that diabetes treatment should be started.

CHAPTER 371: IDIOPATHIC INTERSTITIAL PNEUMONIAS

TALMADGE E. KING, JR.

[Idiopathic Pulmonary Fibrosis/Usual Interstitial Pneumonia](#)
[Desquamative Interstitial Pneumonia and Respiratory Bronchiolitis–Associated Interstitial Lung Disease](#)
[Acute Interstitial Pneumonia](#)
[Nonspecific Interstitial Pneumonia](#)
[Lymphocytic Interstitial Pneumonitis](#)

The idiopathic interstitial pneumonias represent a common and important group of interstitial lung diseases. Liebow proposed a pathologic classification for interstitial pneumonia that included usual interstitial pneumonia (UIP), desquamative interstitial pneumonia (DIP), bronchiolitis obliterans interstitial pneumonia (BIP), lymphocytic interstitial pneumonia (LIP), and giant cell interstitial pneumonia (GIP). It was recognized that these entities had no identifiable cause, so the term “idiopathic” was added. Subsequent additional studies showed that LIP represented a group of lymphoproliferative disorders and most cases of GIP were associated with hard-metal (cobalt) pneumoconiosis. Consequently, over the last decade these entities were excluded from the group of idiopathic interstitial pneumonias (IIPs). In addition, other histologic subtypes have been better recognized and are now included in this group: idiopathic bronchiolitis obliterans–organizing pneumonia (BOOP), acute interstitial pneumonia (AIP), and nonspecific interstitial pneumonia (NSIP). Recently, Katzenstein proposed revisions of the classification of idiopathic interstitial pneumonias to include the following entities: UIP, DIP, respiratory bronchiolitis–interstitial lung disease (RB-ILD), AIP, and NSIP. Most experts combine RB-ILD and DIP because it is believed that they represent different stages of the same process. It remains unsettled as to whether or not to include idiopathic BOOP among the IIPs because most of the connective tissue proliferation characteristic of this process is within airspaces rather than the interstitium.

The histologic patterns seen in UIP, DIP, and AIP are distinctive; unfortunately, they are not specific and can be seen in a variety of conditions. Consequently, the diagnosis of the specific entities requires careful clinical, radiologic, and pathologic correlation ([Table 371.1](#)). This chapter presents an approach to the diagnosis and management of these disorders. Further discussion can be found in [Chapter 360](#) and [Chapter 376](#).

TABLE 371.1. IDIOPATHIC INTERSTITIAL PNEUMONIAS: DIFFERENTIAL DIAGNOSIS

IDIOPATHIC PULMONARY FIBROSIS/USUAL INTERSTITIAL PNEUMONIA

DEFINITION

Idiopathic pulmonary fibrosis (IPF) is the prototypical interstitial lung disease (ILD), and it is characterized by progressive pulmonary parenchymal inflammation and fibrosis. These changes result in exertional dyspnea, bibasilar interstitial opacities on chest radiograph, and restrictive physiologic impairment, and can eventually cause respiratory failure and cor pulmonale. IPF is the preferred term for this disease in North America, but there are many descriptive synonyms, including cryptogenic fibrosing alveolitis, Hamman–Rich syndrome, diffuse interstitial fibrosis, “honeycomb lung,” Osler–Charcot disease, diffuse pulmonary alveolar fibrosis, and idiopathic interstitial pneumonitis.

Until recently, reports of IPF included cases with the histologic patterns of UIP, DIP, idiopathic BOOP, AIP, and NSIP because most investigators tended to “lump” these under this diagnosis. In the last decade there has been a move to narrow the definition of IPF to include only cases of UIP. This paradigm shift has been largely influenced by the identification of different clinical and radiologic (especially high-resolution CT, or HRCT, scanning) features among the other histologic subtypes and, most importantly, a strikingly different response to treatment and thus to survival. For example, it was shown that median survival of patients with the UIP pattern was significantly worse than that for patients with the other chronic interstitial pneumonias.

INCIDENCE AND EPIDEMIOLOGIC FACTORS

The incidence of IPF is unknown. It is thought to occur in 3 to 5 persons per 100,000, but recent data suggest that the incidence may be much higher. Most patients are diagnosed in the fifth to seventh decades of life. No racial, seasonal, or geographic associations have been noted. Males appear to have a slightly greater likelihood of developing IPF in some studies.

ETIOLOGIC FACTORS AND PATHOGENESIS

The cause of IPF is unknown. Its pathogenesis is highly complex and probably multifactorial; genetic, viral, environmental, and autoimmune factors have been implicated. Cigarette smoking has been proposed as a contributory/confounding factor in IPF, but no controlled studies have confirmed this association. A variety of cell, cytokine, and matrix interactions appear to contribute to the parenchymal inflammation and fibrosis seen in IPF; the exact mechanisms of this complex interaction are unclear. Regardless of the inciting cause, much evidence suggests a role for the immune response in the pathogenesis of IPF. A genetic predisposition is strongly supported by the recognition of familial forms of many ILDs, including familial IPF, which appears to have an autosomal dominant inheritance pattern with variable penetrance. A search for “fibrosis susceptibility genes” in the major histocompatibility complex has produced contradictory results. More promising is the association of IPF with the Z and S α_1 -antitrypsin inhibitor alleles and immunoglobulin allotypes on chromosome 14. Efforts to confirm a respiratory viral cause for IPF have been unsuccessful. Other viruses, such as hepatitis C virus, may be implicated in some cases. Airborne environmental factors (other than the known fibrogenic agents inhaled in the occupational environment such as asbestos or silica) may be linked to the development of IPF.

CLINICAL FINDINGS

The symptoms of IPF are nonspecific. Most patients note the insidious development of exertional dyspnea. A nonproductive cough may be present. Constitutional symptoms, such as fatigue, malaise, or weight loss, are less common. As the disease progresses, patients may become dyspneic at rest and develop sputum production. Exertional chest discomfort and peripheral edema are associated with the development of pulmonary hypertension and cor pulmonale. Most patients present for care more than 6 months after the onset of symptoms.

Physical examination of the IPF patient is similarly nonspecific or it may be entirely normal in early stages of the disease. Chest auscultation usually reveals basilar inspiratory crackles. As the disease progresses, crackles become coarser and more widespread; digital clubbing and cyanosis may become apparent. A prominent pulmonic closure sound, palpable pulmonary arterial impulse, or right ventricular heave suggests pulmonary arterial hypertension; jugular venous distention, hepatomegaly, and peripheral edema signal the development of cor pulmonale.

LABORATORY FINDINGS

Routine Laboratory Studies

Laboratory studies may reveal the nonspecific presence of rheumatoid factor, antinuclear antibody, or cryoglobulins, usually in low titers. Complete blood counts are usually normal.

Chest Imaging Studies

Radiographic findings in IPF are not specific. Typically there are bibasilar reticular opacities with reduced lung volumes. As the disease progresses, the upper lung fields become involved, coarse polygonal markings become apparent (honeycombed lung), and pulmonary arterial enlargement and cardiomegaly may be seen. Hilar and mediastinal adenopathy and pleural effusions are not evident in routine cases of IPF and should suggest an alternative diagnosis.

HRCT scans are more sensitive at detecting parenchymal abnormalities. Typical HRCT findings in IPF include peripheral, subpleural, basal distribution; reticular opacities; honeycombing; traction bronchiectasis and bronchiolectasis; focal areas of ground-glass opacities; and architectural distortion ([Fig. 371.1](#)). Unrelated coexistent lung diseases such as smoking-related emphysema are often present in IPF.

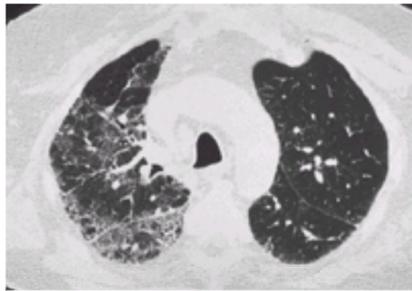

FIGURE 371.1. High-resolution chest computed tomography scan from a patient with idiopathic pulmonary fibrosis. The opacities are patchy and asymmetrical but worse in the dorsal segments of the right lung (*lower left*), where early honeycombing is present. Fine hazy opacities (ground-glass appearance) are interspersed with relatively normal-appearing areas in the remainder of the right lung and left lung.

The gallium lung scan is insensitive and nonspecific, and it correlates poorly with lung biopsy tissue cellularity or response to therapy in IPF. Technetium Tc 99m diethylenetriamine pentaacetate (^{99m}Tc -DTPA) scanning is an index of lung epithelial permeability. Increased permeability results from inflammation. A normal ^{99m}Tc -DTPA clearance at initial measurement in IPF predicted stable disease and rapid clearance identified patients at risk for deterioration. Insufficient data exist to support the routine use of either method in the routine assessment of ILD.

Lung Function Studies

Static pulmonary function testing in IPF typically reveals a reduced forced expiratory volume in 1 second (FEV_1), vital capacity (VC), and total lung capacity; the FEV_1/VC ratio is usually normal or increased (consistent with a restrictive ventilatory impairment due to decreased lung compliance). The single-breath diffusing capacity for carbon monoxide (corrected for hemoglobin) is reduced, reflecting a loss of functional alveolar capillary gas exchange area. Arterial blood gas measurements may be normal at rest but typically reveal varying degrees of hypoxemia and respiratory alkalosis. Carbon dioxide retention causing respiratory acidosis is a late finding. Patients with IPF and coexisting chronic pulmonary obstructive disease may have normal airflow measurements and lung volumes due to the offsetting effects of these two diseases on lung mechanics yet may have severe functional impairment. The diffusing capacity in these patients is usually markedly diminished.

Cardiopulmonary exercise testing in IPF reveals diminished maximal oxygen consumption and exercise capacity. Increased ventilatory equivalents for oxygen and carbon dioxide, elevated physiologic dead space with progressive exertion, widening of the alveolar–arterial oxygen difference, and oxygen desaturation are typical physiologic characteristics in patients subjected to an exercise test. Most patients stop due to dyspnea and fatigue, and demonstrate oxygen desaturation. Occasionally, patients with exertional dyspnea have normal radiographic studies, pulmonary function tests, and arterial blood gas measurements at rest. In these cases, physiologic abnormalities may surface during progressive cardiopulmonary exercise testing and prompt further diagnostic evaluation and lung biopsy.

Bronchoalveolar Lavage

Bronchoalveolar lavage (BAL) findings in IPF are highly variable and are nondiagnostic. Lymphocytes, macrophages, neutrophils, and eosinophils may be increased in varying proportions. Certain soluble factors, such as surfactant phospholipids, may be reduced; others, such as procollagen III peptides, may be increased. The clinical utility of these findings is undetermined.

Lung Biopsy and Histopathologic Examination

There is a tendency to be overconfident of one's ability to make a correct clinical diagnosis of IPF/UIP. Lung biopsy improves the accuracy of the diagnosis and appears most important when an HRCT pattern consistent with UIP is uncertain or unlikely. Fiberoptic bronchoscopy with BAL and transbronchial lung biopsy cause little morbidity and can provide useful information if definitive diagnostic findings are recovered (i.e., infection, granulomatous inflammation, or malignancy). However, findings of nonspecific interstitial fibrosis must not be considered conclusive for identification of IPF because of the sampling error inherent in the technique.

Some controversy exists as to the need for surgical lung biopsy in the diagnosis of ILD. However, examination of representative lung tissue confirms a specific diagnosis, justifies long-term therapy with drugs having significant adverse effects, and may predict the response to therapy and prognosis. Lung biopsy via thoracotomy is the gold standard diagnostic procedure in ILD, and recent experience with video-assisted thoracoscopic lung biopsy suggests that it is equally effective, less morbid, and better tolerated by patients. Biopsies should be obtained from multiple sites, including areas of involved lung and relatively normal lung because of the patchy distribution of the disease and the nondiagnostic histopathologic findings in areas of advanced honeycombed lung. HRCT may help to select locations for surgical lung biopsy and to identify other findings appropriate for biopsy (especially adenopathy and pleural abnormalities). Careful handling and review of the biopsy specimens by an experienced lung pathologist who is aware of the clinical features enhances diagnostic yields.

Gross structural changes occur as the alveolar walls become progressively thickened by fibrosis. Alveolar spaces and vascular beds become obliterated, and the parenchymal architecture becomes distorted into multiple cystic structures surrounded by dense bands of fibrotic tissue known as “honeycombed lung” ([Fig. 371.2](#)). The histopathologic changes of UIP are patchy. Usually the abnormalities are more advanced in the periphery of the basilar lung segments. UIP is characterized by increased fibroblasts, excessive deposition of collagen, and expansion of lymphocyte and plasma cell populations within the alveolar wall. Fibroblasts, alveolar type II epithelial cells, fibrin, and collagen deposition also are present in alveolar spaces (intra-alveolar fibrosis) ([Fig. 371.3](#)). Distortion of airway walls by retracting fibrotic parenchymal tissue can result in “traction bronchiectasis,” and the vascular changes of secondary pulmonary hypertension are a late finding in IPF.

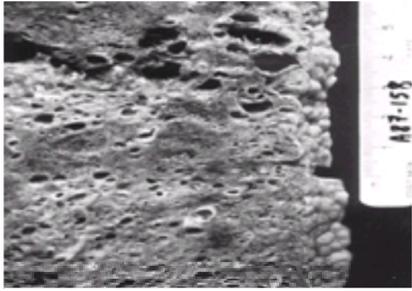

FIGURE 371.2. Gross view of honeycombed lung. The cut surface reveals distortion by irregular dense bands of fibrosis separating numerous cystic spaces of varying size. The pleural surface (adjacent to the label) has an irregular cobbled appearance, reflecting the underlying parenchymal changes.

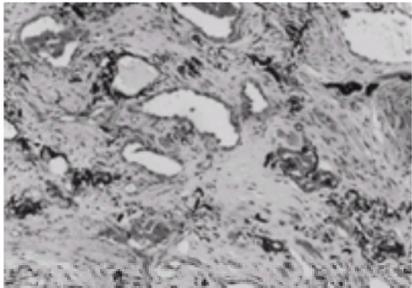

FIGURE 371.3. Photomicrograph of histologic features of usual interstitial pneumonitis. The lung architecture is markedly distorted by fibrosis, involving the replacement of normal alveolar structures by bands of collagen and fibroblasts and scattered cystic spaces.

There are no pathognomonic histologic features that distinguish IPF from most other forms of ILD. Scattered foci of proliferating fibroblasts (so-called fibroblastic foci) are a consistent finding in UIP. The extent of fibroblastic proliferation is predictive of disease progression. Granulomatous and vasculitic changes are incompatible with a diagnosis of IPF, and some other forms of IIP can be excluded by histopathologic study. Honeycombed lung is the final common pathway for all advanced ILD and may be devoid of specific diagnostic features, regardless of the underlying cause.

OPTIMAL MANAGEMENT

The nonspecific clinical, laboratory, and radiographic features described above should suggest the diagnosis of an ILD but do not confirm the diagnosis of IPF. A detailed medical history, meticulous physical examination, and directed laboratory evaluation are essential steps in the diagnosis of IPF, primarily by excluding other forms of ILD (see [Chapter 360](#)). Evaluation of IPF disease progression and therapeutic responses should be based on objective criteria. Static pulmonary function tests and radiographic changes prove insensitive to significant functional changes in the IPF patient. Serial cardiopulmonary exercise tests may be a more sensitive measure of global function. The best measure of disease status in an individual patient is probably a combined clinical, radiographic (HRCT), physiologic, and pathologic index. BAL has contributed enormously to our understanding of the pathogenesis of IPF, but its routine clinical use in the management of IPF patients is controversial. BAL lymphocytosis has been associated with a favorable prognosis, and elevated neutrophil or eosinophil counts or procollagen peptide levels appear to predict a worse prognosis in some patients with IPF; however, the reliability of these observations in individual patients is uncertain.

In most series (combining treated and untreated patients), the median survival after the onset of symptoms is less than 5 years. However, with the narrowing of the diagnosis to cases involving the UIP lesion, the median survival has declined to approximately 3 years following diagnosis. There is no evidence for spontaneous remission in biopsy-proven IPF, and most patients experience a steadily progressive deterioration. In a few patients, treatment appears to lead to stabilization or retardation of disease progression. Rapid clinical deterioration over weeks or months, historically called the Hamman–Rich syndrome, is uncommon and may represent a different process (see section “Acute Interstitial Pneumonia”). Factors that appear to increase survival include younger age, female gender, lesser degrees of radiographic abnormality, more cellular or inflammatory changes on the lung biopsy, and an early response to treatment.

The goal of therapy for IPF is to prevent disease progression and improve survival. No curative therapy exists, but efforts to suppress the inflammatory response appear justified based on the immunopathogenesis of the disease. There are no controlled studies to guide the dosage and duration of therapy. Because only a few IPF patients improve significantly on corticosteroids alone, combined therapy with an immunosuppressive agent (azathioprine or cyclophosphamide) has been recommended as initial treatment. Treatment with prednisone is usually initiated at 40 to 60 mg per day and continued for 4 to 6 months. If the patient stabilizes or shows objective improvement, the dose is gradually tapered to the minimum effective level (usually 0.25 mg per kilogram per day). Azathioprine or cyclophosphamide at 2 to 3 mg per kilogram per day lean body weight (LBW) to a maximum dose of 150 mg per day orally is recommended as part of the initial regimen. Dosing should begin at 25 to 50 mg per day and increase gradually, by 25-mg increments every 7 to 14 days until the maximum dose is reached. Clear response to therapy may not be evident until the patient has received 3 months or more of therapy. Consequently, in the absence of complications or adverse effects of the medications, combined therapy should be continued for at least 6 months. At that time, repeat studies should be performed to determine the response to therapy. Therapy with alternative agents such as colchicine, interferon gamma, pirfenidone, methotrexate, D-penicillamine, antioxidants, and cyclosporine may be helpful, but there is little data available to justify their routine use.

Treatment for IPF is generally lifelong for patients who respond, and complications of therapy must be considered at the outset. A tuberculin skin test should be performed and preventive antituberculous therapy offered to positive reactors before corticosteroid therapy. The routine use of trimethoprim–sulfamethoxazole (one single-strength tablet thrice weekly) as prophylaxis against *Pneumocystis carini* has been recommended for patients receiving immunosuppressive therapy. In addition to cushingoid features, the possibility of developing cataracts, hypertension, hyperglycemia, hyperlipidemia, myopathy, osteoporosis, osteonecrosis, opportunistic infection, psychosis, and other adverse effects should be considered. Patients receiving cytotoxic therapy should be closely monitored for evidence of hematologic or hepatic toxicity.

Basic medical management can help alleviate many of the clinical manifestations of IPF. Smoking cessation is vital. Oxygen should be prescribed when the resting PaO₂ falls below 60 mm Hg or when exercise oxygen desaturation below 90% occurs. Judicious diuretic therapy can help manage cor pulmonale, and opiates may be palliative measures for the relief of terminal dyspnea or intractable cough. Pneumococcal and influenza vaccinations should be administered. New symptoms and focal radiographic abnormalities should be evaluated for infectious and malignant causes. IPF patients have an extraordinarily high incidence of lung cancer (10% to 15%). Lung transplantation is a realistic option for many patients with IPF who do not respond to medical therapy. Referral to a transplant center should be timed to avoid a long and fruitless course of corticosteroids in patients with advanced fibrosis, or premature demise during the pretransplantation evaluation and inevitable wait for organ availability.

DESQUAMATIVE INTERSTITIAL PNEUMONIA AND RESPIRATORY BRONCHIOLITIS–ASSOCIATED INTERSTITIAL LUNG DISEASE

DEFINITION

Like UIP, the term desquamative interstitial pneumonia (DIP) is used to describe both an idiopathic clinicopathologic entity and a histologic pattern. Previously, under the clinical concept of IPF, the cellular DIP and fibrotic UIP were considered part of the spectrum of the same disease. Currently, each is viewed as a separate clinicopathologic entity with the radiographic and histologic pattern of UIP being required for the diagnosis of IPF. The term respiratory bronchiolitis–associated

interstitial lung disease (RB-ILD) is more anatomically accurate as it conveys important pathogenetic implications, which the older term, DIP, does not.

The histologic criteria for diagnosis of DIP has been narrowed following the description of the histologic pattern of RB-ILD and refinement of the criteria for UIP. Consequently, the clinicopathologic entity of DIP is very rare, whereas RB-ILD and UIP are more common. The cause is unknown. However, DIP/RB-ILD is seen almost exclusively in cigarette smokers or persons exposed to passive cigarette smoke.

CLINICAL FINDINGS AND LABORATORY FINDINGS

Most patients are in the fourth to fifth decade of life. It is more common in men than women (2:1). Most patients present with a subacute (weeks to months) illness characterized by dyspnea and cough. The chest radiograph may be normal in up to 20% of cases. The chest radiograph and HRCT scan pattern shows diffuse ground-glass opacity in the middle and lower lung zones ([Fig. 371.4](#)). Lung function testing shows a restrictive pattern with reduced single-breath diffusing capacity of carbon monoxide and hypoxemia on blood gas analysis.

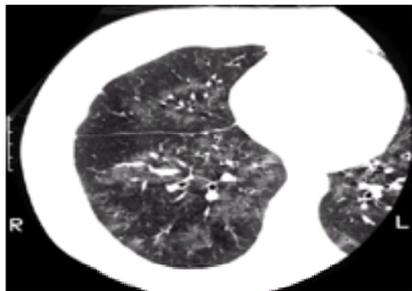

FIGURE 371.4. A high-resolution computed tomography (HRCT) scan of the chest from a patient with respiratory bronchiolitis–associated interstitial lung disease showing extensive ground-glass opacities. The diagnosis was confirmed by thoracoscopic lung biopsy. The symptoms and HRCT scan improved following cessation of smoking.

The histologic hallmark of DIP is diffuse marked intra-alveolar macrophage accumulation—smoker's macrophages with a golden brown pigment with numerous tiny black particles ([Fig. 371.5](#)). Lung biopsy reveals a uniform, diffuse, intra-alveolar macrophage accumulation. The macrophage accumulation is accentuated around respiratory bronchioles and extends diffusely throughout the lung parenchyma. There is little fibrosis, with only mild or moderate thickening of alveolar walls. Unlike UIP, there is no scarring fibrosis causing remodeling of the lung architecture. Fibroblastic foci are absent or inconspicuous, and the fibrous connective tissue that is present appears about the same age. Interstitial inflammation is usually mild in extent and severity, consisting of lymphocytes and a few plasma cells.

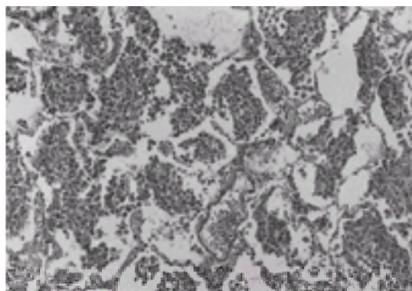

FIGURE 371.5. Photomicrograph of histologic features of desquamative interstitial pneumonitis. The lung architecture is relatively preserved, with minimal thickening or inflammation of the alveolar walls, but the alveolar spaces are filled with alveolar macrophages.

A DIP-like reaction can occur as a nonspecific reaction adjacent to a variety of pathologic lesions: pulmonary Langerhans' cell histiocytosis, IPF, drug reactions (e.g., amiodarone), chronic alveolar hemorrhage, eosinophilic pneumonia, pneumoconioses (e.g., talcosis, hard-metal disease, asbestosis), obstructive pneumonias, exogenous lipoid pneumonia, histiocyte-rich infections (e.g., *Mycobacterium avium* complex, HIV infection). Chronic eosinophilic pneumonia without eosinophils may resemble DIP.

OPTIMAL MANAGEMENT

Clinical recognition of DIP/RB-ILD is important because the process is associated with a better prognosis than IPF, with an overall survival of about 70% after 10 years. Smoking cessation should be required treatment. Corticosteroid administration, which is occasionally required, usually results in improved function and resolution of DIP/RB-ILD.

ACUTE INTERSTITIAL PNEUMONIA

DEFINITION

AIP is a rare fulminant form of lung injury causing rapidly progressive parenchymal fibrosis. AIP likely represents the subset of cases of idiopathic adult respiratory distress syndrome (ARDS). The cases of pulmonary fibrosis originally reported by Hamman and Rich had clinical and histopathologic features of AIP rather than IPF. AIP is rare. The pathogenesis is unknown and appears to involve a complex array of cellular events involving a wide variety of cells such as epithelial cells, endothelial cells, neutrophils, histiocytes, fibroblasts, and smooth muscle cells as well as the extracellular matrix.

CLINICAL FINDINGS AND LABORATORY FINDINGS

AIP presents acutely (days to weeks from onset of symptoms) in a previously healthy person usually over the age of 40 years. There is no sexual predilection. A prodromal illness, lasting usually 7 to 14 days before presentation, is common. The clinical signs and symptoms include fever, cough and shortness of breath.

Routine laboratory studies are nonspecific and generally not helpful. Most patients have moderate to severe hypoxemia and develop respiratory failure. Mechanical ventilation is often required. A rigorous search for infectious and inflammatory conditions causing acute lung injury is essential. The radiographic findings are similar to those seen in ARDS. Diffuse, bilateral, air-space opacification is seen on chest radiograph. CT scans show bilateral, patchy, symmetric areas of ground-glass attenuation. Bilateral areas of air space consolidation may also be present. A predominantly subpleural distribution may be seen. Mild honeycombing, usually involving <10% of the lung may be seen on CT examination. A surgical lung biopsy is required to confirm the diagnosis. The histopathologic features are typical of diffuse alveolar damage, with extensive hyaline membranes and varying degrees of interstitial and alveolar organization with fibrosis.

OPTIMAL MANAGEMENT

The mortality from AIP is high (>60%) with the majority of patients dying within 3 months of presentation. It is not clear that corticosteroid therapy is effective in AIP. The main treatment is supportive care because unlike other chronic forms of IIP, AIP may regress or resolve with supportive therapy. In fact, those who recover usually do not have recurrence of the disease and most have substantial or complete recovery of lung function.

NONSPECIFIC INTERSTITIAL PNEUMONIA

DEFINITION

Nonspecific interstitial pneumonia does not appear to be a discrete entity, and the risk is that it will become a “wastebasket” designation for any interstitial inflammatory and fibrotic processes that does not have the classical clinical or histopathologic features of other IIPs. The importance in recognizing NSIP is to separate these cases from UIP since the overall survival is substantially better in NSIP than in UIP. The incidence and pathogenesis are unknown.

CLINICAL FINDINGS AND LABORATORY FINDINGS

Most patients are middle-aged adults with a subacute onset of symptoms of approximately 8 months prior to diagnosis. There appears to be a slight female predominance (1.4:1). Dyspnea and cough are the most common presenting complaints. Fever and systemic flu-like symptoms are common.

The chest radiograph usually shows bilateral reticular or hazy opacities. HRCT scan findings in NSIP include bilateral patchy ground-glass attenuation, bilateral areas of consolidation, irregular lines, and bronchial dilatation.

Surgical lung biopsy is required to confirm the diagnosis. NSIP is characterized by the presence of varying degrees of inflammation and fibrosis within alveolar walls. The changes are temporally uniform, but the process may be patchy with intervening areas of unaffected lung. The process is frequently accentuated in the peribronchiolar interstitium and the density of the inflammatory infiltrate is considerably greater than that occurring in other IIPs. The fibrotic cases of NSIP involve dense interstitial fibrosis with a diffuse or patchy pattern. Type II cell hyperplasia often accompanies the interstitial inflammation and may be prominent. Fibroblastic foci are far less common than that seen in UIP. However, foci of honeycomb fibrosis may be present.

OPTIMAL MANAGEMENT

Patients with this lesion appear to have different clinical outcomes compared to patients with AIP, UIP, DIP, or BOOP. Importantly, unlike patients with IPF/UIP, the majority of patients with NSIP have a good prognosis, with most showing improvement after treatment with corticosteroids. The prognosis appears to depend on the extent of fibrosis.

LYMPHOCYTIC INTERSTITIAL PNEUMONITIS

DEFINITION

Lymphocytic interstitial pneumonia is an uncommon pathologic process characterized by the presence of widespread, monotonous sheets of lymphocytic infiltration in the interstitium of the lung. LIP is no longer included among the IIPs, but it is included in the chapter because it can have similar modes of presentation. In addition to being differentiated from IPF, it must be distinguished from lymphocytic infiltrations associated with pseudolymphoma, primary lymphomas, lymphomatoid granulomatosis, benign lymphocytic angiitis and granulomatosis, plasma cell interstitial pneumonia, and angioimmunoblastic lymphadenopathy. LIP is associated with autoimmune conditions such as Sjögren's syndrome and has been found with hypogammaglobulinemia and HIV infection and after allogeneic bone marrow or solid organ transplantation.

CLINICAL FINDINGS

Lymphocytic interstitial pneumonia occurs more commonly in women, usually in the fourth to sixth decade of life. It is also seen in children, particularly those with hypogammaglobulinemia or AIDS. The clinical manifestations of LIP are dominated by those related to the underlying disease, such as Sjögren's syndrome. Progressive dyspnea and cough are the most common presenting symptoms, while weight loss, pleuritic pain, arthralgias, and fever also occur. Bibasilar rales on chest examination, cyanosis, and finger clubbing are common physical findings.

LABORATORY FINDINGS

The chest roentgenogram is nonspecific, with reticular opacities being the most common abnormality. A mixed alveolar–interstitial pattern appears as the disease progresses, as a result of the coalescence of the opacities. Cysts, honeycombing, and pulmonary hypertension are also late manifestations. Pleural effusions are uncommon and are suggestive of a complicating lymphoma. A restrictive defect is commonly seen, often associated with a reduction in the carbon monoxide diffusing capacity and arterial hypoxemia. A striking T-cell lymphocytosis is seen on bronchoalveolar lavage.

Surgical lung biopsy is required for the diagnosis in almost all cases. The lymphocytic infiltration involves the alveolar septa and peribronchiolar and perivascular interstitium, and is usually extensive and severe. The lymphocytes are polytypic (both B and T cells may be found), distinguishing them from the monotypic lymphocytic infiltrates characteristic of pulmonary lymphoma. The number of plasma cells and macrophages is also increased in these infiltrates. Other prominent histopathologic features include the accumulation of large interstitial reticuloendothelial cells, mononuclear cells, and giant cells forming noncaseating granulomas, as well as the presence of perivascular and paraseptal amyloid deposition and well-formed lymphoid germinal centers.

OPTIMAL MANAGEMENT

The clinical course of idiopathic LIP is unknown. In cases where LIP is associated with another disease, the underlying disease largely determines the outcome. Progression to end-stage fibrosis can occur, and the development of lymphoma is a recognized complication of LIP. Marked improvement or complete resolution followed corticosteroid therapy in many cases. Progressive pulmonary fibrosis, cor pulmonale, and death can occur despite therapy. Infection is a common complication in such patients, especially those with an associated dysproteinemia.

were unaffected as were responses to parenteral injection of antigens.

PATHOLOGIC FACTORS

Clinical hypersensitivity pneumonitis is often a benign illness in which the history is of paramount importance in making the diagnosis. Pathologic specimens are obtained in general only from unusual examples of the syndrome (when the diagnosis is in doubt or when the lesion is unusually severe). Pathologic series of cases from the literature are plagued with this problem; there is no prospective series. In one large series reported from an area endemic for farmer's lung, a useful, lucid description of the incidence of specific lesions detected in 60 biopsy specimens is provided.

The most common finding (100% of specimens) was an interstitial infiltrate composed predominantly of lymphocytes but containing variable numbers of neutrophils and eosinophils. Granulomas were detected in 70% of specimens. Some evidence of foreign-body accumulation was present in 60% of specimens, and there was a component of bronchiolitis in half of the cases. In this series vasculitis was not noted, and it is rare in other descriptions as well. These histologic findings are not specific, but the constellation of a pleomorphic interstitial infiltrate, predominantly of lymphocytes, with some granuloma formation and a component of bronchiolitis should be suggestive of the diagnosis. Some overlapping may be seen with sarcoidosis and with the more recently described entity of bronchiolitis obliterans with organizing pneumonitis. Granulomas are not a feature of bronchiolitis obliterans with organizing pneumonitis, however, and lymphocyte subset analysis of lavage or biopsy specimens would allow some discrimination between hypersensitivity pneumonitis and sarcoidosis (T8 cells are increased in hypersensitivity pneumonitis and T4 cells are expanded in sarcoidosis). The pathologic process also mirrors the common physiologic finding of restriction (interstitial infiltrate) with varying amounts of obstruction (bronchiolitis), described later.

CLINICAL FINDINGS

Patients with exposure to relevant antigens may develop a variety of symptoms. Although these presentations can be divided into three groups, these groups constitute a spectrum of clinical cases, and considerable overlap is seen for individual patients. Important in the clinical presentation is the tendency for the illness to attack nonsmokers. Epidemiologic studies indicate that the disease is two- to ten-fold more common in nonsmokers. Although a similar "protective" effect of smoking is seen in sarcoidosis, the mechanism of this effect is unknown.

ACUTE PNEUMONITIS

Heavy acute exposure may result in sudden onset of clinical illness. Symptoms include fever, chills, malaise, headache, and dyspnea. Cough is variable. Although the chief lung insult is to the alveolar zone and small airways, occasionally patients with prior history of allergies (e.g., rhinitis or asthma) may present with a component of wheezing indicative of large-airway involvement. This syndrome usually peaks in intensity 3 to 6 hours after initial exposure. The degree of disability at the peak of symptoms may range from moderate illness reminiscent of influenza to noncardiogenic pulmonary edema requiring mechanical ventilatory support. Death has been reported.

This illness should be distinguished from another, similar clinical syndrome: organic dust toxic syndrome. This illness is characterized by fever beginning a few hours after exposure to dust contaminated by endotoxins. Immunity to organic antigens is absent. The patient may experience flulike symptoms. However, dyspnea is absent. Workers in several occupations that involve exposure to dust have reported these symptoms. Some of these occupations also are associated with hypersensitivity pneumonitis.

SUBACUTE ILLNESS

Some patients may have minimal symptoms at the time of acute exposures. These subjects may note only vague malaise and chilliness after exposure—symptoms similar to those of a mild viral syndrome. With recurrent exposure these symptoms continue, and weight loss, anorexia, night sweats, and headache may develop. Respiratory symptoms of chest tightness and cough gradually dominate the illness. Some hemoptysis has been noted in up to one-fourth of patients. As in the acute syndrome, the constitutional symptoms and chest tightness tend to peak about 6 hours after each exposure. Furthermore, the patient may feel remarkably better after avoiding exposure for several days. For example, subjects with occupational exposure may note gradual progressive improvement during vacation periods. Eliciting a history of such symptom fluctuation is of paramount importance in establishing a firm diagnosis.

CHRONIC FIBROSIS

Some exposed individuals may have chronic lung scarring after prolonged exposure to the relevant stimulus. Dyspnea becomes chronic, and the symptom fluctuation with exposure may be lost. However, all of these patients have clear histories of chronic exposure to large amounts of antigen and of previous acute or subacute bouts of illness. At this point, the disease is otherwise indistinguishable from other chronic inflammatory lung diseases. The outcome from the chronic phase of the illness is similar to that described for idiopathic pulmonary fibrosis.

LABORATORY FINDINGS

Although a welter of tests is available, none of these tests is specific for this illness. This nonspecificity results from both the intrinsic nonspecificity of the tests (e.g., chest radiograph, leukocyte count) and from the tendency for most END subjects to have some reaction to the antigen (e.g., serum precipitins). Because no test is diagnostic per se, the diagnosis rests on construction of the elements of a clinical syndrome. The foundation for this syndrome is a careful clinical history of exacerbation of symptoms that occurs 3 to 6 hours after acute exposure and a remission in symptoms that follows avoidance of contact with the antigen. A history of potential sources of antigen in the workplace (e.g., antigenic dust, hapten fumes, or farming) or at home (e.g., pigeon coops, humidifiers) is necessary. It is important to remember that certain sources of antigens (humidifiers, heaters, and air conditioners) are not obvious. Although symptoms develop in only about 10% to 20% of those exposed, a history of others in the same environment with similar symptoms may be helpful in these cases. A history of antigen exposure, coupled with the constitutional and respiratory tract symptoms listed earlier, is mandatory for the diagnosis.

STANDARD LABORATORY TESTS

Standard laboratory tests are nonspecific. Leukocytosis is usually found after acute exposure to antigen. Polymorphonuclear leukocytes (PMNs) are most prominent, but an increase in circulating eosinophils is occasionally reported. The erythrocyte sedimentation rate is elevated, and polyclonal hypergammaglobulinemia is noted. Chest radiographs disclose a variety of findings. These include a normal examination, patchy alveolar shadows, diffuse alveolar opacities, and miliary nodules. Significant adenopathy and pleural reaction are rare. Some reports suggest that computed tomography imaging provides useful information. Computed tomography scans show widespread ground-glass changes and poorly defined small nodular densities. These findings should suggest the diagnosis. They are not definitive but are seen in most patients.

SEROLOGIC TESTING

Serologic testing is an important adjunct to the diagnosis. Although all exposed persons may react to the offending antigen, antibody reactions are highest in patients with active disease. Virtually all acutely or subacutely ill patients have circulating precipitating antibodies when screened with the appropriate antigen. Unfortunately, the antigen panels for hypersensitivity screening contain only the more common antigens (e.g., pigeon serum, *Saccharopolyspora rectivirgula*, and thermophilic *Actinomyces*). Other antigens that have been described are not commercially available, and there is no uniform method to test for hapten antigens. Finally, about half of the group of subjects with chronic disease test negative for antibody. Many of these subjects have not had recent exposure, and it is believed that the intensity of the antibody response wanes during this interval.

PULMONARY PHYSIOLOGY

Pulmonary physiology is usually that of a restrictive ventilatory defect. This is most dramatic after acute exposure to antigen. Lung volumes and diffusing capacity are reduced in most patients. The signs of restriction may be accompanied by varying amounts of small-airway obstruction, as suggested by the pathologic distribution of the lesions. Some patients may have evidence of significant amounts of airway obstruction because of asthma, predominant bronchiolitis with minimal alveolitis, or

even emphysema. These abnormalities in lung function are usually associated with significant arterial oxygen desaturation.

BRONCHOALVEOLAR LAVAGE

Bronchoalveolar lavage is indicated for most patients suspected of having this syndrome. These patients often have complex histories and laboratory findings that are nonspecific. In many patients, the diagnosis is not obvious, and the physician is forced to consider the differential diagnosis of diffuse parenchymal lung lesions. Furthermore, treatment options may be associated with some morbidity and with significant alterations in lifestyle, and therefore should not be recommended without an attempt to elucidate the diagnosis fully. A reasonable approach in these patients is to perform a bronchoscopy with wedged lavage and transbronchoscopic biopsy. The recovered material is processed to exclude infectious causes of the syndrome. Specifically, mycobacterial, parasitic, and fungal pathogens should be sought in recovered fluids and biopsy specimens. Cytologic examination of recovered cells is most useful. Pathogens are absent (e.g., mycobacteria and *P. carinii*). Differential counts of recovered cells obtained from the lungs of subacutely ill patients reveal the classic finding of lymphocytosis, which may be striking (often more than 60% of recovered cells are lymphocytes; Table 372.3). Small numbers of PMNs, including neutrophils and eosinophils, may be seen as well. Patients who have had acute exposure (within 24 hours) have higher numbers of PMNs. If access to assessment of lymphocyte surface markers is available, lymphocytes in recently exposed patients are of the suppressor–cytotoxic subset, and cytotoxic cells predominate. Transbronchoscopic biopsy specimens tend to show a pleomorphic alveolitis. Infectious pathogens must be absent. Although these bronchoscopic findings of hypersensitivity pneumonitis are never diagnostic, they may significantly increase the physician's confidence in the diagnosis and reduce the diagnostic possibility of infection.

Patient Group	% PMN ^a	% Lys	CD4/CD8
Hypersensitivity pneumonitis			
Acute	41	38	NA
Subacute	2	78	0.41
Sarcoidosis	2 ^b	40	>2
HIV infection	2 ^c	53	0.02
Tuberculosis	4 ^d	11	3.6

^a %PMN and %Lys are the percentages of polymorphonuclear leukocytes and lymphocytes, respectively, among lower respiratory tract cells. CD4/CD8 is the ratio of lower respiratory tract cells staining positive for CD4 and CD8.

^b May be increased in stage III sarcoidosis.

^c May be increased in infected patients.

^d Quite variable in this disease and in fungal infection.

NA, not available.

TABLE 372.3. LOWER RESPIRATORY TRACT CELLS FROM PATIENTS WITH LYMPHOCYTIC ALVEOLAR INFLAMMATION

Some confusion may result, with the lavage finding of at least two other relatively common diagnoses: sarcoidosis and AIDS. Sarcoid lavage fluid contains an increased number of lymphocytes, although usually fewer lymphocytes than in hypersensitivity pneumonitis. These cells are predominantly of the helper phenotype. Many patients with AIDS have some degree of lymphocytosis of the lower respiratory tract during their illness and, similar to findings in the peripheral blood, the suppressor–cytotoxic subset predominates. Symptomatic lung disease in these patients is most commonly associated with infection, and such infections are readily sampled by lavage.

OPEN-LUNG BIOPSY

Some patients may need to undergo open-lung biopsy. This procedure should be used in patients whose diagnosis is still uncertain owing to atypical history or confusing lavage findings. Again, the tissue findings are not diagnostic by themselves. They exclude other diagnoses and refocus attention on the possibility of hypersensitivity pneumonitis. Renewed attempts at eliciting a compatible history may now meet with success.

RESPIRATORY TRACT ALLERGEN CHALLENGE TESTING

Challenge testing has been used in some cases. The subject is exposed to the suspected antigen, and a clear response of reduction in lung function and the evolution of constitutional symptoms usually occurs 4 to 8 hours after inhalation. Unfortunately, antigens are not commercially available for these tests, and the tests themselves are not standardized. Furthermore, the clinical reactions to laboratory challenge can be severe. These factors argue against routine use of this potentially useful diagnostic modality.

OPTIMAL MANAGEMENT

Hypersensitivity pneumonitis is initiated and perpetuated by exposure to organic antigens or haptens. Because of its dependence on antigen exposure, the disease may be controlled by antigen avoidance. For example, once the offending agent has been identified, the environment may be purged, as in the case of contaminated humidifiers or car heaters. In some cases, the environment cannot be controlled easily. Farmers who deal with stored hay are unable to prevent fungal contamination. In such instances, a change in work habits could be considered. Because total avoidance of antigen is the best approach, a change in occupation may be necessary. For some patients this is unrealistic. For patients who must continue their exposure, commercial respirators may reduce the amount of inhaled antigen to a sufficient degree as to prevent recurrence of the illness. Electrostatic particle removal devices have successfully cleaned home air.

A period of corticosteroid therapy has been advocated for patients with constitutional symptoms and reduction in lung function. Treated patients usually show a dramatic improvement in symptomatology and lung function. Furthermore, corticosteroid therapy prevents the late symptoms and drops in lung function attendant to antigen challenge testing. Although patients may indeed feel better, corticosteroid treatment is not an ideal therapy. In one randomized trial, treated patients improved more rapidly. However, 5 years later both groups had similar lung function. Treated patients were found to have an excess number of relapses in comparison with untreated subjects. Thus, therapy should probably be reserved for patients with severe acute symptoms or significant lung dysfunction. The optimum dose and duration of treatment are also uncertain. Initial doses of 30 to 60 mg of prednisone daily and a 2-month treatment course (including a period of taper) have been most frequently advocated. Corticosteroid therapy does not absolve the patient and physician from attempting to control exposure. Corticosteroids are merely an adjunct to the primary therapy—avoidance of the antigens responsible for the illness.

DEFINITION

Sarcoidosis is a systemic granulomatous disorder of unknown cause that most commonly affects adults. Its manifestations are diverse, affecting virtually any organ, especially the lungs, lymphatics, eyes, and skin.

INCIDENCE

Sarcoidosis occurs worldwide, affecting persons of all ages, races, and gender. It may be more common in Scandinavian countries, the United Kingdom, Ireland, the United States, and Japan. Estimated prevalence rates range from 1 to 40 per 100,000 population, with age-adjusted annual incidence rate of 10.9 per 100,000 for whites and 35.5 per 100,000 for blacks in the United States. Because the disease is often misdiagnosed or goes unrecognized, these rates likely underestimate the frequency of this disorder.

ETIOLOGIC FACTORS

The cause or causes of sarcoidosis remain unknown. Reports of work-related risk for health care workers, community outbreaks, and studies tracing case contacts to previously diagnosed cases suggest either shared environmental exposures or spread by person-to-person transmission. Careful environmental investigation of new cases can uncover clusters of disease cases and sometimes point to sources of antigen exposure. No infective agent or single antigen has been consistently linked to sarcoidosis. The disease most likely represents a hypersensitivity response to one or many agents (bacteria, fungi, virus, chemicals) by a person with either an inherited or acquired predisposition. It is likely that multiple genetic factors play a part in the pathogenesis. Associations with human leukocyte antigen genes have been reported, but specifics vary with the population studied. Excess rates among twins and in African-American families suggest genetic risk.

PATHOGENESIS

The basic pathologic lesion in sarcoidosis is the noncaseating granuloma made up of radially arranged epithelioid cells with pale nuclei, a few multinucleated giant cells, and lymphocytic infiltration. Caseation is absent; occasionally, a small area of fibrinoid necrosis may be present. Schaumann and asteroid inclusion bodies may be found in giant cells of the granuloma. Sarcoidal granulomas may resolve spontaneously, leaving no scar; may persist for a long time with little or no fibrosis; may be surrounded by a rim of fibrosis with intercalated fibroblasts and mast cells; or may undergo complete hyalinization and fibrosis, resulting in loss of tissue architecture.

At our present level of understanding, development of sarcoidal granulomas requires at least three events to occur: (a) antigen exposure; (b) a cellular immune response directed against the antigen; and (c) a more nonspecific inflammatory response that amplifies the antigen-specific immunologic reaction. An overexuberant reaction by antigen-specific T cells and other accessory cells, including macrophages, dendritic cells, mast cells, and fibroblasts, results in eventual tissue injury and physiologic dysfunction if the cellular immune hypersensitivity response fails to abate spontaneously or with immunosuppressive medications. For example, in the lung, a T-cell alveolitis occurs, followed by granuloma formation. CD4⁺ T cells usually predominate, associated with excessive production of interleukin-2, interferon- γ , and tumor necrosis factor- α , among other proinflammatory cytokines. Further inflammation is propagated by changes in vascular/alveolar permeability and the influx or local proliferation and activation of inflammatory macrophages and other cells.

CLINICAL FINDINGS

Sarcoidosis may involve one organ system or several. Routine chest radiography may identify asymptomatic cases of sarcoidosis. However, the majority of patients present with nonspecific systemic symptoms, such as fatigue, weight loss, fever, anorexia, and, occasionally, chills and night sweats.

ORGAN INVOLVEMENT

RESPIRATORY TRACT

The respiratory tract is involved in over 90% of patients. Chest symptoms typically include dyspnea, retrosternal chest discomfort, and nonproductive cough. Hemoptysis is rare but may occur with endobronchial disease or when mycetomas complicate stage IV disease. Interstitial involvement results in clinical findings of inspiratory crackles in fewer than 20% of patients, with restricted lung volumes and abnormalities of gas exchange on pulmonary function testing. Bronchial involvement often results in airflow limitation and bronchial hyperreactivity. Sarcoidosis of the upper respiratory tract occurs in 2% to 18% of patients, producing nasal obstruction, recurrent or persistent sinusitis, hoarseness, and, rarely, palatal destruction. Uncommon lung manifestations include pleural effusion, pneumothorax, chylothorax, pleural thickening and calcification, lymph node calcification, and cavity formation.

The modified Scadding classification of lung involvement based on chest radiograph findings, which is widely accepted, is as follows:

Stage 0, no abnormality

Stage I, bilateral hilar adenopathy without parenchymal opacities

Stage II, hilar adenopathy with parenchymal opacities

Stage III, parenchymal infiltrates without hilar adenopathy, and

Stage IV, fibrosis with honeycombing, hilar retraction, bullae, cysts, or emphysema

The Scadding system scores radiographic appearance only; it does not score the extent of disease. Radiographic evidence of disease does not necessarily progress through all stages or in a linear manner. The differential diagnosis of the chest radiograph, by stage, is summarized in [Table 373.1](#).

Chest Radiograph Stage	Differential Diagnosis
I. Bilateral hilar lymphadenopathy	Lymphoma, tuberculosis, coccidioidomycosis, histoplasmosis, brucellosis, metastatic carcinoma
II. Bilateral hilar lymphadenopathy and parenchymal opacities	Same as stage I, chronic beryllium disease
III. Pulmonary opacities without hilar lymphadenopathy	Extrinsic allergic alveolitis, fibrosing alveolitis, histiocytosis, systemic lupus erythematosus, rheumatoid lung, scleroderma, tuberculosis, chronic beryllium disease
IV. Advanced fibrosis, bullae, cysts	Advanced tuberculosis, bullous emphysema, metastasis, bronchiectasis

TABLE 373.1. RADIOGRAPHIC MANIFESTATIONS OF SARCOIDOSIS

LYMPHATIC AND HEMATOLOGIC SYSTEMS

Palpable peripheral lymphadenopathy occurs in 5% to 30%, and glands are discrete, mobile, and nontender. Cervical, epitrochlear, axillary, and inguinal lymph nodes are the most frequently affected. Splenomegaly occurs in about 10% of patients, often resulting in mild leukopenia or thrombocytopenia due to splenic sequestration. Peripheral lymphopenia is the most common hematologic manifestation. Mild anemia occurs due either to granulomatous bone marrow involvement or to the chronic disease state. Thrombocytopenia can be observed in association with splenomegaly or bone marrow involvement.

HEART

Serious cardiac involvement is detected in 5% to 10% of patients, although the autopsy incidence appears to be much higher. Symptoms may include chest pain and palpitations, and previously asymptomatic sudden death occurs occasionally. Half of patients with cardiac sarcoidosis have electrocardiographic abnormalities of rhythm, conduction, and repolarization, more easily detected with 24-hour cardiac event or Holter monitoring than with routine electrocardiography. Other manifestations include infiltrative cardiomyopathy with congestive heart failure, pericarditis, and papillary muscle dysfunction. Echocardiography can identify valvular abnormalities, left ventricular dysfunction, pericardial effusion, and ventricular aneurysms. Thallium 201 myocardial scintigraphy may reveal segmental defects from granulomatous or fibrous infiltrates, although findings are nonspecific. The diagnostic yield of endomyocardial biopsies is low. Early suspicion and diagnosis of myocardial sarcoidosis is essential, since treatment improves the prognosis. Management includes systemic corticosteroids, pacemakers, implantable defibrillators, and antiarrhythmic agents.

EYES

Ocular lesions occur in approximately 25% of patients, with granulomatous uveitis being the most common finding. Symptoms of acute uveitis include blurred vision, photophobia, and excessive lacrimation. Anterior uveitis may respond to local corticosteroid drops and ointments, but posterior disease requires systemic corticosteroids. Chronic uveitis may lead to cataracts, glaucoma, and blindness. Other ocular lesions include conjunctival follicles, lacrimal gland enlargement, keratoconjunctivitis sicca, retinal vasculitis, dacryocystitis, and optic nerve involvement.

SKIN

Approximately 25% of patients will have dermal manifestations of sarcoidosis. Definite cutaneous findings include (a) erythema nodosum, a vasculitic lesion manifesting as painful, 1- to 2-cm, red bumps over the shins, often accompanied by arthralgias and occasionally fever; (b) lupus pernio, a characteristic violaceous nodular or plaque-like lesion over the nose, cheeks, and ears; (c) purple-red, indurated, annular skin lesions; and (d) any skin lesion showing granulomas on biopsy. In the setting of biopsy-confirmed sarcoidosis, new areas of hyper- or hypopigmentation, macules, papules, nodules, and keloids, especially if changed in appearance, indicate probable dermal sarcoidosis.

CENTRAL NERVOUS SYSTEM

Neurologic manifestations of sarcoidosis, affecting less than 10% of patients, may involve cranial nerves, brain, leptomeninges, or peripheral nerves. Though any cranial nerve can be affected, unilateral facial nerve palsy from seventh-nerve involvement is the most common. Syndromes related to hypothalamic disease include hypopituitarism, diabetes insipidus, and hyperprolactin secretion. Headache, confusion, and malaise, usually accompanied by cerebrospinal fluid lymphocytosis and elevated protein level and magnetic resonance imaging abnormalities, reflect leptomeningeal sarcoidosis. Unexplained peripheral neuropathy, myopathy, and abnormal electromyographic test results suggest possible neuromuscular sarcoidosis.

RENAL

Kidney disease is usually related to nephrolithiasis associated with overproduction of calcitriol, leading to hypercalciuria with or without hypercalcemia. Severe granulomatous kidney disease causing renal dysfunction is rare.

LIVER

Although liver biopsy reveals granulomatous involvement in two-thirds of patients, clinically significant hepatic dysfunction is uncommon. Up to one-third of patients have hepatomegaly or a cholestatic pattern of biochemical abnormalities, with elevations in serum alkaline phosphatase, total bilirubin, and aminotransferase levels.

OTHER ORGAN SYSTEMS

Salivary and parotid gland involvement may cause dry mouth, and probably occurs in about 10% of patients. Symmetrical parotid swelling associated with uveitis, with or without facial nerve palsy, is termed Heerfordt's syndrome. Arthritis most commonly occurs as symmetrical swelling and tenderness of ankles, knees, and fingers. Löfgren's syndrome is distinguished by fever, arthralgias, erythema nodosum, and bihilar lymphadenopathy, and portends a generally good prognosis. Muscle involvement is rare and may include nodules, acute polymyositis, or chronic myopathy.

LABORATORY FINDINGS

Since there is no single or specific diagnostic test for sarcoidosis, diagnosis depends on a compatible clinical picture, histologic findings of noncaseating granulomas in affected organs, and the exclusion of other granulomatous diseases. The evaluation of patients with sarcoidosis must (a) provide histologic confirmation of disease; (b) assess extent and severity of organ system involvement; (c) map which organs are clinically involved; (d) determine whether disease is stable or likely to progress; and (e) assess the need for treatment. [Table 373.3](#) summarizes the baseline tests recommended for any patient with newly diagnosed sarcoidosis. Asymptomatic organ system involvement may be missed without sophisticated and expensive testing. Such involvement is usually mild and of little clinical significance except for uveitis. A slit-lamp examination is recommended for all patients with sarcoidosis. Subclinical hypercalciuria is associated with risk for kidney stones, and baseline 24-hour urine calcium measurement is useful.

Occupational/environmental history
 Medication history
 Exam emphasizing lung, lymphatics, skin, eye, liver, heart
 Biopsy of an affected organ, with special stains, cultures
 Chest radiography
 Pulmonary function tests, including gas exchange
 Electrocardiogram
 Slit-lamp exam
 Liver function tests, renal function tests
 Serum calcium
 Other tests, depending on clinical/organ system presentation

TABLE 373.3. RECOMMENDED BASELINE CLINICAL EVALUATION

BIOPSY CONFIRMATION

Transbronchial lung biopsy is the usual procedure of choice, with a diagnostic yield of up to 90%. Examination of the patient may disclose other possible biopsy sites such as conjunctiva, skin, lip, or peripheral lymph node. When transbronchial biopsies are nondiagnostic and no other biopsy site has been identified, biopsy of enlarged mediastinal lymph nodes and surgical lung biopsy have high diagnostic yields. Biopsies should be carefully examined and cultured for infectious organisms capable of causing granulomatous diseases.

BLOOD TESTS

Baseline complete blood count is recommended to evaluate the presence of anemia, leukopenia, and thrombocytopenia. Assessment of serum calcium and liver function may show abnormalities reflecting organ system involvement that affect treatment decisions. Serum angiotensin converting enzyme level is elevated in more than half of patients with sarcoidosis but can be found in many other diseases as well. Thus, the test has limited diagnostic value but may be useful in monitoring the course of disease.

PULMONARY FUNCTION TESTS

Pulmonary function tests (PFTs) are required to assess lung function impairment and to monitor disease progression or remission. PFT abnormalities are found in approximately 20% of those with stage I disease compared with 40% to 70% of patients with stage II, III, or IV disease. Exercise physiology testing is a sensitive means for evaluating dyspnea on exertion and for determining the presence of hypoxia. In the lung, the granulomatous infiltration and fibrosis occurring in some patients with sarcoidosis results in low lung compliance, impaired diffusing capacity, and reduced lung volume. Many patients have a low forced expiratory volume in 1 second/forced vital capacity ratio and increased airway resistance. Ventilation–perfusion imbalance and widening of the alveolar–arterial oxygen difference are common. In the early stages, PaO₂ may be within normal limits at rest but decreases with exercise.

CHEST RADIOGRAPHY

Chest roentgenography is necessary and usually sufficient to determine extent of radiographic disease. High-resolution lung computed tomography scanning may be indicated to detect complications of more advanced disease such as bronchiectasis, mycetoma or pulmonary fibrosis, or to evaluate an atypical chest radiograph or superimposed infection or malignancy.

OTHER DIAGNOSTIC TESTS

Kveim–Stilzbach skin testing, in which spleen or lymph node homogenate from a patient with sarcoidosis is injected intradermally and later biopsied, is not widely available, not well standardized, and not approved for general use by the U.S. Food and Drug Administration. Gallium 67 scanning adds little of diagnostic value due to poor specificity. Analyses of bronchoalveolar lavage fluid and cells has provided insight into disease pathogenesis, but none of the findings are specific to sarcoidosis, including the ratio of CD4 to CD8 lymphocytes. Lavage may be helpful in excluding infection or chronic beryllium disease. A comparison of sarcoidosis and chronic beryllium disease is presented in [Table 373.2](#).

Feature	Sarcoidosis	Berylliosis
Hilar adenopathy	Common	Common but less pronounced
Erythema nodosum	Common in acute stage	Absent
Parotid involvement	May be present	Absent
Bone changes	May be present in chronic stage	Absent
Beryllium lymphocyte proliferation test (blood or bronchoalveolar lavage)	Negative	Positive
Clinical course	Remission common	Remission rare
Response to therapy	Good	Good

TABLE 373.2. COMPARISON OF SARCOIDOSIS AND CHRONIC BERYLLIUM DISEASE

DIFFERENTIAL DIAGNOSIS

The major categories of disease which may mimic sarcoidosis are (a) infections, including those caused by mycobacteria, fungi, bacteria, and parasites capable of inducing a granulomatous disease; (b) occupational or environmental lung diseases, including hypersensitivity pneumonitis, chronic beryllium disease, and other metal-induced lung diseases; (c) drug-induced granulomatous pneumonitides; and (d) autoimmune disorders associated with granulomatous lesions such as Wegener's granulomatosis, primary biliary cirrhosis, and Churg–Strauss syndrome. A complete occupational, environmental, and pharmacologic history is necessary for all patients who may have sarcoidosis to exclude exposure to known antigens. Other specific diagnostic tests should be used where appropriate, such as the blood or bronchoalveolar lavage beryllium lymphocyte proliferation test for chronic beryllium disease, antineutrophil cytoplasmic antibody tests for Wegener's granulomatosis and related vasculitides, antimitochondrial antibody tests for primary biliary cirrhosis, and serologic or culture technique tests for fungal or mycobacterial infections. Some neoplasias are associated with sarcoid-like granulomatous reactions in regional lymph nodes, spleen, or liver. The term *granulomatous lesions of unknown significance* describes patients in whom isolated granulomatous involvement of liver or lymph node is found. Therefore, isolated lymph node granulomas are not definitive for diagnosing sarcoidosis.

NATURAL HISTORY OF UNTREATED PULMONARY SARCOIDOSIS

It is not known why some sarcoidosis patients recover spontaneously while others progress. Even after apparent recovery, recrudescence of disease can occur months to years later, although more commonly sarcoidosis is thought to resolve without relapse. Stage I disease remits in 60% to 80% of cases; stage II in 50% to 60%; and stage III in less than 30%, without treatment. Factors associated with poorer prognosis include older age at onset, black race, symptoms lasting more than 6 months, splenomegaly, lupus pernio, and multiorgan and extrathoracic involvement. In a Swedish study, patients with acute disease who expressed human leukocyte antigens DR3 and DQ2 had a particularly favorable prognosis, whether or not they had erythema nodosum. Pulmonary infiltration, if it persists for more than 2 years,

is unlikely to remit without therapy.

OPTIMAL MANAGEMENT

Important considerations and tests to be performed as part of the baseline evaluation of any newly suspected sarcoidosis patient are summarized in [Table 373.3](#). Corticosteroids are the mainstay of therapy for sarcoidosis and its complications. In most cases, a 3-month period of observation prior to treatment allows for assessment of disease activity. If there is interval deterioration in lung function or gas exchange, oral corticosteroids can be started. Usual dosage starts at prednisone 40 mg per day for 6 weeks to 3 months with gradual taper to a lower dose (5 to 10 mg daily or alternate-day) for 6 to 12 months. There is no single well-established regimen for corticosteroid dosing. Factors that warrant more immediate or more prolonged therapy are presented in [Table 373.4](#). Alternative forms of treatment may be required if corticosteroids fail to control the disease or if significant side effects occur. Of the alternative immunosuppressives, methotrexate (7.5 to 15 mg per week orally) has been best studied as a corticosteroid-sparing agent, often in combination with lower dose prednisone. Hydroxychloroquine has efficacy for cutaneous sarcoidosis and for hypercalcemia (200 mg twice daily orally). Other agents have yielded varying results or have been studied less thoroughly, including azathioprine, cyclosporine, chlorambucil, and cyclophosphamide.

Disease Status	Recommendations
Asymptomatic, no organ dysfunction	No treatment, observe
Mild to moderate pulmonary dysfunction, symptoms	Observe 3 months and reassess
Airflow limitation and/or cough	Consider trial of high-dose inhaled steroids
Eye/lens involvement (generally good prognosis)	Observe
Symptomatic pulmonary disease with moderate to severe pulmonary dysfunction	Treatment with corticosteroids
Extrapulmonary disease affecting vital organs, including but not limited to heart, CNS, eyes, liver	Treatment with corticosteroids
Deterioration during observation period	Treatment with corticosteroids
Moderate to severe disease that fails to respond to corticosteroids	Add another immunosuppressive to corticosteroid regimen (e.g., methotrexate)
End-stage pulmonary disease	Lung allograft
Cardiac sarcoidosis with arrhythmias	Consider pacemaker or implanted cardioverter defibrillator in addition to corticosteroids
Dermatologic sarcoidosis	Hydroxychloroquine and/or corticosteroids, especially for disfiguring lesions

TABLE 373.4. GUIDELINES AND INDICATIONS FOR THERAPY

Before implementing therapy, it is important to establish objective measures that can be followed serially to assess therapeutic response. Where possible, it is more valuable to monitor physiologic alterations in vital organs. For example, gas exchange alterations are more sensitive than chest radiographic changes for monitoring pulmonary involvement and response to therapy.

SPECIAL SITUATIONS

PREGNANCY

Many patients improve and are able to discontinue or curtail corticosteroid therapy during pregnancy. The disease does not have any damaging effect on gestation or on the fetus. In some patients the disease worsens after parturition. Certain immunosuppressive agents used to treat sarcoidosis, including methotrexate and azathioprine, can cause miscarriage or damage to the fetus.

INFECTION

The frequency of bacterial and viral infections in patients with sarcoidosis is not greater than in the general population. Aspergilloma is the common fungal colonizer in chronic fibrotic sarcoidosis.

SARCOIDOSIS, MALIGNANCY, AND LYMPHOMA

Sarcoid-like granulomatous lesions may be found in regional lymph nodes draining a carcinoma or even among the tumor cells at the site of the primary neoplasm. It is important that the local “sarcoid reaction” be differentiated from multisystem sarcoidosis. Large population-based studies suggest increased risk of lymphoproliferative malignancy in patients with chronic sarcoidosis.

LUNG TRANSPLANTATION

Transplantation can improve quality of life for some patients, although sarcoidosis patients may have a higher than normal rate of rejection. Sarcoidosis granulomas can develop in the pulmonary allograft.

CHAPTER 374: THE GRANULOMATOUS VASCULITIDES

ULRICH SPECKS

[Wegener's Granulomatosis](#)
[Churg–Strauss Syndrome](#)
[Bronchocentric Granulomatosis](#)
[Necrotizing Sarcoid Granulomatosis](#)
[Lymphomatoid Granulomatosis](#)

The term *granulomatous vasculitis* refers to a very heterogeneous group of disorders consisting of Wegener's granulomatosis (WG), Churg–Strauss syndrome (allergic angitis and granulomatosis), bronchocentric granulomatosis, necrotizing sarcoid granulomatosis, and lymphomatoid granulomatosis. This grouping is merely of historic interest and does not reflect our current understanding of the nosology of these diseases. The term *pulmonary angiitis and granulomatosis* applied to this group of disorders was coined by Liebow because they share the infiltration of blood vessels by inflammatory cells (angiitis) and necrotizing inflammation of the pulmonary parenchyma, resulting in nodules or masses with variable degrees of cavitation (granulomatosis). The clinical presentations—particularly the pulmonary manifestations of these disorders—may occasionally resemble one another. However, in most instances the clinical and histopathologic differentiation is no longer a problem. New serologic markers, such as antineutrophil cytoplasmic antibody (ANCA) and the application of immunohistochemical techniques, have facilitated the clinicopathologic differentiation of these disorders and contributed to a more appropriate classification that reflects an enhanced understanding of their pathogenesis.

Wegener's granulomatosis and Churg–Strauss syndrome are granulomatous inflammatory processes that usually originate in the respiratory tract and evolve into systemic vasculitis, affecting predominantly small vessels and capillaries. Therefore, they are classified together with microscopic polyangiitis in the group of primary necrotizing small-vessel vasculitides, which are usually associated with ANCA ([Table 374.1](#)). Bronchocentric granulomatosis and necrotizing sarcoid granulomatosis are extremely rare granulomatous inflammatory processes that are limited to the lung. They need to be differentiated primarily from infectious granulomatous diseases. Vascular inflammation in these two disorders is secondary. It occurs as the result of extension of the inflammatory process from adjacent areas (bronchocentric granulomatosis) or in the form of non-necrotizing granulomas infiltrating or replacing portions of the vessel walls (necrotizing sarcoid granulomatosis). Both processes respond favorably to corticosteroids and may occasionally even resolve spontaneously. Some authors have argued that bronchocentric granulomatosis and necrotizing sarcoid granulomatosis represent atypical tissue reactions, rather than separate disease entities, and are part of the spectrum of allergic bronchopulmonary aspergillosis and of sarcoidosis, respectively. The term *lymphomatoid granulomatosis* was originally introduced to reflect the clinical and radiographic similarities of this disorder with WG in association with histopathologic features of lymphomas. The prolonged misclassification of lymphomatoid granulomatosis among the vasculitides is the result of the prominent vascular infiltration by lymphoid cells. Advanced immunohistochemical staining techniques now allow most cases of lymphomatoid granulomatosis to be appropriately classified as true lymphomas.

TABLE 374.1. SYSTEMIC VASCULITIDES DEFINED BY THE 1992 CHAPEL HILL INTERNATIONAL CONSENSUS CONFERENCE ON THE NOMENCLATURE OF SYSTEMIC VASCULITIS^a

WEGENER'S GRANULOMATOSIS

DEFINITION

Wegener's granulomatosis is a multisystem disorder that is characterized histopathologically by the presence of necrotizing granulomatous inflammation and vasculitis affecting predominantly the small and medium-size vessels. The upper and/or lower respiratory tracts are most frequently involved, followed by the kidneys. However, any organ system may be involved. WG is unique among the systemic vasculitides because its clinical and histologic findings cannot be explained solely on the basis of the inflammation of the vessels, and a primary necrotizing granulomatosis of the tissues (particularly of the respiratory tract) is an integral part of the lesion, frequently overshadowing the vasculitis. Correspondingly, the clinical course of WG is highly variable. It may range from a protracted illness limited to the respiratory tract with predominantly necrotizing granulomatous pathology to a rapidly progressive illness in which capillaritis is the predominant histopathologic feature, resulting in acute renal or respiratory failure.

The American College of Rheumatology put forth diagnostic criteria that allow the differentiation of WG from other forms of vasculitis ([Table 374.2](#)). The Chapel Hill Consensus Conference ([Table 374.1](#)) proposed the following definition of Wegener's granulomatosis: “granulomatous inflammation involving the respiratory tract, and necrotizing vasculitis affecting small to medium-sized vessels (i.e., capillaries, venules, arterioles, and arteries).” WG is closely associated with the presence of ANCA (particularly cytoplasmic-staining ANCA, C-ANCA, with specificity for proteinase 3, PR3). The diagnosis of WG depends on a correlation of clinical, pathologic, and serologic features.

Criterion	Definition
(1) Nasal or oral inflammation	Development of painful nasal or oral ulcers or purulent or bloody nasal discharge
(2) Abnormal chest radiograph	Nodules, fixed infiltrates, or cavities
(3) Urinary sediment	Microhematuria (>5 red cells per high-power field) or red cell casts
(4) Granulomatous inflammation on biopsy	Histologic changes showing granulomatous inflammation within the wall of an artery or in the perivascular or extravascular area

^a *Arthritis Rheum* 1990;33:1125–1127.
 Note: A patient with vasculitis is said to have Wegener's granulomatosis if two or more of the four criteria have been satisfied.

TABLE 374.2. ACR 1990 CRITERIA FOR WEGENER'S GRANULOMATOSIS^a

INCIDENCE AND EPIDEMIOLOGIC FACTORS

The exact incidence and prevalence of WG are unknown. The available limited epidemiologic studies suggest that the incidence is increasing. However, this may be the result of heightened awareness about the disease, changes in diagnostic criteria, and the availability of ANCA testing. The annual incidence is estimated to be 2.8

to 5 per million. Women and men are affected equally. WG can affect patients of any age, with a median onset at age 45 to 55. In contrast to microscopic polyangiitis, WG is more common in patients of Northern European descent, compared to those with Mediterranean background. The disease is rare in African Americans. Whether this reflects a genetic predisposition or environmental factors remains unclear.

ETIOLOGIC FACTORS AND PATHOGENESIS

The cause of WG remains unknown. The pathogenesis of the symptoms and clinical manifestations is linked to the nature and evolution of the histopathologic lesions. The characteristic histopathologic features of WG are (a) vasculitis, (b) necrosis, and (c) inflammatory background. The vasculitis typically involves medium-size and small vessels, including arteries, arterioles, capillaries, venules, and veins. The large vessels are rarely affected. There may be simply a mural cellular infiltrate or fibrinoid necrosis. More frequently, an intramural eccentric necrotizing granulomatous lesion is found. The capillaritis may be neutrophilic or, rarely, granulomatous. The necrosis is granulomatous in nature. Microabscesses appear to be the initial lesion. They enlarge and coalesce until the typical geographic and basophilic appearance of the necrosis has developed. The necrotic center is surrounded by palisading histiocytes and scattered giant cells. Occasionally, the necrosis may be bronchocentric. The inflammatory background of the granulomatous necrosis and vasculitis can cause extensive parenchymal consolidation mimicking organizing pneumonia. The cellular infiltrates are mixed, consisting of lymphocytes, plasma cells, scattered giant cells, and eosinophils. Sarcoid-like non-necrotizing granulomas are absent. Several atypical histopathologic patterns have also been described.

There is increasing evidence that the interaction of monocytes and T cells is significant in the pathogenesis of WG. T cells from patients with active disease overproduce interferon- γ and tumor necrosis factor- α , apparently due to dysregulated interleukin-12 production by monocytes. In addition, the ANCA target antigen, PR3, was shown to enhance T-lymphocyte proliferation in WG patients compared to controls.

Clinical, in vitro, and even some animal model observations support a pathogenic role for ANCA in the development of small-vessel vasculitis. ANCA is present in most patients with active generalized WG; however, they cannot be detected in about a third of patients with biopsy-proven active WG limited to the respiratory tract. ANCA titers change in relation to disease activity in most patients. Finally, patients in complete remission do not appear to relapse in the absence of ANCA, even though the converse is not always the case. Many in vitro studies have shown proinflammatory effects of ANCA on neutrophils, monocytes, and endothelial cells such as oxygen radical release, degranulation, cytokine release, and expression of cell adhesion molecules, all of which, directly or indirectly, alone and in combination, may contribute to cell injury and tissue destruction. While ANCA may not be essential for the initiation of WG, its presence seems to play a crucial role in the modulation of the inflammatory cascade leading to small-vessel vasculitis.

Upper respiratory tract infections have been implicated in the pathogenesis of WG, but the exact mechanisms by which they may trigger the initial onset of disease or subsequent relapses remain unclear.

CLINICAL FINDINGS

Wegener's granulomatosis usually affects the respiratory tract first. Symptoms caused by predominantly necrotizing granulomatous inflammation of the upper airways and/or the lung may predominate and persist for variable amounts of time (limited phase of the disease) before progressing to the generalized phase of the disease, during which the organ injury caused by small-vessel vasculitis determines the clinical picture and outcome. The limited phase of the disease may be associated with minimal morbidity. Usually it is associated with few constitutional symptoms, and nonspecific markers of inflammatory activity such as the erythrocyte sedimentation rate and the C-reactive protein are only minimally elevated. The generalized vasculitic phase of the disease is usually associated with prominent constitutional symptoms such as malaise, fevers, night sweats, and weight loss. The presence of migratory arthralgias affecting the large joints is also a sign of generalized disease. The erythrocyte sedimentation rate and the C-reactive protein are markedly elevated, as are other markers of acute-phase reaction. While most patients, if untreated, will progress from limited disease to generalized disease with kidney involvement, this progression does not occur in every patient. The presence of C-ANCA appears to be a prognostic indicator in this context.

The clinical manifestations of WG may be highly heterogeneous ([Table 374.3](#)), and any organ system can be affected. At first, when all of these symptoms may occur in isolation, a positive PR3-ANCA test may be the only indicator of an impending systemic disease.

Organ	Pathogenesis	Pathogenesis
Eye	Chronic conjunctivitis, scleritis, episcleritis, corneal ulcerations, and uveitis	Chronic conjunctivitis, scleritis, episcleritis, corneal ulcerations, and uveitis
Ear	Chronic otitis media with effusion or mastoiditis	Chronic otitis media with effusion or mastoiditis
Nose	Chronic rhinitis with or without epistaxis and nasal crusting	Chronic rhinitis with or without epistaxis and nasal crusting
Throat	Chronic pharyngitis, laryngitis, and tracheobronchitis	Chronic pharyngitis, laryngitis, and tracheobronchitis
Lung	Chronic bronchitis, emphysema, and pulmonary nodules or masses	Chronic bronchitis, emphysema, and pulmonary nodules or masses
Kidney	Chronic glomerulonephritis and crescentic glomerulonephritis	Chronic glomerulonephritis and crescentic glomerulonephritis
Heart	Chronic myocarditis and pericarditis	Chronic myocarditis and pericarditis
Central nervous system	Chronic meningitis and encephalitis	Chronic meningitis and encephalitis

TABLE 374.3. ORGAN-SPECIFIC SYMPTOMS AND FINDINGS OF WEGENER'S GRANULOMATOSIS

Eye involvement occurs in about 40% to 70% of patients over the course of their disease, and the frequency and type of eye involvement do not differ between patients with limited and generalized disease. The "red eye" may be the initial manifestation of the disease. Conjunctivitis, scleritis, episcleritis, corneal ulcerations, and uveitis may all persist as the only organ manifestation of the disease for protracted periods of time. Inflammatory pseudotumor of the orbit associated with proptosis, lid swelling, chemosis, and limitations of ocular movement can affect one or both eyes and should be differentiated from metastatic malignancies, lymphoma, and sarcoidosis of the orbit. Retinal vasculitis and optic neuropathy are more commonly encountered in patients with generalized disease. Involvement of the nasolacrimal system can be the cause of epiphora, dacryocystitis, and draining fistulas.

Most frequently, chronic rhinitis with or without epistaxis and nasal crusting, chronic sinusitis, and recurrent or chronic serous otitis are the first symptoms of the disease. Destruction of the nasal cartilage may be the cause of the typical nasal septal perforation or saddle-nose deformity. Ulcerations of the oropharynx, gingival hyperplasia with clefting and petechiae, and salivary gland involvement are other potential manifestations of otorhinologic inflammation and may represent a convenient site for a diagnostic tissue biopsy. Tracheobronchial involvement can cause symptoms that may initially be mistaken for asthma. The inspiratory and expiratory flow-volume loop allows a preliminary determination of the location of the airway obstruction. The acute inflammation of the airways may present as tracheobronchial ulceration, intraluminal inflammatory pseudotumor, or, if the cartilage is involved, bronchomalacia. The most common location of tracheobronchial involvement is the immediate subglottic area. The healing of tracheobronchial lesions may result in significant scarring and be the cause of persistent morbidity, such as airway obstruction, bronchomalacia, and recurrent postobstructive pneumonia. The airway lesions observed in WG may be identical to those observed more rarely in microscopic polyangiitis and difficult to differentiate from those associated with relapsing polychondritis.

Necrotizing granulomatous lesions of the lung may present as solitary pulmonary nodules or masses. More frequently these lesions are multiple, and characteristically they cavitate. While these granulomatous lesions of the lung can be the cause of mild hemoptysis, they are usually somewhat asymptomatic. The differential diagnosis of the lung nodules or masses of WG include primary or metastatic malignancies of the lung, including lymphomatoid granulomatosis, infectious processes such as fungal or nocardia infections, and other idiopathic pulmonary processes such as necrotizing sarcoid granulomatosis.

Alveolar hemorrhage resulting from capillaritis of the lung is a less frequent pulmonary manifestation of WG. It may rapidly lead to respiratory failure and is associated with a mortality of about 50%. While alveolar hemorrhage may occur as an isolated disease manifestation, it is usually associated with renal involvement. In the absence of other granulomatous features of WG, such a presentation is clinically indistinguishable from microscopic polyangiitis or Goodpasture's syndrome, and only the serologic detection of ANCA reacting with PR3 may allow a nosologic distinction from these other syndromes. Pleural effusions (small, exudative), pleural inflammatory pseudotumors (rare), and hilar adenopathy (usually only detectable by computed tomography scan) occur in less than 10% of patients.

Skin involvement may develop in up to 50% of patients over the course of their disease. In 10% it is part of the initial presentation. Leukocytoclastic vasculitis presenting as palpable purpura with or without petechial lesions is the most common manifestation and usually an indicator of the generalized phase of the disease. The presence of PR3-ANCA in patients with isolated leukocytoclastic vasculitis can predict the later development of other characteristic lesions of WG. Necrotizing granulomatous lesions of the skin or pyoderma gangrenosum-like lesions are encountered more rarely.

Nervous system involvement is rarely an initial presentation of WG, but during the course of the disease it affects up to one-third of patients. Peripheral neuropathy, frequently in the form of multiple mononeuropathy, is the most common abnormality, followed by cranial neuropathies. The neuropathy of WG is thought to be caused by vasculitis of the vasa nervorum and consequently to be an indicator of generalized disease. Contiguous spread of the granulomatous inflammation from the respiratory tract can also lead to neurologic symptoms, particularly cranial nerve palsies. Granulomatous infiltration of the pituitary gland can cause diabetes insipidus. Cerebrovascular events, seizures, and meningeal involvement are other rare complications of nervous system involvement.

The glomerulonephritis of WG affects up to 70% of patients and is the result of capillaritis. It requires prompt immunosuppressive therapy to prevent irreversible loss of renal function. The characteristic renal lesion is focal, segmental necrotizing glomerulonephritis with or without crescent formation. This lesion is not specific for WG and is also found in microscopic polyangiitis, Goodpasture's syndrome, or systemic lupus erythematosus (SLE). Immunofluorescence microscopy shows no or only scant immune deposits in WG and microscopic polyangiitis ("pauci-immune"), in contrast to the linear distribution of immune deposits along the basement membranes in Goodpasture's syndrome or the granular immune complex deposits in SLE and other forms of glomerulonephritis. Granulomatous lesions that would allow a distinction between WG and microscopic polyangiitis are rarely detected on renal biopsy specimens. On rare occasions, renal involvement precedes other specific organ manifestations of WG.

The clinical course of WG is unpredictable and the degree and extent of organ involvement determine the outcome. Renal involvement and alveolar hemorrhage carry the worst prognosis.

LABORATORY FINDINGS

Laboratory tests that should be obtained on all patients with suspected WG include an erythrocyte sedimentation rate (ESR), C-reactive protein, a complete blood count, a serum chemistry group, urinalysis, and urine microscopy. If renal involvement becomes apparent on urine testing or if impaired renal function is suspected based on serum chemistry abnormalities, the renal function should be assessed quantitatively. In patients with limited-phase WG most of these parameters are within normal limits, with the exception of a mildly elevated ESR or C-reactive protein. Patients with active small-vessel vasculitis, i.e., generalized-phase WG, usually display a high ESR (more than 70 mm per hour), as well as mild anemia and elevated white blood cell and platelet counts. Active renal involvement is indicated by microhematuria (more than 10 red blood cells per high-power field), red blood cell casts, or serum creatinine rise (more than 25%). Proteinuria is the result of renal injury that may persist after the active inflammation has subsided.

The greatest advance in laboratory testing for WG has come about with the discovery of ANCA. C-ANCA directed against PR3 as target antigen are highly specific for WG. The sensitivity of C-ANCA for WG is affected by the extent of the disease, its activity at the time of sampling, and the methodology used for detection.

OPTIMAL MANAGEMENT

Optimal management of patients with WG requires a close collaboration between the patient's primary care provider and subspecialists who have experience with the clinical heterogeneity of this disease. Early diagnosis and implementation of appropriate therapy are crucial determinants of outcome. Treatment regimens should be individualized depending on organ systems involved, severity of disease, and rate of progression at the time of diagnosis. Complete remissions can be induced in the majority of patients within 6 months of therapy.

Immunosuppression remains the principal mode of therapy for WG. Combined use of oral prednisone and cyclophosphamide is still the most effective therapy and is required for all patients who have rapidly progressive disease and organ involvement associated with the risk of irreversible damage, particularly renal involvement. Patients with alveolar hemorrhage or rapidly progressive glomerulonephritis should receive intravenous methylprednisolone (1 g per day for 3 days) as initial therapy, followed by standard oral therapy. The combination of oral prednisone with low-dose weekly methotrexate (orally or subcutaneously) appears to be equally effective for patients with more limited disease that is sparing the kidneys. Patients with necrotizing granulomatous pathology limited to the respiratory tract lacking evidence of rapid disease progression, and particularly those who are ANCA-negative, may be treated with co-trimoxazole (800/160 mg twice daily), with or without oral prednisone, under careful clinical observation. Other treatment modalities, including plasmapheresis, intravenous gammaglobulin, newer drugs such as mycophenolate mofetil, etanercept, interleukin-10, or lufinomide, remain under investigation and should only be applied on a protocol basis or under specific circumstances by an experienced subspecialist.

Once complete remission has been achieved, prevention of relapse and avoidance of complications of long-term prednisone and cyclophosphamide use become the major goals of therapy. Following successful prednisone dose reduction, cyclophosphamide can be switched to a less toxic agent, such as methotrexate or azathioprine, after about 6 to 9 months of therapy. Long-term co-trimoxazole therapy has also been shown to significantly reduce the rate of relapses.

As most patients with WG require prolonged and repeated courses of immunosuppressive therapy, the prevention and treatment of therapy-related complications becomes a significant aspect of disease management. Infectious complications can be minimized if the white blood count is monitored frequently (no less than every 2 weeks) during cytotoxic therapy and dose adjustments are implemented promptly. White blood counts should not drop below 3.5×10^9 per liter. *Pneumocystis carinii* pneumonia prevention is mandatory during the entire period of immunosuppressive therapy, even if methotrexate is the only agent used. Symptoms of infection should be evaluated immediately and treated accordingly. Diabetes and hypertension should be managed aggressively, particularly in patients who have had renal involvement. Appropriate osteoporosis prevention measures need to be implemented at the onset of corticosteroid therapy. Patients who have received cyclophosphamide require lifelong surveillance for their significant risk of developing cancers of the urinary tract. To preserve future fertility in young patients, consideration should be given to the use of pulse intravenous instead of oral cyclophosphamide application, as well as to sperm banking and ovarian protection measures for male and female patients, respectively.

CHURG-STRAUSS SYNDROME

DEFINITION

Churg-Strauss syndrome was originally called allergic granulomatosis and angiitis and was thought to be related to, yet clearly distinct from, classic polyarteritis nodosa. It is characterized by severe asthma, fever, and hypereosinophilia in association with a systemic vasculitis. The histopathologic features comprise necrosis in association with an eosinophilic exudate, severe "fibrinoid" collagen alteration, and granuloma formation with accumulation of epithelioid and giant cells that Churg and Strauss termed "allergic" granuloma. These granulomatous changes could be found in the connective tissue of any organ, as well as in vessel walls. The most common histopathologic features include prominent eosinophilia of vessels and perivascular tissues with accompanying lymphocytes, plasma cells, and some histiocytes, as well as necrotizing vasculitis of the small arteries and veins, necrotizing extravascular granulomatosis, and, occasionally, fibrinoid necrosis of vessel walls.

The diagnosis of Churg-Strauss syndrome cannot be established based on histopathologic findings alone. The "allergic" Churg-Strauss granuloma may occur as a nonspecific cutaneous reaction in association with a wide range of systemic diseases. At times, Churg-Strauss syndrome may be associated with eosinophilic pulmonary infiltrates indistinguishable from Löffler's eosinophilic pneumonia, and indeed, Churg and Strauss themselves have considered Löffler's eosinophilic pneumonia a limited form of Churg-Strauss syndrome. In addition, cases involving eosinophilic vasculitis and/or extravascular granuloma in isolated organs, particularly the gastrointestinal tract, without evidence of systemic disease have been reported. The term "limited forms of Churg-Strauss syndrome" has been proposed for such cases. Finally, the necrotizing vasculitis of Churg-Strauss syndrome may be indistinguishable from that of microscopic polyangiitis or WG, and prominent tissue eosinophilia has been described in some cases of WG. Consequently, Churg-Strauss syndrome is a clinicopathologic diagnosis, and other forms of systemic vasculitis or eosinophilic syndromes need to be excluded. A study of the American College of Rheumatology (ACR) found that criteria proposed by Lanham and co-workers were more than 95% sensitive and specific for the distinction of Churg-Strauss syndrome from other forms of vasculitis. To be diagnosed with Churg-Strauss syndrome, a patient must have at least four of the six ACR criteria listed in [Table 374.4](#).

- (1) Asthma
- (2) Eosinophilia (>10% on differential white blood cell count)
- (3) Mono- or polyneuropathy attributable to a systemic vasculitis
- (4) Migratory or transient pulmonary infiltrates
- (5) Paranasal sinus abnormalities
- (6) Extravascular eosinophils on a biopsy including artery, arteriole, or venule

^a Arthritis Rheum 1990;33:1094-1100.

Note: A patient with vasculitis is said to have Churg–Strauss syndrome rather than another form of vasculitis if four or more of the six criteria have been met.

TABLE 374.4. ACR 1990 CRITERIA FOR CHURG-STRAUSS SYNDROME^a

At the Chapel Hill Consensus Conference ([Table 374.1](#)), Churg–Strauss syndrome was defined as “an eosinophil-rich and granulomatous inflammation involving the respiratory tract, and necrotizing vasculitis affecting small to medium-sized vessels, and associated with asthma and eosinophilia.”

INCIDENCE AND EPIDEMIOLOGIC FACTORS

Churg–Strauss syndrome is distinctly rare. Between 1950 and 1992, 77 patients have been diagnosed with Churg–Strauss syndrome at the Mayo Clinic. Only 20 of the 807 patients with vasculitic syndromes submitted to the ACR classification study had Churg–Strauss syndrome. For the adult population of 414,000 of the Norwich Health Authority, an annual incidence of 2.4 per million has been reported for Churg–Strauss syndrome. Both sexes are affected equally.

ETIOLOGIC FACTORS AND PATHOGENESIS

The cause and pathogenesis of Churg–Strauss syndrome remain unknown. It appears that the allergic background and associated eosinophilia play a significant role in the modulation of the clinical disease manifestations. Serum markers of T-cell activation (soluble interleukin-2 receptor), eosinophil activation (eosinophil cationic protein), and endothelial damage (soluble thrombomodulin) are markedly elevated during active disease, suggesting a close relationship between T-cell and eosinophil activation and vascular damage. It is unclear as to what extent ANCA also contributes to the pathogenesis of the vasculitic complications of this syndrome. Recent reports of Churg–Strauss syndrome in asthmatic patients who used the leukotriene receptor antagonist zafirlukast are intriguing. They raise the question of whether this association is a consequence of steroid dose reduction or of a unique effect of this drug not shared with other steroid-sparing agents used for the treatment of asthma.

CLINICAL FEATURES

Lanham and co-workers gave a detailed description of the clinical features and course of the disease. They identified three phases of the disease: a prodromal phase that may persist for years, consisting of allergic disease (allergic rhinitis, nasal polyposis, frequently followed by asthma). The second phase of the disease is characterized by the onset of peripheral blood and tissue eosinophilia, frequently causing a picture resembling Löffler's syndrome, chronic eosinophilic pneumonia, or eosinophilic gastroenteritis associated with abdominal pain, diarrhea, or gastrointestinal bleeding. Nonspecific constitutional symptoms including fever, malaise, and weight loss are common at this stage of the disease. The eosinophilic infiltrative disease may remit and recur over years before the third phase is reached, which consists of a life-threatening systemic vasculitis. However, these three phases do not necessarily follow one another in that order. In 20% of cases asthma, eosinophilia and vasculitis develop simultaneously.

Most deaths from Churg–Strauss syndrome are caused by cardiac involvement. This may present as pericarditis, eosinophilic infiltrative myocarditis giving rise to congestive heart failure or mural thrombus formation, or coronaritis causing ischemia. Skin lesions, such as granulomas or palpable purpura typical for leukocytoclastic vasculitis, are common. Neurologic manifestations occur in two-thirds of patients with Churg–Strauss syndrome. Peripheral neuropathy is the most common finding, usually in the form of multiple mononeuropathy. Cerebral infarction is a rare feature of Churg–Strauss syndrome (less than 10%) and is usually a consequence of thromboembolism.

Churg–Strauss syndrome must be differentiated from other granulomatous processes and vasculitis conditions, as well as from other hypereosinophilic syndromes. Peripheral blood eosinophilia, a defining feature of Churg–Strauss syndrome, is only an occasional and minimal finding in WG, and an allergic background is no more common in WG than in the general population. Whereas the upper respiratory tract frequently manifests allergic rhinitis in Churg–Strauss syndrome, necrotizing lesions as seen characteristically in WG are rare. Renal involvement in Churg–Strauss syndrome is much less prominent than in WG or microscopic polyangiitis.

LABORATORY FINDINGS

Peripheral blood eosinophilia (more than 10% of total white blood cell count) is a defining feature of the Churg–Strauss syndrome. The degree of eosinophilia appears to correlate well with systemic disease activity, with the exception of the asthmatic component. Churg–Strauss syndrome is classified as part of the ANCA-associated vasculitides, yet data on ANCA testing in Churg–Strauss syndrome and its clinical value for the differential diagnosis are limited. However, most Churg–Strauss syndrome patients have perinuclear ANCA (P-ANCA) with specificity for myeloperoxidase (MPO). Only few patients have been reported to have C-ANCA. However, many patients with Churg–Strauss syndrome do not have detectable ANCA. If present, MPO-ANCA levels seem to correlate with disease activity in Churg–Strauss syndrome patients. Other laboratory abnormalities, including elevation of erythrocyte sedimentation rate and C-reactive protein, leukocytosis, hypergammaglobulinemia, and elevated IgE levels, nonspecifically reflect the degree of inflammatory activity.

Pulmonary function testing usually shows reversible airways obstruction consistent with asthma. Serial peak flow measurements are useful for monitoring the asthma activity and treatment response. Chest roentgenographic abnormalities are also nonspecific. Transient alveolar infiltrates of various intensity, location, and distribution are the most common abnormality, but interstitial infiltrates and multiple nodules (usually without cavitation) can also be encountered. Eosinophilic pleural effusions (usually small) occur in up to 30% of patients. Electromyography is helpful in assessing the degree and course of neuropathies associated with Churg–Strauss syndrome.

OPTIMAL MANAGEMENT

The systemic vasculitis of Churg–Strauss syndrome responds generally well to corticosteroids. The challenge in the management of patients with Churg–Strauss syndrome is to minimize the cumulative prednisone dose and its associated morbidity. The asthma symptoms should be managed according to asthma treatment principles. Zafirlukast should be avoided as steroid-sparing agent because of its reported association with Churg–Strauss syndrome. The role of cytotoxic agents, such as cyclophosphamide, is not as clearly defined as in WG. Azathioprine is the steroid-sparing immunosuppressive agent of choice for Churg–Strauss syndrome, and cyclophosphamide should be reserved for patients with refractory vasculitis symptoms.

BRONCHOCENTRIC GRANULOMATOSIS

DEFINITION

Bronchocentric granulomatosis is a necrotizing granulomatous inflammation that is limited to the lung. Characteristically, the inflammatory process originates in the wall of the bronchiole and remains mostly confined to the peribronchiolar tissue. There is minimal extension of inflammation to the surrounding lung parenchyma. Occasionally, the inflammation extends to adjacent vessel walls; however, this does not represent a form of vasculitis. Consistent with the clinical history, histopathologic changes of asthma, such as mucoid impaction, increased numbers of goblet cells, thickened basement membrane, and dense eosinophilic infiltrates, are typically seen.

ETIOLOGIC FACTORS AND PATHOGENESIS

The cause of bronchocentric granulomatosis is unknown. However, it is suspected that this type of inflammatory response represents a hypersensitivity reaction to fungal antigens, particularly from *Aspergillus*, but also *Candida* and *Mucor* species.

CLINICAL FINDINGS

The clinical symptoms are somewhat nonspecific. Younger patients usually present with cough, hemoptysis, pleuritic chest pains, and dyspnea in association with asthma and peripheral blood eosinophilia. In elderly patients, asthma and eosinophilia may be less prominent. Constitutional symptoms, such as fever and night sweats, are common. Most patients satisfy the diagnostic criteria for allergic bronchopulmonary aspergillosis. Chest roentgenograms usually show well-circumscribed, solitary segmental or lobar consolidations or atelectasis.

OPTIMAL MANAGEMENT

As the illness is closely related to allergic bronchopulmonary aspergillosis and usually occurs in asthmatics, the diagnosis should be questioned in the absence of asthma. Bronchocentric granulomatosis needs to be carefully differentiated from a variety of granulomatous infections (fungal, mycobacterial, and parasitic), particularly since similar tissue reactions have been reported in association with such infections. Occasionally, bronchocentric granulomatous inflammation has also been reported in association with rheumatoid arthritis and WG.

Bronchocentric granulomatosis responds promptly to short-term, high-dose oral corticosteroid therapy. Relapses requiring repeated courses of therapy are frequent. Consequently, long-term follow-up is indicated. If the inflammatory reaction is localized and always recurs in the same location, resection of the involved segment or lobe should be considered. Nonasthmatic patients and those without other underlying condition may recover without therapy.

NECROTIZING SARCOID GRANULOMATOSIS

DEFINITION

Necrotizing sarcoid granulomatosis was originally described as a separate disease entity by Liebow in 1973. This extremely rare disorder is characterized by multiple large confluent necrotizing granulomas and nonnecrotizing vasculitis, usually limited to the lung. Whether necrotizing sarcoid granulomatosis is a unique disorder has been the subject of debate. Some authors have argued that cases of necrotizing sarcoid granulomatosis represent variants of nodular sarcoidosis. Other cases may represent granulomatous infection in which the organisms are no longer detectable. Necrotizing sarcoid granulomatosis remains a diagnosis of exclusion, particularly of granulomatous infections but also of WG and lymphomatoid granulomatosis limited to the lung.

ETIOLOGIC FACTORS AND PATHOGENESIS

The cause and pathogenesis are completely unknown. Histopathologically, necrotizing sarcoid granulomatosis is characterized by aggregate-forming necrotizing epithelioid cell granulomas and prominent vasculitis. The granulomas are surrounded by lymphocytes and plasma cells. Langerhans-type multinucleated giant cells are always found; granulocytic necrosis and eosinophilia are rare. In distinction to the necrotizing granulomatous inflammation of WG, the inflammatory areas of necrotizing sarcoid granulomatosis are well circumscribed and clearly demarcated from normal lung tissue. The inflammatory infiltrate can contiguously affect bronchial walls and may cause bronchial obstruction. Three types of vasculitis are distinguishable: an epithelioid-granulomatous form; a giant cell reaction resembling giant cell arteritis; and a lymphocytic form lacking granuloma formation and giant cells. Small foci of fibrinoid necrosis may be encountered in vessel walls, but, in contrast to WG, the vasculitis is not necrotizing. Both arteries and veins may be affected. Even though vascular involvement is often seen in sarcoidosis, the degree of vasculitis and necrosis characteristic of necrotizing sarcoid granulomatosis would be unusual for sarcoidosis.

CLINICAL FINDINGS

The characteristic pulmonary nodules, which are usually bilateral, may be an incidental finding in asymptomatic patients. Alternatively, patients may complain of cough, phlegm production, dyspnea, or pleuritic chest pains. Generalized constitutional symptoms occur rarely. Patients of any age may be affected, and a female predominance of 4:1 has been suggested.

Chest roentgenographic findings consist of usually bilateral, potentially cavitating, and rarely solitary nodules. Hilar adenopathy is usually not prominent. Pleural effusions are uncommon. Pulmonary nodules or masses, and pleural involvement, are unusual for sarcoidosis. Extrapulmonary involvement has only rarely been documented in necrotizing sarcoid granulomatosis.

OPTIMAL MANAGEMENT

The differential diagnosis includes primarily infectious processes. Special sputum and tissue stains and cultures should always be obtained to exclude mycobacterial or fungal disease. The therapy of necrotizing sarcoid granulomatosis can be approached in the same fashion as that of chronic pulmonary sarcoidosis. Decisions about the use of oral corticosteroid therapy should be individualized based on symptoms, pulmonary function data, and their evolution over time. The prognosis is good and spontaneous remissions may occur.

LYMPHOMATOID GRANULOMATOSIS

DEFINITION

Lymphomatoid granulomatosis was first described as a distinct entity by Liebow in 1972. It is defined as an angiocentric lymphoproliferative process with predominant involvement of the lungs, skin, and central nervous system. Many cases previously described as *lethal midline granuloma* and those with the destructive lymphomatoid upper respiratory tract process referred to as *polymorphic reticulosis* represent the same disease process. The nomenclature of lymphomatoid granulomatosis continues to be the subject of debate. The application of the term *granulomatosis* by Liebow to describe the focal necrosis that is part of the lymphocytic inflammatory nodules is misleading, should not be confused with granulomas in the classical sense, and does not reflect the lymphomatous nature of the lesion. However, Katzenstein proposed to preserve the term *lymphomatoid granulomatosis* as it implies that the patient has lung involvement associated with certain characteristic clinical features. The term *angiocentric immunoproliferative lesion*, graded from 1 to 3 depending on the degree of cellular atypia, has been proposed for the same disease process, irrespective of pulmonary involvement. Myers and co-workers suggested doing away with both terms and using terms according to the National Cancer Institute's working formulation instead (*angiocentric mixed small- and large-cell lymphoma* and *angiocentric large-cell lymphoma*). Despite their merits, the different terminologies complicate the interpretation of the literature for clinical practice. The most important message is that lymphomatoid granulomatosis is neither a granulomatous disease nor a vasculitis; rather, it must be understood as a malignant lymphoproliferative process with a wide spectrum of clinical manifestations and a variable course.

INCIDENCE AND EPIDEMIOLOGIC FACTORS

Lymphomatoid granulomatosis is extremely rare. Population-based studies that would allow an estimation of incidence and prevalence are not available. Between 1979 and 1989 only 28 cases were diagnosed as lymphomatoid granulomatosis at the Mayo Clinic. The largest reported series includes 152 cases. Patients of all ages ranging from 20 to 80 years may be affected, and men are affected 1.7 to 3 times more often than women.

ETIOLOGIC FACTORS AND PATHOGENESIS

Lymphomatoid granulomatosis is characterized by lymphocytic infiltrates consisting of predominantly small lymphocytes and plasma cells and variable amounts of atypical mononuclear cells. These infiltrates can form centrally necrotizing nodules. The term *angiitis* was used for the transmural lymphocytic infiltration of vessel walls affecting arteries and veins. Subsequent immunophenotyping studies indicated that the predominant cell type consisted of mature T cells. Because of these

pathologic and clinical similarities to angiocentric T-cell/natural killer cell lymphoma, lymphomatoid granulomatosis was thought to be part of the same disease spectrum until recently. Most recent studies have identified the large lymphoid cells in the infiltrate as B cells, leading to the classification of most cases as T-cell-rich B-cell lymphoma. However, in a few cases the large lymphoid cells have been identified as T cells, indicating that some cases of lymphomatoid granulomatosis represent T-cell lymphomas and that different types of lymphoma may present as the clinical syndrome of lymphomatoid granulomatosis. A relationship between lymphomatoid granulomatosis and Epstein–Barr virus infection could be confirmed for most cases of apparent B-cell origin but not for those of T-cell origin. The chemokines interferon-inducible protein-10 (IP-10) and monokine induced by interferon- γ (Mig) appear to mediate the Epstein–Barr virus–associated necrosis and vascular damage observed in lymphomatoid granulomatosis.

CLINICAL FINDINGS

Constitutional symptoms, such as fever, malaise, and weight loss, are common. Dyspnea, productive or nonproductive cough, and, occasionally, pleuritic-type chest pains are symptoms of pulmonary involvement encountered in most patients with lymphomatoid granulomatosis. Hemoptysis may occur transiently and is rarely fatal. Chest roentgenograms reveal multiple peripheral, usually bilateral, but occasionally unilateral (20%) nodules predominantly in the lower lungs. Cavitation occurs in about one-third of cases. Massive diffuse infiltrates leading to acute respiratory insufficiency are observed rarely. Small pleural effusion may occur in one-third of patients. Hilar adenopathy is rare.

Involvement of the upper respiratory tract may precede systemic involvement and rarely occurs in isolation. A prodrome of nonspecific nasal and sinus congestion is followed by erythematous swelling of the facial skin and infiltration of the oropharyngeal mucosa. This sequentially leads to ulcerations of the skin and mucosa, with subsequent destruction of the facial cartilaginous and bony structures.

Skin involvement occurs in 43% of patients, typically in the form of erythematous macular lesions or subcutaneous nodules. Skin lesions usually occur simultaneously with lung lesions, but may precede them by days to years, and rarely occur later. The presence of skin lesions does not affect the overall prognosis.

Confusion, ataxia, hemiparesis, seizures, amaurosis fugax, sensorineural hearing loss, or vertigo are suggestive of central nervous system involvement affecting about one-third of patients. These symptoms are caused by infiltration of the meninges, blood vessels, and brain parenchyma associated with occasional tumor formation. Cranial nerve palsies and paresthesias may result from infiltration of cranial nerves or peripheral neuropathies. The prognosis associated with central nervous system involvement is poor, and most patients die despite immunosuppressive therapy.

Any organ system may be involved in lymphomatoid granulomatosis. Hepato- and splenomegaly, bone marrow, cardiac, adrenal, pancreatic, and gastrointestinal involvement have been found at autopsy in 7% to 9% of cases. Renal parenchymal infiltration is detectable histopathologically in 40% of patients but, in contrast to WG, clinically relevant loss of renal function is extremely rare. Glomerulonephritis does not occur.

The differential diagnosis includes chronic infectious granulomatous process, WG, other lymphomatous process, or solid malignancy. If the destructive process is isolated to facial structures, chronic cocaine abuse also needs to be excluded, as it can cause significant nonspecific necrotizing inflammation, with destruction of facial structures on rare occasions. Chest roentgenographic abnormalities are similar to those encountered in WG. Skin lesions that occur on the lower extremities should be differentiated from erythema nodosum.

LABORATORY FINDINGS

Laboratory abnormalities are nonspecific, such as elevation of erythrocyte sedimentation rate, hypochromic anemia, polyclonal hypergammaglobulinemia, or relative monocytosis. ANCA testing may help in the differentiation from WG. The few cases of lymphomatoid granulomatosis tested have all been negative for C-ANCA with PR3 specificity. The diagnosis of lymphomatoid granulomatosis is based on the histopathologic and immunohistochemical findings. Gene rearrangement studies to identify monoclonal proliferation of lymphocytes on bronchoalveolar lavage specimens may facilitate the diagnosis.

OPTIMAL MANAGEMENT

When a diagnosis of lymphomatoid granulomatosis or pulmonary lymphoma is suspected clinically, an open-lung biopsy procedure, such as video-assisted thoracoscopic biopsy, promises the highest yield. In one study, the histopathologic diagnosis of lymphomatoid granulomatosis was established in all of 20 open-lung, but only in 3 of 11 transbronchial lung, biopsy specimens. Significant histopathologic heterogeneity and different degrees of cellular atypia may be detected within the same biopsy specimen as well as at different sites sampled at the same time. Consequently, biopsy specimens should be obtained from all apparent sites of disease before therapy is initiated.

The prognosis of lymphomatoid granulomatosis is generally poor. The median survival of the disease is estimated to be about 2 years; however, the clinical course is highly variable. Patients with limited disease or those who are asymptomatic at the time of diagnosis appear to have a better prognosis. The degree of atypia of inflammatory cells detected on the biopsy specimen appears to determine the outcome. Most patients die of respiratory failure resulting from extensive parenchymal necrosis, hemorrhage, or infectious complications. The combined use of prednisone and cyclophosphamide is not nearly as effective as in WG. This fact and the more appropriate classification and staging according to lymphoma classification systems has led to the application of aggressive combination chemotherapy regimens early in the course of the disease. However, patients presenting with few symptoms and displaying low levels of cellular atypia may be treated with prednisone alone for prolonged periods. Surgical debridement and radiation therapy may control disease activity localized to the upper respiratory tract and facial structures. Interferon alfa-2b has been used because of its antiviral, antiproliferative, and immunomodulatory effects. Success with cyclosporin A in otherwise refractory patients has also been reported.

CHAPTER 375: OCCUPATIONAL LUNG DISEASE

PATRICK G. HARTLEY AND DAVID A. SCHWARTZ

[Clinical Evaluation and Management](#)
[Specific Occupational Pulmonary Disorders](#)
[Impairment/Disability Evaluation](#)
[Prevention: Controlling Occupational Health Hazards](#)

There are several reasons for clinicians and clinical investigators to be interested in occupational lung disease. First, the identification of an etiologic agent can result in the resolution of a disease process. This is perhaps best illustrated for occupational asthma, where diminishing the exposure to the inciting agent can improve and even cure the underlying disease process. In contrast, persistent exposure to the causative agent may exacerbate the need for medications and accelerate the progression of airway disease. Second, detection of occupational or environmental causes of lung disease provides the opportunity to minimize or even prevent disease in a similarly exposed larger group of individuals. Further evaluation of a patient's home or workplace may lead to identification of the causative agent, recognition of other affected and at-risk individuals, and recommendations for specific interventions in the local environment that would reduce future exposures. Third, occupational lung diseases provide ideal models for the study of pathophysiologic processes for which the cause is less well known ([Table 375.1](#)). Models of occupational asthma have been used to advance our understanding of the physiologic and biologic mechanisms that cause airflow obstruction, and these findings have proven relevant to other forms of asthma. Similarly, the pneumoconioses have provided substantial clinical, physiologic, and pathogenic findings that appear to be applicable to nonoccupational forms of pulmonary fibrosis. Thus, understanding the occupational and environmental contribution to lung disease will potentially have a substantial impact on the burden of lung disease in our society. Finally, this discipline is intellectually stimulating, focusing on the etiologic factors and biologic responses that account for the development of lung disease. It is very likely that this interface between the host and the environment is largely responsible for the development of most forms of lung disease. This point is even illustrated in genetic diseases, such as cystic fibrosis, which have a diverse clinical expression despite a well-defined genetic abnormality. Moreover, investigating the interaction between host and environment will allow us to understand the individual development and expression of lung disease.

Lung Disease	Occupational and Environment Factors
Asthma	Aeroallergens, organic dusts, chemicals (isocyanates), metals, and irritants
Chronic obstructive lung disease	Cigarette smoke and cadmium
Bronchitis	Chronic dust inhalation
Granulomatous lung disease	Beryllium
Hypersensitivity pneumonitis	Organic dusts
Pulmonary alveolar proteinosis	Silica
Acute respiratory distress syndrome	Noxious gases
Pulmonary fibrosis	Asbestos, silica, tungsten carbide, and paraquat
Bronchogenic carcinoma	Asbestos, dichloromethyl ether, and radon

TABLE 375.1. POTENTIAL CAUSES OF SPECIFIC TYPES OF LUNG DISEASE

The lung is a common site of occupationally induced disease, primarily because of its direct contact with the external environment. Thousands of environmental toxins and commercial chemicals are in use today, the particles of which may become aerosolized or airborne in the form of fibers, fumes, mists, or dust. Individuals living in major metropolitan areas may inhale more than 2 mg of dust every day, and workers in occupations involving exposure to dust may inhale up to 100 times that amount. Despite these circumstances, pulmonary function in most individuals is rarely affected because the lung is equipped with a complex system to reduce the effect of potentially harmful inhaled toxins and to preserve the sensitive gas-exchange mechanism of the alveolar surface.

The development of occupational lung disease in an individual worker is dependent on the toxicity of the inhaled substance, the intensity and duration of exposure, and the physiologic and biologic susceptibility of the host. The physical state of the inhaled substance (e.g., solid, fume, or mixture) and its solubility and aerodynamic dimensions principally determine the initial location of disease activity. Smaller particles (0.1 to 1.0 μm) are more likely to reach the alveoli, but airborne toxins, up to 5 μm , have been demonstrated in the alveolus. In general, larger particles (10 μm or greater) are trapped and removed by the mucous and ciliated epithelia of the upper respiratory tract. Although the respiratory tract is resilient in its response to the plethora of agents contacted in the environment, disruption of the alveolar clearance mechanism may occur if the individual is exposed to highly concentrated particles under certain working conditions, or if exposure occurs during strenuous labor when minute ventilation is increased and mouth breathing is more likely. Depending on the solubility and reactivity of the inhaled substance, acute or chronic reactions occur as particles are deposited on the alveolar surface. Acute reactions with associated edema or inflammation, or more chronic reactions, characterized by fibrosis or granuloma formation, have been demonstrated following inhalation of many environmental agents.

Several factors may increase an individual's susceptibility to inhaled toxins in the workplace. These include genetic factors related to inflammation and fibrosis, an individual's ability to clear substances from the lower respiratory tract, the presence of coexisting pulmonary diseases, and the effects of coexisting exposures such as cigarette smoking. Occupational lung disease can be challenging to diagnose and even more difficult to study epidemiologically because of the extended time from exposure to clinical expression of disease, often ranging from years to decades. In addition, most individuals are exposed to a variety of substances at one time and may participate in a number of occupations in their lifetime. Thus, many factors may be involved in the development of occupational lung disease. In this chapter, we first address the importance of an organized approach to the patient with suspected inhalation exposure in the workplace and then discuss several specific forms of occupational pulmonary disease.

CLINICAL EVALUATION AND MANAGEMENT

The diagnosis of a work- or occupation-related form of lung disease requires three distinct pieces of information: a relevant exposure history, definitive diagnosis of a specific type of lung disease, and literature supporting an association between the exposure and the disease process. The physician involved in the diagnosis of an occupational lung disease needs to approach these three domains objectively, fully and critically assessing the available data.

Assessment of exposure is unique to the diagnosis of occupational lung disease. Since the clinical presentations of occupational forms of lung disease are not pathognomonic, the exposure history has become an essential component of the medical evaluation for occupational lung disease and should be included in any examination of a patient with lung disease. In cases where the inhaled agent is acutely toxic, little additional information may be needed. However, even under these circumstances, details of the exposure, such as the chemical agent, the extent of the exposure, and its inherent toxicity, contribute substantially to the clinical evaluation. Because of the highly variable period of time between exposure and onset of lung disease, a detailed exposure history should be administered to all individuals with lung disease. The essential features of an occupational history include the following:

- Characterizing the job process
- Listing known toxic exposures
- Assessing the degree of exposure
- Ascertaining temporal relationships between exposures and symptoms, and
- Identifying the use of respiratory protective equipment

Many workers have part-time or summer employment, have been enlisted in the military, or have hobbies that may account for additional exposure risks. Other nonoccupational risk factors, such as cigarette smoking, should be fully characterized. The goal of this history is to establish a list of agents that potentially cause or exacerbate the lung disease.

With few exceptions, the diagnosis of occupational pulmonary disease is based on standard diagnostic procedures in pulmonary medicine. Measurement of lung function, although nonspecific in regard to diagnosis, is essential for characterizing the functional correlates of occupational lung disease. However, care must be exercised in the use of standard nomograms to interpret lung function. Factors that select workers for a specific job and the healthy-worker effect, which allows them to maintain their job, may contribute to higher baseline measures of lung function in the individual who is being evaluated for occupational lung disease when compared to standard reference populations. Clearly, the most useful approach to the assessment of lung function is to have more than one measure over time and to define whether the rate of change is within the expected or acceptable range. Although the chest radiograph is currently the cornerstone of our diagnostic armamentarium for the pneumoconioses, the chest radiograph is neither a sensitive nor a specific method for identifying the parenchymal or pleural manifestations of these diseases. For example, 15% to 20% of individuals with pathologic evidence of asbestosis will have normal-appearing parenchyma on the chest radiograph. In addition, autopsy studies and studies using computed tomography (CT) scans indicate that the chest radiograph can identify 50% to 80% of pleural plaques. Moreover, the chest radiograph is not particularly effective in distinguishing asbestos-induced pleural fibrosis from subpleural fat (specificity = 71% in comparison to conventional CT scans). In this context, CT scanning of the chest represents a potentially important advance that may substantially improve our ability to noninvasively identify and quantify early and more advanced parenchymal and pleural lesions caused by inhalation of fibrogenic agents ([Fig. 375.1](#)). While the high-resolution CT (HRCT) scan can identify parenchymal abnormalities that are not evident on the plain chest film, visual interpretation of the HRCT scan is prone to the same problems observed with the chest film. A reliable and valid system has not been developed to evaluate the type and extent of interstitial or pleural lung disease identified on the HRCT scan. Although attempts have been made to apply the International Labor Organization (ILO) criteria to the interpretation of CT scans, these criteria have inherent problems with reliability and validity. Moreover, the ILO criteria may not be applicable to the CT scan.

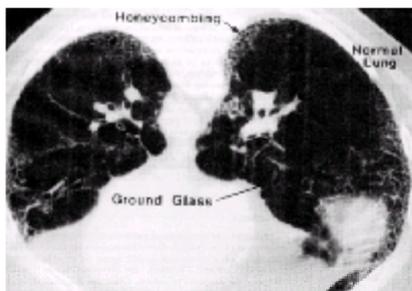

FIGURE 375.1. High-resolution computed tomography scan (HRCT). HRCT is becoming increasingly useful as a more sensitive test than chest x-ray for evaluating workers with occupational exposures. This HRCT from a patient with severe asbestosis demonstrates both honeycombing and an area of ground-glass infiltrate. Importantly, this HRCT scan also demonstrates that asbestosis is a heterogeneous disease with radiologically abnormal lung adjacent to normal-appearing lung parenchyma.

The medical literature establishing a clear relationship between occupational exposures and specific forms of lung disease is readily accessible through the standard sources (medical texts and primary literature referenced by Medline). The clinician can obtain additional information from the Material Safety Data Sheet (MSDS), which contains information about the potential health effects of toxic agents and is now required by federal law to be available in the workplace. Occasionally, other less commonly used databases, such as Toxline or Chemline, are needed to access the relevant medical literature. The literature linking exposures with diseases is readily available and should be accessed when one is considering the diagnosis of occupational lung disease. In cases where the temporal sequence of events or the histopathologic picture strongly supports an occupational cause but convincing literature does not exist, the clinician should consider referral to an academic center for further evaluation and consideration.

SPECIFIC OCCUPATIONAL PULMONARY DISORDERS

Occupational lung disease can arise from a vast array of occupational exposures, representing every major industrial sector. As mentioned previously, the spectrum of occupational pulmonary disease may be a continuum of several pathologic processes, with severity and onset of symptoms dependent on length and types of exposures and associated individual risk factors. Disease classification is divided into occupational airways disease, parenchymal lung disease, mixed airway and parenchymal disease, and occupational neoplastic diseases ([Table 375.2](#)).

Airways Disease
Occupational asthma
Industrial bronchitis
Byssinosis
Reactive airways dysfunction syndrome
Parenchymal Lung Disease
Asbestosis
Silicosis
Coal worker's pneumoconiosis
Silicate pneumoconioses
Miscellaneous pneumoconioses and other conditions
Mixed Airway and Parenchymal Diseases
Hypersensitivity pneumonitis
Bronchiolitis
Berylliosis
Neoplastic Diseases
Bronchogenic carcinoma
Mesothelioma

TABLE 375.2. OCCUPATIONAL PULMONARY DISORDERS

OCCUPATIONAL AIRWAYS DISEASE

Occupational Asthma

Definition and Epidemiologic Factors

Occupational asthma may be defined as reversible airflow obstruction associated with hyperreactivity of the airways either caused or exacerbated by exposure to excessive concentrations of irritants or contact with sensitizing agents in the workplace. Increased mucus production, cough, and bronchospasm are hallmarks of this disorder, with symptoms initially evident after exposure to inhaled dusts, gases, fumes, or vapors. Although the incidence of occupational asthma is not known, the prevalence has been estimated to be approximately 5% of all cases of asthma; however, one study suggests that occupational asthma may account for as many as one-fourth of cases seen in the clinical setting. Importantly, some agents, such as isocyanates, organic dusts, and high concentrations of irritant gases, result in a much higher proportion of airway disease among exposed workers. Recognition of the occupational factors that contribute to the development or exacerbation of asthma assists in the treatment and control of the disease process.

Pathogenesis

It has been reported that more than 200 chemicals or agents are known to cause or precipitate occupational asthma. These compounds have been divided into three groups: (a) high molecular weight compounds, (b) low molecular weight compounds, and (c) high-concentrate gaseous or particulate toxic irritants. High molecular weight compounds, consisting mainly of biologic proteins, are often the inciting agents responsible for airway hyperreactivity associated with allergic mechanisms. Specific examples include exposure to animal dander, *Bacillus subtilis* enzymes, organic dusts, castor beans, or vegetable gums. Patients are usually atopic and have a positive skin-prick test in reaction to dust extracts. Specific IgE antibodies to dust antigens may be identified using radioallergosorbent tests. Importantly, nonallergic

mechanisms may contribute to the development of airflow obstruction in individuals exposed to high molecular weight compounds. Conversely, low molecular weight substances (less than 2,000 d) are usually inorganic compounds and are not commonly mediated by acute inflammatory mechanisms. Examples of low molecular weight agents that cause occupational asthma include platinum compounds, concentrated fumes of epoxy resins, nickel sulfate, isocyanates, and other chemicals (e.g., formaldehyde). Several exceptions to this have been noted with IgE or IgG antibodies identified in workers exposed to phthalic anhydrides, trimetallic anhydrides, and plicatic acid (the agent responsible for asthma in workers exposed to Western red cedar dust).

In general, the pathogenesis of occupational asthma is multifactorial and may involve any of several pathogenetic mechanisms. Classic allergic mechanisms, involving IgE, mast cells, eosinophils, and histamine, are responsible for a small percentage of the cases of occupational asthma. In most cases, occupational asthma appears to be caused by inflammation and edema of the bronchial mucosa, with the stimulus for the inflammatory response originating from airway macrophages and airway epithelia. Neutrophils, eosinophils, and specific proinflammatory cytokines appear to play an important role in the inflammatory lesion. Moreover, local production and release of inflammatory agents (cytokines, growth factors, arachidonic acid metabolites, and oxygen radicals) may contribute to the chronic remodeling of airway observed in patients with persistent occupational asthma. Further understanding of the acute inflammatory response is likely to provide new directions for treatment and early diagnosis.

Diagnosis

The diagnosis of occupational asthma is dependent on the demonstration of reversible airflow obstruction that occurs in conjunction with inhalation of specific agents reported to cause or exacerbate asthma. Therefore, the physician should initially focus on the diagnosis of asthma. Once this diagnosis is clearly established, further examination of environmental or occupational causes should be considered. Pulmonary function testing is an essential component in the evaluation of patients suspected of having occupational asthma. Spirometric patterns of airflow obstruction (see [Chapter 388](#)) and the physiologic changes typical of asthma (see [Chapter 363](#)) are identical to those of occupational asthma. However, unlike nonoccupational forms of asthma, obstructive airways disease induced or exacerbated by workplace exposures is temporally related to specific occupational exposures. Physiologic testing, either by spirometry, peak flow measurements, or periodic nonspecific bronchoprovocative challenge, can and should be used to evaluate the temporal relation between occupational exposures or environmental agents and the development of airflow obstruction. For instance, demonstration of consistent decreases in peak flows of at least 20% following exposure to a specific agent in the workplace not only helps to establish the diagnosis of occupational asthma but also may assist in identifying the agent. Although specific airway challenges are the most definitive method of making the diagnosis, this test is not entirely accurate, and very few centers are equipped to perform these potentially hazardous exposure–response studies.

Several laboratory tests have been proposed to evaluate patients with suspected or proven occupational asthma; however, their ultimate clinical usefulness is questionable. Serologic or immunologic testing can assist in determining atopic status with respect to environmental allergens. Reactions to specific allergens are limited to the relatively few that have been completely purified, such as extracts of flour and grain dusts, animal products, and certain chemicals. Serum IgG or IgE antibodies may also be measured by radioimmunoassay or enzyme-linked immunosorbent assay methods. Unfortunately, these tests lack the sensitivity and specificity required for making a definitive diagnosis; however, when used in conjunction with other testing methods and a careful patient history, these tests may help document a specific cause.

Optimal Management

Once standard medical treatments have been initiated, including inhaled b-sympathomimetics, anticholinergics, inhaled or oral corticosteroids, cromolyn sodium, or leukotriene antagonists, emphasis should be placed on avoiding or minimizing further exposure. Isocyanates and other sensitizers must be completely eliminated from the environment of those with occupational asthma caused by these agents. However, individuals with irritant-induced asthma may continue to be exposed as long as the concentration of the exposure is reduced to tolerable levels. A majority of individuals have persistent symptoms despite their completely avoiding the offending agent. It has been observed that patients with the most severe symptoms have the longest exposure histories and the most abnormal pulmonary function tests. When complete avoidance of the offending agent is impractical or if the exposure is occasional, the use of respirators or, preferably, improved local ventilation may alleviate symptoms. However, it is uncertain as to whether these measures halt airway injury; therefore, these patients must be monitored very closely.

Industrial Bronchitis

Industrial bronchitis, a disorder characterized by dyspnea and cough productive of sputum at least 3 months each year, is associated with occupational exposure to high concentrations of airborne dusts or where mixed exposures occur. Industries where there are significant mixed-dust exposures include construction and demolition, mining and smelting, food processing, and animal confinement. Workers in industries that manufacture complex materials, such as ceramics, furniture, or rubber, are exposed to a variety of agents that may contribute to increased airway symptoms. Firefighters and emergency response workers are frequently exposed to complex mixtures of potentially harmful agents by inhalation. Confounding the occupational exposures may be a history of cigarette smoking, which further contributes to morbidity. Impaired pulmonary function may result in hypersecretion of mucus in the more proximal airways. Although not all workers are affected by industrial bronchitis and those who are affected often become less symptomatic once removed from the source of irritation, treatment should be directed to minimizing airway irritants, including smoking cessation, and using antibiotics with postural drainage to decrease any infected airway secretions.

Byssinosis

Workers exposed to dust from cotton, flax, hemp, or jute used in the textile industry may experience chest discomfort, cough, or dyspnea. Characteristically, patients complain of Monday-morning fever, referring to the onset of symptoms immediately upon exposure after some time away from the work environment. A majority of patients with these symptoms experience a decreased forced expiratory volume in the first second (FEV₁) over the course of a work shift and, at least initially, develop symptoms to exposures only after having been away from the inciting agent. As the disease progresses, the symptoms of dyspnea, wheezing, and cough persist and are exacerbated throughout the work week.

These organic dusts contain live microorganisms, endotoxins, mycotoxins, and tannins, all of which are capable of initiating an inflammatory response. Direct epithelial cell injury may occur, and inflammatory cells such as macrophages may actively participate in the inflammatory response by releasing proinflammatory cytokine. Although most workers do not develop chronic byssinosis for 10 years or more after inhaling cotton dust, presenting symptoms may vary from mild cough and occasional chest discomfort to marked respiratory failure with dyspnea at rest. Byssinosis, like most inflammations caused by inhaled irritants, is managed by minimization of future exposures and treatment of airway inflammation.

Reactive Airways Dysfunction Syndrome

Definition and Clinical Presentation

The persistence of airway reactivity following acute exposure to respiratory irritants has been termed *reactive airways dysfunction syndrome* (RADS). A variety of inhaled irritants have been associated with this syndrome, including sulfuric acid, chlorine, ammonia, household cleaners, and smoke. Most often, the initial inhalation injury is due to a single, acute, high-intensity exposure. Symptoms of airflow obstruction, including cough, dyspnea, and wheezing, are reported immediately or several hours after the end of the exposure, and may persist for months to years. Previous exposure or sensitization to the toxic agent does not appear to be necessary. By definition, individuals who develop RADS have no history of respiratory illness. Pulmonary function tests may be normal or they may demonstrate airflow obstruction. Individuals with RADS have persistent, positive responses to methacholine challenge testing, even in the presence of normal pulmonary function tests. Nonspecific bronchial reactivity may persist for months to years following the initial inhalation injury.

Pathogenesis

Inhaled toxins exist in many forms and may be categorized by taking into account their physical properties. General categories include gases, vapors, fumes, aerosols, and smoke. [Table 375.3](#) and [Table 375.4](#) summarize the physical properties and clinical manifestations of these inhalants. The initial pathologic responses to a harmful inhaled agent depend on a number of factors, including the concentration of the substance in the ambient air, the pH of the inhaled substance, the presence and size of particles, the relative water solubility of the inhaled agent, the duration of exposure, and whether the exposure occurs in an enclosed space versus an area with adequate ventilation and free circulation of fresh air. In addition, an undetermined number of host factors, including age, smoking status, presence of preexisting pulmonary or extrapulmonary disease, and the use of respirators or other protective breathing apparatus, all impact on an individual's

response to the inhalation of a toxic substance.

Irritant Gas	Water Solubility	Mechanism of Injury
Ammonia	High	Alkali burns
Chlorine	Intermediate	Acid burns, reactive oxygen species
Hydrogen chloride	High	Acid burns
Oxides of nitrogen	Low	Acid burns, reactive oxygen species
Ozone	Low	Reactive oxygen species
Phosgene	Low	Acid burns
Sulfur dioxide	High	Acid burns

TABLE 375.3. PHYSICAL PROPERTIES AND MECHANISMS OF LUNG INJURY OF GASEOUS RESPIRATORY IRRITANTS

Substance	Acute Clinical Manifestations			Chronic Clinical Manifestations		
	Onset	Upper Airway Irritation	Pneumonitis, ARDS	Bronchiolitis Obliterans, BOOP	Obstructive Lung Disease	RADS
Inhaled gases						
Ammonia	Minutes	Severe	+	+	+	+
Chlorine	Minutes to hours	Moderate	+	+	+	+
Hydrogen chloride	Minutes	Severe	+	+	+	+
Oxides of nitrogen	Hours	Mild	+	+	+	+
Ozone	Minutes to hours	Mild	+	+	+	+
Phosgene	Hours	Mild	+	+	+	+
Sulfur dioxide	Minutes	Severe	+	+	+	+
Mists						
Cadmium	Hours	Mild	+	+	+	+
Mercury	Hours	Mild	+	+	+	+
Zinc chloride	Minutes	Mild	+	+	+	+
Zinc oxide	Hours	Mild	+	+	+	+

TABLE 375.4. PULMONARY MANIFESTATIONS OF TOXIN INHALATION

Inhaled gases with potential irritant effects manifest their actions at different anatomical locations in the respiratory system. In general, substances that are highly water-soluble, such as ammonia, sulfur dioxide, and hydrogen chloride, can cause immediate irritant injury to the upper airway. The acute effects of highly water-soluble irritants on the upper airway, exposed skin, and other mucous membranes often produce such unpleasant symptoms that exposed persons quickly leave the area of exposure, thus avoiding continued inhalation of the harmful toxins. In contrast, inhaled toxins that have low water solubility, such as phosgene, ozone, and oxides of nitrogen, often have little or no acute effect on the upper airway and instead produce irritant effects at the level of the terminal bronchiole and alveolus. Because agents of low water solubility do not produce immediately noticeable upper-airway irritation (except in episodes of massive acute exposure), exposed persons may inadvertently remain in the area of exposure and thus increase their duration of exposure to harmful inhalants. Agents that exhibit intermediate water solubility, such as chlorine, can have pathologic effects throughout the respiratory system. However, extreme exposure to any one of these irritants may result in upper and lower respiratory tract involvement. Furthermore, absorption of any one of these irritants on particulate matter may also alter the area of involvement.

Bronchial biopsies of patients with RADS demonstrate an inflammatory response characterized by epithelial desquamation and mucus cell hyperplasia. The exact mechanisms of the pathophysiologic processes involved in RADS are unclear, but implicated mechanisms include altered neural tone and vagal reflexes, modified b-adrenergic sympathetic tone, and influences of a number of proinflammatory mediators. The direct irritant injury may expose and damage subepithelial irritant receptors. Subsequently, repair mechanisms that are not fully understood may result in alteration of the irritant receptor threshold and lead to airway hyperreactivity. Changes in epithelial permeability may also contribute to the resultant hyperreactivity. None of these proposed mechanisms is completely understood at this time.

Optimal Management

Treatment of RADS includes the use of corticosteroids to help minimize inflammatory mechanisms and bronchodilators to reverse bronchospasm. There is limited, mostly anecdotal, evidence for the efficacy of corticosteroids. Bronchodilators may only partially reverse airflow obstruction, especially in later, chronic stages of the syndrome. Despite treatment with corticosteroids and bronchodilators, many exposed individuals are left with persistent asthma-like symptoms, airflow obstruction, and nonspecific bronchial hyperreactivity.

OCCUPATIONAL PARENCHYMAL DISEASE

Parenchymal lung disease may arise from a vast array of occupational exposures that represents every major industrial sector. The most important class of occupational lung diseases is the pneumoconioses, which result from the inhalation of and tissue reactions to various naturally occurring or synthetic mineral dusts. Pneumoconiosis is still relatively common among older men who have been employed in jobs with exposure to mineral dust. In fact, interstitial lung disease (ILD) is much more common than previously thought, and the pneumoconioses account for approximately 14% of the incident cases of ILD. Prior to 1970, when the federal government began regulating the amount of concentrated particulate material to which workers could be legally exposed, dust levels were often extremely high; those exposures that occurred 20 to 30 years ago are reflected in the manifestation of various pneumoconioses today.

Asbestosis and Asbestos-Induced Pleural Fibrosis

Definition and Epidemiologic Factors

Exposure to asbestos (occupational and nonoccupational) constitutes the most pervasive of the mineral dust exposures and has had the greatest impact on morbidity and mortality in these exposed workers. The National Institute for Occupational Safety and Health (NIOSH) estimated that in 1990 alone more than 40,000 workers were directly exposed to asbestos while working with insulation and that between 3 million and 5 million individuals were indirectly exposed. As many as 25 million more Americans have had occupational exposure to asbestos in the past 40 years and remain at increased risk for asbestos-related diseases. Many millions more have environmental exposures to asbestos from insulation, building products in homes and public buildings, brake and clutch facings, and demolition of asbestos-containing buildings in urban areas. Asbestos has been federally regulated by the Occupational Safety and Health Administration (OSHA) of the Department of Labor since its inception in 1972.

Asbestos refers to a group of six separate fibrous mineral silicates that can be woven and contain properties that allow for resistance to heat and acids. The vast majority of asbestos produced in North America, called *chrysotile* or *white asbestos*, consists of hydrated magnesium silicate. Other forms of asbestos include crocidolite, amosite, anthophyllite, tremolite, and actinolite. Despite decreased demand for asbestos in Europe and North America, its production has remained stable secondary to continued use of this material in developing nations. Most exposures to asbestos occur during the milling and manufacture of asbestos, while installing and replacing insulated packing around heating pipes and furnaces, or while using asbestos-containing cement. All of these applications cause the fibrous asbestos particles to become airborne.

Pathogenesis

The pathogenesis of asbestos-induced fibrosis of the lung parenchyma is unknown. Despite the absence of definitive knowledge regarding the biologic mechanisms that result in pulmonary fibrosis, it is very clear that the chronic inflammatory response is progressive, the inflammation and fibrosis are distributed heterogeneously throughout the lung, and the chronic inflammatory process is associated with extensive remodeling and fibrosis of the lower respiratory tract. Retention of fibers in the

lung parenchyma appears to be associated with the severity of disease. Cigarette smoking, which may reduce the clearance of fibers, has been shown to enhance the risk of developing asbestosis. In the lung parenchyma, this chronic inflammatory process eventually leads to proliferation of mesenchymal cells, intra-alveolar fibrosis, and loss of alveolar capillary units. The mechanisms for asbestos-induced lung fibrosis are complex and likely to involve several lung cells and cell mediators ([Fig. 375.2](#)). Inflammatory cells (neutrophils and macrophages) and lung epithelial cells are affected by asbestos.

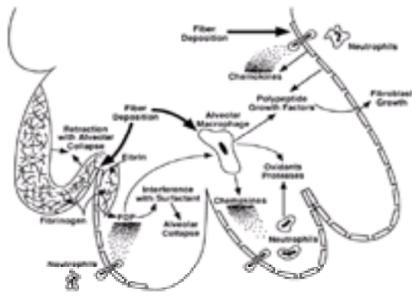

FIGURE 375.2. The predominant biologic processes involved in the development of fiber-induced pulmonary fibrosis. Fiber deposition stimulates alveolar macrophages and terminal airway and type I alveolar epithelial cells to release chemotactic factors that attract neutrophils to the alveolar duct. Oxidants, myeloperoxidase, and proteolytic enzymes directly injure the alveolar wall, growth factors enhance mesenchymal proliferation and collagen production, and alveolar injury increases permeability to fibrinogen and other plasma proteins which ultimately result in induration and collapse of the bronchoalveolar unit.

Clinical Presentation

Asbestosis and asbestos-induced pleural fibrosis, unlike silicosis or coal worker's pneumoconiosis, often present clinically as progressive dyspnea. Among patients with asbestosis, dyspnea is often a more prominent complaint than tests of lung function would suggest. These patients complain of a dry cough and pleuritic chest pain. Physical findings include rales, which may be absent in early asbestosis and are best heard laterally over the lower thoracic wall. In advanced cases of asbestosis, clubbing and cyanosis may be observed.

Radiographic Abnormalities

Pleural fibrosis with circumscribed pleural plaques and diffuse pleural thickening is the most common radiographic abnormality among persons who have been exposed to asbestos, and these chest wall lesions have recently been found to be independently associated with progressive restrictive function. Asbestosis tends to radiographically progress slowly over several years, even in the absence of additional exposure. The chest radiograph may reveal only pleural plaques and no clear evidence of the small linear opacities in the lower lung zones that are classically seen in asbestosis. Using the chest HRCT scan, several groups of investigators have shown that clinically significant interstitial abnormalities are missed by the standard chest radiograph. With more advanced disease, diffuse linear opacities, often in association with pleural plaques, are observed in middle and lower lung zones. A pleural effusion may be caused by asbestos exposure and is believed to contribute to the formation of diffuse pleural thickening. In those patients who develop diffuse pleural thickening, the lower lung zones have a ground-glass appearance, making interpretation of small linear opacities difficult without the use of the HRCT scan.

Physiologic Abnormalities

Because asbestosis initially involves the respiratory bronchiole, early stages of the disease may involve airflow obstruction. Alternatively, no detectable abnormalities may be demonstrated on routine pulmonary function testing. As the disease progresses, both asbestosis and asbestos-induced pleural fibrosis may result in the development of restrictive lung function. Asbestosis may also involve abnormalities in gas exchange (decreases in the diffusing capacity or increases in the alveolar–arterial oxygen difference).

Diagnosis

The diagnosis of asbestosis is based on objective evidence of both exposure (history, fibers in bronchoalveolar lavage fluid, fibers in lung parenchyma, or bilateral pleural fibrosis) and disease (characteristic radiographic findings on chest radiograph or HRCT, restrictive lung function, or reduced diffusing capacity), without other explanations for the radiographic or physiologic abnormalities. In most cases, the diagnosis is based on a clear exposure history occurring at least 15 years before the onset of disease and on typical radiographic features on the standard chest radiograph. Because the risk of lung cancer is known to decrease with cessation of smoking, it is critical that the physician provide strong incentives for asbestos-exposed workers to stop smoking.

Optimal Management and Prevention

Although there appears to be no effective treatment for asbestosis other than providing supportive therapy for patients who develop respiratory compromise, physicians should consider treating for progressive asbestosis in patients just as they treat for other forms of interstitial lung disease (see [Chapter 360](#)). Despite the fact that all new mining and application of asbestos have been restricted by federal regulating agencies, existing structures containing asbestos remain a potential source of exposure in the United States. In addition, use of asbestos continues in developing countries because it remains a very inexpensive form of insulation.

Silicosis

Definition and Epidemiologic Factors

The diagnosis of silicosis dates back to the times of Hippocrates and the ancient Egyptians. Despite being recognized for centuries as a preventable disease, both classic nodular silicosis and the rapidly fatal acute form, silicoproteinosis, continue to be diagnosed around the world. In the United States, a diverse working population numbering more than 2 million is at risk of developing silicosis from exposure to “free” or crystalline silica. Those at risk include persons working with silica abrasives, refractories, or ceramics and those involved in coal mining and milling, metal and nonmetal mining and milling, foundry work, filler manufacture and handling, quarrying, tunneling, and many other occupations.

Pathogenesis

Silicosis typically progresses slowly over many years, even in the absence of further exposure. Recent reports indicate, however, that workers without clinical or physiologic abnormalities and with lesions less than 5 mm have long-term survival similar to that of the general population. Once silica is inhaled and penetrates into the alveoli, a series of inflammatory events is postulated to involve the alveolar macrophage. Macrophages ingest the foreign antigens and package the material into phagosomes that in turn release lytic enzymes, rupturing the phagosome and allowing the irritant to interact with the cytoplasm. The cell is autolyzed when inflammatory mediators are released and the silica is reingested by additional macrophages, which perpetuate the inflammatory cycle. Tumor necrosis factor, released primarily by alveolar macrophages, may be an essential component of the inflammatory response to inhaled silica. In fact, one provocative animal study has shown that antibodies to tumor necrosis factor prevent the development of silica-induced pulmonary fibrosis. Chronic inflammatory responses lead to fibrosis. Over time, collagenous fibers are deposited in concentric layers and undergo hyalinization, becoming a whorled nodule encapsulated by a mostly acellular, discrete layer of collagen ([Fig. 375.3](#)). Silicotic particles may be seen pathologically as birefringent material under polarized light. Although the exact mechanisms of pathogenesis are unclear, recent reports have suggested that the electrostatic charge on the surface of the silica particle is an important component of the inflammatory response.

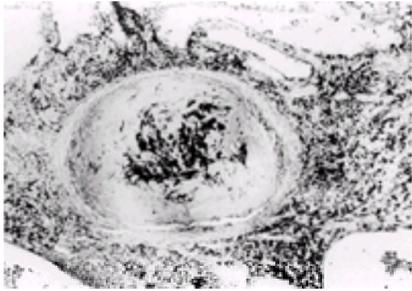

FIGURE 375.3. Light microscopic view of a typical silicotic nodule demonstrating a whorled fibrous center (original magnification $\times 70$).

Clinical Presentation

Clinically, silicosis may appear in many different forms. *Chronic or pure nodular silicosis* typically occurs after 20 to 40 years of low or moderate exposure to silica-containing dust with less than 35% quartz. Chronic silicosis is often first detected by a routine chest radiograph and in the early stages may have no respiratory symptoms apart from possibly a cough. With more advanced silicosis, the patient is more often dyspneic and frequently complains of chronic cough and phlegm production. Lung sounds are usually normal or reflect concurrent airway disease. Radiographically, chronic silicosis is characterized by symmetrical, rounded opacities in the upper and middle lung zones. Hilar lymph nodes rimmed with calcium may also be seen on chest radiograph; these opacities are termed *eggshell calcifications*. It is well recognized, however, that a patient with somewhat dramatic radiographic evidence of silicosis may remain free of symptoms and functional impairment. Physiologically, patients with silicosis typically present with a restrictive pulmonary impairment but may have a mixed obstructive–restrictive pattern or a purely obstructive pattern. In fact, epidemiologic studies have shown that workers exposed to silica may develop mild airflow obstruction, independent of the effect of cigarette smoking.

Progressive massive fibrosis (also known as complicated or conglomerate silicosis) may develop in a small percentage (less than 5%) of patients with silicosis. These lesions result from coalescence of the initial fibrotic nodules, which engulf obliterated blood vessels and bronchi. The conglomerate masses typically appear symmetrically in the upper lung zones, may assume a *butterfly* distribution, and may develop cavitates; they are typically associated with scar emphysema. Patients with progressive massive fibrosis are severely impaired by end-stage dyspnea, which is the predominant symptom. The disease is usually progressive despite removal from the inciting agent. Pulmonary function evaluation usually reveals both marked obstructive and restrictive pulmonary impairment. Patients with this disease are at increased risk for tuberculosis and other respiratory infections (influenza virus and *Pneumococcus*). In fact, it has been suggested that tuberculosis may contribute to the development of progressive massive fibrosis.

Accelerated silicosis is seen in workers, such as sandblasters, who receive more concentrated exposures of dust containing greater than 50% quartz. Lesions may develop after only 5 years of exposure, with nodules appearing on radiographs somewhat smaller than those of classic silicosis and concentrated in the middle zones of the lung.

Very high concentrations of silica may result in *acute silicosis*, also known as silicoproteinosis. This rapidly progressive and often fatal disease has been reported in the United States among workers using sand as an abrasive (a practice banned in many Western countries decades ago), among drillers of highly siliceous rock, among tombstone sandblasters, and among workers milling silica to produce silica flour. These processes result in high concentrations of respirable particles with a high percentage of *free silica*—two important factors influencing silica toxicity. Within months of exposure, patients may present with profound dyspnea, weight loss, and fatigue that may progress to death from respiratory failure. Lipids and proteinaceous material reactive to periodic Schiff reagent are found histologically in the alveoli. Milky-appearing lavage fluid containing high concentrations of surfactant is considered diagnostic of silica-induced pulmonary alveolar proteinosis. Similar to patients who have idiopathic alveolar proteinosis, whole-lung lavage has been successfully used in isolated cases to reverse the excess production of surfactant.

Optimal Management and Prevention

Removal from the exposure site and elimination of exacerbating factors, such as cigarette smoking, are the mainstays of therapy. In individuals with progressive disease, tuberculosis should be considered and, if present, treated aggressively.

Coal Worker's Pneumoconiosis

Definition and Epidemiologic Factors

For many years, coal miners were believed to be suffering from silicosis. Surveys of coal tipplers and graphite workers exposed to either coal dust or graphite, but not silica, revealed a form of pneumoconiosis that is radiographically indistinguishable from chronic silicosis but pathologically quite different. Although many miners are also exposed to silica and may therefore have both silicosis and coal worker's pneumoconiosis (CWP), the latter is recognized as a distinct form of pneumoconiosis with its own natural history and pathology.

About 300,000 miners in the United States are exposed to coal dust each year. However, an increasing proportion of these workers are involved in strip mining, in which exposures are considerably lower than in underground mining. The exposure to coal dust for underground miners was greatly reduced as a result of the Federal Coal Mine Health and Safety Act of 1969, which provided benefits for miners with documented exposures and mandated that employers prevent workers from receiving exposures of coal dust greater than 2 mg per cubic meter. The act was subsequently revised to include workers suffering disabilities not only from pneumoconiosis but also from chronic obstructive pulmonary disease arising from coal dust exposures. Today more than 90% of mine sections are in compliance with federal standards. NIOSH provides an ongoing medical surveillance program for underground coal miners and reports that less than 5% of working miners have radiographic evidence of CWP. Those with advanced simple CWP or progressive massive fibrosis (PMF) typically have had mine exposures of 20 years or more.

Clinical Presentation

As with silicosis, the risk of CWP depends on the cumulative dose of exposure (the amount of dust concentration multiplied by the duration of exposure). Simple CWP, in the absence of other respiratory disease, usually is detected radiographically and most often is not accompanied by respiratory symptoms. Industrial bronchitis is common among coal miners (20% to 50%) and is clearly related to the cumulative dose of coal dust. Similarly, airflow obstruction and progressive loss in lung function have been observed to be dose-related in cohorts of miners with high exposure to coal dust. Smoking does not appear to increase the incidence of simple CWP or PMF, but it does act in an additive fashion to increase the risk of developing airflow obstruction and bronchitis among coal miners. As in silicosis, CWP may present as a restrictive impairment, although obstructive and mixed patterns are more often observed. Simple CWP typically presents without dyspnea, but the patient often complains of chronic cough and phlegm production.

The chest examination is usually not helpful but may reveal breath sounds arising from airway obstruction. The combination of peribronchiolar deposition of coal dust, macrophages, and fibrosis, together with adjacent focal emphysema, makes up the classic coal macule, the earliest pathologic lesion of CWP ([Fig. 375.4](#)). Particle deposits continue to accumulate and typically form rounded micronodules (less than 7 mm in diameter) and later macronodules (more than 7 mm in diameter). Nodular pneumoconiosis arising from coal dust exposures typically occurs symmetrically and predominantly in the upper lobes of the lung. Rapidly developing nodules in the presence of CWP with rheumatoid arthritis is recognized as *Caplan's syndrome*.

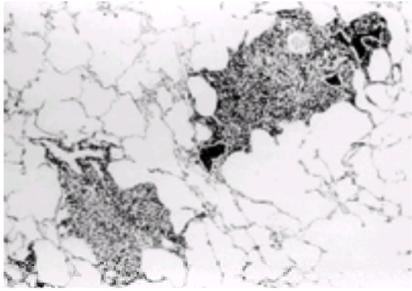

FIGURE 375.4. Histologic section demonstrates a coal macule (heavily pigmented lesion comprised of dust-laden macrophages) surrounded by emphysema (light microscopic magnification, $\times 70$.)

Unlike silicosis, simple CWP tends not to progress with removal from dust exposure. A small proportion (less than 5%) of those with simple CWP may progress to PMF. The risk of developing PMF depends on the extent of simple CWP and previous exposure to silica. Although those with early PMF (one or more large radiographic opacities greater than 1 cm in diameter) may not be impaired, those with more advanced PMF are typically severely impaired with progressive dyspnea and mixed obstructive–restrictive physiology. The lesions of PMF appear histologically as encapsulated dense fibrotic tissue surrounding coalesced coal macules, destroyed vascular tissue, collagen-containing scars, and proteinaceous acellular material saturated with coal dust (see [Fig. 375.4](#)). Investigators have recently suggested that alveolar macrophages contribute to pulmonary injury in CWP through generation of a superoxide anion, although the precise mechanisms involved in the disease pathogenesis remain unclear.

Optimal Management and Prevention

Therapy for symptomatic CWP is limited to treatment of complications; clinical intervention should focus on removal from the exposure site, discontinuation of additional exacerbating factors such as cigarette smoking, and treatment of the bronchitic phase of this disease. In addition, the presence of tuberculosis should be carefully considered among those with progressive disease.

Silicate Pneumoconioses

In addition to asbestos, other silicates may cause pneumoconiosis, given sufficient dust concentration and duration of exposure. The occupational populations at risk for these exposures are diverse because of the wide distribution of these products in consumer goods. For most of these exposures, limited environmental and epidemiologic data are available. The pneumoconioses arising from mining, milling, or subsequent processing of minerals are often more closely related to the more toxic “contaminants” of the host rock, such as crystalline silica or fibrous amphibole asbestos. As a result, silicate pneumoconiosis may closely resemble silicosis or asbestosis. Of particular importance is talc, a widely used consumer product and industrial material. NIOSH estimated the population occupationally exposed to talc in 1980 to be 1.8 million. Cosmetic talcs, now regulated by the Food and Drug Administration to prevent fiber contamination, consist of platy talcs, which may produce a reticulonodular form of pneumoconiosis known as talcosis. Exposure to this type of talc has not been associated with lung cancer. Fibrous talcs, commonly contaminated with significant amounts of asbestiform fibers, produce lung lesions that are typical of the asbestos-related lung diseases and include interstitial fibrosis, pleural plaques, diffuse pleural thickening, lung cancer, and mesothelioma.

Other silicates are being more widely used as asbestos substitutes in the absence of adequate data on health effects. A fibrous calcium silicate, wollastonite, appears to be relatively nontoxic, causing at most mild pneumoconiosis in the small work forces mining and milling it in the United States and Finland. Some vermiculite sources have been found to be contaminated with asbestiform fibers, resulting in lung fibrosis, lung cancer, and mesothelioma.

Miscellaneous Pneumoconiosis and Other Conditions

Occupational exposure to aluminum, barium, iron, and tin dusts may result in pneumoconiosis. These exposures result in nodular pneumoconiosis, often with striking chest radiographs due to the deposition of metal in the lung. In most cases, in the absence of other respiratory risk factors, the radiographic findings are not associated with symptoms, physical findings, or impairment.

Exposure to cemented tungsten carbide (hard metal), commonly used as an abrasive or metal cutting tool, may result in hard-metal lung disease. Patients with hard-metal lung disease can present with either airflow obstruction or diffuse interstitial fibrosis. The asthma-like syndrome is characterized by cough and chest tightness, which usually develop toward the end of the work shift or in the evening. This pneumoconiosis may develop rapidly within a year of employment, with the onset of cough, sputum, and dyspnea on exertion. Physical examination reveals basilar rales. The chest radiograph is characterized by irregular opacities with some hilar prominence.

Manufactured mineral fibers include slag wools, rock wools, glass wools and filaments, and ceramic fibers. These materials have numerous industrial applications and are frequently used as asbestos substitutes. Because the morphology of these fibers is similar to that of asbestos, there has been a good deal of concern about their potential for causing interstitial fibrosis, lung cancer, and mesothelioma. Epidemiologic studies reveal some linear opacities, similar to those of mild asbestosis, in a low prevalence among fiberglass manufacturing workers. However, exposure to manufactured mineral fibers does not appear to be associated with an excess risk of either lung cancer or mesothelioma.

MIXED OBSTRUCTIVE–PARENCHYMAL DISEASE

Hypersensitivity Pneumonitis

Definition

Hypersensitivity pneumonitis, also referred to as extrinsic allergic alveolitis, is a syndrome characterized by a granulomatous inflammatory reaction of the interstitium and terminal bronchioles. A complete description of hypersensitivity pneumonitis, including a discussion of its pathogenesis, diagnostic evaluation, and treatment, is found in [Chapter 372](#). The lung disease in hypersensitivity pneumonitis is often accompanied by systemic symptoms and is caused by exposure to airborne organic dusts and other agents. This disorder differs from allergic asthma in that the immunologically mediated inflammatory response is in the terminal bronchioles and interstitium rather than in the more proximal airways; however, the two disorders are caused by many of the same organic dusts. A wide variety of offending agents has been identified, but most agents are rare and the majority of reported cases comprise a few well-substantiated syndromes. Diagnosis of hypersensitivity pneumonitis is based on recognition of a pattern of clinical, radiographic, and pathophysiologic criteria. Farmer’s lung and pigeon breeder’s disease are the prototypic syndromes in hypersensitivity pneumonitis (see [Chapter 372](#) for further discussion).

Depending on the frequency and intensity of exposure to the causative agent, the clinical presentation differs from worker to worker. Acute, subacute, and chronic forms of hypersensitivity pneumonitis have been used to describe the variety of presentations. Acute disease is associated with such symptoms as cough, fever, chills, malaise, and dyspnea, which may begin 6 to 8 hours after the initial exposure to the antigen and spontaneously resolve once further exposure has ceased. This latent period makes it difficult for the patient to directly relate the exposure to the symptoms. Pulmonary examination often reveals tachypnea and bibasilar crackles, but wheezes are usually absent. The subacute pattern is characterized by progressively worsening cough and dyspnea that occurs over weeks and may progress to severe dyspnea and cyanosis, requiring hospitalization if the worker has been exposed repeatedly to the antigen. Typically, these patients have fleeting infiltrates and a history of being treated for recurrent episodes of suspected pneumonia. Fewer numbers of individuals develop the chronic pattern of disease, which involves progressive dyspnea with clinical features of interstitial fibrosis occurring after multiple symptomatic exposures. Fever is uncommon in the chronic form of hypersensitivity pneumonitis; however, evidence of cor pulmonale has been reported in advanced cases of pulmonary fibrosis associated with hypersensitivity pneumonitis.

Laboratory and Physiologic Findings

A leukocytosis with neutrophil predominance is often seen in acute cases, with white blood cell counts approaching 30,000 per milliliter. Most patients have acquired specific IgG antibodies to the antigen responsible for their symptoms, measurable as precipitins using radioimmunoassay or enzyme-linked immunosorbent assay. Establishing the quantity of a specific precipitin, although providing valuable clues to the clinician in making a diagnosis, is not alone diagnostic of the syndrome and simply indicates that an individual has been exposed to a potentially hazardous organic dust. Pulmonary function testing often reveals a decrease in the forced vital capacity (FVC) and a corresponding elevation of the FEV₁/FVC ratio. Total lung capacity is usually decreased. Impairment of the carbon monoxide diffusion in the lung may also be observed with associated low arterial PO₂ levels measured at rest. Importantly, in the acute phase of the disease all of the physiologic changes are reversible. Radiographically, there are no findings specific for hypersensitivity pneumonitis, although many cases reveal bilateral alveolar infiltrates with involvement of both upper and lower lung fields. Occasionally, these infiltrates present in different locations when imaged over time, but long-term exposures frequently show interstitial infiltrates appearing much like other forms of interstitial lung disease.

Optimal Management and Prevention

Absolute avoidance of the inciting antigen is the mainstay of therapy. If the work environment cannot be significantly altered to eliminate exposure to the antigen, respiratory protection is of little value because small amounts of inhaled antigen may cause acute symptoms in a sensitized individual. Although corticosteroids and supplemental oxygen may be administered for acute attacks, chronic treatment should focus on the prevention of antigenic exposures.

Bronchiolitis

Definition

Bronchiolitis represents an inflammatory injury to the bronchiolar epithelium that results in fibrosis and obliteration of the airway. Post injury, the subsequent healing leads to excessive proliferation of granulation tissue within the airway walls, lumen, or both. The nomenclature for bronchiolitis is quite large; other diagnostic entities that are used to describe this condition include bronchiolitis obliterans, bronchiolitis fibrosa obliterans, bronchiolitis obliterans–organizing pneumonia (BOOP), cryptogenic-organizing pneumonia, and follicular bronchiolitis. While a more complete description of this disease is outlined elsewhere (see [Chapter 376](#)), we have included it in this chapter because bronchiolitis is associated with occupation-related exposure to toxic fumes.

Pathogenesis

There are two classification systems used to characterize bronchiolitis—a clinical system based on cause [inhalation ([Table 375.4](#)), infection, drug reaction, and idiopathic] and a system based on histopathologic signs. The histopathologic signs can be separated into those associated with proliferative bronchiolitis and those associated with constrictive bronchiolitis. Proliferative bronchiolitis is more common and is characterized by organizing intraluminal exudate with intraluminal fibrotic buds (Masson bodies) in respiratory bronchioles, alveolar ducts, and alveoli. This is primarily an inflammatory condition associated with collagen vascular diseases, acute infections, hypersensitivity pneumonitis, organ transplantation, or a reaction to drugs. Constrictive bronchiolitis is characterized by damage to the membranous and respiratory bronchioles, with concentric narrowing or complete obliteration of the airway lumen; the alveolar ducts may be spared. Step sections are often required to make the diagnosis. In addition to the causes listed for proliferative bronchiolitis, constrictive bronchiolitis may be caused by inhalation of toxic fumes ([Table 375.4](#)) (nitrogen dioxide, sulfur dioxide, ammonia, chlorine, phosgene, ozone, chloropicrin, trichlorethylene, cadmium oxide, methyl sulfate, hydrogen sulfide, and hydrogen fluoride), mineral dust–induced airway disease (asbestos, silica, iron oxide, aluminum oxide, talc, mica, and coal), or cigarette smoke.

Although the pathogenesis of bronchiolitis is unknown, it has been hypothesized that whereas constrictive bronchiolitis is initiated by injury to the airway epithelia, proliferative bronchiolitis primarily involves an alveolitis. In constrictive bronchiolitis, it is thought that the initial airway injury is followed by neutrophilic inflammation and that the repair process results in intramural and intraluminal fibrosis. In proliferative bronchiolitis, the primary alveolitis results in an inflammatory exudate in the distal airspace. Fibroblast proliferation forms Masson bodies and extracellular matrix that further occlude the lumen of the respiratory bronchioles and alveolar ducts.

Diagnosis

Although a lung biopsy is essential for the diagnosis of bronchiolitis (see above), several clinical features are suggestive of this disorder. The history is essential to establish the specific exposures or inflammatory conditions that are associated with either constrictive or proliferative bronchiolitis. In constrictive bronchiolitis, the chest radiograph is often normal, whereas the HRCT scan may show marked heterogeneity in lung density (e.g., ground-glass infiltrates). In contrast, the radiographs in proliferative bronchiolitis demonstrate interstitial opacities that may be migratory. While the lung physiology in constrictive bronchiolitis is obstructive, the typical lung physiology in proliferative bronchiolitis is restrictive or mixed. However, there is no clear separation between the diagnostic categories of bronchiolitis, and overlap clearly exists between constrictive and proliferative bronchiolitis.

Optimal Management

Corticosteroids are the mainstay of treatment for bronchiolitis. Proliferative bronchiolitis is steroid-responsive and can be cured with an extensive course of treatment (usually requiring a year of therapy). Although corticosteroids should be used in constrictive bronchiolitis, this condition is relatively unresponsive and progressive, despite aggressive treatment.

Berylliosis

Definition

Metallic beryllium, simple salts of beryllium, and complex beryllium silicates, commonly referred to as beryllium compounds, cause both acute and chronic lung disease. Beryllium is widely used in the production of copper and nickel alloys, dental alloys, computers, x-ray tubes, electronic and nuclear reactors, and foundry products; in tool and die manufacturing; and in the aerospace industry. NIOSH estimated in 1990 that as many as 1 million U.S. workers are potentially exposed to beryllium oxides.

Beryllium lung disease may be divided into acute and chronic forms. The acute disease comprises those beryllium-related conditions that last for less than 1 year and that occur during beryllium exposure. Acute manifestation appear to be dose-related and include dermatitis (which may ulcerate), conjunctivitis, nasopharyngitis, tracheobronchitis, and acute chemical pneumonia. Chemical pneumonitis is rare but can be fulminant and fatal. Patients present with dyspnea, cough, fatigue, blood-tinged sputum, and substernal pain. Rales, tachypnea, and cyanosis are seen in advanced cases. Radiographic findings include diffuse or patchy infiltrates. Lung volumes are reduced, and hypoxemia is common. Of the 892 cases of beryllium-induced lung disease in the Beryllium Case Registry, 212 were acute, and of these only 17% progressed to chronic beryllium disease.

Chronic beryllium disease (berylliosis) is both a pulmonary and a systemic granulomatous disease. Clinically, berylliosis is very similar to sarcoidosis. However, berylliosis can be distinguished from sarcoidosis by exposure history and the absence of either central nervous system disease or altered calcium metabolism. The duration of exposures may vary from months to years, with a latent period from initial exposure to disease manifestations of 10 to 15 years. As with uncomplicated pneumoconiosis, chronic beryllium disease may present as a radiographic finding without respiratory symptoms. Chronic berylliosis, however, may result in severe dyspnea and end-stage pulmonary fibrosis. Physical findings include bibasilar rales, peripheral lymphadenopathy, hepatosplenomegaly, clubbing, and skin lesions. Lung function abnormalities may include airflow obstruction, reduced lung volume, and isolated diffusion defects. Bronchoalveolar lavage with measurement of the proliferative response of the lung lymphocytes to beryllium salts has been shown to be a sensitive marker for determination of chronic beryllium disease. The disease course is highly variable: with cessation of exposure some patients progress, some remain stable, and some improve. It is thought that corticosteroid treatment promotes resolution of chronic beryllium disease, but no controlled trial data are currently available.

Pathogenesis

Chronic beryllium disease is an immune-mediated systemic disorder. This position is strongly supported by the variable susceptibility to this metal, the presence of

noncaseating granulomas with mononuclear cell infiltrates on histologic examination of the lung, an antigen-specific immune response, and the accumulation of major histocompatibility complex (MHC) class II–restricted beryllium-specific CD4⁺ T lymphocytes in the lungs of patients with chronic beryllium disease. Furthermore, peripheral mononuclear cells and lung T cells proliferate and release lymphokines (tumor necrosis factor- α , interleukin-2, interleukin-6) when exposed to beryllium salts *ex vivo*. However, CD4⁺ T lymphocytes from the lung exhibit enhanced beryllium-induced proliferation when compared to peripheral T cells, and the magnitude of the antigen-specific cellular response in the lung is strongly associated with the degree of the local inflammatory process. These findings suggest that the pulmonary immune response in chronic beryllium disease is compartmentalized, and this inflammatory response is antigen-specific and mediated by activated CD4⁺ T lymphocytes. However, the immunogenicity of this innocuous-appearing metal is not understood. It has been hypothesized that macrophages ingest aggregates of this metal, slowly releasing it and thus causing a chronic granulomatous response. Alternatively, beryllium has been hypothesized to complex with proteins and act as a hapten. However, there are no data to support either hypothesis.

Understanding these beryllium-specific immunologic responses has provided a reliable method to distinguish chronic beryllium disease from sarcoidosis. This is particularly important because the presence or absence of beryllium in lung tissue does not prove or refute the diagnosis of berylliosis. The beryllium lymphocyte proliferation test (BeLPT) has been standardized, is an essential component of the diagnostic criteria for berylliosis, and results in negative findings in patients with sarcoidosis. The BeLPT quantifies the cellular proliferative immune response to beryllium and is positive in peripheral blood specimens in over 90% of patients with berylliosis. The remaining individuals with chronic beryllium disease will have abnormal BeLPT responses in lymphocytes obtained by bronchoalveolar lavage. The BeLPT also appears to function as a screening test, since exposed workers with a positive BeLPT may have subclinical granulomatous lung disease and are at excess risk of developing beryllium disease. In fact, a longitudinal study has shown that approximately 50% of those with a positive BeLPT go on to develop chronic beryllium disease.

A recent study suggests that allelic substitution of the *HLA-DP* gene may place individuals at higher risk of developing beryllium disease. Specifically, chronic beryllium disease was found to be strongly associated with a base-pair substitution that resulted in glutamic acid (rather than lysine) at position 69 of the *HLA-DP* gene. It was further postulated that residue 69 of the *HLA-DP* gene, which is a negatively charged site when glutamic acid is present, may directly interact with beryllium and be involved in the immunopathogenesis of this disease. The finding that allelic alteration of the *HLA-DP* gene is associated with enhanced susceptibility to an immune-mediated lung disease is consistent with the finding that alterations in MHC class II genes (*HLA-DR*, *HLA-DQ*, and *HLA-DP*) are associated with susceptibility to autoimmune diseases. These findings in the *HLA-DP* gene may be relevant to other forms of granulomatous lung disease. Moreover, these observations provide further evidence that host susceptibility may be an important determinant of occupational lung disease and indicate that minor alterations in the human genome may substantially modify the biological response to environmental stimuli. Given the tools available in human molecular genetics, gene–environment interactions represent a feasible and very important area for further investigation in chronic beryllium disease, as well as other forms of occupational lung disease.

OCCUPATIONAL NEOPLASTIC DISEASES OF THE LUNG

Lung cancer is the leading cause of cancer deaths in the United States and in many other industrialized countries. Importantly, occupational exposures can play an important role in the development of bronchogenic carcinoma. Although the clinical aspects of lung cancer will be discussed elsewhere in this text (see [Chapter 377](#)), we focus on the etiologic considerations of bronchogenic carcinoma. Mesothelioma, a malignancy originating from the cells that line the pulmonary surface (mesothelium), is exclusively associated with previous exposure to asbestos and is discussed in detail later.

Bronchogenic Carcinoma

In 1987, approximately 100,000 men and 50,000 women in the United States developed lung cancer. The disease accounts for nearly one-fourth of all cancer deaths. The four major malignant cell types of bronchogenic carcinoma are large-cell, small-cell, squamous cell, and adenocarcinoma. Occupational exposures may involve any one of these cell types, and all forms of neoplasia are increased with cigarette smoking. Signs and symptoms, laboratory findings, and diagnosis of lung tumors are discussed elsewhere in this text (see [Chapter 377](#)). Therapy for occupation-related lung tumors is dependent on the cell type and is no different from treatment of lung cancer due to other exposures.

Cigarette smoking is the most important risk factor for developing pulmonary malignancies in the general population. In more recent studies, passive exposure to cigarette smoke was also found to contribute to development of lung cancer deaths. This trend is expected to decline gradually, however, as smoking decreases and as cigarette manufacturers develop products containing less nicotine and tar. Occupational exposures to cigarette smoke are important to consider because the carcinogenic potential of several substances encountered in the workplace can be greatly enhanced by concomitant exposure to cigarette smoke.

Asbestos inhalation is generally considered to have the highest carcinogenic risk in the workplace. Many studies have documented an increase in all forms of bronchogenic carcinoma in workers exposed to asbestos, and all fiber types have been implicated in carcinogenesis. Most asbestos-related pulmonary tumors have a long latency period (20 to 30 years) and a dose–response relationship has been observed between the exposure and development of the tumor. Investigators estimate a 6- to 8-fold increase in lung cancer risk in nonsmoking workers exposed to asbestos and 50- to 100-fold excess risk in asbestos workers who are heavy smokers. Lung cancer accounts for up to 25% of all deaths in asbestos-exposed workers.

Excess mortality rates from lung carcinoma have also been reported in workers exposed to other compounds and chemicals. Uranium miners were discovered to develop lung disease by inhaling the breakdown products of uranium ore, one of which is radon, an inert gas found to increase the risk of lung cancer in a dose-dependent fashion. The risk related to domestic radon exposures, however, remains controversial.

Chloromethyl ethers are one example of chemical carcinogens in the workplace. These substances, which are used in the process of manufacturing a number of organic substances such as water repellents, fireproofing agents, and pesticides, have been implicated in increasing small-cell lung cancer rates. Chloromethyl ether causes small-cell lung carcinoma even among individuals who have never smoked.

Workers exposed to chromium, beryllium, nickel, and cadmium have higher lung cancer rates, and these metals are considered to be carcinogenic in humans by the International Agency for Research on Cancer (IARC).

Mesothelioma

Mesothelioma, a rare tumor of the cells lining the lung surface, was first reported in the 1940s. The annual incidence, although small, continues to increase with rates of approximately 2.5 cases per million for men and 0.7 case per million for women in North America. Asbestos exposure has been directly linked as a causative agent in almost all cases of this disease; isolated exposures to erionite (a mineral in the silicate zeolite family) and radiation may possibly contribute to the development of mesothelioma. Unlike bronchogenic carcinoma, no specific association between mesothelioma development and cigarette smoking has been established. The latency period for this disease often is greater than 30 years.

Pathogenesis

Although all fiber types have been found to cause mesothelioma, crocidolite has been noted to be the most carcinogenic. Since chrysotile was the primary asbestos fiber to which U.S. workers were exposed, chrysotile asbestos accounts for a disproportionate number of cases of mesothelioma in the United States. Formation of mesothelioma appears to be dependent on the size of the fiber and its dimensions, but the exact mechanism of tumor development is not known.

Pathologic Factors

Mesotheliomas often may appear grossly as multiple gray or white nodules or granules on the visceral or parietal pleura. As the tumor load multiplies, the affected pleura becomes progressively thicker and in its later stages may eventually encase the entire hemithorax. The tumor may advance and spread to the diaphragm, liver, the parietal pleura of the opposite side, or even the pericardium. Hematologic spread has been identified in approximately half of affected patients.

The tumor is classified into three discrete types: epithelial (50% of all cases), mesenchymal (16%), or mixed (34%). Epithelial tumors may appear in cordlike or sheetlike patterns, but may also show papillary or tubular arrangements. Mesenchymal tumors have been described as having cells that are spindle-like and contain elongated nuclei. The mixed form has both spindle-shaped cells and features of the epithelial tumor.

Clinical Presentation

Malignant mesothelioma most commonly presents in the sixth decade of life. Patients often present with nonpleuritic chest pain and dyspnea, although complaints of shoulder or upper abdominal pain referred from areas of diaphragmatic involvement may be observed. Pleural effusions are common at presentation and patients may also have fever and weight loss.

Diagnostic Testing

On radiographs, pleural effusions are commonly seen and pleural plaques are often present in the opposite hemithorax. Mediastinal widening, soft-tissue masses, and enlargement of the cardiac silhouette is seen on chest radiograph with progression of the disease. Chest CT scans are valuable in the evaluation of mesothelioma because large pleural effusions may make evaluation of pleural lesions quite difficult. The chest CT shows thickened pleura with a somewhat nodular margin. The major fissure may also be abnormal secondary to fibrosis or tumor invasion. Evaluation of pleural fluid reveals a cellular serosanguinous exudate that contains not only benign and malignant mesothelial cells but also varying numbers of lymphocytes and polymorphonuclear leukocytes. Pleural fluid pH and glucose levels may be significantly diminished in patients with mesothelioma. Occasionally, patients may present with skin deposits, which, after biopsy, can be used to establish a diagnosis.

Diagnostic tissue for malignant mesothelioma is obtained in nearly all patients by thoracoscopy or open thoracotomy. Because of the varying microscopic features in isolated lesions, multiple biopsies should be obtained. Histochemical staining using the periodic acid–Schiff method, immunohistochemical testing with monoclonal antibodies, and electron microscopy have all been used to differentiate malignant mesothelioma from metastatic adenocarcinoma. Definite pathologic diagnosis of a mesothelioma, however, relies on electron microscopic findings. Long microvilli, identified by electron microscopy ([Fig. 375.5](#)), are characteristic of a mesothelioma and distinguish it from an adenocarcinoma, which characteristically has very short microvilli.

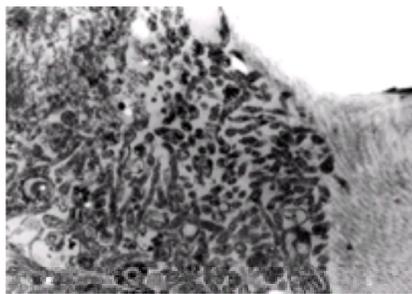

FIGURE 375.5. Electron microscopy reveals long microvilli, characteristic of malignant mesothelioma (magnification $\times 15,300$.)

Optimal Management

Although chemotherapy, gene therapy, and surgical interventions have been attempted, no effective life-prolonging therapy is currently known for malignant mesothelioma. Mesotheliomas are not responsive to radiation. The median survival of patients with malignant mesothelioma has been reported at about 18 months.

IMPAIRMENT/DISABILITY EVALUATION

Physicians involved in the evaluation of patients with occupational lung disease are frequently asked to provide an impairment rating and to make determinations regarding causation. Impairment is defined as a measurable decrement in a physiologic function and is based on objective clinical tests. Disability, on the other hand, considers not only the physical and mental impairment but also the social, psychological, or vocational factors associated with a person's ability to work. The latter is an administrative assessment and is generally not performed by a physician. Using guidelines established by the American Medical Association (AMA) and American Thoracic Society (ATS), percentage impairment can be calculated based on the results of a clinical evaluation, spirometric testing, and diffusion capacity assessment. In circumstances where spirometry and diffusion capacity are thought to underestimate the degree of impairment, an exercise test with measurement of maximal exercise capacity (VO_2) can be performed. The standard AMA impairment guidelines generally address patients with stable, irreversible pulmonary disorders and are not suitable for rating patients with reversible airflow obstruction. Consequently, the ATS has developed guidelines for impairment rating in patients with asthma, which takes into account factors such as post-bronchodilator FEV_1 , reversibility of airflow obstruction, degree of airway hyperresponsiveness, and medication usage. It is recommended that physicians performing impairment ratings familiarize themselves with relevant AMA or ATS guidelines on this topic.

PREVENTION: CONTROLLING OCCUPATIONAL HEALTH HAZARDS

Industrial hygiene involves recognizing and testing for hazards and modifying the work environment where occupational health hazards exist. Once a complete survey of the manufacturing or production process involved is completed (including a thorough understanding of the workplace environment), specific exposures can be measured and compared with existing standards. Exposures may be measured by devices that monitor the air immediately surrounding an individual worker or that monitor an entire work area. If unacceptable levels of a substance are identified, all possibilities of replacing that substance with a nontoxic product should be explored. Recommendations should be made for encouraging employers to minimize exposures among all employees through engineering controls and improved ventilation.

For potentially damaging occupational pulmonary disease, personal respiratory protection may be required, but this is less desirable than other methods (substitution and ventilation) because it is difficult to ensure that the equipment is properly used by each worker. Respirators provide a method of temporary protection from airborne hazards, from benign odoriferous fumes to toxic materials, that are potentially life threatening. Employers are responsible for instituting the use of respiratory protection, providing appropriate equipment, and ensuring that the equipment meets established standards. Programs for proper maintenance and inspection of the respirator must also be implemented. Three general classifications of respirators are as follows: (a) air-purifying respirators, (b) atmosphere-supplying respirators, and (c) a combination of the two. Air-purifying respirators contain a mechanical filter that removes particulate matter from the air, using a fibrous padded mesh. Inhaled air is drawn in through filters before entering the face piece, and exhaled air is guided out through a different pathway, using a system of valves in the mask itself or through air-tight tubing. Cartridges and canisters are occasionally used for removal of specific gases or vapors. Atmosphere-supplying respirators provide a portable external source of oxygen and virtually eliminate exposure to work site air.

In summary, a well-supervised control program emphasizes replacement of the inciting agent as a first line of therapy. If substitution is unrealistic or infeasible, then isolating the substance from the majority of workers through administrative controls, local exhaust ventilation, or personal protection may be required.

AMYLOIDOSIS

DEFINITION

Amyloidosis is a term applied to disorders associated with extracellular tissue deposition of amyloid, an insoluble homogeneous proteinaceous material that typically has apple-green birefringence with polarized light after staining with Congo red. Amyloidosis can be classified into subtypes according to the composition of the protein component. Examples are immunoglobulin light chains, amyloid A protein, and transthyretin related protein. Many different fibril proteins have been associated with both systemic and localized amyloidosis; however, all protein subtypes share a β -pleated sheet configuration.

ETIOLOGY AND PATHOGENESIS

Amyloidosis may be a primary systemic disorder in which amyloid (in this case, monoclonal light chains) is produced by a clone of bone marrow–derived plasma cells, or it may be secondarily associated with inflammatory, infectious, or other neoplastic diseases. Familial amyloidosis is the rarest form of systemic amyloidosis. The most common of these autosomal dominant diseases is associated with a mutant transthyretin, a liver transport protein. Generally in systemic amyloidosis, many organs, including the lung, have amyloid protein deposition. Diffuse infiltration interferes with organ function. Much more rarely, fibril deposition is limited to a single organ, such as the bladder, eye, tongue, or respiratory tract.

CLINICAL FINDINGS AND STRATEGIES FOR OPTIMAL CARE

In primary and secondary systemic amyloidosis, as many as 30% of patients have dyspnea, a cough, or both. Although the lung parenchyma may be infiltrated with amyloid, clinical symptoms usually are dominated by cardiac involvement. Congestive heart failure from cardiac infiltration can cause dyspnea, pulmonary infiltrates, and pleural effusion. The prognosis of systemic amyloidosis once was poor—a median survival period of 1 year, but therapeutic options have improved in the past few years. Therapy is tailored to the specific underlying disease mechanism, and survival rates have increased. Unlike systemic amyloidosis, localized pulmonary amyloidosis typically has a good prognosis. The most common respiratory tract manifestation is hoarseness from laryngeal deposition. In the lower respiratory tract, tracheobronchial involvement includes submucosal plaques and pseudotumors; parenchymal involvement includes nodules and diffuse septal deposition. Plaques and pseudotumors may be asymptomatic, incidental findings at bronchoscopy or cause hemoptysis, wheezing, or obstruction with atelectasis. Patients with symptomatic lesions have been successfully treated with endoscopic laser resection, although recurrence is common.

Alveolar deposition may cause single or multiple pulmonary nodules that can cavitate or calcify. Although benign and generally asymptomatic lesions, these nodules are difficult to differentiate radiographically from malignant or tubercular lesions and so are frequently resected. The rarest form of localized disease is diffuse alveolar septal deposition. Patients typically have progressive dyspnea and a cough that often progress to respiratory failure. Pulmonary function tests show a restrictive pattern. Like advances in the management of some types of systemic amyloidosis, therapeutic options for localized disease are emerging. If diffuse alveolar septal deposition of amyloid is found, a search for a subtle form of a primary systemic amyloidosis and a subspecialty consultation may be warranted.

BRONCHIOLITIS OBLITERANS–ORGANIZING PNEUMONIA

DEFINITION

Bronchiolitis obliterans–organizing pneumonia (BOOP) is a clinical pathologic entity characterized by a subacute respiratory illness with plugs of loose granulation tissue in distal airways and associated organizing pneumonitis. Although the term *bronchiolitis obliterans–organizing pneumonia* was proposed in the 1980s, the disease is not new, having been recognized pathologically since the beginning of the twentieth century. Unfortunately, the term *bronchiolitis obliterans* sometimes is used to imply BOOP or a different airway disease, obliterative bronchiolitis. The distinction is important. BOOP is a relatively benign disease that resolves completely in most patients. Obliterative bronchiolitis typically is a progressive disease that irreversibly scars the airways. Adding to the confusion, in Europe the idiopathic form of BOOP is called *cryptogenic organizing pneumonia* (COP).

INCIDENCE AND EPIDEMIOLOGY

The overall incidence of BOOP is unknown. Most reported cases of BOOP are idiopathic. Idiopathic BOOP occurs among men and women equally, the incidence peaking in the fourth through sixth decades of life. In the idiopathic form, there is no common pattern of occupational exposure, and smoking does not appear to be a risk factor. Secondary BOOP has been associated with viral infection, *Legionella* and *Mycoplasma* infections, exposure to toxic fumes, HIV infection, inflammatory bowel disease, connective tissue disease (especially rheumatoid arthritis and dermatomyositis-polymyositis), radiation therapy, myelodysplasia syndrome, bone marrow transplantation, and use of various drugs. Although some rare cases of secondary BOOP have been associated with pulmonary infection, in most cases culture results from biopsy specimens are negative, and results of viral serologic testing do not suggest recent infection.

ETIOLOGY AND PATHOGENESIS

BOOP may represent a reparative process to a variety of insults to the distal airways. In the most distal airways, the respiratory bronchioles and alveolar ducts, extensive loose granulation tissue protrudes from the airway wall into the lumen to form tufts or plugs. These intraluminal polypoid masses extend into alveolar ducts and alveoli, and organizing pneumonitis develops ([Fig 376.1](#)). Alveoli contain a fibrinous exudate, and alveolar macrophages appear foamy from endogenous lipid ingestion characteristic of airway obstruction. The adjacent alveolar walls have mild chronic inflammatory infiltration, but generally there is an absence of extensive interstitial fibrosis. The process is patchy and of uniform, generally recent age; mature collagen deposition is unusual.

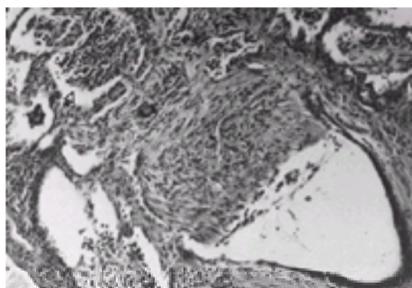

FIGURE 376.1. Bronchiolitis obliterans organizing pneumonia. Thoracoscopic lung biopsy specimen contains a bronchiole with intraluminal granulation tissue (*asterisk*). An adjacent alveolus (*arrow*) is filled with inflammatory cells. (Pathology slide courtesy of Martha L. Warnock, MD.)

CLINICAL PRESENTATION

In idiopathic BOOP, patients have a subacute, flulike illness with mild dyspnea, a nonproductive to mildly productive cough, fatigue, and fever. They may have mild weight loss. Hemoptysis is rare, but it does occur. Duration of symptoms typically is 2 to 3 months before diagnosis. Physical examination reveals inspiratory rales in two-thirds of patients and wheezing or normal auscultatory findings in the others. Cyanosis is unusual; clubbing is not associated with this disease.

LABORATORY AND RADIOGRAPHIC FINDINGS

Laboratory abnormalities in BOOP may include mild to moderate hypoxemia, an elevated erythrocyte sedimentation rate, and an elevated peripheral white blood cell count. BOOP is a restrictive not an obstructive physiologic process in that only the most peripheral airways are affected. Pulmonary function testing reveals reduced lung volume and reduced diffusion capacity for carbon monoxide. Airflow obstruction does not occur, except among current or former smokers. Chest radiographs reveal bilateral, patchy, often peripheral, alveolar infiltrates. Infiltrates may be dense or partially opaque with a ground glass appearance. Nodules or linear opacities are present in one-third of cases but are rarely the sole radiographic manifestation. Infiltrates may resolve spontaneously and reappear in different lung segments, so-called *fleeting infiltrates*. Computed tomography (CT) and high-resolution CT also reveal the patchy dense and ground glass alveolar infiltrates that have a predilection for subpleural and perivascular areas. Although it does not provide enough information to confirm a diagnosis, CT may help differentiate BOOP from interstitial pulmonary fibrosis and can help direct the pulmonologist or surgeon to optimal sites for biopsy. Pleural effusions, cavities, and lymphadenopathy are rare.

STRATEGIES FOR OPTIMAL CARE

BOOP may be suspected when an adult has a prolonged viral-like respiratory illness that does not respond to antibiotics. Lung biopsy is recommended because of the wide differential diagnosis and the prolonged corticosteroid therapy required in most cases. Results of transbronchial biopsy confirm the diagnosis if a piece of tissue of sufficient size is obtained that contains all the elements of the lesion. However, most patients need either thoracoscopic or open lung biopsy. Diagnosis is made when the defining pathologic characteristics are found in the appropriate clinical setting.

Although spontaneous improvement can occur, most patients need a prolonged course of corticosteroids. Prednisone, 1 mg per kilogram per day for 1 to 3 months then a very gradual taper, is recommended. The duration of therapy is empiric, but because relapses are common in courses of less than 3 months, most authors recommend a total course of 6 months to 1 year. Relapse after steroid dosage is reduced or stopped is not uncommon, but BOOP responds favorably to a second course of treatment. With corticosteroids, symptomatic relief is rapid, over days to weeks, and can be dramatic; physiologic and radiographic improvements take longer. More than 80% of treated patients respond to therapy, and approximately 65% have complete resolution. Death of respiratory failure occurs among less than 5% of patients and is caused by a progressive illness that results in end-stage fibrosis. Clear benefit of cytotoxic agents has not been established. BOOP occasionally can be localized or focal, and surgical resection appears to be curative. BOOP also can be a reactive process that forms around a tumor, abscess, or infarct. Pathologic specimens from bronchoscopic transbronchial biopsy of or near solitary lesions should be interpreted within the context of the clinical scenario.

OBLITERATIVE BRONCHIOLITIS

DEFINITION

Obliterative bronchiolitis is an inflammatory disease with concentrically scarred or stenotic small airways from extrinsic bronchiolar and peribronchiolar narrowing. This process is a lesion confined to the bronchioles and usually lacks an associated organizing pneumonitis. A more precise term is *constrictive bronchiolitis*.

EPIDEMIOLOGY AND PATHOGENESIS

Obliterative bronchiolitis is a rare disease, less common than BOOP. Most instances are idiopathic and occur mostly among women in their fifth through seventh decades. Secondary causes include viral infection, exposure to toxins and fumes, drug reaction, and connective tissue disease, especially rheumatoid arthritis. Why a toxin, infection, or other secondary cause triggers the relatively benign reaction of BOOP in some or obliterative bronchiolitis in others is unknown. Obliterative bronchiolitis also occurs after bone marrow, heart-lung, and lung transplantation. With obliterative bronchiolitis after bone marrow transplantation, most patients have clinical evidence of graft versus host disease. The incidence of obliterative bronchiolitis among patients with chronic graft versus host disease is approximately 10%. There is a high case fatality rate despite aggressive therapy with steroids, immunosuppressive agents, and bronchodilators. Obliterative bronchiolitis develops among 30% to 50% of long-term survivors of heart-lung or lung transplantation and is the leading cause of death. There may be many cofactors, but the primary event appears to be chronic transplant rejection.

CLINICAL, LABORATORY, AND RADIOGRAPHIC PRESENTATION

Patients have progressive dyspnea and a nonproductive cough that can develop over months to years in idiopathic cases or within months after transplantation. Fever is rare. Findings at physical examination may be unremarkable or reveal diffuse expiratory wheezing. Chest radiographs may be normal or have evidence of hyperinflation with or without interstitial infiltrates. Pulmonary function usually reveals an obstructive pattern. Because small airways are irreversibly scarred and occluded, little improvement occurs with use of bronchodilators.

STRATEGIES FOR OPTIMAL CARE

The diagnosis of obliterative bronchiolitis usually is made when lung biopsy reveals concentrically scarred small airways in the appropriate clinical setting. Presumptive diagnosis without biopsy may be appropriate in the care of patients with graft versus host disease after bone marrow transplantation who have new onset of obstructive airway disease. Bronchoalveolar lavage is recommended to exclude opportunistic infection.

The clinical course of obliterative bronchiolitis is variable, but the disease tends to be progressive, often ending in respiratory failure, especially among patients with underlying rheumatoid arthritis. Most patients have little response to steroids, although a therapeutic trial is warranted for most. Although many airways may be irreversibly scarred, some may be in earlier stages of the inflammatory process. For patients who have undergone bone marrow, lung, or heart-lung transplantation, augmentation in immunosuppression and vigilance for opportunistic infection may slow or stabilize the lung disease.

IDIOPATHIC EOSINOPHILIC PNEUMONIA: SIMPLE, ACUTE, AND CHRONIC

DEFINITION

Eosinophilic pneumonia is pneumonia with infiltration of the lung parenchyma by eosinophils that may or may not be accompanied by excess eosinophils in the peripheral blood. This type of pneumonia is associated with helminthic, bacterial, and fungal infection, drug reactions, connective tissue disease, vasculitis, Hodgkin's disease, sarcoidosis, systemic hypereosinophilic syndrome, Churg–Strauss syndrome, allergic bronchopulmonary aspergillosis, and other forms of bronchocentric granulomatosis. When underlying diseases or specific causes are excluded, there remain the idiopathic eosinophilic types of pneumonia, which have no discernible cause but do have distinctive clinical and radiographic presentations. The classification of eosinophilic pneumonia has changed over the past several decades to include such terms as *Löffler's syndrome* for simple pulmonary eosinophilia and pulmonary infiltrates with eosinophilia (PIE) syndrome to describe a broad range of eosinophilic types of pneumonia. Because these terms denote mixed idiopathic and secondary eosinophilic types of pneumonia, the terms *acute* and *chronic eosinophilic pneumonia* are now used to mean the idiopathic forms of these types of pneumonia. The distinction between these idiopathic forms is based on differences in clinical observation and may be arbitrary or valid. Most patients with simple eosinophilic pneumonia have a parasitic infection or drug reaction; however, no cause is found in as many as one-third of these patients.

INCIDENCE AND EPIDEMIOLOGY

All eosinophilic types of pneumonia are rare disorders. Although these diseases can occur at any age and affect either sex, case series suggest a male predominance

that peaks in the third decade of life for the acute form and a female predominance that peaks in the fifth decade for the chronic form. There does not appear to be any regional or geographic clustering.

ETIOLOGY AND PATHOGENESIS

Idiopathic eosinophilic pneumonia is a diagnosis made after drugs, infection, and associated diseases are excluded as etiologic factors. Patients with the acute form typically have been healthy before the onset of disease. A high percentage of patients with the simple idiopathic form have atopy or allergic diathesis found with skin testing to common antigens. Most patients with chronic eosinophilic pneumonia have established or new-onset asthma, allergic rhinitis, or another form of atopy.

In eosinophilic pneumonia, eosinophils mixed with alveolar macrophages, lymphocytes, and neutrophils accumulate in the airway, interstitium, and alveoli for unknown reasons. The eosinophils may be nonspecific markers of inflammation or the direct perpetrators of lung injury. In the acute form, inflammatory cells and edema occur within the alveolar and bronchial walls. In the chronic variant, alveolar walls may be thickened; interstitial fibrosis occurs in one-half of cases.

CLINICAL FINDINGS

Acute Eosinophilic Pneumonia

Patients with acute eosinophilic pneumonia have rapidly progressive pulmonary disease with dyspnea, a nonproductive cough, fever, and myalgia. The time from onset of symptoms to respiratory failure that necessitates mechanical ventilation may be as rapid as a few days. Physical examination typically reveals rales and rarely wheezes on chest auscultation.

Simple Eosinophilic Pneumonia

Patients with simple eosinophilic pneumonia can have an asymptomatic presentation with an unexpected elevated eosinophil count, an abnormal chest radiograph, mild dyspnea, or a cough typically of less than 1 month's duration. Fever may be present. Findings at physical examination may be normal or reveal rare rales or wheezes on chest auscultation.

Chronic Eosinophilic Pneumonia

Patients with chronic eosinophilic pneumonia have an insidious onset, usually lasting more than 2 months, of dyspnea, cough occasionally productive of mucoid sputum, low-grade fevers, and malaise (Fig 376.2). Wheezing and weight loss may be present. Physical examination may reveal rales, wheezes, and occasionally hepatomegaly from eosinophil infiltration of the liver.

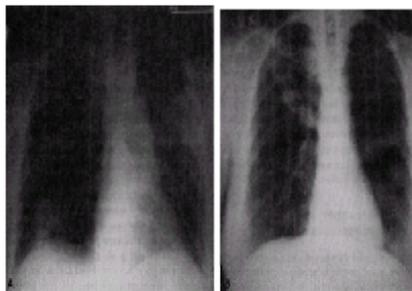

FIGURE 376.2. Chronic eosinophilic pneumonia. A 42-year-old woman had dyspnea, a nonproductive cough, and a low-grade fever. Eosinophilia was present in the serum and bronchoalveolar lavage fluid. Chest radiograph (A) shows peripheral infiltrates in the left upper and right lower lobes. Symptoms and infiltrates resolved with glucocorticoid therapy. Several months later, during steroid taper, the patient had a flare of symptoms, elevation of serum eosinophil count, and a new right upper lobe infiltrate (B). Symptoms and infiltrate resolved with resumption of steroid therapy. (Radiographs courtesy of Marcia McCowin, MD).

LABORATORY AND RADIOGRAPHIC FINDINGS

Acute Eosinophilic Pneumonia

The number of eosinophils in peripheral blood typically is normal or is minimally elevated when the patient comes to medical attention, although most patients have some elevation during the clinical course. Total peripheral blood white blood cell count, erythrocyte sedimentation rate, and IgE level may be elevated. In the acute form as opposed to the simple and chronic forms, hypoxemia may be marked. Chest radiographs may reveal unilateral or bilateral, diffuse or patchy, interstitial or alveolar infiltrates. Small pleural effusions are common.

Simple Eosinophilic Pneumonia

Simple eosinophilic pneumonia is much less well-described than the acute and chronic forms. Many patients with simple eosinophilic pneumonia have peripheral blood eosinophilia. Chest radiographs characteristically show transient, migratory, peripheral infiltrates.

Chronic Eosinophilic Pneumonia

Mild to moderate elevation of eosinophil count in the peripheral blood is typical; the count usually is higher than in the acute variety. Total peripheral blood white blood cell count, erythrocyte sedimentation rate, and IgE level may be elevated. Hypoxemia or an elevated alveolar-arterial gradient may be present. On radiographs the classic pattern of chronic eosinophilic pneumonia—migratory, dense, bilateral, peripheral infiltrates—occurs among only 25% of patients; however, the infiltrates are peripheral (outer two-thirds of the lung field) in 65% of patients. CT findings confirm the typically peripheral nature of the infiltrates. Some patients also have hilar or mediastinal adenopathy. In both forms, reduced lung volume and a decreased diffusion capacity for carbon monoxide occur. Although more frequent among patients with asthma, an obstructive pattern may occur among patients without such a history. In all forms, even though peripheral blood eosinophilia may be absent or minimal, lung eosinophil count is invariably elevated. The number of eosinophils recovered at bronchoalveolar lavage by means of bronchoscopy correlates well with the presence of lung eosinophils.

STRATEGIES FOR OPTIMAL CARE

Secondary causes should be considered when a patient has any type of eosinophilic pneumonia, especially that caused by a drug reaction or parasitic infection. Patients with simple eosinophilic pneumonia may have spontaneous resolution of symptoms, eosinophilia, and radiographic abnormalities within several weeks even without glucocorticoid treatment. Relapse is unusual. Among patients with fulminant acute eosinophilic pneumonia, the rapid progression mimics that of acute respiratory distress syndrome ARDS or rapidly progressive community-acquired pneumonia. Bronchoalveolar lavage, which reveals eosinophilia and allows exclusion of infectious causes for the infiltrates, may be the most opportune way to make a rapid diagnosis. High-dose steroid therapy causes rapid reversal of the disease. Steroids are tapered over several weeks, and recurrence is not a feature of this form of eosinophilic pneumonia.

Patients with chronic eosinophilic pneumonia need glucocorticoid therapy because spontaneous resolution occurs among less than 10% of patients. Patients with classic bilateral peripheral infiltrates on radiographs, an elevated peripheral eosinophil count, and typical symptoms do not need lung biopsy. Marked eosinophilia (more than 25% of recovered cells; normal is less than 1%) at bronchoalveolar lavage supports the diagnosis of eosinophilic pneumonia. Therapy for chronic

eosinophilic pneumonia with prednisone 1 mg per kilogram per day brings about rapid improvement of symptoms within several days and radiographic improvement over 1 to 2 weeks. The dramatic clinical response to steroids supports a presumptive diagnosis. Steroid therapy for chronic eosinophilic pneumonia should continue for approximately 6 months. Relapse after withdrawal of steroids is common, but not predictable. Many patients need long-term daily or alternate-day therapy. The long-term prognosis is good. Relapses typically respond to re-initiation of steroid therapy.

GOODPASTURE'S SYNDROME

DEFINITION

Goodpasture's syndrome is alveolar hemorrhage and glomerulonephritis associated with the presence of anti-glomerular basement membrane (GBM) antibody in serum or evident on immunofluorescent stains of renal or lung tissue. *Anti-glomerular basement membrane antibody disease* is the preferred term because it clearly differentiates Goodpasture's syndrome from other pulmonary-renal syndromes and includes patients with isolated anti-GBM antibody renal disease.

INCIDENCE AND EPIDEMIOLOGY

Anti-GBM antibody disease is a rare disorder. The true incidence is unknown, but this disease has been estimated to account for 1% to 5% of all cases of glomerulonephritis. Case reports suggest the disease is more prevalent among whites and men, although the male to female ratio varies from 2:1 to 9:1 in different reports. Although the disease occurs among persons of all ages, the peak incidence is in the twenties through fifties.

ETIOLOGY AND PATHOGENESIS

Anti-GBM antibody disease is a true autoimmune disorder in which antibodies form against basement membrane for unknown reasons. Possible triggers include viral upper respiratory tract infection (20% to 60% of patients) and exposure to hydrocarbon solvent (less than 5% of patients). This disease is strongly associated with smoking (75% to 80% of patients), especially among patients with pulmonary hemorrhage. It has been postulated that a noxious event, such as infection or exposure to a toxin, among genetically predisposed persons damages basement membrane and exposes an antigen that triggers IgG autoantibody production.

Basement membrane is heterogeneous in the body; anti-GBM antibody appears to have specificity for an $\alpha 3$ domain on type IV collagen present in high concentrations in alveolar and GBM. This binding specificity may account for the organ specificity of this disease. Once formed, the circulating autoantibody has direct access to GBM. In contrast, alveolar capillaries lack the large fenestrations of glomeruli. An increase in capillary permeability appears to be necessary for antibodies to gain access to alveolar basement membrane. This hypothesis is supported by the clinical observations that alveolar hemorrhage is more common among smokers and that episodes of hemoptysis often occur after infection and fluid overload. Once the anti-GBM antibody is bound to basement membrane, complement binding occurs, and there is an influx of neutrophils and other inflammatory cells. Light microscopic examination of the kidney tissue reveals focal segmental necrotizing glomerulonephritis with epithelial crescents. Lung findings include alveolar red blood cells, hemosiderin-laden macrophages, and type II cell hyperplasia. In both the kidney and lung, immunofluorescent microscopic examination reveals linear deposits of IgG along the basement membrane.

CLINICAL FINDINGS

The most common presenting symptom is hemoptysis (80% to 90% of patients), which can be mild to life threatening. Most patients also have dyspnea, a cough, and fatigue. Patients may report fever and chills, chest pain, weight loss, and for 10% to 40% of patients, gross hematuria. Unlike the situation with systemic vasculitis, joint pain and skin rashes are uncommon. At physical examination, pallor from anemia is common (50% to 90% of patients). Lung examination may have normal findings or reveal rales, rhonchi, or decreased breath sounds. Patients with advanced renal disease may have peripheral edema. Unlike the situation with many other forms of active glomerulonephritis, systemic hypertension is uncommon. Hemoptysis can precede clinically apparent renal disease by months to years, although renal involvement usually is evident on immunofluorescent staining of renal biopsy specimens. Ten percent to 20% of patients with anti-GBM disease have renal manifestations only.

LABORATORY AND RADIOGRAPHIC FINDINGS

Circulating anti-GBM antibodies found with enzyme-linked immunosorbent assay can be detected among more than 90% of patients. The finding of these antibodies appears to have a specificity of more than 95%. Anemia occurs among 90% of patients and is caused primarily by pulmonary blood loss. Serum iron levels may be decreased, though microcytic anemia is not common. The white blood cell count may be elevated. One-half of patients have some degree of azotemia. Urinalysis reveals hematuria or proteinuria (not in the nephrotic range) among 80% to 100% of patients. Radiographs of patients with alveolar hemorrhage show nonspecific patchy or diffuse alveolar infiltrates that typically, though not invariably, spare the apexes and bases. Several days after a bout of alveolar hemorrhage, a reticulonodular pattern may emerge that is thought to reflect clearance of hemoglobin by macrophages into lymphatic vessels and the interstitium. After repeated bouts of hemorrhage, interstitial fibrosis may occur. CT does not appear to add any clinically relevant information. Pulmonary function testing may reveal an elevated diffusion capacity for carbon monoxide consistent with recent alveolar hemorrhage. Many patients are too dyspneic for the breath holding required for this maneuver. Serious pulmonary hemorrhage sometimes occurs without apparent hemoptysis. Bronchoscopy performed to investigate an undiagnosed infiltrate suggests alveolar hemorrhage if the recovered lavage material is or becomes increasingly bloody during lavage. Lavage typically reveals hemosiderin-laden macrophages; this is a nonspecific finding that occurs with any type of bleeding in the lung.

STRATEGIES FOR OPTIMAL CARE

Because the disease can have a rapidly progressive and fulminant course, prompt diagnosis and initiation of therapy for anti-GBM antibody disease are extremely important. An elevated anti-GBM antibody level in the appropriate clinical setting establishes the diagnosis. When uncertainty exists, or if there is delay in obtaining antibody levels, tissue may be obtained for immunofluorescent staining. The kidney is the preferred biopsy site because use of lung tissue is associated with higher reported false-positive and false-negative rates of immunofluorescent staining. Therapy, a combination of immunosuppression and plasma exchange, is directed at removal of the pathogenic anti-GBM antibodies and suppression of future production. Compared with results for historical controls, who had 75% to 90% mortality, the survival rate for combination therapy is 50% to 85%. Prednisone 1 to 2 mg per kilogram per day and cyclophosphamide 2 mg per kilogram per day are recommended. Some authors recommend 1 to 3 days of higher doses of glucocorticoids initially and for additional bouts of alveolar hemorrhage.

Plasmapheresis should be repeated every 1 to 3 days until circulating anti-GBM antibodies disappear (approximately 2 weeks). The addition of plasmapheresis to immunosuppression is associated with a faster decline in circulating antibody levels and better recovery of renal function. Renal failure with poor chance of recovery occurs among patients who come to medical attention with anuria, a creatinine level greater than 7 mg per deciliter, or more than 50% glomeruli with crescent formation at renal biopsy. Early relapse is not uncommon and has been associated with concurrent infection, fluid overload, resumption of cigarette smoking, and taper of immunosuppression. Late recurrence is very rare.

PULMONARY ALVEOLAR PROTEINOSIS

DEFINITION

Pulmonary alveolar proteinosis (PAP) is a disorder of unknown causation characterized by alveolar accumulation of an acellular amorphous insoluble lipoproteinaceous material that resembles surfactant. Although complicated in rare instances by secondary right heart failure, the disease is otherwise limited to the lungs.

INCIDENCE AND EPIDEMIOLOGY

PAP appears to be a rare disease. Although the disease has distinct pathologic findings, PAP was not reported in the medical literature until the late 1950s. The disease appears to be twice as common among men as among women. The typical age at onset is in the third to sixth decades. Primary or idiopathic PAP occurs among previously healthy persons. Secondary PAP has been associated with hematologic malignant disease, especially myeloid leukemia; immunosuppression, including HIV disease; and acute exposure to dust and fumes, especially silica in sandblasting.

ETIOLOGY AND PATHOGENESIS

The cause of PAP is unknown. The association between some exposures and secondary PAP suggests a nonspecific alveolar injury response from known and as yet unknown factors. At light microscopic examination, alveoli and small airways are filled with large amounts of an acellular eosinophilic material that stains with periodic acid–Schiff (PAS) reagent. The main components of this material are phospholipids and proteins that appear to be mainly derived from lung surfactant. Alveolar macrophages are vacuolated (filled with ingested lipoproteinaceous material), giant, and poorly mobile. Inflammation and fibrosis have been detected in some cases but are not prominent features. Electron microscopic examination reveals numerous lamellar bodies composed of layers of phospholipids in the alveolar material and in the vacuoles of alveolar macrophages. Overaccumulation of surfactant or surfactant-like material in alveoli may be caused by overproduction, oversecretion, or abnormal reabsorption by type II pneumocytes, poor clearance by alveolar macrophages, or a combination of several dysfunctions.

Pneumocystis carinii infection is characterized by the presence of foamy eosinophilic alveolar material containing cysts, trophozoites, and macrophages. Although *P. carinii* pneumonia is typically pathologically distinct from PAP, in some cases extracellular material has PAP-like lamellar structures evident at electron microscopic examination.

CLINICAL PRESENTATION

Patients most commonly notice a gradual onset of exertional dyspnea and coughing, usually nonproductive but occasionally productive of gummy or chunky sputum. Patients may also have low-grade fevers, pleuritic chest pain, scant hemoptysis, and weight loss. Physical examination may reveal rales or lack of breath sounds in densely consolidated lung segments. Cyanosis and clubbing have been reported among about one-fourth of patients. Some patients have no symptoms and have radiographic abnormalities only. Some patients may have a sudden onset of fever, coughing, and dyspnea from PAP or a superimposed infection. Patients with PAP appear to be prone to pulmonary infection with *Nocardia* organisms, mycobacterial species, fungi, and viruses. Alveolar macrophages in PAP exhibit poor phagocytic function. This acquired defect may be caused by overingestion of the surfactant material. Filling of alveoli with this insoluble material may impede other infectious clearance mechanisms.

LABORATORY AND RADIOGRAPHIC PRESENTATION

Most patients with PAP have a mildly elevated lactate dehydrogenase level. Serum levels of lung surfactant proteins A and D can be markedly elevated, but these levels may be elevated with idiopathic pulmonary fibrosis and interstitial lung disease associated with connective tissue disease. Hypoxemia may be present and worsens with exercise. Pulmonary function testing typically reveals an increased shunt fraction, a mildly restrictive defect with a disproportionate decrease in diffusion capacity for carbon monoxide. Chest radiographs typically show bilateral, symmetrical alveolar infiltrates with air bronchograms that are worse in the bases but spare costophrenic angles. Unilateral infiltrates also are present. Pleural effusions and lymphadenopathy are unusual and suggest another pathologic or infectious process. In long-standing cases of PAP, fibrosis may occur, and an interstitial or reticulonodular pattern may be seen. High-resolution CT ([Fig 376.3](#)) may reveal a characteristic, though not pathognomonic crazy paving pattern of polygonal areas of ground-glass opacification next to radiographically uninvolved tissue.

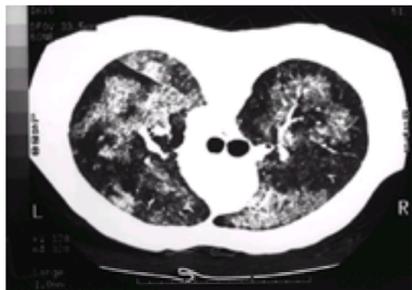

FIGURE 376.3. Pulmonary alveolar proteinosis. A 39-year-old man had gradual onset of dyspnea and a nonproductive cough. High-resolution CT scan shows the characteristic crazy paving pattern that corresponds to polygonal areas of ground-glass opacification next to areas that are closer to normal. The diagnosis was confirmed through examination of bronchoalveolar lavage fluid. The patient's condition improved after whole-lung lavage therapy. (Image courtesy of Marcia McCowin, MD).

STRATEGIES FOR OPTIMAL CARE

The diagnosis of PAP is made most conveniently by means of bronchoalveolar lavage. The lavage material is turbid, opaque, and opalescent and has a tan, dense sediment after gravity centrifugation. Under a light microscope, the sediment stains pink with PAS reagent. Results of transbronchial or open lung biopsy confirm the diagnosis when characteristically acellular, eosinophilic, PAS-positive material fills the alveoli ([Fig 376.4](#)). Electron microscopic demonstration of lamellar bodies also confirms the diagnosis. Because PAP can histologically mimic and perhaps be triggered by *P. carinii* infection, lavage material should be examined for this organism. Lavage material also should be cultured for fungi, *Nocardia* organisms, and mycobacterial species, because PAP may be a predisposing factor for these infections. The incidence, however, of these coexistent infections is lower in more recent case series.

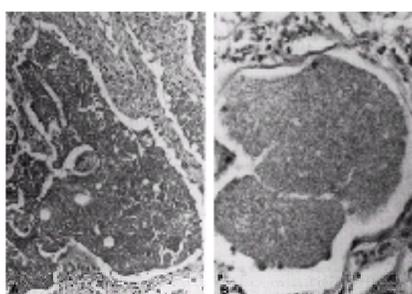

FIGURE 376.4. Pulmonary alveolar proteinosis. Lung biopsy specimens from a patient with pulmonary alveolar proteinosis (**A**) and a patient with *Pneumocystis carinii* pneumonia (**B**). Both specimens reveal alveolar filling of an amorphous, acellular material that stains pink with routine hematoxylin and eosin stain. The distinction is important. The exudate in **B** appears foamy. Silver stain of this specimen demonstrated characteristic cysts of *P. carinii* organisms. (Pathology slides courtesy of Martha L. Warnock, MD).

PAP occasionally resolves spontaneously; therefore observation for several months may be appropriate, especially when a patient has no symptoms or mild symptoms. Therapy is indicated for moderate to severe symptoms, failure of resolution, progression of symptoms, or physiologic abnormalities such as resting or exertional hypoxemia. Therapy is unique and consists of endotracheal intubation with a double-lumen tube and single whole-lung lavage with sterile saline solution with the aid of general anesthesia. The therapeutic efficacy of lavage is largely due to the mechanical removal of intra-alveolar phospholipids. Substantial symptomatic and physiologic improvement is typical, and lavage of the contralateral lung can be performed at a later time. One-third to one-half of patients who need whole-lung lavage need additional lavage because of recurrences until the disease dissipates, usually within a few years. As many as 20% of patients do not respond

to lavage and may progress to pulmonary fibrosis and respiratory failure or die of pulmonary infection. Glucocorticoids are not effective therapy for this disease.

RADIATION PNEUMONITIS AND RADIATION FIBROSIS

DEFINITION

Radiation pneumonitis is a syndrome of radiation toxicity, generally in lung tissue unintentionally or unavoidably irradiated. It is characterized by localized interstitial edema and interstitial and alveolar inflammation. Radiation fibrosis is a late toxic sequela of this inflammatory process characterized by interstitial fibrosis.

INCIDENCE AND EPIDEMIOLOGY

Radiation therapy for malignant disease in the thorax is associated with early acute pneumonitis in 5% to 15% of patients and with late fibrosis in as many as 75% of patients. Pneumonitis typically develops 6 to 12 weeks after completion of therapy of 4,000 cGy or more, although cases have been reported as early as 2 weeks and as late as 6 months after therapy. Earlier onset usually is associated with higher radiation doses. Pneumonitis is unusual at doses less than 3,000 cGy. Risk factors for the development of pneumonitis include daily radiation dosage, rate of delivery, total radiation dose, volume of lung irradiated, prior radiation, older age, presence of collagen vascular disease, recent withdrawal from steroid therapy, and previous sensitizing or concurrently administered chemotherapeutic agents, especially bleomycin, doxorubicin, cyclophosphamide, and mitomycin.

ETIOLOGY AND PATHOGENESIS

Ionizing radiation induces formation of free radicals from lung water. The free radicals cause direct damage to cell membranes, protein, and DNA. Radiation therapy also induces an inflammatory response with infiltration of the lung parenchyma by neutrophils and lymphocytes. The mechanism by which these injuries cause pneumonitis has not been fully elucidated. Radiation exposure also appears to cause microcapillary vascular damage and ischemic injury, which with the inflammatory response may be responsible for collagen deposition and eventual fibrotic healing.

CLINICAL, LABORATORY, AND RADIOGRAPHIC FINDINGS

Patients with radiation pneumonitis have a subacute onset of a nonproductive cough, dyspnea, and fever. Physical examination may reveal rales or consolidation on the affected side. Hyperpigmentation of the skin within the radiation port is common but does not correlate with the presence or severity of pneumonitis. Laboratory studies may reveal hypoxemia, an elevated white blood cell count, and elevated erythrocyte sedimentation rate. Chest radiographs and CT scans show homogeneous or patchy alveolar infiltrates, which classically coalesce to have sharp borders that corresponding to radiation ports and not to anatomical lung segments ([Fig 376.5](#)). Radiographic changes may occur in patients who do not have symptoms.

FIGURE 376.5. Radiation pneumonitis. A 77-year-old woman underwent radiation therapy to the left upper hemithorax and mediastinum for lung cancer. Two months after therapy, she reported dyspnea and a dry cough. CT scan shows an area of increased opacity in left upper lobe with a straight edge, which corresponded to the radiation port. (Image courtesy of Marcia McCowin, MD).

STRATEGIES FOR OPTIMAL CARE

The differential diagnosis of radiation pneumonitis includes infection, local tumor recurrence, or lymphangitic spread of tumor. The condition of most patients gradually improves over the course of several weeks. With time the involved area contracts, and fibrosis, scarring, and volume loss occur. Therapy consists of symptomatic relief with cough suppressants, analgesics, and antipyretics. Although there are no controlled trials of steroid use by humans, most clinicians agree that in severe cases, prednisone 1 mg per kilogram per day should be instituted. Guidelines for tapering steroids are not well defined, but because radiation pneumonitis has been reported during steroid withdrawal, slow tapering over weeks is advisable. Steroid prophylaxis has not been shown to be beneficial. Pneumonitis may occasionally involve areas outside the radiation port, even the contralateral lung. Several theories, such as radiation scatter, unsuspected infection, including viral infection, and obstruction of lymphatic flow have been proposed to explain cases of bilateral pneumonitis after unilateral radiation. Bronchoalveolar lavage studies have found activated T lymphocytes in segments of lung within and outside the radiation port. This finding suggests that ionizing radiation may stimulate a generalized lymphocyte-mediated reaction.

Some degree of lung fibrosis and scarring within the radiation field occurs in most patients undergoing thoracic irradiation, even in patients without clinically apparent radiation pneumonitis. Nearly all patients with radiation pneumonitis eventually have fibrosis in the region of the radiographic abnormality. Fibrotic radiographic changes usually are present within 1 year of completion of therapy and consist of linear interstitial thickening. Volume loss may cause tracheal deviation and mediastinal shift toward the affected area. Most patients have no symptoms, and stable fibrosis is evident only on radiographs. A few patients, especially those with previous severe pneumonitis, have widespread scarring with physiologic abnormalities. Patients with severe underlying lung disease may have symptomatic pneumonitis with otherwise tolerable amounts of radiation fibrosis. Patients have an insidious onset of dyspnea, which may progress to marked hypoxemia and respiratory failure. Glucocorticoids do not appear to be effective in the management of radiation fibrosis.

HISTIOCYTOSIS X OR LANGERHANS CELL HISTIOCYTOSIS

DEFINITION

Histiocytosis X or Langerhans cell histiocytosis (LCH) is a group of disorders characterized by excessive proliferation of Langerhans cells. Clinical presentations are varied and include Letterer–Siwe disease, a fulminant visceral form that occurs mainly among infants; Hand–Schüller–Christian disease, a multifocal form with lytic bone lesions, exophthalmus, and diabetes insipidus; isolated bony lesions; and pulmonary LCH, sometimes called *eosinophilic granuloma of the lung*.

INCIDENCE AND EPIDEMIOLOGY

Pulmonary LCH is a rare disorder, thought to represent approximately 1% to 5% of all cases of interstitial lung disease. Although LCH can occur at any age, pulmonary LCH typically occurs in the third to fifth decade. Most case series but not all suggest a male predominance. The disease appears to be less common among African Americans and very rare among Asians.

ETIOLOGY AND PATHOGENESIS

The cause of pulmonary LCH is unknown. More than 90% of patients are smokers and frequently heavy smokers. There is no known association with any other environmental or infectious agent. All forms of LCH are thought to represent clonal proliferation of Langerhans cells. Langerhans cells are histiocytes derived from

bone marrow precursors and are related to dendritic cells. They occur normally in the skin and sparsely in oral, esophageal, and colonic mucosa and the peribronchiolar interstitium. The function of these cells includes presentation of antigen to lymphocytes. LCH is thought to represent an uncontrolled immune response or hypersensitivity reaction initiated by Langerhans cells to some unknown antigen. Despite the monoclonal nature of the proliferation, the disease appears to be more consistent with a reactive rather than a neoplastic process. The primary lesion in the lung is an accumulation of Langerhans cells at terminal and respiratory bronchioles surrounded by lymphocytes, neutrophils, and eosinophils. This granulomatous lesion destroys nearby bronchiolar walls and causes bronchiolitis, which may cavitate. As the lesions progress, stellate scarring occurs with surrounding traction emphysema or cyst formation. Often in advanced fibrotic lesions, only rare Langerhans cells remain.

CLINICAL FINDINGS

The clinical presentation of pulmonary LCH among adults is variable. Although most patients have a cough and exertional dyspnea with or without constitutional symptoms such as fatigue, fever, and weight loss, approximately 25% have no symptoms, and the condition is found when a chest radiograph is abnormal. Ten percent to 20% of patients have chest pain, most commonly from a spontaneous pneumothorax and occasionally from a lytic rib lesion. Fifteen percent to 20% of patients have focal lytic bony lesions in long bones, the spine, the jaw, and most commonly the skull. As many as 5% of patients initially or eventually have diabetes insipidus from posterior pituitary involvement. The findings at physical examination may be normal, or the patient may have rales and rarely wheezes at chest auscultation. In rare instances clubbing may be present. With advanced fibrotic lung disease, right-sided heart failure and cor pulmonale may develop.

LABORATORY AND RADIOGRAPHIC FINDINGS

Laboratory findings of mild anemia, elevated white blood cell count, low positive titers of rheumatoid factor and antinuclear antibodies may be present but are nonspecific. Blood eosinophilia is not a feature of this disease. A bone scan may be useful to identify bony lesions. Chest radiographs typically reveal a diffuse, bilateral micronodular and cystic process, especially in mid and upper lung zones, that spare costophrenic angles and preserve lung volume. In advanced disease, honeycombing may be present. Enlarged hilar lymph nodes are not present. Pleural abnormalities are unusual unless there is current or previous pneumothorax. High-resolution CT can depict the characteristic combination of cysts and nodular lesions even if a chest radiograph appears normal or reveals only a reticular-nodular pattern. Pulmonary function tests reveal a combination of restriction and obstruction, the latter becoming worse if the disease progresses. Bronchoalveolar lavage can recover increased numbers of Langerhans cells among nonaffected smokers and those with pulmonary LCH. Lavage cell counts with more than 5% Langerhans cells support the diagnosis of pulmonary LCH. Because of sampling error, a low cell count of Langerhans cells does not rule out the diagnosis.

STRATEGIES FOR OPTIMAL CARE

Definitive diagnosis requires tissue biopsy. Transbronchial biopsy typically is inadequate; pathologic diagnosis usually requires open lung or thoracoscopic biopsy. Biopsy specimens reveal bronchiolar-centric granulomatous lesions with Langerhans cells (end-stage fibrotic areas may have very few Langerhans or other inflammatory cells). Langerhans cells are differentiated from other dendritic cells by the presence of CD1a surface antigen and the presence at electron microscopic examination of pentilaminar cytoplasmic organelles called *Birbeck bodies*. Although the diagnosis can be made with confidence at biopsy, a combination of suggestive pulmonary function tests, high-resolution CT findings, and more than 5% Langerhans cells recovered from bronchoalveolar lavage is very supportive of the diagnosis.

The clinical course for patients with pulmonary LCH is highly variable, although most patients have a good prognosis. Many of those without symptoms and only radiographic or pathologic abnormalities have a self-limited course with radiographic resolution. Patients with symptomatic disease may have periods of stability and even remission. A minority of patients progress to end-stage pulmonary fibrosis and right heart failure; the overall mortality is 2% to 6%. Therapy has included smoking cessation, steroids, and cytotoxic therapy. Though smoking cessation has many beneficial health effects and theoretical support (a strong epidemiologic association and the peribronchiolar location of the lesions suggest an inhaled antigen as the trigger for inflammation), the effect of smoking cessation on the course of pulmonary LCH is unclear.

CHAPTER 377: LUNG CANCER

ERIC J. OLSON AND JAMES R. JETT

[Definition](#)
[Incidence and Epidemiology](#)
[Etiology](#)
[Pathogenesis](#)
[Clinical Findings](#)
[Diagnosis](#)
[Staging](#)
[Strategies for Optimal Care](#)

DEFINITION

The term *lung cancer* usually applies to neoplasms arising from the respiratory epithelium called *bronchogenic carcinoma*. Bronchogenic carcinoma accounts for more than 90% of pulmonary tumors ([Table 377.1](#)). To account for differences in clinical and pathologic characteristics, bronchogenic carcinoma is divided into two main types—small-cell lung carcinoma (SCLC) and non-small cell lung carcinoma (NSCLC). SCLC is part of the spectrum of neuroendocrine tumors and has a notable propensity for early metastases. The mainstays of treatment are chemotherapy and radiation therapy. NSCLC includes adenocarcinoma, squamous cell carcinoma, large-cell carcinoma, and their subtypes. Surgery is the therapy of choice for early-stage disease. Smoking is the preeminent risk factor for lung cancer. Outcome depends on the cell type of the tumor, the stage of disease, and the performance status of the patient.

Squamous cell carcinoma	Carcinoid tumor
Small-cell carcinoma	Bronchial gland carcinoma
Adenocarcinoma	Adenoid cystic carcinoma
Large-cell carcinoma	Mucoepidermoid carcinoma
Adenosquamous carcinoma	Other

TABLE 377.1. WORLD HEALTH ORGANIZATION HISTOLOGIC CLASSIFICATION OF LUNG CANCER

INCIDENCE AND EPIDEMIOLOGY

During the twentieth century, lung cancer became one of the most common and lethal forms of cancer worldwide. Lung cancer is now the second most common malignant disease diagnosed among both men and women in the United States. At present, 170,000 to 180,000 new cases are diagnosed each year, an incidence of approximately 60 per 100,000 of the U.S. population. Lung cancer remains more common among men, but the sex difference is narrowing. The incidence among men has declined since peaking in 1984, whereas the incidence among women continues to climb. The result is that 47% of all new cases of lung cancer occur among women. Fortunately, the annual rate of increase in incidence among women is slowing. The age-adjusted incidence of lung cancer is consistently higher among black men than among white men. The disparity may be caused by differences in smoking behavior, socioeconomic factors, and susceptibility to tobacco smoke. Lung cancer is most commonly diagnosed among persons 55 to 74 years of age. Diagnoses before the age of 35 years are rare. NSCLC is the histologic type in 75% of cases. Adenocarcinoma has increased in incidence in recent years faster than any other cell type.

No other cancer currently claims more lives each year than lung cancer. One-third of all cancer deaths are attributable to lung cancer. The overall 5-year survival rate is a disappointing 14%. The worldwide incidence and mortality rate of lung cancer will continue to increase as a result of ongoing use of tobacco products.

ETIOLOGY

TOBACCO SMOKING

Tobacco smoking is undeniably the leading risk factor for lung cancer. It is estimated that smoking is responsible for 80% to 90% of cases of lung cancer. The evidence establishing a causal relation between tobacco smoking and lung cancer among men was initially summarized in the landmark 1964 report of the U.S. Surgeon General. The association among women was delineated in a 1980 report of the U.S. Surgeon General. The risk of lung cancer is related to the number of cigarettes smoked, age at starting to smoke, and the duration of smoking. The relative risk for death of lung cancer is 9 to 15 times greater among current smokers than among never smokers, and may be as high as 25 times greater among persons who smoke more than 25 cigarettes per day. Greater cigarette consumption or longer, more frequent puffs may negate the use of lower-tar or filtered cigarettes.

Women appear to be more susceptible to the carcinogenic effects of cigarette smoking. Odds ratios for lung cancer are 1.2 to 1.7 times higher among women smokers than among men. This disparity is not simply due to differences in smoking habits or anthropomorphic factors. Pipe and cigar smoking increase the risk of lung cancer, but the risk ratios are generally lower than for cigarette smoking. Approximately 25% of the U.S. population smoke cigarettes, almost all having started before 21 years of age. Use of cigarettes by teenagers has risen in recent years.

The relative risk of lung cancer actually increases for 1 to 4 years after smoking cessation, presumably because some cessation is motivated by symptoms of occult lung cancer. Relative risk then declines substantially. Whether the risk of lung cancer among former smokers ever equals that of nonsmokers remains unclear. In a 40-year study of smoking among British physicians it was concluded that the degree of risk reduction was greater among those who smoked fewer cigarettes for a shorter period of time and who stopped at a younger age. For example, smokers who stopped before the age of 35 years had a survival rate similar to that of nonsmokers.

ENVIRONMENTAL TOBACCO SMOKE

Environmental tobacco smoke is composed of sidestream smoke that emanates from the burning end of cigarettes and of mainstream smoke exhaled by smokers. Some components of tobacco smoke may be more concentrated in sidestream smoke than in mainstream smoke. The cumulative data on environmental tobacco smoke indicate that nonsmokers living with smokers have a 20% to 30% higher risk of lung cancer than do persons in smoke-free homes. In 1992 the U.S. Environmental Protection Agency estimated that environmental tobacco smoke accounts for 3,000 new cases of lung cancer each year in the United States.

RADON

The link between radon, a breakdown product of uranium, and lung cancer was initially established among underground miners of uranium, tin, and iron ore in areas of high radioactivity. Exposures now occur in residences as radon and its decay progeny pervade basements. Extrapolating from the mining experience is difficult, but in a meta-analysis of eight case-control studies it was concluded that indoor radon exposure caused a 1.14 increased relative risk of lung cancer. It has been estimated by the Committee on Biologic Effects of Ionizing Radiation that radon is responsible for 10% of cases of lung cancer in the United States.

OCCUPATIONAL EXPOSURE

The International Agency for Research on Cancer of the World Health Organization classifies chemicals and industrial processes with respect to their association with lung cancer ([Table 377.2](#)). Industrial carcinogens usually are not exclusively associated with a specific lung cancer cell type. Typically there are synergistic effects between exposure to occupational agents and smoking, and there are prolonged latency periods (years) between occupational exposure and the clinical emergence of lung cancer.

Agent	Industrial Process
Arsenic	Ore (copper, lead, zinc) smelting; pesticide use
Asbestos	Mining, milling, manufacturing, installation, or removal of asbestos-containing products (pipe filters, boiler-makers, ship builders, textile workers, cement workers, automotive brake workers)
Di (chloromethyl) ether	Manufacturing of ion exchange resins, plastics
Chromium	Alloy production; dye and paint manufacturing; welding; electroplating
Nickel	Electroplating; steel and alloy production; manufacture of ceramics or storage batteries; petroleum refining; manufacture of electric circuits
Polycyclic aromatic hydrocarbons	Smelting of nickel-containing ores; iron and steel founding; coke oven emissions; organic material combustion
Radon	Mining
Vinyl chloride	Manufacture of plastics or packaging materials

*Classification of the International Agency for Research on Cancer.

TABLE 377.2. OCCUPATIONAL AGENTS AND THE RESPECTIVE INDUSTRIAL PROCESSES WITH ESTABLISHED LINKS TO LUNG CANCER^a

Asbestos includes a group of naturally occurring serpentine or straight, needlelike silicates, the unique properties of which have broad commercial application. Inhalation of asbestos fibers increases risk of pulmonary parenchymal fibrosis (asbestosis), pleural abnormalities (pleural plaques, pleural thickening, effusions, rounded atelectasis) and malignant tumors (lung cancer, mesothelioma). It is estimated that nonsmokers exposed to asbestos are at fivefold greater risk of lung cancer than are nonsmokers not exposed to asbestos. The combination of tobacco smoking and asbestos exposure may increase lung cancer risk 50-fold. Risk of lung cancer usually increases 20 to 30 years after the initial exposure. Amphibole (straight) fibers are considered more carcinogenic than chrysotile (serpentine) fibers. Whether a threshold asbestos exposure level exists for lung cancer remains unclear.

OTHERS

Chronic obstructive pulmonary disease (COPD) is an independent risk factor for lung cancer. The relative risk of lung cancer is 4 to 6 times greater in the setting of airway obstruction. This risk increases in proportion to the magnitude of airway obstruction. A genetic predisposition is suggested by numerous investigators who have demonstrated increased risk of lung cancer among close relatives of patients with lung cancer. This familial clustering may be caused by shared tobacco smoke, common environmental factors, or heritable elements. Genes proposed to increase susceptibility for lung cancer include those coding for enzymes that metabolize procarcinogens, such as the cytochrome P450 constituents *CYP1A1* and *CYP2D6*. Air pollution, principally with polycyclic hydrocarbons generated from fossil fuel combustion, may be associated with an increased risk of lung cancer, but establishing a causal link has been methodologically challenging. An inverse relation has been found between fresh fruit and vegetable consumption and risk of lung cancer. Major attention has focused on the vitamin A-related compounds, especially beta carotene, in light of their abilities to neutralize reactive oxygen species and regulate gene expression. However, several randomized chemoprevention trials of use of beta carotene alone or with other antioxidants by subjects at increased risk of lung cancer have shown a higher incidence of lung cancer among the actively treated groups. The preventive agent or agents in fruits and vegetables remains elusive.

PATHOGENESIS

Lung cancer is thought to arise from pluripotent respiratory epithelial stem cells that undergo neoplastic transformation as a result of the accumulation of numerous carcinogen-induced genetic mutations. The exact sequence of events remains to be elucidated, but the putative stages are initiation, promotion, and progression. Genetic alterations caused by radicals produced by the various compounds of the tar and gas phases of cigarette smoke are major initiators and promoters of lung cancer. Pertinent genes affected are believed to be those that regulate cell growth, namely tumor suppressor genes, such as p53 and *RB*, and oncogenes, such as *c-myc*, *K-ras*, and *her2/neu*. The frequently observed chromosomal deletions of 3p, 5q, 9p, and 17p in both SCLC and NSCLC occur at locations of known or suspected tumor suppressor genes. Loss or inactivation of tumor suppressor genes may be integral to development of lung cancer, but the causal relation of these mutations remains unproved. Oncogene activation may be associated with abnormal expression of growth factors, which may have mitogenic effects on the parent cell (autocrine stimulation) and neighboring cells (paracrine stimulation).

The multistep model of lung carcinogenesis is consistent with the myriad cytogenetic abnormalities demonstrated in resected lung cancer, the increase in incidence of lung cancer with age, and the progressive histologic changes of metaplasia, dysplasia, and carcinoma in situ that occur during malignant transformation (at least in the case of squamous cell carcinoma). The proposed pluripotent respiratory epithelial stem cell that gives rise to lung cancer has yet to be identified, but the concept is supported by the histologic variability in tumor specimens. Major heterogeneity (features of more than one histologic type) can be identified in as many as 45% of cases of lung cancer.

CLINICAL FINDINGS

Most cases of lung cancer are symptomatic at diagnosis. Locoregional effects of lung cancer, metastasis, or paraneoplastic phenomena may cause symptoms and physical signs ([Table 377.3](#) and [Table 377.4](#)).

Locoregional
Cough
Dyspnea
Hemoptysis
Chest pain
Hemidiaphragm paralysis
Hoarseness
Pericardium effusions, tamponade
Dysrhythmias
Intrathoracic metastases
Nodules
Lymphangitic carcinomatosis
Pleural effusion
Superior vena cava syndrome
Pancoast's syndrome
Sites of metastasis
Adrenal glands
Liver
Central nervous system
Bone

TABLE 377.3. PRESENTATION OF LUNG CANCER: LOCOREGIONAL AND METASTATIC CONSIDERATIONS

calcium level relative to serum albumin level), normal or low PTH level at immunoassay, and exclusion of other causes of hypercalcemia (such as bone metastasis). PTH can be differentiated from PTHrP by carboxy and amino terminal PTH assays. Patients with hypercalcemia caused by ectopic PTHrP usually have extensive disease with liver involvement. Treatment includes volume repletion with normal saline solution, loop diuretics to increase calcium excretion, bi-phosphonates or calcitonin to decrease bony resorption, and therapy for the malignant disease.

Benign	Malignant
Infectious granulomas	Bronchogenic carcinoma
Histoplasmosis	Metastatic lesion

Scar	

TABLE 377.5. CAUSES OF SOLITARY PULMONARY NODULES

In the setting of cancer, the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) is nearly always caused by SCLC. Antidiuretic hormone promotes free water retention in the distal renal tubule. The diagnostic criteria for SIADH are hyponatremia, serum hypo-osmolality (<275 mOsm per kilogram), inappropriately increased urine osmolality (>200 mosm per kilogram), inappropriately increased urine sodium concentration (>20 mEq per liter), clinical euvolemia without edema, and normal thyroid, adrenal, and renal function. Fluid restriction (less than 1 L per day) is the initial treatment of patients with no or mild symptoms. Demeclocycline, which blocks the renal effects of antidiuretic hormone, may be added if necessary. More serious symptoms, such as changes in mental status and seizures or more profound hyponatremia (serum sodium concentration <120 mEq per liter) necessitate administration of normal saline solution with a loop diuretic. Serum sodium level should be increased at a maximum rate of 2 mEq per liter per hour (maximum 20 mEq per liter per day) to a target of 120 to 125 mEq per liter. More aggressive sodium correction can cause central pontine myelinolysis, a neurologic insult characterized by flaccid quadriplegia and usually death. SIADH occurs among approximately 10% of patients with SCLC. Serum sodium level normalizes for 80% to 90% of patients within 6 weeks after initiation of chemotherapy.

SCLC and carcinoids can cause Cushing's syndrome through ectopic production of corticotropin (ACTH) or corticotropin-releasing hormone. The 5% of patients with SCLC who have Cushing's syndrome have a poor prognosis. The presence of Cushing's syndrome is confirmed by elevation of 24-hour urinary free cortisol level and failure to suppress cortisol production during low-dose dexamethasone challenge. Ectopic production of ACTH as a cause of Cushing's syndrome is suggested by lack of cortisol suppression with high-dose dexamethasone and plasma ACTH levels greater than 200 pg per milliliter. Treatment options include management of the underlying tumor (surgery for carcinoid and chemoradiation therapy for SCLC), bilateral adrenalectomy, or pharmacologic adrenal suppression. All patients with Cushing's syndrome should undergo CT of the chest and entire abdomen to find occult carcinoid tumor in the lung, thymus, or pancreas.

The paraneoplastic neurologic manifestations of lung cancer include a group of conditions thought to be autoimmune phenomena. Ectopic expression by tumor cells of antigens homologous to those normally present in the nervous system triggers an immune response. Neural tissue expressing the same antigen is attacked. The result is clinical deficits ranging from focal deficits to more widespread dysfunction. An example is Eaton–Lambert myasthenic syndrome, a condition that occurs among 1% to 3% of patients with SCLC and is characterized by proximal muscle weakness, hyporeflexia, and autonomic dysfunction. SCLC cells express P/Q type voltage-gated calcium channels similar to those normally found at presynaptic cholinergic synapses. These channels mediate the release of acetylcholine by allowing influx of calcium on arrival of an action potential. Anti-calcium channel antibodies are generated and are demonstrated in the serum.

The clinical manifestations of Eaton–Lambert myasthenic syndrome are caused by the interference of acetylcholine release by the antibody–calcium channel interaction. Approximately one-third to one-half of patients with Eaton–Lambert myasthenic syndrome improve with therapy for SCLC. Other examples include the diverse set of neurologic manifestations associated with antineuronal nuclear autoantibodies (ANNA-1). These polyclonal IgG antibodies, also known as anti-Hu, recognize a family of nuclear mRNA-binding proteins expressed in SCLC cells and throughout the nervous system. The pathogenetic role of ANNA-1 remains undefined.

The neurologic manifestations associated with ANNA-1 precede the cancer diagnosis more than 90% of the time and usually progress subacutely. These manifestations include neuropathy (sensory, mixed somatic, autonomic, cranial nerve, motor), cerebellar ataxia, limbic encephalitis (neurocognitive and neurobehavioral deficits with or without seizures), polyradiculopathy, Eaton–Lambert myasthenic syndrome, myopathy, myelopathy, opsoclonus or myoclonus, motor neuronopathy, abnormality of the brachial plexus, aphasia, and gastrointestinal dysmotility. Antiretinal antibodies have been found in some patients with cancer-associated retinopathy, a condition of reduced visual acuity caused by the strikingly focal loss of retinal cells among patients with SCLC. The autoimmune response also may be directed at the tumor itself. This may explain why the underlying SCLC can be localized and difficult to detect with noninvasive imaging. There are no standard, effective therapies for these syndromes.

Cachexia is a common paraneoplastic syndrome and is of multifactorial causation. Clubbing of the fingers and toes is characterized by flattening of the angle between the base of the nail bed and cuticle, curved nails, and bulbous enlargement of the digit tips. Clubbing may be accompanied hypertrophic osteoarthropathy, which is painful periosteal inflammation of the long bones of the arms and legs. The affected bones have periosteal elevations on plain radiographs and symmetrically increased uptake on radionuclide studies. Hypertrophic osteoarthropathy is managed with aspirin or nonsteroidal anti-inflammatory drugs and therapy for the underlying lung cancer. Lung cancer may increase thrombotic potential, which manifests as nonbacterial thrombotic (marantic) endocarditis or recurrent thrombophlebitis (Trousseau's syndrome). An extensive search for a malignant tumor is unjustified when venous thromboembolism develops without conventional risk factors. However, patients with idiopathic venous thromboembolism have a 10% to 15% likelihood of having cancer, so additional investigations for cancer are warranted when the findings of the history, examination, and routine laboratory studies suggest the diagnosis.

SCREENING

To the extent that symptomatic lung cancer has a worse prognosis than cancer detected among persons without symptoms and that the outcome of lung cancer depends heavily on the extent of disease at diagnosis, there has been considerable interest in lung cancer screening. The American Cancer Society does not currently recommend routine screening for lung cancer because multiple studies, including three large prospective, randomized U.S. studies sponsored by the National Cancer Institute in the 1970s did not demonstrate decreased lung cancer mortality in populations screened with sputum cytologic examination and chest radiography. Lung cancer screening is being reassessed as groups at high risk of lung cancer become more clearly defined, understanding of lung carcinogenesis increases, and newer technologies become available (such as monoclonal antibodies to detect malignancy-associated antigens in sputum, spiral CT to obtain rapid and detailed images of the lung, and autofluorescence bronchoscopy to detect early malignant tumors through the differential mucosal uptake of photosensitizing agents).

DIAGNOSIS

The essential aspects of the lung cancer evaluation are histologic distinction of SCLC from NSCLC, accurate appraisal of the extent of disease, and determination of the patient's performance status. This information is obtained through a combination of clinical findings, imaging modalities, and procedures to procure specimens for cytologic or histologic analysis. Difficulties with histologic differentiation of SCLC from NSCLC are infrequent (<5% cases), but SCLC may be mistaken for carcinoid tumor, lymphoma, or NSCLC in the presence of crush artifact or improper specimen processing. Differentiation of primary lung cancer from pulmonary metastasis from an extrapulmonary neoplasm may require special immunohistochemical tests of the tissue, but even then differentiation may not be possible. Obtaining correct information is crucial given the profound effects on treatment and prognosis.

IMAGING STUDIES

Conventional chest radiography usually is the first study to suggest lung cancer. Chest radiography is 70% to 80% accurate in the detection of lung cancer. Certain radiographic appearances may suggest histologic types of lung cancer, although these generalizations are not absolute. Squamous cell carcinoma often manifests as a large perihilar mass that may cavitate, adenocarcinoma as a peripheral solitary nodule or mass, large cell carcinoma as a large peripheral mass, and bronchioloalveolar carcinoma as either a slow-growing nodule or an alveolar infiltrate that may be diffuse. SCLC classically appears as a rapidly enlarging central mass with early hilar and mediastinal spread. Specificity limitations (that is, determining the relevance of abnormalities on chest radiographs) can be partially overcome by comparing current chest radiographs with previous chest radiographs. The sensitivity of chest radiography is low for detection of lymph node metastasis or invasion of the chest wall or mediastinum.

CT provides further definition of the appearance of the primary lesion, may depict concurrent parenchymal or pleural disease, and guides diagnostic maneuvers. CT is limited in its ability to define the extent of lung cancer. For example, the reported sensitivity and specificity of CT in the detection of hilar and mediastinal lymph node metastasis are 60% to 70% because of the inherent constraints of relying on lymph node size as the main measure of normality. The consensus is that intrathoracic lymph nodes larger than 1 cm in diameter on CT scans are abnormal, yet microscopic metastases occur. Benign etiologic factors such as reactive hyperplasia and granulomatous inflammation can cause lymph node enlargement. CT also is less than ideal in the accurate diagnosis of invasion of the chest wall or mediastinal structures, detection of endobronchial lesions, and differentiation of tumor from adjacent atelectasis or pneumonia. CT is not a substitute for pathologic information. Patients must not be denied surgery for NSCLC simply on the basis of CT findings without tissue confirmation.

A common clinicoradiologic problem is a solitary pulmonary nodule (SPN), defined as a singular rounded lesion less than 3 cm in diameter entirely surrounded by normal lung parenchyma and without associated lymphadenopathy. SPNs may be benign or malignant ([Table 377.5](#)). Most are benign. Most malignant SPNs are early stage lung cancer. Accurate differentiation is crucial so that malignant lesions are promptly resected and benign nodules are not unnecessarily removed. Clinical factors predictive of high risk of malignancy include smoking, advanced age, prior malignant tumors, and larger nodule size (SPNs larger than 3 cm in diameter are malignant more than 90% of the time). The evaluation proceeds, if possible, with a review of previous chest radiographs. An SPN that has been stable for at least 2 years is considered benign, and no further testing is necessary. An enlarging nodule is considered malignant, and immediate resection is indicated.

When comparison studies are insufficient, the next step is CT with thin sections through the nodule to assess the SPN for calcification, contour, and fat. Central, concentric, and popcorn calcification are reliable indicators that the lesion is benign. Eccentric calcification does not rule out malignancy. The more irregular the edge of the SPN, the greater is the likelihood of malignancy. Spiculation increases the likelihood of malignancy. Fat density within an SPN suggests hamartoma, a benign neoplasm, and nothing further need be done.

Additional radiographic modalities may help clarify the nature of an SPN. Positron emission tomography (PET) with [^{18}F]fluorodeoxyglucose may help detect malignant lesions with 90% to 100% sensitivity and 80% to 89% specificity. The expense and availability of PET are serious limitations. The presence of granulomatous disease may cause false-positive results of PET scans. Lesions less than 1 cm in diameter and slowly growing cancer such as bronchioloalveolar cell carcinoma may be false-negative findings. CT contrast enhancement studies, which entail thin-section evaluation of SPN density before and after administration of iodinated contrast material, help identify malignant SPNs through accentuated enhancement (>15 Hounsfield units) with a sensitivity of 98% and a specificity of 58%.

If the clinical features and radiographic studies are inconclusive, the options are resection, biopsy, or observation of the SPN. The patient's wishes must be considered in decision making. Proceeding directly to resection is reasonable when concern about malignancy is high because surgery would be anticipated regardless of the biopsy results. Observation typically involves serial CT every 3 months for the first year and every 6 months during the second year. If the nodule enlarges, resection is indicated.

SPUTUM CYTOLOGY

The yield of sputum cytologic examination depends on the tumor type, size, and relation to major airways. Sensitivity is highest for central squamous cell carcinoma but less than 20% for peripheral nodules. Collection of one to three consecutive, early morning samples or a 3-day pooled sputum specimen is generally recommended, but the appropriate number of specimens to collect is unclear. Malignant cells may be from unsuspected head and neck cancer, so bronchoscopy is needed for a positive cytologic result if chest radiographs do not localize the tumor. If the bronchoscopic findings are normal, an otorhinolaryngologist should perform a careful examination of the upper airway. False-positive cytologic findings can be caused by pulmonary infection and inflammation.

FLEXIBLE FIBEROPTIC BRONCHOSCOPY

Flexible fiberoptic bronchoscopy is used for diagnostic and staging purposes. Diagnostic techniques include forceps biopsy, brushing, and washing. The diagnostic yield depends on tumor location and size. For central NSCLC or SCLC lesions, the overall yield is 70%. The yield climbs to approximately 90% if the tumor is visible at endoscopy. For peripheral lesions, the diagnostic yield of fluoroscopic bronchoscopy is 10% to 20% for nodules less than 2 cm in diameter, 50% to 60% for lesions 2 to 4 cm, and 80% for lesions larger than 4 cm. The chief complications of forceps biopsy are life-threatening bleeding and pneumothorax, which occur in less than 1% of procedures. Diagnostic and staging information may be obtained by means of transbronchial needle aspiration biopsy of paratracheal, subcarinal, and hilar lymph nodes. The outcome of transbronchial needle aspiration biopsy depends heavily on technique. Chest CT to direct location of the biopsy specimen can improve results. The overall sensitivity is 50%. Thus normal findings at transbronchial needle aspiration biopsy do not rule out lymph node metastasis. Bronchoscopy also provides local staging information through assessment of the proximal extent of tumor and occasionally through detection of synchronous neoplasms (1% to 3%).

TRANSTHORACIC NEEDLE ASPIRATION BIOPSY

Peripheral lesions or those with extension to the mediastinum, pleura, or chest wall may be sampled by means of fluoroscopically or CT-guided transthoracic needle aspiration biopsy (TTNA). TTNA usually is performed on patients who need a tissue diagnosis but cannot or should not undergo surgery, will not consent to an operation until a tissue diagnosis is made, have undergone bronchoscopy that did not provide enough information for a diagnosis, or are not able to undergo bronchoscopy. The yield of TTNA for peripheral lesions is 80% to 95%. There is a substantial false-negative rate (10% to 20% of patients with normal findings on TTNA may have a malignant lesion), so a normal TTNA result cannot be interpreted as a diagnostic end point unless a specific benign diagnosis is made from the aspirate. Pneumothorax occurs among 15% to 30% of patients, and approximately one-half of those patients need a chest tube. Massive bleeding or death is rare. Percutaneous radiographically guided needle aspiration is used in the diagnosis of extrapulmonary metastasis.

THORACIC SURGICAL PROCEDURES

Pathologic evaluation of mediastinal lymph nodes larger than 1 cm in diameter should be performed for any NSCLC patient who is considered a candidate for thoracotomy and surgical resection. Right paratracheal and subcarinal lymph nodes traditionally have been approached with cervical mediastinoscopy. Biopsy of left paratracheal, supraaortic, and aortopulmonary window nodes has been through anterior mediastinotomy (Chamberlain procedure). Indeterminate peripheral nodules and pleural abnormalities can be explored by means of video-assisted thoracoscopic surgery (VATS). Pleurodesis of malignant effusions can be accomplished at the time of VATS. Complication rates for mediastinoscopy, mediastinotomy, and VATS are low.

STAGING

NON-SMALL CELL LUNG CANCER

Staging for NSCLC is based on the TNM classification ([Table 377.6](#)). The T component refers to the size, location, and extent of locoregional invasion of the primary tumor. The N element describes locoregional lymph node involvement. The M constituent identifies whether distant metastatic lesions are present. The TNM stage is the most important prognostic factor in NSCLC. The various TNM components can be grouped to identify subsets of patients who have similar prognoses and treatment options ([Table 377.7](#)). In general, the more advanced the stage, the worse is the prognosis. The observation that patients with lesions at identical stages can have widely varying outcomes emphasizes that the TNM system has limitations. The intrinsic sensitivity problems of all staging tests leaves open the chance for understaging. The TNM system does not take into account various clinical factors, such as weight loss or comorbid conditions, nor does it factor in biologic properties, such as tumor genetic markers or histologic subtypes.

Stage	TNM Subset	5-Year Survival Rate (%)
0	Carcinoma in situ	
IA	T1 N0 M0	67

TABLE 377.7. STAGE GROUPING AND FIVE-YEAR SURVIVAL OF TNM SUBSETS

Given the superiority of surgery for NSCLC, the pretreatment evaluation must discern whether the extent of disease prevents resection. Two meta-analyses have revealed that the likelihood of metastatic disease is sufficiently low if a carefully conducted clinical evaluation has normal findings. The American Thoracic Society recommends that all patients with NSCLC undergo a thorough history interview and physical examination, complete blood cell count, serum chemistry profile (electrolytes, alkaline phosphatase, albumin, aspartate aminotransferase, alanine aminotransferase, total bilirubin, and creatinine), chest radiography, and chest CT through the adrenal glands. If results of these evaluations are normal, no further tests are necessary. Further testing should proceed surgery if the evaluation findings are abnormal. Clues to the presence of metastasis include weight loss and anemia. CT of the liver with contrast enhancement or hepatic ultrasonography is indicated if hepatomegaly is detected or results of liver function tests are abnormal. New neurologic symptoms or focal deficits justify performing head CT with contrast enhancement or head MRI. Radionuclide bone scanning is warranted in the presence of hypercalcemia, focal abnormalities of bone, or elevated alkaline phosphatase level (bone fraction).

If NSCLC is believed to be resectable, the patient must be assessed for medical contraindications to surgical treatment. It must be determined whether there is adequate pulmonary reserve for curative lung resection. Tobacco smoking is a risk factor for cardiovascular and cerebrovascular disease. Eighty to ninety percent of patients with lung cancer have COPD; 20% to 30% of these have severe disease. Preoperative spirometry and measurement of the diffusing capacity of the lung for carbon monoxide are strongly recommended. Patients with forced expiratory volume in one second (FEV₁) less than 1.5 to 2 L or more than 60% of predicted normal value, maximal voluntary ventilation more than 50% of predicted normal value, and diffusing capacity greater than 60% of predicted value can proceed directly to thoracotomy. Patients with lower values need quantitative ventilation-perfusion lung scanning (postoperative FEV₁ is estimated by multiplying the preoperative FEV₁ by the percentage of tracer in the area to be resected), measurement of arterial blood gases, or exercise testing. Although no value categorically precludes surgery, predicted postoperative FEV₁ less than 0.8 L or less than 40% of predicted value, hypercapnia (P CO₂ >45), or maximal exercise oxygen consumption less than 10 mL per kilogram per minute indicate high risk of postoperative problems. Consultation with a pulmonologist, thoracic surgeon, radiation oncologist, and medical oncologist, especially in a multimodality clinic, is ideal in borderline cases.

SMALL-CELL LUNG CANCER

The TNM staging system of NSCLC usually is not applied to SCLC because of the limited role of surgery and because more than 90% of patients have locally advanced (stage III) or metastatic (stage IV) disease when they come to medical attention. SCLC is classified with the Veterans Affairs staging system of *limited* and *extensive* disease. *Limited disease* refers to tumor confined to one radiation port (disease within one hemithorax and its regional lymph nodes). *Extensive disease* encompasses everything else. Pretreatment evaluation should include a careful history and physical examination, complete blood cell count, serum chemistry profile (electrolytes, alkaline phosphatase, albumin, aspartate aminotransferase, alanine aminotransferase, total bilirubin, and creatinine), chest radiography, and chest CT. Testing for extensive disease should be directed by the understanding that two-thirds of patients with SCLC have extensive disease when they come to medical attention and that the most common sites of metastatic lesions from SCLC are the liver (25% at initial diagnosis), bone (20-30%), and brain (10%). It is generally recommended that patients with SCLC undergo head CT or MRI of the brain and isotope bone scanning before initiation of treatment.

STRATEGIES FOR OPTIMAL CARE

NON-SMALL CELL LUNG CANCER STAGES 0 THROUGH II

Stage 0 (carcinoma in situ) is uncommon, and the recommended treatments range from surgery to photodynamic therapy, external beam radiation therapy, or brachytherapy (intraluminal radiation therapy). Surgical resection with curative intent is the therapy of choice for stage I and II cancer. Stage 0 to II categorization can only be applied to 20% to 25% of patients with NSCLC when they come to medical attention. The standard operation is thoracotomy with mediastinal lymph node sampling combined with lobectomy, bilobectomy, or pneumonectomy. Less extensive resections are associated with higher rates of local recurrence and should be reserved for patients whose lung status will not allow lobectomy. Operative mortality is 2% to 3% for lobectomy and 5% to 6% for pneumonectomy.

In the latest TNM classification scheme, T3 N0 M0 lesions are downgraded from stage IIIA to IIB because of the reasonable response to en bloc resection of the tumor and adjacent structures. Expected 5-year survivals are shown in [Table 377.7](#). Adjuvant chemotherapy has not been shown to improve survival. Postoperative radiation therapy for resected stage I and II disease has a detrimental effect on survival. Patients who have undergone resection have a 3% to 4% risk per year of development of a second primary lung cancer, so follow-up chest radiographs every 3 to 4 months for the first 2 years and every 6 to 12 months thereafter are recommended. There are no proven chemopreventive agents, although several agents are currently in clinical trials (*cis*-retinoic acid and selenium).

NON-SMALL CELL LUNG CANCER STAGE III

Optimal management of potentially resectable disease remains controversial. Results of phase II studies have suggested but not definitively shown that neoadjuvant (preoperative) chemotherapy with or without radiation therapy followed by surgery improves survival among patients with stage IIIA disease and carefully selected patients with stage IIIB disease. Neoadjuvant therapy may be associated with greater perioperative morbidity and mortality. Thoracic radiation therapy combined with platinum-based chemotherapy is recommended for inoperable stage IIIA and IIIB disease and has been shown to be superior to radiation therapy alone. Palliative radiation therapy alone is an option for patients with limited medical reserve. Expected 5-year survival rates are shown in [Table 377.7](#). Pancoast tumors usually are stage IIB, IIIA, or IIIB. The typical regimen is preoperative radiation therapy with or without chemotherapy followed if possible by surgical resection. The 5-year survival rate is approximately 35%.

NON-SMALL CELL LUNG CANCER STAGE IV

Approximately 50% of patients with NSCLC have M1 disease at presentation. There are no curative options; the goal is to control the disease and palliate symptoms. The median survival period is 5 to 7 months. Radiation therapy may be used to control brain or bone metastasis or to relieve bronchial or superior vena caval obstruction. Airway obstruction can be palliated with bronchoscopic neodymium:yttrium-aluminum-garnet (Nd:YAG) laser tumor resection, stent placement, or brachytherapy. Chemotherapy provides a modest survival benefit (median increase of 1.5 months) over supportive care. Patients who respond to therapy generally have improvement in cancer-related symptoms and quality of life. Persons with poor performance scores or multiple comorbid conditions may not be candidates for systemic therapy.

SMALL-CELL LUNG CANCER

SCLC is highly responsive to systemic therapy. The response rate is 80% to 90%. Therapy for limited disease consists of 4 cycles of chemotherapy with etoposide and cisplatin or carboplatin with concurrent thoracic radiation therapy given in at least 2 of the cycles. Concurrent therapy is thought to be superior to sequential chemoradiation therapy. Complete responses can be obtained by 50% of patients with a median survival time of 18 to 20 months, 2-year survival rate of 40%, and 5-year survival (cure) rate of 15% to 20%. There are no data to show that chemotherapy beyond 4 to 6 cycles is of benefit, but it does increase toxicity.

Extensive disease responds to the same chemotherapeutic agents as limited disease. Complete responses are obtained by 25% of patients, for a median survival time of 9 months and a 2-year survival rate of 10% or less. Almost no one survives 5 years. Thoracic radiation therapy is not recommended for extensive disease.

Prophylactic cranial irradiation (PCI) is controversial and should not be considered unless the disease is in complete remission. It is well established that the chance of CNS relapse is 50% if the patient survives 2 years. PCI decreases the rate of CNS metastasis but it may not prolong survival. PCI may be associated with the late sequelae of cognitive dysfunction and ataxia.

CHAPTER 378: PULMONARY THROMBOEMBOLISM

THOMAS M. HYERS

[Prevention](#)
[Diagnosis](#)
[Strategies for Optimal Care](#)

Venous thromboembolism has two major clinical manifestations: deep venous thrombosis (DVT), most often found in the deep veins of the leg, and pulmonary embolism (PE), which develops as a complication in approximately 50% of persons with DVT. DVT typically originates in a venous valve cusp in a deep calf vein. Approximately one-third of persons with calf vein thrombi have propagation in the direction of venous return into the deep veins of the thigh and pelvis. When the thrombus involves the deep veins of the knee and above, the condition is called *proximal DVT*. Proximal deep venous thrombi are larger and are more likely to dislodge and traverse the venous system to embolize the pulmonary arteries. Larger pulmonary emboli can be life threatening. The patient is most likely to die when the acute embolic burden obstructs more than 50% of the cross-sectional area of the pulmonary arteries.

Venous thromboembolism occurs in approximately one person per 1,000 yearly in North America and Europe. The disease can occur at any age, but its frequency is strongly linked to advanced age. Other acquired risk factors are immobility and any form of trauma, including surgery and childbirth. With the exception of pregnancy, there is no sex predilection. Both inherited and acquired risk factors predispose a person to venous thromboembolism. The leading risk factors are shown in [Table 378.1](#). Risk factors are cumulative. A common scenario is the occurrence of venous thromboembolism in a patient with an unidentified genetic risk factor and a recent surgical procedure ([Table 378.1](#)).

Inherited	Acquired
Factor V Leiden	Trauma (surgery, childbirth)
Prothrombin variant	Immobilization (bedrest, paralysis)
Hyperhomocysteinemia	Cancer
Protein C deficiency	Lupus anticoagulant
Protein S deficiency	(antiphospholipid antibody syndrome)
Antithrombin deficiency	Pregnancy
	Estrogen use

TABLE 378.1. RISK FACTORS FOR VENOUS THROMBOEMBOLISM

Of the genetic risk factors, the condition known as factor V Leiden is particularly prevalent. The point mutation at position 506 on blood coagulation factor V causes substitution of glutamine for arginine. The substituted glutamine occurs at one of three cleavage sites for activated protein C and renders factor V relatively resistant to degradation. This mutation also is known as *activated protein C resistance*, and the heterozygous state is present in approximately 5% of whites. The mutation is quite rare among native Asians and Africans but is present in 1% to 2% of African Americans. Factor V Leiden increases risk of venous thromboembolism approximately fivefold. It should be suspected when a patient has idiopathic venous thromboembolism, venous thromboembolism that occurs early in life, or recurrent venous thromboembolism. Genetic abnormalities such as deficiency of antithrombin, protein C, or protein S are quite rare. Through an entire career, an individual clinician might encounter only one or two affected persons.

PREVENTION

Acute PE is estimated to cause 50,000 deaths in the United States each year. Because most deaths of PE happen suddenly before therapy can be given, ascertaining who is at high risk and instituting effective prevention is extremely important. Preventive therapy includes anticoagulant drugs and mechanical compressive methods that stimulate venous return and fibrinolysis in the lower extremities. Some preventive therapies are more effective than others. [Table 378.2](#) shows recommended preventive measures according to risk of venous thromboembolism. In some studies, combinations of pharmacologic and mechanical methods have proved more effective than either approach alone ([Table 378.2](#)).

Risk Group	Without Prophylaxis		Recommended Prophylactic Methods	With Prophylaxis	
	Proximal DVT (%)	Fatal PE (%)		Proximal DVT (%)	Fatal PE (%)
Hip replacement	25-30	2-4	War, LMWH	5	0.1-0.2
Knee replacement	25-30	2-4	War, LMWH, PC	5	0.1-0.2
Hip fracture	25-35	2-4	War, LMWH	10	0.3-0.4
Major trauma	20	0.5-1.0	LMWH, PC	10	<0.1
Abdominal or pelvic cancer surgery	20	0.5-1.0	LMWH, PC, GAB	10	<0.1
Abdominal surgery, coronary artery bypass graft	5-7	0.5	SA, LMWH, PC, War, ES	<1	<0.1
Medical patients 40 y or older with immobilization	5	<0.5	SA, ES, LMWH	<1	<0.1

War, Warfarin; LMWH, low-molecular-weight heparin; PC, intermittent pneumatic compression; SA, unfractionated heparin; ES, elastic stockings.
 From Hyers TE. Venous Thromboembolism. *State of the Art. Am J Respir Crit Care Med* 1995;151:1-14.

TABLE 378.2. PREVENTION OF VENOUS THROMBOEMBOLISM

No single preventive measure or combination is completely effective. Results of studies with patients at high risk indicate that preventive therapy provides tenfold risk reduction for both clinical events and death. Unfortunately, practice audits show that for many patients at high risk, either preventive therapy is not prescribed or ineffective methods are used. Innovative approaches to prevention are needed.

Vena caval filters are mechanical devices that allow venous return but obstruct the passage of large emboli. The filter usually is placed in the inferior vena cava below the renal veins. These devices prevent fatal PE but do not prevent DVT. Vena caval filters are used when DVT is present and anticoagulation cannot be given or when treatment has failed after an adequate trial.

DIAGNOSIS

Symptoms and signs of DVT and PE are maddeningly nonspecific, so clinical diagnosis is unreliable. Patients with DVT can have nonspecific symptoms of leg pain, swelling, or skin discoloration, but approximately 50% have no symptoms, and the leg appears normal at physical examination. Measurement of circumference at midthigh and midcalf is helpful. A difference in circumference of 1 cm or more is abnormal and mandates further testing. All of these symptoms and findings can be associated with other conditions such as cellulitis, ruptured Baker's cyst, heart failure with edema, and chronic venous insufficiency.

DEEP VENOUS THROMBOSIS

Although findings of a carefully taken history and physical examination cannot confirm the diagnosis of DVT, the information allows the clinician to estimate the probability of disease. The clinician should consider the presence of risk factors, symptoms, and physical findings. Before objective testing, the clinician should assign a probability to the likelihood of disease: low (1% to 19% probability) or high (80% to 100% probability). Indeterminate status (20% to 79% probability) is assigned to instances that fit into neither the low nor the high category. This pretest probability is useful in assessment of the results of objective testing.

The most commonly used diagnostic test for DVT is duplex ultrasonography with manual compression. The study incorporates Doppler flow measurement and B-mode imaging of the vein in question. Although venous thrombi often cannot be imaged directly, the noncompressibility of a venous segment on the B-mode image is good indirect evidence of the presence of a thrombus. This test is most reliable in the knee and thigh, where the veins course near the surface. The test is less reliable in the calf with its multiple overlapping veins and in the pelvis, where the veins cannot be easily compressed.

In contrast venography, radiographic contrast material is injected into a foot vein and plain-film images are obtained as the contrast material ascends through the deep veins of the leg. This test is used when findings at duplex ultrasonography are equivocal and when pretest probability is high and the results of duplex ultrasonography are normal. [Figure 378.1](#) shows a common approach to the diagnosis of DVT with clinical inference and objective testing. Magnetic resonance imaging has shown promise in the diagnosis of DVT, but this technique has been insufficiently tested to be substituted for duplex ultrasonography in the algorithm shown in [Figure 378.1](#).

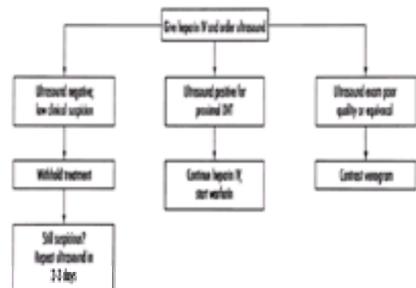

FIGURE 378.1. Clinical pathway for evaluation of deep venous thrombosis (DVT).

PULMONARY EMBOLISM

Patients with PE most often report dyspnea, pleuritic chest pain, or hemoptysis. Physical examination most commonly reveals tachypnea or tachycardia. Each of these symptoms and findings can be associated with other diseases. Although the history and physical findings cannot be used to confirm the diagnosis, patients with PE nearly always have at least dyspnea, pleuritic chest pain, or a respiratory rate faster than 20 breaths per minute. This triad is a sensitive screening tool to help rule out the possibility of PE. That is, patients who have none of these findings are unlikely to have PE. As with the clinical diagnosis of DVT, the clinician should assign a pretest probability for PE before proceeding to more objective testing. The pretest probability should incorporate the history, including risk factors, physical findings, and the presence of other heart or lung diseases that might explain any abnormal findings. A high, low, or indeterminate probability is assigned before objective testing.

Results of routine laboratory tests often are abnormal but cannot be used to confirm the diagnosis of PE. A chest radiograph may show nonspecific findings of hemidiaphragmatic elevation, small pleural effusions, or ill-defined parenchymal infiltrates. Arterial blood gas analysis may show widening of the alveolar to arterial oxygen gradient, often with a low PO_2 . The electrocardiogram most often shows tachycardia with nonspecific ST-segment and T-wave changes.

The most commonly used diagnostic test for PE is ventilation and perfusion lung scanning (\dot{V}/\dot{Q} scans). The perfusion scan shows the distribution of microvascular blood flow in the lungs after intravenous injection of a radionuclide, and the ventilation scan shows distribution of ventilation in the small airways after inhalation of a radioactive gas or aerosol. Normal scans show uniform distribution of the radionuclides throughout both lungs. If the \dot{V}/\dot{Q} scan findings are normal, PE is highly unlikely. The diagnostic hallmark of PE on a \dot{V}/\dot{Q} scan is a normal ventilation pattern with two or more large perfusion defects (>25% of an anatomic lung segment). This pattern is commonly called a \dot{V}/\dot{Q} mismatch and is highly diagnostic of PE, particularly if the patient has a high pretest probability of PE. Unfortunately, fewer than 50% of patients with PE have this classic \dot{V}/\dot{Q} mismatch because they also have preexisting lung or heart disease, which can cause ventilation abnormalities or small perfusion defects. Most patients with PE have abnormal \dot{V}/\dot{Q} scans, but this is not enough information for a diagnosis, and further testing often is necessary.

Pulmonary angiography involves the injection of radiographic contrast material into the main pulmonary artery with subsequent radiographic imaging of the material as it traverses the pulmonary arterial tree. In a patient with a high or indeterminate pretest probability, demonstration of a consistent pulmonary arterial filling defect or vascular cutoff confirms the diagnosis of PE. The test is expensive, invasive, and occasionally difficult to perform and interpret. Many smaller hospitals are not equipped to perform pulmonary angiography. Pulmonary angiography is most often performed when results of \dot{V}/\dot{Q} scans are indeterminate or when there is disagreement with the pretest probability. Spiral computed tomography with radiographic contrast material has shown promise for the diagnosis of PE, particularly emboli that lodge in segmental or larger pulmonary vessels. Further evaluation of this diagnostic modality is needed before it can be widely recommended.

THE COMBINED APPROACH

Because PE is nearly always preceded by DVT in the leg, clinicians often use a combined approach of both leg and lung diagnostic studies. This approach is particularly useful when results of \dot{V}/\dot{Q} scans are indeterminate. If duplex ultrasonography shows DVT, the diagnosis of venous thromboembolism is assured, and treatment can be given with confidence. If the findings of the leg study are normal, pulmonary angiography likely is necessary. [Figure 378.2](#) shows a stepwise approach to the diagnosis of venous thromboembolism using both leg and lung studies.

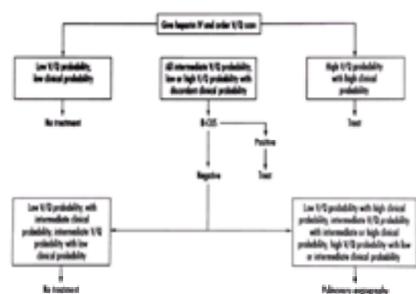

FIGURE 378.2. Clinical pathway for evaluation of pulmonary embolism. *B-CUS*, compressive B-mode ultrasonography.

ANCILLARY DIAGNOSTIC TESTS

The most commonly used ancillary test is measurement of plasma levels of dimerized plasmin fragment D (D-dimer), a degradation product of cross-linked fibrin. Elevations of D-dimer level are nonspecific, but the test result is rarely normal in the presence of acute venous thromboembolism. Some clinicians thus incorporate D-dimer levels into the algorithms in [Figure 378.1](#) and [Figure 378.2](#) in an effort to achieve greater confidence that venous thromboembolism has actually been ruled out.

STRATEGIES FOR OPTIMAL CARE

Unfractionated heparin and low-molecular-weight heparin (LMWH) are rapidly acting anticoagulants that provide effective management of acute venous thromboembolism. The drugs enhance the effect of a circulating coagulation inhibitor, antithrombin, so that the inhibitor combines with and inactivates thrombin, factor IX, and factor X. Both drugs must be given parenterally. When venous thromboembolism is suspected, anticoagulation with heparin or LMWH should be administered until the diagnostic evaluation is complete. If the presence of PE or proximal DVT is confirmed, one or the other drug should be given in a therapeutic dose for 5 to 7 days or until an oral anticoagulant such as warfarin is shown to be fully effective. Patients with symptomatic DVT in the calf should be treated in the same way.

HEPARIN

Unfractionated heparin usually is administered by means of intravenous infusion. The effect is monitored with activated partial thromboplastin time (aPTT). The goal is to maintain the heparin infusion at a rate that keeps aPTT in the therapeutic range. This range is commonly quoted to be a time in seconds that corresponds to a plasma heparin level of about 0.3 to 0.6 IU per milliliter. Even the most experienced clinicians have great difficulty achieving this goal because unfractionated heparin is cleared rapidly and unpredictably from the circulation. Several nomograms and dosing schemes have been devised for heparin administration, but because of the unfavorable pharmacokinetic characteristics of the drug, achieving and maintaining a therapeutic effect continues to be a problem for many patients. Because unfractionated heparin usually is given by means of intravenous infusion, most patients with venous thromboembolism have to stay in the hospital for at least 5 days.

LMWH is fractionated from the parent heparin molecule to have a mean molecular weight of 4 to 5 kd. The smaller molecular size confers more favorable pharmacokinetic properties, so that LMWH can be administered subcutaneously according to body weight without monitoring or dose adjustment. The convenience and portability of use of LMWH has allowed some patients to receive treatment at home or at least to be discharged from the hospital earlier with a component of home therapy.

The worst complication of unfractionated heparin and LMWH is bleeding. Patients can bleed from any location, but gastrointestinal and retroperitoneal bleeding seem to be most common. When localized bleeding occurs, the drug should be stopped and the cause investigated. Administration of blood products may be necessary. Heparin products can be neutralized with protamine sulfate, but this antidote rarely is necessary because the anticoagulant effect of heparin is rapidly cleared from the plasma.

Both unfractionated heparin and LMWH can cause thrombocytopenia through an immune-mediated mechanism. Heparin-induced thrombocytopenia (HIT) can cause paradoxical venous or arterial thrombosis because of intravascular consumption of platelets. Unfractionated heparin appears to cause HIT among 2% to 3% of patients who receive the drug for more than 5 days. LMWH is less likely to cause this complication but should not be substituted for unfractionated heparin if HIT develops. A precipitous decrease in platelet count, usually occurring 5 to 10 days after the start of therapy, signals the onset of HIT. When HIT is suspected, heparin or LMWH should be stopped immediately. The first direct thrombin inhibitor, recombinant hirudin, has become available for anticoagulation of patients with HIT and acute thrombosis.

Long-term administration of unfractionated heparin in high doses can cause severe osteoporosis. This complication is particularly worrisome for pregnant women with venous thromboembolism, who cannot take warfarin. LMWH appears to cause less osteoporosis than unfractionated heparin and should be considered in the care of pregnant patients with venous thromboembolism who need anticoagulation throughout pregnancy.

WARFARIN

Warfarin is an oral agent that interferes with effective synthesis of vitamin K–dependent coagulation factors II, VII, IX, and X. Warfarin also inhibits synthesis of the anticoagulant proteins C and S. The drug is given daily and monitored with prothrombin time as standardized with the international normalized ratio (INR). Daily platelet counts should be monitored during administration of unfractionated heparin. Heparin or LMWH should be continued for at least 5 to 7 days until warfarin is fully effective as evidenced by an INR of 2.0 to 3.0 on two consecutive days. Warfarin then is given for at least 3 to 6 months and the INR maintained in the range of 2.0 to 3.0.

As with the heparin products, bleeding is the most common complication of warfarin therapy. Bleeding risk is related to age, comorbidity (particularly renal or hepatic disease and peptic ulcer), and to an inordinately prolonged INR. Because the anticoagulant effect of warfarin can be affected by numerous drug interactions and diet, therapy with this agent must be closely monitored with prothrombin time and INR.

Warfarin has fetopathic and teratogenic effects and should not be given during pregnancy or to women who might become pregnant. Pregnant women with venous thromboembolism should receive either heparin or LMWH for the full term of pregnancy. At term, the drug is held for 24 hours, and labor is induced. Heparin or LMWH should be restarted post partum along with warfarin. Warfarin should be continued for at least 6 weeks after delivery.

Duration of warfarin therapy should be tailored to the risk of recurrence of venous thromboembolism. Patients who experience venous thromboembolism after a time-limited risk factor such as surgery or transient immobilization probably need no more than 3 months of therapy. Patients who have venous thromboembolism without a risk factor should be treated for at least 6 months. Patients with ongoing risk factors such as cancer, lupus anticoagulant, or one of the genetic causes listed in [Table 378.1](#) should be treated indefinitely because the risk of recurrence is high. Patients with recurrent venous thromboembolism, no matter what the putative risk factor, should receive indefinite therapy. Many times the prescription for therapy of indefinite duration commits a patient to a lifetime of anticoagulation. Therefore the diagnosis of recurrent venous thromboembolism should be firmly established before the recommendation is made.

THROMBOLYTIC AGENTS

Thrombolytic agents dissolve fibrin thrombi by activating the plasma proenzyme, plasminogen, to the active enzyme, plasmin. Plasmin then degrades fibrin, fibrinogen, and several other coagulation proteins. Several thrombolytic agents are available for management of venous thromboembolism. These include streptokinase, a bacterial product, and the human-derived products urokinase and tissue plasminogen activator. Each of these agents causes more thrombolysis than heparin or LMWH, although there is no clear evidence that one thrombolytic agent is preferred over another for treatment of venous thromboembolism. There also is no clear evidence that treatment of patients with venous thromboembolism with thrombolytic agents improves survival. Thrombolytic agents are more likely to cause bleeding than are heparin products. Thrombolytic agents consequently are usually reserved for patients with life-threatening PE or massive iliofemoral thrombosis in which compromise of the adjacent arterial circulation seems imminent. When a thrombolytic agent is infused, heparin or LMWH is held until the fibrinolytic effect has cleared. The heparin product is restarted and given with warfarin as described earlier.

CHRONIC THROMBOEMBOLIC PULMONARY HYPERTENSION

In some patients PE does not resolve even with proper treatment. Other patients seem to have episodes of PE and never come to medical attention. These persons are at risk of chronic thromboembolic pulmonary hypertension (CTPH), a syndrome characterized by progressive dyspnea with normal chest radiographs and results of pulmonary function tests. CTPH develops in less than 1% of patients with PE. Half of patients with CTPH have never received medical care for PE but when questioned give a history of an event that is compatible with the diagnosis. The presence of lupus anticoagulant appears to confer the highest risk, but in one series this abnormality was present in only 10% of patients with CTPH. The hallmark of the syndrome is dyspnea, which progresses from dyspnea with exertion to continuous dyspnea present even at rest. The diagnosis is strongly suggested when a \dot{V}/\dot{Q} scan shows large perfusion defects with relatively normal ventilation. Medical therapy is ineffective, but pulmonary endarterectomy can be lifesaving when performed by an experienced surgeon with a skilled support team.

CURRENT PROBLEMS AND NEW DIRECTIONS

Two unsolved problems with venous thromboembolism are failure to use preventive therapy in the care of patients at high risk and failure to diagnose the condition in the face of suggestive symptoms and findings. Many patients undergoing high-risk surgical procedure still do not receive adequate preventive therapy despite widespread promulgation of preventive guidelines. When venous thromboembolism occurs in such a patient, medical-legal action is likely, particularly if the patient dies. Innovative methods are needed to ensure that adequate preventive therapy is provided when indicated.

The problem of failure of diagnosis relates to clinician error and to inherent deficiencies of the major diagnostic tests, particularly \dot{V}/\dot{Q} lung scanning. Venous thromboembolism can be an insidious disease, and even the most experienced clinician can overlook this diagnosis, especially in the care of younger persons without clear risk factors. Unexplained dyspnea is the most common initial manifestation of PE, and clinicians should always be alert to the possibility of this disease unless there is another plausible explanation for shortness of breath. When a patient dies of undiagnosed venous thromboembolism after seeking medical attention with suggestive symptoms and findings, a lawsuit is likely. If venous thromboembolism is suspected, objective testing must be performed and the results assessed in a timely manner by the responsible physician. If results of first-line diagnostic tests are indeterminate and clinical suspicion is high or indeterminate, further invasive testing with venography and pulmonary angiography should be pursued. In this regard, additional evaluation of spiral computed tomography for the diagnosis of PE is urgently needed, because this modality is available in most hospitals, and pulmonary angiography is not.

Patients with cancer or lupus anticoagulant who have venous thromboembolism are especially difficult to treat because of high risk of both recurrence and bleeding. New methods are needed to prevent venous thromboembolism among cancer patients at high risk. The potential benefits of LMWH in the management of venous thromboembolism among cancer patients should be investigated. Patients with lupus anticoagulant seem to need more intensive warfarin therapy than the usual patient with venous thromboembolism. Many authorities recommend that the INR be maintained above 3.0 for such patients.

Approval of the LMWH enoxaparin for the treatment of patients with venous thromboembolism in the United States has opened the door to outpatient therapy. Physicians should develop and implement algorithms and pathways for outpatient treatment, specifically identifying patients who need hospitalization. Not all patients are good candidates for home therapy, although cost-containment efforts put great pressure on physicians to treat everyone as an outpatient.

Although LMWH offers greater convenience than unfractionated heparin, LMWH still must be given by means of parenteral injection. New derivatives of heparin and LMWH that can be given orally are being developed and when available should offer added convenience and ease of dosing. As these and other new therapeutic agents enter clinical use, the opportunity for enhanced efficacy and greater cost savings should be realized.

CHAPTER 379: DISEASES OF THE MEDIASTINUM AND CHEST WALL

CAMERON D. WRIGHT

[Disorders of the Mediastinum](#)
[Disorders of the Chest Wall](#)

DISORDERS OF THE MEDIASTINUM

The mediastinum is the potential space between the pleural cavities. It is bounded by the sternum anteriorly, the vertebral bodies and costal arches posteriorly, the thoracic inlet superiorly, and the diaphragm inferiorly. The major structures contained are the heart and great vessels, trachea and main bronchi, esophagus, and thymus along with fat, connective tissue, and lymph nodes. Fascial planes connect the mediastinum with the neck and retroperitoneum and allow movement of air, infection, or a mass from one location to another.

The mediastinum is commonly divided into anterior, middle, and posterior compartments ([Fig 379.1](#)). These boundaries are not strictly anatomic but do allow simple classification of masses, which facilitates a proper differential diagnosis. The anterior compartment is bounded by the pericardium and great vessels posteriorly and the sternum anteriorly. It normally contains the thymus, fat, and some lymph nodes. The middle compartment is shaped like a triangle with the diaphragm the base. The anterior margin is the heart and great vessels running from the diaphragm to the thoracic inlet. The posterior margin is the anterior vertebral border. It normally contains the pericardium, heart and great vessels, trachea and pulmonary hila, numerous lymph nodes, and the vagus and phrenic nerves. The posterior compartment is bordered by the projection of the vertebral body as seen on a lateral chest radiograph and contains the descending thoracic aorta, esophagus, azygous vein, thoracic duct, autonomic ganglia, and fat.

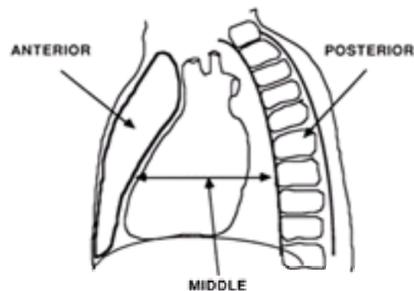

FIGURE 379.1. Anatomic location of mediastinal compartments on an idealized lateral radiograph.

PRESENTATION

Pneumomediastinum

The presence of air in the mediastinum is most commonly caused by barotrauma from mechanical ventilation. Other causes include spontaneous, trauma, esophageal rupture, Valsalva maneuvers, or severe asthma. Substernal pain, often aggravated by breathing, is the most common symptom. Dyspnea, dysphagia, dysphonia, and subcutaneous crepitus are other symptoms. Patients undergoing mechanical ventilation need close observation with radiographs to search for occult pneumothoraces. Prophylactic intercostal drainage should be considered for patients with high inspiratory pressures or those in tenuous clinical condition.

Mediastinitis

Acute mediastinitis is usually caused by esophageal rupture from instrumentation, vomiting (Boerhaave's syndrome), an impacted foreign body, trauma, or surrounding necrotizing infection. Descending necrotizing mediastinitis originates from the head or neck, usually either the teeth or hypopharynx, and dissects down contiguous fascial planes into the chest. Most patients with mediastinitis appear acutely ill with fever, chills, dyspnea, pleuritic chest pain, and systemic toxicity. Hamman's sign (crunching sound of the auscultated heart tones) occasionally may be heard. Cervical subcutaneous emphysema may be palpated from extension of the associated pneumomediastinum. Most patients have abnormal chest radiographs. Radiographic findings include pneumomediastinum, mediastinal widening, pneumothorax, and pleural effusion. Computed tomography (CT) of the chest is more sensitive in picking up all of these radiographic findings. If esophageal rupture is suspected, a radiographic study with a swallow of water-soluble contrast medium is required, and the findings usually confirm the diagnosis. Most patients with esophageal rupture need urgent surgical repair. Descending necrotizing mediastinitis necessitates urgent drainage of the causative neck infection and of the affected areas of the mediastinum. Mediastinitis after sternotomy, usually in cardiac surgery, usually presents within the first week after the operation with fever, wound pain, redness, and drainage. Prompt surgical re-exploration with drainage and debridement usually is curative.

Chronic mediastinitis usually is caused by granulomatous disease from histoplasmosis, although tuberculosis may cause a smoldering infection. Most commonly this condition is asymptomatic and found as mediastinal widening on a chest radiograph. Chest CT usually shows mediastinal adenopathy, most commonly concentrated in the right paratracheal area. Scattered calcified lymph nodes or lung granuloma may be present. The lymph node mass sometimes enlarges enough to compress the airway or superior vena cava to cause symptoms. Mediastinoscopy with biopsy and culture are needed to confirm the diagnosis. Some patients have an excessive host reaction, and acellular fibrosis develops. Mediastinal fibrosis may then compress and obstruct important hollow mediastinal structures and cause clinical syndromes, such as dyspnea, wheezing or stridor, superior vena cava (SVC) syndrome, and dysphagia.

CLINICAL EFFECTS

Most mediastinal masses are asymptomatic and are diagnosed when chest radiography is performed for another reason. About 80% of malignant masses are symptomatic, and only 40% of benign masses are symptomatic. Compression of adjacent structures may cause symptoms that lead to identification of the problem. Symptoms include chest pain, cough, dysphagia, SVC syndrome, hoarseness (from pressure on the recurrent laryngeal nerve), and dyspnea (from mass effect, pleural effusion, or phrenic nerve paralysis). Fever, night sweats, and weight loss may be associated with lymphoma. Myasthenia gravis often is associated with thymoma.

DIAGNOSIS

The presence of a mediastinal mass requires a diagnosis. Old chest radiographs may be helpful, especially if the mass is seen in retrospect. The presence of a characteristic air-fluid level on a lateral radiograph of a hiatal hernia usually indicates a mass. Contrast chest CT is useful to refine the differential diagnosis of most masses. Size, shape, calcification, vascular structures, soft-tissue density (fluid, blood, fat), enhancement, homogeneity, edge characteristics, and effects on surrounding structures can be assessed to generate a probable diagnosis. Magnetic resonance imaging (MRI) is of no additional benefit except to assess spinal cord impingement of neurogenic tumors, evaluate high-density foregut cysts that contain blood or mucus, and assess chest wall invasion.

The location of a mediastinal mass is helpful in making a diagnosis, although a mass may abut or transgress another compartment ([Table 379.1](#)). Once a vascular lesion (a true or false aneurysm or a congenital vascular lesion) is excluded with CT and a short list of possible causes is generated on the basis of location and symptoms, an approach to biopsy can be chosen. CT-guided needle aspiration is helpful in diagnosing metastatic carcinoma but is often unreliable in differentiating

CHAPTER 380: DISEASES OF RESPIRATORY MUSCLES

THOMAS K. ALDRICH

[Causes of Respiratory Muscle Insufficiency](#)
[Specific Conditions that Affect Respiratory Muscles](#)
[Methods for Measuring Respiratory Muscle Function](#)
[Strategies for Optimal Care](#)

Disease can affect both inspiratory and expiratory muscles. Most respiratory work, however, is performed by the inspiratory muscles, and most of the energy required for expiratory airflow is stored as potential energy during the inspiratory phase and released as elastic recoil of lungs and chest wall during the largely passive expiratory phase. Even in the presence of acute asthma or chronic airway obstruction, the inspiratory muscles do most of the work. Expiratory muscle strength is vital, however, for effective coughing. Comfortable breathing requires enough respiratory muscle endurance to manage the respiratory workload. Any disease or condition that weakens respiratory muscles or that increases their workload can contribute to the symptoms and complications of respiratory insufficiency.

CAUSES OF RESPIRATORY MUSCLE INSUFFICIENCY

CHRONIC LUNG DISEASE

In chronic lung disease, the respiratory muscles must contend with major increases in workload. In chronic obstructive pulmonary disease or asthma, and especially in upper airway obstruction, the excessive airway resistance directly increases the work of breathing. When expiratory airway resistance is markedly impaired, as by dynamic airway compression in emphysema, and when dyspnea provokes premature onset of the inspiratory phase, dynamic hyperinflation and intrinsic positive end-expiratory pressure are produced. The result is an inspiratory threshold load, often the most important contributor to the inspiratory work of breathing. Elastic workloads contribute to respiratory muscle overload in congestive heart failure, pneumonia, pleural effusion, and especially in chest wall-restrictive disorders such as kyphoscoliosis. In obesity-hypoventilation syndrome, inertial respiratory loads are prominent.

Although excessive respiratory load is the main contributor to respiratory symptoms and exercise intolerance in chronic lung disease, several factors may impair respiratory muscle endurance. As with all skeletal muscles, respiratory muscle strength increases as the precontraction length of the muscle fibers increases. The pulmonary hyperinflation common in airway obstruction shortens the inspiratory muscles and decreases their strength. It has been suggested that chronic hyperinflation may prompt adaptive drop-out of diaphragmatic sarcomeres and cause a right shift of the length-tension curve of the diaphragm to maintain good diaphragmatic strength despite hyperinflation. However, acute hyperinflation always weakens the diaphragm and perhaps other inspiratory muscles. When hyperinflation is severe, as in advanced emphysema, the diaphragm becomes almost flat, completely losing its effectiveness as a generator of intrathoracic vacuum. Patients with chronic lung disease often are sedentary, and the lack of activity leads to detraining of respiratory and other muscles. To make matters worse, malnutrition, hypoxemia, electrolyte disorders, and several commonly used drugs can impair respiratory muscle function in chronic lung disease.

NEUROMUSCULAR DISEASE

Weakness, the hallmark of generalized neuromuscular disease, usually affects the respiratory muscles as well as other muscles. These diseases also are frequently associated with increased workload. The typical rapid, shallow pattern of breathing in neuromuscular disease can lead to microatelectasis, which decreases lung compliance and increases the work of breathing. When the laryngeal muscles are paretic, vigorous inspiratory efforts may cause paradoxical inspiratory adduction of the vocal cords and functional upper airway obstruction, especially during sleep. Kyphoscoliosis is a complication of many neuromuscular diseases. When severe, this condition dramatically restricts expansion of the chest wall and increases the inspiratory load on the muscles. Impaired cough effectiveness, recurrent aspiration of gastric contents, and the resulting pulmonary infection among patients with generalized neuromuscular diseases can cause inflammatory or fibrotic changes in the bronchi and lungs. These changes increase both the resistive and the elastic work of breathing.

SPECIFIC CONDITIONS THAT AFFECT RESPIRATORY MUSCLES

SPINAL CORD INJURIES

The diaphragm can support breathing in spinal cord injuries below C5 because the phrenic nerves originate from the C3 to C5 roots. Such patients often have recurrent pulmonary infections, however, because of the almost complete absence of expiratory muscle activity and the resulting ineffective cough. Higher levels of cervical injuries affect almost all the respiratory muscles, in many cases causing intractable respiratory failure.

DISEASES OF THE ANTERIOR HORN CELLS

Diseases of anterior horn cells commonly cause respiratory failure because the respiratory muscles are effectively denervated and in many cases because bulbar involvement causes recurrent aspiration pneumonia. Amyotrophic lateral sclerosis usually causes particularly severe and relentless respiratory insufficiency, and death occurs in 1 to 3 years. Bilateral diaphragmatic paralysis, with its characteristic severe orthopnea, sometimes is the presenting manifestation of amyotrophic lateral sclerosis.

NEUROPATHY

Guillain-Barre(c) syndrome often follows a viral infection, especially influenza. Most cases start with leg weakness and progress over 1 to 4 weeks, until, in 20% to 50% of cases, mechanical ventilation is required. Although there is no specific treatment, the prognosis for at least partial respiratory muscle recovery is good. Unilateral diaphragmatic paralysis may be the result of traumatic or neoplastic phrenic nerve injury, but in many cases, no cause can be established. In the absence of pulmonary disease, the paralysis usually is well tolerated, often asymptomatic, and detected only when the characteristic elevated hemidiaphragm is an incidental finding on a chest radiograph. Bilateral diaphragmatic paralysis usually causes severe orthopnea.

DISORDERS OF NEUROMUSCULAR TRANSMISSION

Myasthenia gravis involves the respiratory muscles in most instances but usually not until months or years after the onset of the disease. Myasthenia gravis is characterized by marked muscle weakness after repeated contraction and improvement with rest, but such pathologic fatigability is not clearly demonstrated for the diaphragm. Although they may be less severely affected by myasthenic weakening than are other muscles, respiratory muscles often are more sensitive to the cholinergic toxicity of anticholinesterase inhibitors. This sensitivity can lead to the insidious onset of respiratory insufficiency when other symptoms are responding to treatment.

MYOPATHY

The respiratory muscles are involved in almost all forms of generalized myopathy. Respiratory failure is particularly common with Duchenne's muscular dystrophy, especially when it is complicated by scoliosis and cardiac failure. Dystrophic weakening of the respiratory muscles is the main factor contributing to respiratory insufficiency in myotonic dystrophy. Another possible but as yet speculative factor may be myotonia (delayed relaxation) of the respiratory muscles, which may promote hyperinflation and further weakening of inspiratory muscles. Although no specific therapy is available for any of the dystrophies, dystrophic muscles are capable of improved strength with training and are susceptible to atrophy with disuse.

The inflammatory forms of myopathy, polymyositis and dermatomyositis, affect the respiratory muscles in a high percentage of cases. In 5% to 10% of cases, interstitial lung disease occurs and may contribute to respiratory insufficiency. Acid maltase deficiency is the most important form of glycogen storage myopathy. In the childhood form, respiratory failure causes death by 20 years of age. In the adult form, respiratory muscle involvement usually parallels slowly progressive weakening

of peripheral muscles.

RESPIRATORY MUSCLE WEAKNESS DUE TO NONNEUROLOGIC CONDITIONS

Respiratory muscle weakness occurs in many conditions, including thyroid disease (both thyrotoxicosis and myxedema), malnutrition, cancer, alcoholism, and disorders of potassium, phosphate, calcium, and magnesium homeostasis. A number of drugs, including adrenocorticosteroids, aminoglycoside antibiotics, and possibly calcium channel blockers, can impair respiratory muscle function. Some of these agents are commonly used to treat seriously ill patients who have compromised respiratory reserve and are therefore poorly equipped to handle a decrease in respiratory muscle endurance. Polyneuropathy and polymyopathy, probably mediated by cytokines, are common in serious acute and chronic illnesses. The respiratory muscles, especially the diaphragm, frequently appear to be weakened by such effects. The respiratory muscles are subject to fatigue when the work of breathing is too much for respiratory muscle endurance and is sustained for long periods. Such fatigue may play an important role in the chronic symptoms of patients who have little or no respiratory reserve and may be particularly important in preventing successful weaning from mechanical ventilation.

METHODS FOR MEASURING RESPIRATORY MUSCLE FUNCTION

Tachypnea is a sensitive but nonspecific sign of respiratory insufficiency. An important physical finding that suggests respiratory muscle overload is visible or palpable contraction of accessory muscles. Such contractions can be detected through observation of sternocleidomastoid or intercostal retraction or palpation of scalene muscle activity deep in the posterior aspect of the neck. Active expiratory muscle (abdominal) contractions generally indicate respiratory muscle overload, often with hyperinflation.

Qualitative information about the strength of diaphragmatic contraction can be obtained by means of abdominal palpation if excessive expiratory muscle activity is not present. Paradoxical inward inspiratory motion of the abdomen can be observed in most cases of bilateral diaphragmatic paralysis. Reversible or intermittent abdominal paradoxical breathing is a sign of diaphragmatic fatigue or overload.

Quantitative assessment of respiratory muscle function can be made with a few simple pulmonary function tests, either at the bedside or in the laboratory. Inspiratory muscle strength can be measured as maximal static inspiratory pressure, and expiratory muscle strength can be measured as maximum static expiratory pressure. Both tests are highly effort dependent and unreliable in seriously ill patients. Measurement of transdiaphragmatic twitch pressure, painlessly elicited by means of magnetic stimulation of the phrenic nerves, offers a possible objective test of diaphragmatic strength.

Fluoroscopy of the diaphragm can help confirm suspected diaphragmatic paralysis by revealing paradoxical cephalic motion during the inspiratory phase of respiration. When the results are equivocal, measurement of transdiaphragmatic pressure with gastric and esophageal balloon catheters or measurement of phrenic nerve latency and conduction times may help in the evaluation of diaphragmatic paresis.

STRATEGIES FOR OPTIMAL CARE

Specific therapy for respiratory muscle weakness is available for only a few conditions. In myasthenia gravis, cholinesterase inhibitors prolong the time that acetylcholine is in neuromuscular junctions, improving neuromuscular transmission. For patients with thymoma in association with myasthenia gravis, thymectomy often causes dramatic improvement. For polymyositis, adrenocorticosteroid therapy is often helpful. For myopathy associated with hyperthyroidism and hypothyroidism, malnutrition, electrolyte disorders, and the presence of drugs, management of the underlying condition, if successful, causes improved respiratory muscle function. For most patients with respiratory muscle weakness, however, there is no specific therapy.

For all patients with respiratory muscle weakness, it is important to ensure adequate arterial oxygenation, cardiac output, nutritional intake, acid–base balance, and electrolyte status. Efforts should be made to prevent aspiration of gastric contents. For patients at bed rest, prophylactic low-dose heparin should be given to prevent pulmonary emboli. Coexisting or complicating conditions that increase respiratory workload, such as asthma, atelectasis, or pneumonia, should be actively sought, identified, and corrected.

Three types of treatment—drugs, training, and rest—have been recommended for improving respiratory muscle strength and endurance in a variety of clinical conditions. Methylxanthine drugs such as caffeine and theophylline can immediately improve the diaphragmatic tension elicited by low-frequency phrenic nerve stimulation and possibly improve the strength of submaximal inspiratory efforts. The clinical implications of such effects are uncertain. More chronic improvements in respiratory muscle strength and endurance have been suggested by preliminary studies of treatment with anabolic steroids or human growth hormone. However, results of detailed studies with objective measurements of strength by means of phrenic nerve stimulation have not yet been reported. There has been little experience with methylxanthines, anabolic steroids, or growth hormone in the management of neuropathic or myopathic disease. Thus the role of drugs as respiratory muscle tonics remains uncertain.

Respiratory muscle training has been used to augment respiratory muscle endurance. Therapy entails repeated 15- to 30-minute sessions of isocapnic hyperventilation or inspiratory resistive loading. Although promising results have been obtained in several studies of patients with chronic lung diseases and in a few studies of patients with neuromuscular disease, especially spinal cord injuries and muscular dystrophy, the weight of the evidence suggests that most patients gain little or nothing from respiratory muscle training, at least in part because of poor compliance. It is not clear whether respiratory muscle training is more effective than less specific exercise training. There also is reason to believe that respiratory muscle overuse resulting from training might be harmful to some patients with neuromuscular disease.

Regular nocturnal mechanical ventilation by means of intermittent positive-pressure ventilation delivered through tracheostomy or a nasal mask may help some patients with respiratory muscle insufficiency. Assisted ventilation can allow these patients to sleep without nocturnal dyspnea or sleep apnea. It also provides them with adequate oxygenation for at least part of the day, potentially preventing cor pulmonale. It has been suggested, without definitive proof that nocturnal mechanical ventilation may relieve chronic respiratory muscle fatigue and allow patients to breathe more comfortably off the respirator during the day.

CHAPTER 381: DISEASES OF VENTILATORY CONTROL

CLIFFORD W. ZWILLICH AND SOGOL NOWBAR

[Idiopathic Alveolar Hypoventilation](#)
[Central Alveolar Hypoventilation](#)
[Obesity Hypoventilation Syndrome](#)
[Thyroid Hormone Insufficiency](#)
[Control of Breathing Among Persons with Asthma](#)
[Ventilatory Control in Chronic Obstructive Lung Disease](#)

Advances have been made in understanding the control of breathing. This chapter reviews modern physiologic concepts that explain pathophysiologic events and clinical characteristics of disorders in which abnormalities of ventilatory control appear to play an important role. Fundamental to this discussion is the concept that the adequacy of alveolar ventilation depends on the balance between the impediment to breathing (obstructive and restrictive respiratory disorders) and respiratory drive. Both impediment and drive may rapidly change in response to normal physiologic adaptations or disease or as a result of therapy. Alveolar hypoventilation occurs when ventilatory drive is insufficient to counterbalance the influence of respiratory impediment ([Fig 381.1](#)).

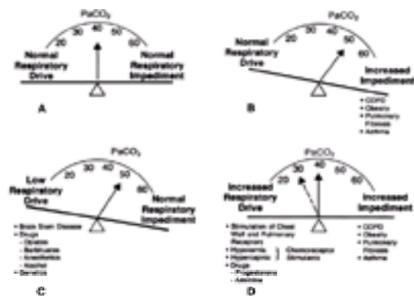

FIGURE 381.1. Interaction between respiratory drive and the impediment to breathing and the effect on arterial carbon dioxide tension (Pa CO_2). **A:** Normal PaCO_2 as the result of a balance between normal respiratory drive and normal respiratory impediment. **B:** High PaCO_2 (hypoventilation) is caused by increased respiratory impediment if respiratory drive remains at baseline (normal) value. **C:** High PaCO_2 is the result of abnormally low ventilatory drive even though the respiratory impediment is normal. **D:** Common clinical situation in which alveolar ventilation (Pa CO_2) remains normal or even slightly increased (low Pa CO_2) in response to frequently encountered respiratory impediments. Alveolar ventilation is maintained because respiratory drive increases as a result of the reflex mechanism shown or in response to drug administration.

When abnormal blood gas values (hypoxemia and hypercapnia) seem out of proportion to the degree of respiratory impediment, an abnormality in ventilatory drive should be considered. This discussion begins with a description of unusual disorders in which hypoventilation occurs among patients with normal respiratory function and markedly deficient drives. Next more common disorders are described, such as hypothyroidism and obesity, in which respiratory impediment is greater than normal but insufficient by itself to cause hypoventilation. When respiratory impediment is combined with attenuation of drive, however, hypoventilation occurs. Asthma and chronic obstructive pulmonary disease (COPD) are discussed last. These are high respiratory impediment states in which alveolar ventilation usually is maintained because of reflex stimulation of ventilatory drive mechanisms. Some patients have a low drive, and hypoventilation occurs.

IDIOPATHIC ALVEOLAR HYPOVENTILATION

A rare disorder in which attenuated ventilatory drive appears to be fundamental in causing alveolar hypoventilation is called *idiopathic alveolar hypoventilation*. This disorder may become clinically apparent in infancy or in adulthood. The most common manifestation is caused by hypercapnia and hypoxemia. Accordingly, these patients have cor pulmonale, polycythemia, or alteration in consciousness. The last is explained in part by the central nervous system dysfunction caused by blood gas derangements and abnormal breathing during sleep. No identifiable central nervous system disease is present to explain the dysfunction in respiratory control. It is interesting that patients with chronic hypercapnia and hypoxemia can normalize the blood gas derangements with a few minutes of voluntary hyperventilation. Careful measurement of respiratory function typically discloses no abnormality of the lung parenchyma, respiratory muscles, or chest-wall mechanics, which suggests that abnormal impediment does not have a role in the pathogenesis of hypoventilation in this disorder.

When challenged in the laboratory with additional carbon dioxide or hypoxia, these patients do not have reflex hyperventilation. Great care must be used to ensure patient safety because unheralded unconsciousness may occur with this form of testing. It is not clear why these patients have this degree of attenuation in ventilatory responses to chemical stimuli. Postmortem brain and spinal cord examination usually is not revealing. Healthy family members of a few of these patients have had attenuated chemosensitivity, which suggests a genetic cause.

CENTRAL ALVEOLAR HYPOVENTILATION

Central alveolar hypoventilation is similar to the idiopathic disorder in that neither respiratory disease nor neuromuscular weakness is present to explain inadequate breathing. As in the idiopathic disorder, abnormalities in respiratory rhythm during wakefulness may be present, but these are typically amplified during sleep, when cortical influences no longer have a strong role in modulating respiratory rhythm. Hypoventilation, apnea, or another form of dysrhythmic breathing therefore is severe during sleep. Unlike patients with idiopathic disease, those with central alveolar hypoventilation have primary central nervous system abnormalities, which are thought to be causative. Intrinsic medullary disorders such as infarction, hemorrhage, encephalitis, polio, tumors, and multiple sclerosis have been implicated in this disorder. Brain stem herniation, cerebellar mass lesions, and bacterial meningitis have been causal. Traumatic injuries to the cervical spine or ventrolateral cordotomy may cause this breathing disorder. Numerous other central nervous system and peripheral neuropathic and myopathic syndromes cause hypoventilation. The cause of hypoventilation among patients with intrinsic brain stem disease is multifactorial. Some patients have anatomic abnormalities in medullary regions in which respiratory motor neuron cells are present. Others have disease in brain stem zones in which both vagal and carotid body chemoreceptor afferents are known to converge. In many such cases, abnormalities in the chemical control of breathing (ventilatory responses to hypoxia and hypercapnia) have been found.

Dyspnea is not prominent among patients with hypoventilation and no lung dysfunction, a contrast to the dyspnea present among patients with hypoventilation caused by severe lung disease. Patients with central hypoventilation have attenuated ventilatory drive and little or no reflex respiratory muscular effort in response to the blood gas derangement. High work of breathing and dyspnea are absent.

Successful treatment of patients with central alveolar hypoventilation is difficult. Many patients need assisted mechanical ventilation, particularly during sleep, when respiration worsens. For some patients, low-flow oxygen improves arterial hypoxemia without worsening hypercapnia. Partial or complete reversal of polycythemia, cor pulmonale, and cognitive dysfunction may result. Great care must be used in the initial administration of oxygen because when alveolar ventilation is low, a further small decrement induced by supplemental oxygen may cause life-threatening hypercapnia. Phrenic nerve pacing may be useful. In summary, idiopathic and central alveolar hypoventilation represent disorders in which underbreathing is present because of markedly attenuated drive but normal respiratory impediment ([Fig 381.1C](#)).

OBESITY HYPOVENTILATION SYNDROME

Most obese people compensate for the increased chest-wall elastic load by augmenting inspiratory drive and maintaining normal alveolar ventilation ([Fig 381.1D](#)). A minority hypoventilate in response to obesity and come to medical attention with the typical clinical abnormalities caused by hypoxemia and hypercapnia. In addition

to polycythemia, cor pulmonale, and cognitive disability, these patients frequently have daytime hypersomnolence, probably caused by coexistent obstructive sleep apnea. They characteristically have a long history of sonorous snoring and morning fatigue.

A disorder of ventilatory control is thought to be present in obesity hypoventilation syndrome (OHS) for numerous reasons. As a group, these patients can typically normalize hypercapnic and hypoxemic blood gas values during voluntary hyperventilation. Although the impediment to breathing is high because of obesity, it usually is not severe enough to explain the blood gas derangement. In OHS, neural respiratory drive to the ventilatory muscles may be greater than that of healthy controls, but it usually is much less than that of equally obese persons who maintain adequate alveolar ventilation. Several studies have demonstrated low ventilatory and attenuated neuromuscular responses to additional (laboratory-induced) hypercapnic and hypoxemic stimuli among persons with OHS. The occasional obese person with hypoventilation appears to have an imbalance between impediment (obesity) and the amount of ventilatory drive necessary to maintain adequate breathing ([Fig. 381.1D](#)). Considerable weight reduction, as with gastric surgery, results in less restriction, improvement in arterial blood gas abnormalities, and reduction of pulmonary hypertension.

The causes of attenuated ventilatory drive among persons with OHS are unknown. Some patients have low drive after weight reduction when blood gas values are normal. This suggests a premorbid attenuation in drive. Among other patients with OHS, continuous positive airway pressure (CPAP) therapy for the accompanying obstructive sleep apnea improves respiratory drive and blood gas values measured during wakefulness even though no loss in body weight or improvement in lung function was found. For some patients CPAP does not affect respiratory drive until the patient has been treated with a period of nasal intermittent positive pressure ventilation (bilevel). Among these patients effective nasal ventilation ameliorates apnea and hypoventilation during all sleep states, which leads to improved respiratory drive. This result suggests that the attenuation in ventilatory drive that causes hypoventilation may have been the result of severe blood gas derangements during sleep or other apnea-related abnormalities such as sleep fragmentation.

Normalization of alveolar ventilation with reversal of polycythemia and cor pulmonale occurs in OHS when the ventilatory drive stimulant progesterone (medroxyprogesterone acetate) is administered. This drug significantly increases the ventilatory response to hypoxemia. Progesterone is believed to be the cause of the alveolar hyperventilation present among normal women during the luteal phase of the menstrual cycle and during pregnancy.

THYROID HORMONE INSUFFICIENCY

Hypercapnic respiratory failure and coma have been documented among some patients with myxedema, although lung disease and chest-wall mechanics (obesity) are not severe enough to explain its occurrence. Patients with thyroid insufficiency have concomitant hypometabolism, which is believed to decrease respiratory drive. Specifically, patients with hypothyroidism have low ventilatory responses to chemical stimuli. Thyroxine replacement raises metabolic rate and improves ventilatory chemosensitivity, suggesting that a cause of hypercapnic respiratory failure complicating myxedema may be related in part to attenuated chemosensitivity. Patients with hypothyroidism do not have adequate inspiratory muscular responses to experimentally increased respiratory resistance loading. Accordingly, several abnormalities in the ventilatory control system are present during wakefulness among persons with inadequate thyroid function.

Derangements in ventilatory control and blood gas abnormalities recorded during wakefulness may be mild compared with those found during sleep. Such appears to be the case for persons with hypothyroidism, among whom severe obstructive sleep apnea is common. These persons have hundreds of nightly occurrences of apnea with associated hypercapnia, oxyhemoglobin desaturation, and bradycardia. An obese patient with hypothyroidism is particularly prone to sleep apnea. Thyroid hormone replacement greatly diminishes the frequency of sleep apnea even if weight reduction is not achieved.

CONTROL OF BREATHING AMONG PERSONS WITH ASTHMA

The diffuse bronchoconstriction of asthma increases resistive respiratory impediment, hyperinflation, and stimulation of intrapulmonary vagal afferent reflexes. These derangements predictably increase ventilatory drive and the sensation of breathlessness. Patients are dyspneic and display alveolar hyperventilation (hypocapnia). Ventilatory control testing among persons with moderately severe but stable asthma has demonstrated greatly increased diaphragmatic neural drive. Most persons with asthma have hypoxemia during severe exacerbations, suggesting that it may cause their high drive to breathe, dyspnea, and hyperventilation. This appears not to be the case, however, because reversing the hypoxemia with supplemental oxygen usually has only a minor effect on dyspnea and hyperventilation. Intrapulmonary vagal afferent stimulation and hyperinflation during asthma may be responsible for both the high drive and dyspnea. Some persons with asthma who have severe bronchoconstriction also have hypercapnic respiratory failure, but most do not. Therefore the severity of the impediment to breathing (bronchoconstriction) does not completely explain this complication.

Persons with asthma who have had an episode of hypercapnic respiratory failure have low ventilatory chemosensitivity and attenuated perception of dyspnea. Studies with persons fully recovered from asthma have shown that those who had had hypercapnic respiratory failure during an asthma attack had much lower ventilatory and neuromuscular response to experimental hypoxemia than did healthy persons or persons with asthma who did not have respiratory failure during an attack. Persons with asthma who are prone to respiratory failure have little dyspnea during externally applied resistive breathing loads designed to simulate bronchoconstriction. These observations may explain why some persons with severe asthma have respiratory failure without the apparent warning suggested by progressive dyspnea. These new findings place additional emphasis on the need for home self-monitoring of lung function by persons with asthma when decrements in peak expiratory flow signal the need for accelerated antiasthma therapy.

VENTILATORY CONTROL IN CHRONIC OBSTRUCTIVE LUNG DISEASE

During the course of progressive COPD, airflow obstruction typically worsens, so that on average, the forced expiratory volume in 1 second (FEV_1) decreases about 80 mL per year. This eventually causes a large mechanical load against which the patient must breathe. Arterial hypoxemia is a frequent finding among persons with progressive airflow obstruction. These features of severe COPD explain the high respiratory drive and dyspnea that occur among most such patients.

Some patients with chronic airflow obstruction are less likely to detect and respond to additional respiratory resistive loads when compared to healthy persons or to persons with asthma. This loss of load compensation appears to be caused by increased endogenous endorphin activity because naloxone transiently reestablishes respiratory load compensation. Numerous factors may influence the control of breathing among persons with COPD.

The fundamental cause of hypoventilation among this population is of great interest because its presence is associated with severe hypoxemia and a worse prognosis. There is wide variability between the impediment to breathing, measured with FEV_1 , and the occurrence of hypoventilation, measured with $PaCO_2$. Although some patients with COPD and carbon dioxide retention fit the profile for having chronic bronchitis and patients with normocapnia often have emphysema, this correlation is weak. Patients with carbon dioxide retention generally have a breathing pattern of rapid and shallow respiration that enhances dead-space rebreathing and may help explain carbon dioxide retention. Respiratory muscle fatigue and the inappropriate use of sedatives and analgesics cause hypoventilation among some patients.

Persons with hypercapnia generally have a lower ventilatory response to laboratory-induced hypercapnia than do patients with the same amount of obstruction but normocapnia. In addition, measures of neural respiratory drive are different for the two groups. All patients with COPD typically have high resting electromyographic diaphragm signals (drive). Patients with normocapnic COPD, however, usually have a greater enhancement of drive to the respiratory muscles in response to added hypercapnia than do patients with COPD and chronic hypercapnia. Similar experimental results are found for laboratory-induced hypoxemia. In general, patients with hypercapnia have lower but clearly measurable responses to laboratory-induced hypoxemia than do normocapnic patients with COPD.

Factors that may explain attenuated ventilatory drive among some patients with COPD include acquired and genetic influences. The hypercapnic patients with COPD may have attenuated drives because of chronic hypoxic depression of ventilatory autonomic function. Although acute hypoxemia is a ventilatory stimulant, it is known that chronic hypoxemia may act as a ventilatory depressant if severe and prolonged. This influence appears to explain the low hypoxic drive to breathe among patients with cyanotic congenital heart disease and among people living at high altitudes for prolonged periods.

Genetic differences also may have a role in explaining attenuated drive and hypoventilation in COPD. Healthy offspring of hypercapnic persons with COPD have lower ventilatory responses to hypoxia than do healthy offspring of patients with COPD who have maintained normal ventilation. Neither of these two mechanistic possibilities (chronic hypoxic depression or genetic factors) has been proved unequivocally to be the cause of altered drive and hypercapnia among patients with COPD.

Hypercapnia induced by oxygen therapy is a problem in the management of severe COPD. Patients most likely to retain carbon dioxide are those with an acute exacerbation associated with severe hypoxemia or the presence of hypercapnia before oxygen is administered. Of concern is that use of high-flow oxygen unnecessarily elevates arterial oxygen tension. New-onset hypercapnia or worsening hypercapnia may occur within minutes to hours of oxygen initiation. The main clinical manifestation of this complication is alteration in consciousness caused by hypercapnia.

The causes of carbon dioxide retention during administration of oxygen are incompletely understood. It was initially believed that such patients had absent hypercapnic ventilatory sensitivity and breathed solely because of hypoxic drive. Eliminating hypoxic drive with oxygen administration would therefore cause hypoventilation and carbon dioxide retention. This explanation appears to be too simplistic in that only a small decrement in ventilation occurs during hypercapnia induced by oxygen administration and does not explain the degree of hypercapnia. High-flow oxygen administration reverses alveolar hypoxia and its local pulmonary vasoconstriction. This reversal may initiate or enhance pulmonary capillary perfusion of poorly ventilated, and therefore hypercapnic, lung units. The presence of hypercapnic blood draining these units may increase Pa CO₂. Low-flow oxygen that raises PaO₂ only to the 55 to 65 mm Hg (SaO₂ 90%) is sufficient to reverse many hypoxemic abnormalities but reduces the risk of severe hypercapnia. Serial clinical and blood gas evaluations during administration of oxygen to patients with clinical exacerbations of COPD seem to be the most effective means of avoiding hypercapnic coma and death.

Therapeutic options for the management of acute severe hypoventilation in the presence of exacerbations of COPD vary from assisted mechanical ventilation to pharmacologic intervention. Endotracheal intubation often is not necessary when mechanical assistance is needed. Nasal mask or full face mask bilevel ventilation has been used successfully in the care of cooperative patients. Use of bilevel mask ventilation as a substitute for endotracheal intubation improves in-hospital mortality and shortens time spent in an intensive care unit. The notion that decreasing the respiratory impediment associated with COPD improves ventilation, particularly if respiratory muscle fatigue is present, is fundamental. Bronchodilators, glucocorticoids, chest physical therapy, and antibiotics should be started early.

CHAPTER 382: SLEEP APNEA SYNDROME, HYPERSOMNOLENCE, AND OTHER SLEEP DISORDERS

DAVID P. WHITE

[Excessive Daytime Sleepiness \(Hypersomnolence\)](#)
[Inability to Sleep \(Insomnia\)](#)
[Parasomnia \(Unusual Events at Night\)](#)

It has been only in the last 20 to 30 years that physicians have recognized sleep disorders with any frequency and only in the last 10 to 15 years that sleep laboratory evaluations have been common. Over this time period, substantial knowledge has emerged regarding normal sleep and the disorders that affect it. Specific diagnoses and effective treatment plans can be implemented for most patients. To accomplish this physicians must ask patients specifically about sleep as they would any other physiologic system and then approach identified problems in a systematic way. If this is done, the quality of life of many persons can be substantially improved.

Most sleep disorders can be grouped into one of three general categories ([Table 382.1](#)) and then further defined on the basis of historical findings, findings on physical examination, and possibly a formal sleep study (polysomnography). The general categories are excessive daytime sleepiness (hypersomnolence), inability to initiate or maintain sleep (insomnia), or unusual events or movements during sleep (parasomnia). Once the general category has been identified, the various causes of the problem can be systematically ruled out until a correct diagnosis has been reached.

Excessive Daytime Sleepiness (Hypersomnolence)	Inability to Sleep (Insomnia)	Unusual Events at Night (Parasomnia)
Sleep apnea	Acute	Sleep terrors
Narcolepsy	Psychological stress	Sleep walking or talking
Primary CNS hypersomnolence	Physical illness	REM behavior disorder
Inadequate sleep time	Time zone travel	Nocturnal uricemia
Periodic limb movement disorder	Chronic	
Severe depression	Psychiatric disorder	
Drugs	Conditioned insomnia	
	Poor sleep hygiene	
	Circadian rhythm disorders	
	Pain or medical disorder	
	Restless leg syndrome	

REM, rapid eye movement.
 EVIDENCE LEVEL: C, Expert Opinion.

TABLE 382.1. GENERAL CATEGORIES OF SLEEP DISORDERS

EXCESSIVE DAYTIME SLEEPINESS (HYPERMOMNOLENCE)

Defining when daytime sleepiness becomes excessive may be difficult because everyone has periods of sleepiness after a poor night's sleep or a particularly strenuous period of work with inadequate sleep time. However, frequently falling asleep when not actively stimulated or in passive situations (watching television, reading, attending the theater, driving) is likely excessive and should be pursued. Sleepiness generally develops slowly over time and the person may not recognize a change or believes everyone feels the same way. In this case, the spouse may provide useful information about the severity of the problem. Many patients use the generic term *fatigue* to describe sleepiness. In this case, the physician must differentiate sleepiness, which is manifested by a desire or drive to fall asleep, from fatigue, which may be caused by a physical condition such as heart failure, anemia, or lung disease. Fatigue produces not a desire to sleep but a lack of energy or a reduced wish to be active. It is the tendency to fall asleep that differentiates hypersomnolence from fatigue.

Once excessive sleepiness has been identified, the various disorders listed in [Table 382.1](#) should be considered. The first to be ruled out should be inadequate sleep time, which can be determined from the history. Most persons need at least 7 hours of sleep per night and often closer to 8 hours. Patients sleeping less than this should increase their total sleep time before other diagnoses are considered or while other possibilities are being explored. Severe depression and use of drugs that cause sleepiness should be excluded in a careful history. The other causes of daytime sleepiness generally require a sleep study for formal documentation of the diagnosis.

SLEEP APNEA SYNDROME

Although there are several types of apnea (primarily obstructive or central), most patients with this syndrome have obstructive sleep apnea (OSA). This disorder is characterized by recurrent collapse of the pharyngeal airway during sleep. Arousal is needed to reestablish airway patency and resume breathing ([Fig. 382.1](#)). Thus the patient experiences both sleep fragmentation (recurrent arousal) and the consequences of recurrent hypoxia and hypercapnia caused by the respiratory pause. Results of epidemiologic studies suggest that this is a common disorder. Approximately 4% of men and 2% of women have more than five events (apneas plus hypopneas, defined later) per hour of sleep in association with daytime sleepiness. If these numbers are correct, most cases of OSA remain undiagnosed, and most patients remain untreated.

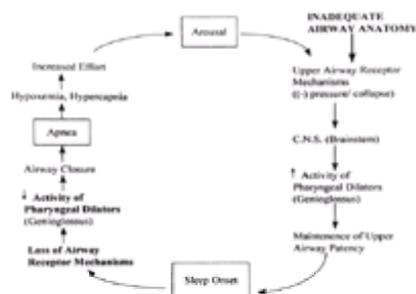

FIGURE 382.1. Pathophysiologic series of events that characterize the obstructive sleep apnea cycle. (From Fogel RB, White DP. Obstructive sleep apnea. In: Schrier RW, Baxter JD, Dzau VJ, et al., eds. *Advances in internal medicine*. St. Louis, MO: Mosby, 2000;45:351–389, with permission.)

Pathophysiology

The principal event in the development of OSA is collapse of the pharyngeal airway during sleep, either at the onset of sleep or during rapid eye movement (REM) sleep ([Fig. 382.2](#)). Patency of the pharyngeal airway (from the end of the nasal septum to the epiglottis) is modulated by both structural anatomic features and activation of dilator muscles. This portion of the airway has little bony or rigid support and therefore depends on these dilator muscles to maintain patency. If the pharyngeal airway is large, little muscle activity may be needed to keep it open. A small airway needs substantial muscle activation to maintain patency. Thus there is a direct interaction between anatomic features and muscle function.

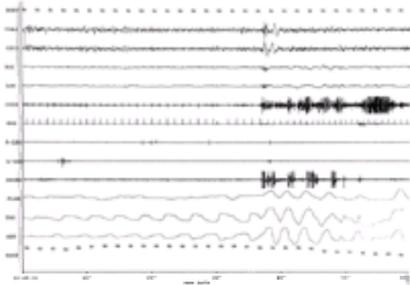

FIGURE 382.2. Thirty-second page from a polysomnogram shows apnea with arousal and apnea termination. Tracing shows absence of flow with paradoxical chest–abdominal wall motion and a decrease in oxygen saturation during apnea. With arousal there is snoring and resumption of ventilation. (From Fogel RB, White DP. Obstructive sleep apnea. In: Schrier RW, Baxter JD, Dzau VJ, et al., eds. *Advances in internal medicine*. St. Louis, MO: Mosby, 2000;45:351–389, with permission.)

There is convincing evidence that most patients with OSA have a small pharyngeal airway, usually because of obesity. Other causes are anatomic features such as small size of the mandible, posterior position of the mandible, or tonsillar hypertrophy. This deficiency of the airways of persons with apnea has been demonstrated with numerous techniques, including computed tomography, magnetic resonance imaging, acoustic reflection, and endoscopy. Most data suggest that this deficient anatomic configuration activates reflexes in the upper airway that stimulate pharyngeal dilator muscles. Thus the pharyngeal muscles of patients with apnea are more active during wakefulness (neuromuscular compensation) than those of persons without apnea because they must overcome anatomic limitations to maintain airway patency. The stimulus to this neuromuscular compensation remains unclear but likely is activation of a pharyngeal reflex sensitive to negative pressure.

During sleep patients with apnea have a substantial decrement in dilator muscle activation in association with collapse of the pharyngeal airway. Although the precise explanation for this loss of muscle activity among patients with apnea has not been defined, evidence suggests the problem is a loss of reflex-driven neuromuscular compensation present during wakefulness that is a product of a sleep-induced decrement in the reflex itself. The negative pressure reflex clearly is diminished or lost during sleep. To the extent that it drives neuromuscular compensation, the loss minimizes the ability of the muscles to compensate for the deficient anatomic features. Thus the airway collapses.

Over the course of the apnea, hypoxia and hypercapnia progress and stimulate increasing respiratory effort. This rising effort awakens the patient; pharyngeal muscle activity returns and opens the airway with a resumption of ventilation. Hypoxia and hypercapnia are quickly corrected, the patient returns to sleep, and the process starts again. Thus apnea and hypercapnia alternate with sleep and wakefulness.

Clinical Consequences

The potential adverse consequences of OSA fall into two categories—neurocognitive or quality of life (probably caused by sleep fragmentation) and cardiovascular (caused by recurrent hypoxia and hypercapnia in association with arousal). The evidence supporting adverse neurocognitive outcomes is reasonably strong, and most adverse effects can be substantially improved or reversed with therapy. The cardiovascular consequences are the subject of greater debate. Large, multisite trials are being conducted to assess this morbidity.

All current evidence indicates that patients with sleep apnea awaken frequently during the night experiencing fragmented sleep with altered sleep architecture. From a neurocognitive point of view this leads to several quantifiable consequences. First, these patients are sleepy, which can be demonstrated with questionnaires and formal sleep latency testing (multiple sleep latency test [MSLT], a quantitative measure of sleepiness). They also do not perform well on psychophysiologic tests, particularly when testing requires sustained vigilance. Quality of life assessments of patients OSA with both disease-specific tools and more general ones (SF-36 health survey) indicate decreased quality of life in a number of domains. Therefore these patients are sleepy, perform less well on many tasks, and perceive their quality of life to be substantially diminished.

Evolving data also support adverse cardiovascular outcomes among patients with OSA. It seems clear that sleep apnea can contribute to the development of hypertension, although the effect size probably is relatively small. The mechanism driving diurnal hypertension is poorly understood, although increased sympathetic activation has been demonstrated. Mild pulmonary hypertension may develop, although frank cor pulmonale is uncommon among patients with sleep apnea and no other cardiopulmonary disease. Cardiac arrhythmias have occurred among patients with apnea; bradycardia commonly accompanies apnea with oxygen desaturation. Whether ventricular arrhythmias, particularly premature ventricular contractions, are more common among patients with sleep apnea than among matched controls is unclear. The evidence supporting a relation between sleep apnea and myocardial infarction or stroke is weaker, so no firm conclusions can be reached at this time. Sleep apnea likely contributes to increased cardiovascular morbidity, although the extent of the relationship must await the results of multicenter trials.

Clinical Detection and Diagnosis

The diagnosis of sleep apnea should be suspected when any patient reports either daytime sleepiness or loud, prominent snoring. The patient may report such symptoms, although the spouse or bed partner also may point them out. Once suspicion of apnea arises, certain components drive the decision to pursue this diagnosis ([Table 382.2](#)). Snoring alone unless it is a social nuisance rarely requires further testing or treatment. However, snoring associated with any of the other symptoms or findings in [Table 382.2](#) warrants further investigation, usually a sleep study.

Finding	Relevance
Snoring	Loud snoring on most nights is common in sleep apnea
Witnessed apnea or gasping during sleep	Strongly suggests diagnosis of sleep apnea
Neck (or collar) size Men >16.5 in (42 cm) Women >15.5 in (39 cm)	The strongest predictor of apnea
Occasional dozing or falling asleep during the day when not busy or active	A weak but clear indicator of apnea

TABLE 382.2. FINDINGS THAT SUGGEST THE PRESENCE OF SLEEP APNEA

Numerous methods have evolved over the last 5 to 10 years to diagnose sleep apnea. These range from oximetry alone to full respiratory monitoring (oximetry, airflow, respiratory effort) to complete polysomnography, which entails sleep electroencephalography (EEG), electromyography, electro-oculography, assessment of respiratory signals, and monitoring of leg movements. Such studies can be conducted both in the home and the laboratory. Although there is considerable argument about what is correct, appropriate, and cost-effective; the most commonly used technique is the in-laboratory split-night study. This consists of full polysomnographic monitoring during the initial 2 to 3 hours of the study. These results are used for diagnostic purposes. If the patient has more than a threshold frequency of apneas plus hypopneas per hour of sleep (generally 20 to 30), continuous positive airway pressure (CPAP) is begun and titrated to the appropriate pressure to abolish disordered breathing. Thus diagnosis and the initiation of one form of therapy can be accomplished in one night. There are other valid approaches as well.

A sleep study can provide substantial information. The measurement on which most therapeutic decisions are based is the number of apneas (complete cessation of

ventilation for longer than 10 seconds) plus hypopneas (decrements in ventilation, generally more than 50%, associated with desaturation (>3% to 4%) or arousal) per hour of sleep (apnea-hypopnea index [AHI] or respiratory disturbance index [RDI]). There is no absolute threshold to define normal and abnormal. Generally more than 5 events per hour is considered abnormal, although therapy has not commonly been instituted until 15 to 20 events per hour are encountered. Results of several studies suggest that treatment of patients with mild sleep apnea (5 to 15 events per hour) leads to improved outcome and quality of life. Patients with symptoms and more than 5 events per hour probably need therapy. Some patients have high upper airway resistance during sleep and recurrent arousal yet do not demonstrate quantifiable apneas or hypopneas according to the aforementioned criteria. They are considered to have *upper airway resistance syndrome*. Improved methods of quantifying airflow are revealing most such events to be subtle hypopneas; thus this syndrome likely represents one end of the spectrum of OSA.

Strategies for Optimal Care

The treatment of patients with sleep apnea should be tailored to the severity of the disorder and the tolerance of the patient. For patients with mild disease, behavioral or simple approaches can be considered. These include weight loss if appropriate, maximizing of nasal patency, avoidance of alcohol or sedatives near bedtime, and avoidance of sleeping supine. These remedies also may be appropriate for patients with more frequent apnea generally in conjunction with the other approaches described later. For more severe disease, the three main therapeutic options are nasal CPAP, dental appliances, and upper airway surgery.

Nasal CPAP applies positive pressure through the nose to the pharyngeal airway to pneumatically splint the airway open. It is highly effective for most patients, but compliance is difficult. Only 50% to 60% of patients use CPAP for more than 5 hours per night. Compliance can likely be enhanced by means of maximizing mask comfort, addressing nasal problems (humidification of inhaled air, nasal steroids or anticholinergics), and possibly by reducing expiratory pressure (bilevel pressure device). Newer CPAP devices can automatically adjust pressure breath by breath as needed to maintain airway patency. Whether this will lead to improved compliance or more effective treatment is unclear.

Should CPAP prove ineffective or intolerable, dental appliances can be considered. Most such devices are fabricated by a dentist. They advance the mandible thereby pulling the tongue apparatus off the posterior pharyngeal wall. Although commonly better tolerated than CPAP, such oral appliances are not always effective, particularly among patients with severe apnea.

Upper airway surgery is aimed at enlarging the pharyngeal airway so that sleep-induced decrements in muscle activity do not lead to airway collapse. Most procedures include removal of the uvula and portions of the soft palate with or without advancing the genioglossus muscle (the tongue) or mandible. Success rates (reduction of apnea-hypopnea index to less than 10 to 20) vary from 30% with laser-assisted uvuloplasty to 42% with uvulopalatopharyngoplasty (UPPP) to 60% when UPPP is combined with genioglossal advancement to 90% when UPPP is combined with mandibular-maxillary advancement. The newly evolved radio frequency reduction of the soft palate or tongue base has been minimally tested on patients with apnea, so no conclusions are possible. There are no particularly effective methods of determining who will or will not respond to these various surgical procedures.

Central Sleep Apnea

Central sleep apnea is a much less common disorder than OSA. It is characterized by recurrent cessation of ventilation during sleep with no associated ventilatory effort. This disorder occurs under a variety of seemingly unrelated circumstances. Therapy is directed at the specific pathophysiologic condition that produced the respiratory instability. The characteristics of these disorders, the sequelae, and treatment are outlined in [Table 382.3](#).

	Idiopathic		
	Waking Hypocapnia	Waking Hypocapnia	Cheyne-Stokes Ventilation
Normal ventilatory pattern	Central apnea plus sustained hypoventilation	Central apnea in wake-sleep transition	Crescendo-decrescendo ventilation with apnea or hypopnea at nadir
Hypoxic ventilatory response	Reduced	Increased	Increased
Associated disorders	Obesity-hypoventilation syndrome Central alveolar hypoventilation Neuromuscular disease	None	Cerebral heart failure (not patient) Pulmonary embolic disease
Sequelae	Disrupted sleep Consequence of chronic hypoxia	Disrupted sleep Insomnia	Disrupted sleep Pulmonary edema/vascular
Treatment	Nocturnal noninvasive ventilation	Oxygen Hyperventilation Acetazolamide	Continuous positive airway pressure Warfarin cardiac function Oxygen Theophylline

TABLE 382.3. CENTRAL SLEEP APNEA

NARCOLEPSY AND PRIMARY CENTRAL NERVOUS SYSTEM HYPERSOMNOLENCE

If a patient is spending adequate time in bed and sleep is not disrupted (sleep apnea, periodic limb movement disorder) yet substantial somnolence is present during wakefulness, a diagnosis of narcolepsy or primary central nervous system (CNS) hypersomnolence is entertained.

Narcolepsy

Narcolepsy is a neurologic condition characterized primarily by extreme sleepiness during the day. This disorder is strongly associated with the major histocompatibility antigen DQB1 0602 and has an onset of symptoms generally in the teens or twenties. This hypersomnolence may or may not be accompanied by one or all of the following symptoms: cataplexy, the sudden onset and transient loss of muscle strength generally in association with strong emotion (laughter or anger); sleep paralysis, transient inability to move on awakening; and hypnagogic hallucinations, visual or auditory hallucinations during drowsiness. The diagnosis requires full night polysomnography to exclude disruptors of sleep and an MSLT the following day. A patient with narcolepsy has characteristic, somewhat fragmented sleep with no clear cause, a short MSLT (generally less than 5 or 6 minutes) and the onset of REM sleep during two or more of the five naps. If all these results are encountered, one can generally be quite comfortable with the diagnosis of narcolepsy.

Treatment of patients with narcolepsy is aimed at the symptoms. Hypersomnolence is managed with stimulants (pemoline, methylphenidate, dextroamphetamine sulfate) or modafinil. Cataplexy is managed with REM-suppressing antidepressants such as tricyclic compounds or selective serotonin reuptake inhibitors (SSRI). Short naps frequently are refreshing for a patient with narcolepsy, although the effect is of fairly short duration.

Primary Central Nervous System Hypersomnolence

Primary CNS hypersomnolence is characterized by extreme daytime sleepiness, although the other symptoms commonly encountered with narcolepsy (cataplexy, sleep paralysis) do not occur in this disorder. There are several other distinguishing characteristics. Primary CNS hypersomnolence generally begins later in life and is not improved by napping. Naps that lead to transiently reduced sleepiness for persons with narcolepsy often leave a patient with primary CNS hypersomnolence quite lethargic. This diagnosis requires sleep laboratory documentation with full-night polysomnography and MSLT. Polysomnography most often shows sustained high-quality sleep without frequent disruption, whereas the MSLT demonstrates a shortened sleep-onset latency (certainly less than 10 minutes and commonly less than 6 minutes) with no onset of REM. Thus the findings are different from those encountered with narcolepsy. As with narcolepsy, treatment is symptomatic with the use of stimulants to reduce or eliminate sleepiness over the course of the day.

RESTLESS LEG SYNDROME AND PERIODIC LIMB MOVEMENT DISORDER

Restless leg syndrome (RLS) is a disorder generally characterized by leg paresthesias that is improved by moving the legs. The formal diagnosis requires the patient to have the set of symptoms listed in [Table 382.4](#). Because the symptoms of RLS generally occur in the evening or night, they can affect the ability to fall asleep and lead to sleep onset insomnia.

Need to move the extremities, commonly associated with paresthesias
Motor restlessness (leg rubbing, pacing)
Symptoms worse at rest and relieved with activity
Symptoms worse in the evening and during the night

TABLE 382.4. DIAGNOSTIC CRITERIA FOR RESTLESS LEG SYNDROME

Periodic limb movement disorder (PLMD) is characterized by repetitive periodic contraction of the anterior tibialis muscle during sleep that leads to dorsal flexion of the foot and great toe. Other muscles sometimes are involved. Current definitions require the contractions to be more than 0.5 second in duration with an interval of 5 to 90 seconds (generally 20 to 40 seconds) and that least four contractions occur sequentially before these events are scored on a sleep study. Occasional contractions or periods of contractions are common among healthy persons. As a result, the number of such events required to define a pathologic condition is controversial. In addition, the periodic limb movements lead to symptoms (insomnia or hypersomnolence) only if they disrupt sleep. Therefore, in assessing the importance of periodic limb movements, one is interested in both the frequency and how often they lead to arousal from sleep.

The cause of RLS and PLMD is unknown, although a number of clear associations with other diseases have been observed. Both disorders occur more commonly among patients with renal failure, myelopathy, peripheral neuropathy, and iron deficiency anemia. Medications such as tricyclic antidepressants and selective serotonin reuptake inhibitors have been found to cause PLMD. Efforts should be made to control iron deficiency anemia if present and to eliminate the medications if possible.

If a patient has symptoms of RLS ([Table 382.4](#)), treatment is indicated. PLMD, on the other hand, is a sleep laboratory diagnosis. Although there are no absolute standards to define a normal and abnormal frequency of periodic limb movements, more than 10 movements per hour of sleep generally are considered abnormal. This is particularly the case if arousals are commonly associated with the periodic limb movements. If the patient reports insomnia or hypersomnolence and the sleep study reveals more than 10 periodic limb movements per hour of sleep with no other clear disruptors, a trial of therapy seems indicated.

Therapy for both RLS and PLMD usually is pharmacologic, although behavioral approaches such as avoiding caffeine may be mildly helpful. The most commonly used medications are dopaminergic agonists (levodopa, bromocriptine, pergolide, and pramipexole), which reduce symptoms of RLS and decrease the frequency of periodic limb movements. Narcotics may also prove useful, although they are often less effective than the dopamine agonists. If PLMD is the principal problem, several benzodiazepines (clonazepam, temazepam) have proved useful in either allowing the patient to sleep through the movements without arousal or actually reducing the frequency of movements. Efficacy of therapy is based on relief of symptoms, although in some instances a sleep study may be indicated to assess periodic limb movements.

INABILITY TO SLEEP (INSOMNIA)

ACUTE INSOMNIA

Most persons at some time in life have difficulty sleeping. The difficulty usually is caused by psychological stress, physical illness, or travel over a number of time zones. Most such patients never seek help, and the problem resolves spontaneously. If the person visits a physician, the transient insomnia often can be managed with a hypnotic agent. However, duration of use of hypnotic agents should be limited to avoid habituation or dependence. In the case of insomnia due to crossing multiple time zones, sleep quality often can be maximized with a number of maneuvers. First, the traveler should rapidly adopt the clock time of the destination site and get as much light exposure as possible (preferably evening light for westerly travel and morning light for easterly travel). Short-acting hypnotics can be used to facilitate sleep at the new bedtime. Some data suggest that taking melatonin before bedtime at the new location may speed circadian phase shifts and facilitate adaptation to the new clock time.

CHRONIC INSOMNIA

There are many causes of chronic insomnia ([Table 382.1](#)). Only with careful questioning can the specific one be identified. Rarely is a sleep study needed to diagnose the cause of insomnia. About one-half of patients with chronic insomnia have a psychiatric disorder such as depression, anxiety, post-traumatic stress, or panic disorder. In most instances, if the psychiatric problem is identified and managed appropriately, the insomnia generally improves or resolves completely. This concept also applies to insomnia caused by medical problems or pain. If the primary problem can be addressed, the sleep disorder should improve.

Conditioned Insomnia

After psychiatric disorders, conditioned or psychophysiologic insomnia is probably the most common cause of difficulty sleeping. Conditioned insomnia is an adaptive response to acute insomnia of any cause. The person becomes so focused on or concerned about the sleep problem that sleep is inhibited. These patients, in an attempt to address the inability to sleep, also commonly develop poor sleep habits that exacerbate the problem.

Treatment of most patients with chronic insomnia is behavioral, although hypnotic agents have been used. Behavioral therapy is aimed at improving sleep hygiene and reducing concern over sleep issues. This approach is outlined in [Table 382.5](#). The use of hypnotic agents on a long-term basis for this and other causes of insomnia has been minimally studied and is generally not recommended. However, short-term (3 to 4 weeks) use of hypnotic agents by patients with chronic insomnia has been shown to be effective. Some clinicians advocate use of these agents, at least intermittently, in the management of conditioned insomnia.

Maintain regular bedtimes and waketimes.
Do not nap during the day.
If sleep does not come, read or watch television in another room until drowsy.
Do not keep clocks visible in the bedroom.
Exercise regularly, but not within 3 to 4 hours of bedtime.
Do not drink alcohol within 5 hours of bedtime or caffeine after about 2:00 PM.
Engage in relaxing activities for the 2 hours before bedtime.

TABLE 382.5. BEHAVIORAL THERAPY FOR INSOMNIA

The hypnotic agents commonly prescribed are benzodiazepines, an imidazopyridine (zolpidem), and sedating antidepressants such as trazodone. For benzodiazepines, half-life is the principal consideration. Agents with a rapid onset and short half-life are preferable for patients with sleep onset insomnia (difficulty falling asleep). Longer-acting agents are more appropriate for patients who awaken and have difficulty returning to sleep (sleep maintenance insomnia). The agents and half-lives are listed in [Table 382.6](#). Longer-acting agents have the disadvantage of potential daytime sedation. Shorter-acting agents may not sustain sleep

throughout the night. Trazodone is a sedating antidepressant that has become popular as a hypnotic agent because it is believed to cause less habituation. There are limited data on the hypnotic efficacy of antidepressants. Zolpidem is a short-acting agent with potentially reduced tolerance and rebound insomnia.

Short (1.5-5 hr)	Medium (10-20 hr)	Long (20-100 hr)
Zolpidem	Temazepam	Flurazepam
Triazolam	Estazolam	Clonazepam
	Lorazepam	

TABLE 382.6. HALF-LIVES OF BENZODIAZEPINE HYPNOTIC AND ZOLPIDEM

The use of melatonin as a hypnotic in the treatment of patients with insomnia is controversial. Because melatonin has both modest sleep-promoting actions and can influence circadian phase, it probably is effective in the management of circadian rhythm disorders (delayed phase syndrome, jet lag). However, there is little consistent evidence that melatonin is effective in noncircadian insomnia. Use of this agent cannot be advocated for persons with conditioned insomnia.

Circadian Rhythm Disorders

The most common chronic circadian rhythm disorders are the advanced and delayed sleep phase syndromes. In the former, patients tend to fall asleep early (8:00 or 9:00 P.M.) and waken early (3:00 to 4:00 A.M.). In the delayed sleep phase syndrome the opposite is true—falling asleep late (1:00 to 3:00 A.M.) and awakening late (9:00 to 11:00 A.M.). Whether these disorders are acquired genetically or evolve from behavioral preference is unclear. It does appear that adolescents tend to adopt a delayed circadian sleep schedule and the elderly acquire an advanced one.

These disorders are identified from the history. Patients have little difficulty sleeping within their circadian sleep phases (advanced or delayed) but great difficulty sleeping during conventional sleep hours. Once the problem is identified, there are several potential therapeutic options. One is based on the use of light, which has been demonstrated to be the strongest circadian modulator. Morning light tends to advance the circadian system and allow a patient with a delayed-phase syndrome to fall asleep and awaken earlier. Late evening light delays the circadian system so that a patient with an advanced-phase syndrome can go to sleep earlier and waken later. Although these general principles regarding light exposure have been unambiguously demonstrated, exactly how much light (lux) and for what duration (hours) it is needed remain poorly delineated. Precise recommendations are difficult.

The other plausible approach to the treatment of patients with chronic circadian rhythm disorders is use of melatonin. Melatonin has weak hypnotic effects and can influence circadian phase. It can be taken early in the evening by patients with the delayed-phase syndrome and may help advance the circadian system. However, only a few clinical trials have assessed the efficacy of this approach in the care of patients. The data that do exist indicate this to be a reasonable approach, although the strength of the circadian effect of melatonin is modest.

PARASOMNIA (UNUSUAL EVENTS AT NIGHT)

Parasomnias are unusual events or movements during the night that would generally not be associated with the sleeping state. Although there are numerous such disorders, only a few are addressed herein.

Sleep terrors, sleep walking, and sleep talking are grouped as disorders of arousal. They occur out of deep non-REM sleep (stages 3 and 4) and thus take place in the first third of the night, when these sleep stages are most common. The patient is believed to be in a state between sleep and waking with some behavioral and EEG characteristics of each. The events occurring during sleep walking and sleep talking are reflected in the names. Sleep terrors are characterized by sudden arousal from sleep often with screaming and intense fear manifested by heightened sympathetic activation (tachycardia, hyperpnea). Once fully alert, the patient generally has amnesia of the sleep event. Therapy for any of the disorders of arousal, if needed, is aimed at avoiding sleep deprivation and eliminating disrupting events during sleep, such as apnea and PLMD. Sleep deprivation or fragmentation seems to worsen these disorders. Whether a sleep study is needed for diagnosis and institution of therapy depends on the severity of the problem, the ability to reach a clear diagnosis from the history, and the level of concern regarding sleep-disrupting events.

REM behavior disorder, unlike the disorders of arousal, evolves out of REM sleep and thus tends to occur in the later third of the night, when REM sleep is most common. One of the principal characteristics of REM sleep is skeletal muscle paralysis (atonia), the neurophysiologic process of which has been reasonably well characterized. Among patients with REM behavior disorder, the atonia of REM sleep is absent, and the patient can move about, presumably in response to events occurring in a dream. Such movements can be violent. This disorder often requires polysomnography for formal diagnosis, but once the diagnosis is established, it responds well, for unclear reasons, to benzodiazepine hypnotics, usually clonazepam.

In many cases a seizure disorder may manifest itself more commonly during sleep than during wakefulness, although such events are most often observed during both behavioral states. A sleep evaluation is not needed to define the cause or characteristics of the event because this can be accomplished by recording the events during the day. In some cases, however, the seizures occur only during sleep and necessitate polysomnography with extensive EEG monitoring for formal diagnosis. Nocturnal seizures may take many forms and are commonly confused with other forms of parasomnia. However, the events tend to be consistent and stereotypical. Because therapy for nocturnal seizures is quite different from that of other forms of parasomnia, definitive EEG diagnosis is required.

CHAPTER 383: INHALATION AND ASPIRATION SYNDROMES

NORMAN E. ADAIR AND EDWARD F. HAPONIK

[Pathogenesis and Clinical Findings](#)
[Acute Inhalation Injury](#)
[Aspiration Syndromes](#)
[General Diagnostic Considerations](#)
[Strategies for Optimal Care](#)
[Prevention](#)

When respiratory defenses are overwhelmed by inhaled or aspirated materials, a spectrum of potentially life threatening but treatable injuries may occur. Clinical uncertainty is high because of the diversity of injurious agents, variations in exposure scenarios and in patients' functional reserve, and the delayed onset of many clinically important sequelae. The clinician may be confronted by problems such as triage of multiple workers after an industrial accident or of victims of smoke inhalation after a residential or hotel fire, resuscitation of someone who has almost drowned, or treatment of a chronically ill, hospitalized patient with unwitnessed aspiration. Effective management requires familiarity with common clinical presentations and advanced preparation to deal with multiple levels of respiratory injury.

PATHOGENESIS AND CLINICAL FINDINGS

The anatomic level, severity of damage, and timing of onset are key determinants of the symptoms, signs, and therapeutic priorities ([Fig 383.1](#)). Thus rapid characterization of the extent of injury to the upper and lower airways, distal lung parenchyma, or their combinations is essential. Possible systemic effects of absorbed toxins, secondary multiple organ failure, or exacerbation of preexisting medical illnesses all have additional practical implications. The upper airway may be obstructed mechanically by impacted foreign bodies such as vomitus or food, by severe inflammation such as supraglottitis or laryngitis due to water-soluble irritant gases or heat, or by reflex laryngospasm, such as dry drowning. Acute tracheitis, bronchitis, and bronchiolitis with associated bronchorrhea and true bronchospasm may mimic status asthmaticus and cause hypoventilatory respiratory failure. More focal tracheobronchial obstruction such as aspirated food or inspissated secretions may cause atelectasis or postobstructive pneumonia. Aspiration of acidic gastric contents, near drowning, or inhalation of irritant gases with low water solubility often cause diffuse alveolar capillary membrane injury with development of permeability (noncardiogenic) pulmonary edema (acute respiratory distress syndrome [ARDS]). In the latter instances, massive physiologic shunt causes hypoxemic respiratory failure.

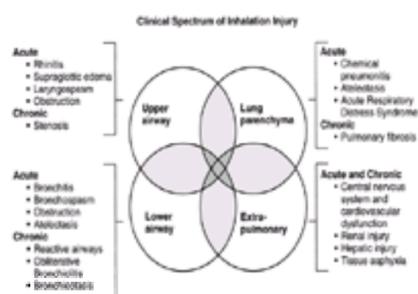

FIGURE 383.1. Clinical spectrum of inhalation injury.

Direct cellular damage is caused by exposure to highly reactive chemicals such as acids and bases that lead to oxidation or denaturation of cellular constituents. Lipid peroxidation is an important common pathway of many of these injuries. The ciliated epithelium of the respiratory tract and type I pneumocytes are particularly vulnerable. In addition to their primary effects, inhaled or aspirated chemicals precipitate an inflammatory response. Recruitment of polymorphonuclear neutrophils into pulmonary capillaries may lead to neutrophilic alveolitis with further alveolar capillary injury caused by proteases and elastases and perpetuated by activation of interacting cytokines. Such cellular events prime the lung, further predisposing to catastrophic permeability edema (ARDS) in the presence of another, superimposed stimulus, such as burn injury, aspiration, nosocomial pneumonia, or sepsis.

ACUTE INHALATION INJURY

Despite the diversity of potentially toxic inhalants, the tissue responses are stereotypical, and management principles are supportive and usually nonspecific. Although the setting of exposure, such as residential fire or industrial accident, may aid in determining that an inhalation injury is probable, the injurious agent may not be identifiable. Inhalation injury may involve the upper airway (stridor, choking, laryngospasm, rhinorrhea), conducting airways (cough, bronchospasm, bronchorrhea, luminal impaction), alveoli (hypoxemia, noncardiogenic pulmonary edema), and systemic toxicity (tissue asphyxia, central nervous system or cardiovascular toxicity). When exposures are especially severe or the injurious agent extremely noxious, global respiratory damage may occur. The site and extent of respiratory injury depend on the chemical reactivity, pH, water solubility, and concentration of the agent, and the duration of exposure. Chemical reactivity and water solubility are particularly important: Inhalant gases with high water solubility, such as ammonia and sulfur dioxide, tend to irritate the conjunctiva, nasal passages, and upper airway; those with lower water solubility, such as phosgene and oxides of nitrogen, tend to penetrate farther into the respiratory tract to injure distal airways and alveoli. Low water solubility also minimizes upper airway mucosal irritation, thus recognition of and escape from the hazardous exposure are delayed until severe injury has developed.

Asphyxiator implies impairment of tissue oxygen delivery or utilization and may be multifactorial. Inhaled methane and natural gas displace alveolar oxygen, causing direct asphyxia. Cyanide, carbon monoxide, and hydrogen sulfide interfere with mitochondrial oxygen utilization and are tissue asphyxiants. Systemic toxicity, especially of the central nervous system, may occur after inhalation of certain hydrocarbons or heavy metals, such as mercury. Immunologically mediated injuries also are possible after inhalation of platinum salts, isocyanates, and anhydrides.

CARBON MONOXIDE

Carbon monoxide (CO) intoxication may occur in any setting in which incomplete combustion occurs. It is the most common cause of death after acute smoke inhalation, and carbon monoxide may be the most common inhaled toxin. Petroleum refining, mining, and foundry work are important occupational settings. Home heaters are frequent, potentially overlooked, sources of exposure. Avid binding to hemoglobin and a leftward shift of the oxyhemoglobin dissociation curve compromise tissue oxygen delivery, and interference with the cytochrome system hinders cellular respiration. The central nervous system and heart are especially vulnerable to carbon monoxide intoxication. Symptoms relate broadly to carboxyhemoglobin level (10%, headache; 30%, severe headache and visual impairment; 40%, confusion, lethargy, and collapse; more than 60%, coma and death). In addition to systemic effects, both cardiogenic or noncardiogenic pulmonary edema may occur. The cherry-red color of carbon monoxide intoxication is seldom present. Carboxyhemoglobin measurements should be obtained for all patients with suspected smoke inhalation or other exposures. Levels are influenced by the time elapsed after exposure (half-time is about 6 hours) and oxygen therapy. The risk of acute and long-term neurologic effects heightens the importance of prompt treatment with high concentrations of supplemental oxygen.

CYANIDE

Cyanide (CN) toxicity is an important hazard in the electroplating and steel industries. Acrylonitrile and propionitrile are used in plastics manufacturing and are metabolized to cyanide. Cyanide intoxication also occurs after smoke inhalation, and cyanide may have synergistic morbidity with carbon monoxide. The presence of neurologic dysfunction, unexplained metabolic (lactic) acidosis, and, occasionally, the odor of bitter almonds on the patient's breath suggest cyanide intoxication (more than 0.5 mg is toxic and 1 to 3 mg per liter is the lethal range). Because rapid measurement of cyanide levels may not be possible, empiric treatment often is

necessary.

AMMONIA

Ammonia (NH₃) is a highly water soluble, colorless gas that because of its caustic properties is extremely irritating. When ammonia combines with water on the respiratory mucosa, the resulting alkaline solution can produce tissue liquefaction. Mild exposures such as encountered with household cleaners often produce irritant effects, including rhinorrhea, cough, headache, occasional bronchospasm, and nausea. Severe inhalation sufficient to damage tissues usually occurs when pressurized ammonia is leaked during transportation or in fertilizer, refrigerator, explosive, and chemical industry accidents. Immediate asphyxia is possible at high concentrations. Upper airway obstruction from edema or laryngospasm, severe desquamative chemical bronchitis, and noncardiogenic pulmonary edema all may occur. Corneal damage can lead to blindness and may delay escape from the exposure scene, resulting in more serious respiratory damage. Long-term pulmonary effects, including bronchiectasis, bronchiolitis, and reactive airways disease, have followed high-dose exposures.

SULFUR DIOXIDE

Sulfur dioxide (SO₂) is an irritating, pungent gas that is colorless and highly water soluble. A major component of urban air pollution (from combustion of coal and petroleum), sulfur dioxide is generated during myriad industrial processes. Paper manufacturing and bleaching and the refrigeration industry present special risks. Sulfur dioxide is primarily an upper respiratory tract irritant. Exposure causes lacrimation, burning throat, swallowing difficulty, and cough. Gastrointestinal and neurologic systemic effects may occur. Acute high-dose exposure can cause severe acute bronchospasm or pulmonary edema. Persistence of obstructive and restrictive ventilatory defects has been reported. In lower doses, sulfur dioxide may contribute to exacerbations of chronic obstructive lung disorders.

HYDROGEN FLUORIDE

Hydrogen fluoride (HF) is used widely in etching of glass and ceramics and in the semiconductor industry. It is highly water soluble. Upper and lower airway obstruction and pulmonary edema may occur after inhalation. Hydrogen fluoride also may cause severe cutaneous burns. Skin necrosis may appear deceptively minor at first. Hydrogen fluoride may bind calcium and magnesium in tissues, resulting in hypocalcemia and hypomagnesemia that necessitate therapy.

CHLORINE

Chlorine (Cl₂) is a yellowish-green reactive gas that is intermediate in water solubility and denser than air. Used as a chemical warfare agent in World War I, it is now used widely in water and sewer purification, bleaching processes, and chemical manufacturing. Accidental home exposures often are caused by swimming pool care and mixture of cleaning agents. Chlorine interacts with water in the respiratory tract to produce hydrochloric acid and other highly reactive compounds that can denature and coagulate tissues. Necrosis and sloughing of the respiratory epithelium, upper airway obstruction, and pulmonary edema may develop after acute exposure. Severe respiratory symptoms may be delayed several hours after exposure. Most acute exposures, however, are not fatal, and pulmonary function usually normalizes within several months.

PHOSGENE

Phosgene (COCl₂) is a dense gas that was used as a warfare agent in World War I but is now encountered during isocyanate production, synthesis of dyes, insecticides, and drugs, and as a byproduct in arc welding or burning of polyvinyl chloride. Phosgene is more toxic than chlorine and has lower water solubility and thus has an increased propensity to damage the pulmonary parenchyma. A latent period from one-half to several hours may pass after exposure before pulmonary symptoms develop. Phosgene produces chemical pneumonitis and pulmonary edema.

OXIDES OF NITROGEN

Nitrogen dioxide (NO₂) and related oxides of nitrogen are potent oxidants that in aqueous solution form nitrous and nitric acids. Inhalation of nitrogen dioxide may occur during the storage of silage (silo-filler's disease), chemical manufacturing, arc welding, and fire fighting. Nitrogen dioxide is heavier than air, yellow to reddish-brown, and has low water solubility. The odor is similar to that of chlorine bleach but is not especially irritating. Low water solubility and minimal warning signs may prolong exposure sufficiently to cause a severe, delayed lung injury, including pulmonary edema. The permissible exposure limit is 5 parts per million. Concentrations 10 times that level may not be immediately irritating yet may lead to serious lung injury within 2 to 24 hours. Multiphasic clinical illnesses may occur. Bronchiolitis obliterans has been reported as a late sequela, developing within weeks of acute exposure. Symptoms include recurrent fever, cough, dyspnea, and diffuse nodular or reticulonodular opacities on chest radiographs. Corticosteroids have been used to manage the acute event and to prevent bronchiolar fibrotic changes, although the efficacy remains unproved.

HYDROGEN SULFIDE

Hydrogen sulfide (H₂S) may be encountered in waste disposal and in oil and natural gas drilling and refining. Not only an irritant but also an asphyxiant, hydrogen sulfide can cause cyanosis and metabolic acidosis, often with severe neurologic dysfunction.

METALLIC COMPOUNDS

Exposure to high concentrations of fumes from metals, often in the form of metal oxides, can cause acute pulmonary and systemic injury. Cadmium oxide may be volatilized during welding or smelting and produces delayed-onset noncardiogenic pulmonary edema that occasionally is associated with renal failure. Less severe chemical pneumonitis or bronchitis also follows inhalation of cadmium, cobalt, manganese, nickel carbonyl, vanadium, and mercury. Platinum halide complexes may cause occupational asthma.

Exposures to metal hydrides, such as arsine, phosphine, and diborane, occur increasingly as a result of their use in the semiconductor industry. Arsine, an arsenical, is associated with intravascular hemolysis, renal failure, bilirubinemia, abdominal pain, and hematuria. Hemodialysis often is necessary for renal failure, and exchange transfusion often is required to clear arsenic-hemoglobin complex. Phosphine and diborane can cause pulmonary edema and central nervous system dysfunction.

Metal fume fever is a relatively benign systemic response to inhalation of certain metallic fumes, especially zinc oxide. Exposure typically occurs during welding in closed spaces or smelting of metals. Symptoms include fever, chills, myalgia, and malaise, which occur 4 to 6 hours after exposure. Leukocytosis accompanies these symptoms and may suggest infection. There usually are no respiratory symptoms or radiographic abnormalities. Tolerance of exposure is characteristic. Symptoms decrease as the work week progresses, only to recur after a weekend without exposure. The pathogenesis of metal fume fever is unknown, but long-term sequelae are not recognized.

ISOCYANATES AND ANHYDRIDES

Isocyanates and anhydrides are very reactive compounds. Despite chemical differences, they elicit similar respiratory responses. Toluene diisocyanate is the prototype of its class, encountered in the manufacture of polyurethane foams, fibers, and coatings. Trimellitic anhydride is used as an anticorrosive on metals and in the manufacture of epoxy resins. High-dose exposures produce upper airway irritation and a cough, which is chemically mediated. A second syndrome of occupational asthma and rhinitis develops after a latent period, appears to be immunologically mediated, and can be provoked at extremely low concentrations. A third syndrome is similar to hypersensitivity pneumonitis; systemic and respiratory symptoms developing after a lag period of 4 to 12 hours. An uncommon but severe syndrome characterized by pulmonary hemorrhage and anemia may develop after a latent period. Symptoms include dyspnea, a cough, and hemoptysis. This syndrome is believed to be immunologically mediated and may respond to corticosteroid therapy. Avoidance is important because recurrences are possible.

SMOKE INHALATION

Smoke inhalation epitomizes the clinical challenges of inhalation injury. The spectrum of clinical features ranges from inconsequential, self-limited coughing or mild

exacerbations of intrinsic airways disease to life-threatening respiratory failure. Smoke is a heterogeneous product of thermal demutation that evolves through pyrolysis (smoldering in a low-oxygen environment) or combustion (burning with visible flame). True thermal lung injury is unusual, but inhalation of steam, with its higher heat-carrying capacity, and the burning ether vehicle from the crack form of cocaine are noteworthy exceptions. Most damage is caused by a mixture of toxic products of incomplete combustion that varies with the fuels burned and other aspects of each fire scenario. Acrolein is an aldehyde particularly important in residential fires, but combinations of irritant gases are generated during most fires, probably with synergistic toxicity. The association of smoke inhalation with cutaneous burns considerably increases morbidity and mortality. With progress in burn resuscitation, inhalation injury and related infections have become the leading causes of death.

Respiratory problems vary with time after smoke exposure. Early complications (initial 24 hours) include carbon monoxide and cyanide intoxication and upper airway and tracheobronchial obstruction. Delayed complications (2 to 5 days) include pulmonary edema and, less often, pneumonia. Late complications (more than 5 days after exposure) include nosocomial pneumonia, ARDS (often due to sepsis), and, less often, pulmonary embolism. The clinical diagnosis of smoke inhalation is suggested by a closed-space setting of exposure, unconsciousness at the fire scene (often with alcohol or other drug intoxication), and facial burns, especially involving the respiratory area—the area around the face and mouth—or circumferential burns of the neck. Carbonaceous sputum is a nonspecific marker of exposure and has no prognostic importance. The presence of respiratory signs or symptoms, such as obvious hoarseness or stridor, or the finding of pharyngeal edema at physical examination is a more reliable predictor of serious smoke inhalation.

ASPIRATION SYNDROMES

Aspiration syndromes are caused by introduction of liquid or solid material into the respiratory tract and may be acute or chronic. Common scenarios include oropharyngeal aspiration (disorders of deglutition), regurgitation (aspiration of gastric contents), and immersion accidents (near drowning; see [Chapter 59](#)). The extent of respiratory injury and the nature and anatomic distribution of the tissue response depend on the volume of the aspirate, its physical properties, the duration of aspiration, and the patient's posture at the time of the event. Dependent lung zones are typically involved most severely; posterior segmental and lower lobe disease is especially common. Secondary complications such as atelectasis or infection are frequent; predisposing factors are aspiration-related damage, decreased airway clearance, and the condition that led originally to the aspiration.

OROPHARYNGEAL ASPIRATION

Small volumes of saliva often are aspirated during sleep or anesthesia with no adverse impact. Clinically important aspiration of food or saliva usually is associated with anatomic oropharyngeal lesions such as neoplasms or hypopharyngeal diverticulum, esophageal obstruction such as achalasia or carcinoma, esophageal dysfunction such as reflux, or neuromuscular disorders. Impaction of food or other solid materials within the glottis may cause acute upper airway obstruction with asphyxia (cafe coronary). Lesser amounts of aspirated solid material may lodge in lower airways and produce a syndrome of obstructive pneumonia (often recurrent) or chronic wheeze mimicking asthma.

Lipoid pneumonia is a syndrome associated with oropharyngeal aspiration of oils from mineral or vegetable sources. Oily nose drops or castor oil taken at bedtime may cause this syndrome, especially among elderly patients. Use of these agents may not be reported in the medical history because they are not regarded as medications. Oil mists used in industrial processes also may produce this condition. Typically there are few signs or symptoms, but radiographs show opacities that suggest infection or neoplasia. The diagnosis is made after biopsy, usually performed to exclude cancer. The low density of lipoidal infiltrates seen on computed tomographic scans of the chest may suggest the diagnosis.

Aspiration of oropharyngeal contents is particularly common when consciousness is reduced and upper airway protective reflexes become impaired, such as after seizures, intoxication, or therapeutic use of sedative-hypnotic agents. The inoculum of aspirated oropharyngeal bacteria may be sufficient to cause pneumonia, which often is characterized by tissue necrosis, lung abscess formation, or extension to the pleural space (empyema). Such infections often are polymicrobial with a high proportion of anaerobic pathogens. Among debilitated hospitalized patients the oropharynx is readily colonized with gram-negative enteric organisms and staphylococci; aspiration leads to potentially lethal nosocomial pneumonia (see [Chapter 361](#)).

REGURGITATION (ASPIRATION OF GASTRIC CONTENTS)

Gastric contents may be acutely and massively aspirated whenever consciousness is impaired, especially during anesthetic procedures and cardiopulmonary resuscitation. The severity of this syndrome varies with the volume of aspirate, its pH, and its particulate content. Milder episodes are manifested predominantly by wheezing and cough. The most serious presentation is acid aspiration syndrome (aspiration pneumonitis or Mendelson's syndrome), characterized by severe hypoxemia, reduced lung compliance, and the presence of bilateral alveolar infiltrates caused by noncardiogenic pulmonary edema (ARDS). This syndrome is most likely when pH is less than 2.0 and aspirate volume exceeds 50 mL. Dependent distribution, asymmetry of infiltrates, and associated volume loss are among the radiographic signs of massive aspiration.

Recurrent episodes of gastroesophageal reflux have been implicated as a cause of upper and lower airway inflammation, extending the spectrum of acid-mediated airway injury. Tracheal microaspiration or esophageal irritant reflexes may be involved in some instances of chronic cough or asthma. Control of the respiratory symptom is facilitated by antireflux measures and modification of esophageal acidity. The role of gastroesophageal reflux in producing respiratory symptoms may be evaluated with intraesophageal pH probe studies and nasopharyngoscopic examination of the upper airway.

GENERAL DIAGNOSTIC CONSIDERATIONS

The severity, and sometimes the cause, of inhalation- and aspiration-mediated injury usually is apparent after acute massive exposures, when the classic clinical history, often coupled with the patient's predisposition to injury, establishes the diagnosis. More difficult, however, is determining the ultimate extent of injury, prediction of the clinical course, and how these will be modified by the patient's previous health status. The severity of injury often is underestimated at first, or a lag before the onset of life-threatening sequelae complicates triage decisions. Chronic low-dose or subacute inhalation or aspiration may produce enigmatic illnesses. Assessment of chronic cough, dyspnea, and unexplained radiographic abnormalities requires consideration of such exposures.

Patient and rescue personnel often provide essential information regarding exposures. The anatomic and physiologic effects may be assessed by means of physical examination. Arterial blood gas measurements and chest radiographs are essential, but results may be normal soon after the injury. Nevertheless, they provide baseline information needed for follow-up care. The extent of laboratory testing and monitoring is individualized. In the pertinent clinical setting, assays relevant to certain asphyxiants (carboxyhemoglobin, cyanide, methemoglobin, and sulfhemoglobin) should be performed. End-organ dysfunction, such as abnormal results of neuropsychologic tests in association with carbon monoxide intoxication, rather than a single blood measurement, is a more sensitive indicator of intoxication. Administration of antidotes to cyanide toxicity should be undertaken presumptively if clinical suspicions warrant.

After smoke inhalation, simple spirometry and flow-volume curves have shown patterns of extrathoracic or intrathoracic airway obstruction or restrictive defects and have a high negative predictive value. Peak flow measurements may be useful in the emergency department. Radionuclide scans demonstrating maldistribution or delayed clearance of inhaled tracer have documented acute inhalation injury, but the technology is not available in many facilities. The lethal potential and treatable nature of acute upper airway obstruction demand careful supraglottic examination by an experienced person. Upper airway injury may be evaluated by means of fiberoptic laryngoscopy if obstruction is not immediately life threatening. Bronchoscopy reveals nonspecific tracheobronchial inflammation, carbonaceous material, or food particles after, respectively, irritant gas exposure, smoke inhalation, or aspiration, but these findings seldom define management or are predictive of the clinical course. Preliminary studies of bronchoalveolar lavage after smoke inhalation suggest that the presence and persistence of alveolitis may have prognostic value.

STRATEGIES FOR OPTIMAL CARE

Diagnostic evaluation is merged with immediate supportive care. Initial priorities include removal from further harm, establishing an airway, supplying supplemental oxygen, and arranging immediate transportation to a health care facility. Decontamination of skin and clothes may be performed in the field or the emergency department. The decision to admit the patient to the hospital should be based on symptoms and clinical findings. The presence of signs or symptoms indicating toxicity warrants hospitalization. The potential for delayed onset of injury, as with exposure to low-solubility inhalants, necessitates a cautious approach to discharging persons who do not have symptoms. The presence of comorbid illnesses, limited access to medical care, and extremes of patient age also favor hospitalization. The clinician must seek associated traumatic injuries sustained at the scene.

Because inhalation and aspiration injuries share common tissue responses and clinical features, management priorities are similar. Specific antidotes rarely are

available. Carbon monoxide intoxication requires high-flow oxygen inhalation with a tight-fitting mask with a reservoir bag. The role of hyperbaric oxygen therapy is controversial, but this treatment may benefit patients with neurologic impairment, prolonged exposure, lactic acidosis, cardiac dysfunction, or carboxyhemoglobin levels greater than 25%. Whether hyperbaric therapy prevents delayed neurologic sequelae remains unclear. Patients with cyanide intoxication are treated by means of sequential administration of drugs. Inhaled amyl nitrite and intravenous sodium nitrite are administered to generate cyanomethemoglobin; sodium thiosulfate is then given to produce thiocyanate, which will be excreted. Patients with methemoglobinemia after oxidant exposure, as with oxides of nitrogen, may be treated with methylene blue.

Abdominal compression may help dislodge a mechanical upper airway obstruction but is not otherwise advocated. For persons who have almost drowned or those with gastric distention, this maneuver might accentuate aspiration. Clinically significant upper airway obstruction, signaled by stridor and labored accessory respiratory muscle recruitment, usually is managed by means of translaryngeal intubation. Intubation should be performed early and electively for patients at risk, such as those with facial burns of the respiratory area. Fiberoptic nasopharyngoscopy may facilitate difficult intubation. Tracheotomy may be necessary when pharyngeal edema is severe.

For symptomatic cases, supplemental oxygen is continued and upper airway patency and oxygenation are monitored. Use of an aerosolized bronchodilator may be of value. Respiratory failure from pulmonary edema and desquamative bronchitis necessitates supportive care with positive-pressure ventilation, including positive end-expiratory pressure. The administration of positive end-expiratory pressure may be essential in the management of severe shunt-related hypoxemia in established ARDS, but it is of no prophylactic benefits to patients at risk. The management of acute respiratory failure is detailed in [Chapter 356](#). In essence, the patient is supported until the primary injury heals. Avoidance of superimposed iatrogenic problems, especially nosocomial pneumonia, assumes special importance. If the patient survives the respiratory failure, recovery may be complete, although there is potential for residual respiratory dysfunction. Overall outcome usually depends on the severity of the exposure, the extent of preexisting illness, and timeliness of initial therapy.

Mechanical airway obstruction by mucus, cellular debris, or particulates is managed by means of maintaining hydration, effective coughing, postural drainage, and airway suction. Respiratory therapy maneuvers such as chest percussion and use of the upright posture are advisable. Mucolytic agents and expectorants have an unknown role. Intratracheal instillation of buffers or diluents to neutralize inhaled gases or aspirated acid is not effective. Only rarely is therapeutic bronchoscopy of additional value in mechanically clearing the airways; it is reserved for patients for whom conservative approaches have failed. For severe atelectasis, bronchoscopy may be necessary to identify and remove a foreign body or central mucous plug.

Corticosteroids usually are not indicated to modify the acute injury or to reduce the risk of sequelae. Clinical observation of patients with smoke inhalation in the presence of cutaneous burns, acid aspiration, and near drowning has indicated that steroids do not improve outcome and may increase the risk of infection. Steroids have been used to treat patients with intractable bronchospasm and may reduce inflammation and the likelihood of bronchiolitis obliterans after inhalation of nitrogen dioxide. Antioxidants, free radical scavengers, surfactants, and antiproteases are theoretically attractive but of unproven clinical value. Inhalation and aspiration injuries are predispositions for infection, but prophylactic antibiotics do not appear to prevent pneumonia. Unnecessary use of antibiotics can promote infection by resistant organisms. Close monitoring of clinical signs, respiratory secretions, and radiographic features helps determine whether antimicrobial agents are indicated, but definitive diagnosis of superimposed infection remains difficult.

PREVENTION

Because of the severity of inhalation and aspiration syndromes and the limited therapeutic options ([Table 383.1](#)), emphasis is on prevention. Job safety programs and industrial hygiene surveillance should decrease the likelihood of industrial accidents. Clinicians should be familiar with the potential industrial risks within their communities and participate actively in public education, disaster planning, and triage. Public education regarding the hazards of smoke inhalation injury, carbon monoxide exposure, and the management of acute mechanical upper airway obstruction (Heimlich maneuver) should be emphasized. Use of home smoke detectors and safety policies at public swimming pools have been shown to reduce fatalities from fires and near drowning, respectively. Basic fire safety practices and familiarity with escape routes are other important general preventive measures.

Smoke detectors in home, office, and other work sites
Heating system inspection (wood, coal, gas)
Adequate engine exhaust systems
Adequate ventilation for smoke and volatiles
Respiratory protective equipment around high-risk exposure sites
Air monitoring at industrial sites

TABLE 383.1. PREVENTION OF INHALATION-AND ASPIRATION-INDUCED RESPIRATORY INJURY

Enhanced physician awareness of risk of aspiration of gastric contents has led to routine practices regarding food abstinence before general anesthesia, caution in the use of sedative-hypnotic agents, and increased use of antacids and histamine-2 antagonists to alter gastric acidity. Simple nonpharmacologic measures, such as maintenance of an upright posture in bed, the use of bed blocks during sleep, and for hospitalized patients, early mobilization, should minimize the likelihood of aspiration. For patients receiving enteral nutrition, the use of continuous low-volume feedings, rather than large-bolus administration, and avoidance of large gastric residuals may be effective prophylactic measures.

Oropharyngeal aspiration can be a recurrent problem, depending on the cause. When substantial aspiration has occurred and the patient has recovered from the acute episode, a search for correctable predispositions is important to minimize the likelihood of another event. A multidisciplinary approach has been helpful that includes combined neurologic, otolaryngologic, and speech assessments and radiologic swallowing studies.

CHAPTER 384: DISEASES OF HIGH ALTITUDE

ROBERT B. SCHOENE

[Adaptation](#)
[Clinical Syndromes](#)
[High-Altitude Natives](#)
[Clinical Diseases at High Altitude](#)

Aided by the speed of modern travel, sojourners to high altitudes have unrivaled access to mountains for recreation and work. Awareness of high-altitude illnesses is even more important for medical practitioners today than it was as recently as 30 to 40 years ago. This chapter discusses adaptation and maladaptation to high altitude, the clinical signs and symptoms of altitude-related illness, and the treatment of healthy sojourners, the high-altitude dwellers, and persons with medical problems at low altitude who go to high altitude.

ADAPTATION

Understanding the acute and chronic adaptations to high altitude provides a sound basis for comprehending the complex series of physiologic events that occur in patients at lower altitudes who have hypoxemia from heart, lung, or blood disease. At high altitude, the problem begins with the lower inspired partial pressure of oxygen, a result of the lower barometric pressure. For example, despite a fixed fraction of oxygen in the earth's atmosphere (0.2093), the oxygen available in the inspired air (P_{IO_2}) at 14,000 feet (4,200 m) (barometric pressure at 450 mm Hg) is approximately 94 mm Hg, whereas at sea level (barometric pressure at 760 mm Hg), the P_{IO_2} is about 150 mm Hg. The P_{IO_2} is the beginning of the oxygen cascade, in which oxygen from the atmosphere goes to the lungs to the blood to the cells. A number of mechanisms are invoked along this cascade that compensate in part for the lower P_{IO_2} .

The first immediate response is an increase in ventilation, which is caused by stimulation of the carotid body by hypoxemia. At any attained altitude, this process continues to augment ventilation for several weeks after arrival, effects a higher alveolar and arterial oxygen content, and is called *ventilatory acclimatization*.

The next step is transfer of oxygen by means of diffusion across the alveolar–capillary membrane. This process is limited at high altitude because of the decreased driving pressure of oxygen from air to blood and is particularly impaired during exercise, when a decreased transit time of blood across the blood–gas interphase allows less time for diffusion. Oxygen then becomes bound to hemoglobin, the carrier that takes oxygen to the tissues. Two further adaptive mechanisms take place. First, the number of red blood cells increases over 2 to 3 weeks owing to the erythropoietic stimulus from hypoxia. Second, the oxygen–hemoglobin dissociation curve shifts to the left because of progressive respiratory alkalosis, which facilitates loading of oxygen at the lung, where there is a lower pressure gradient from the air to the blood. This leftward shift is presumed not to impair unloading to the cells. Tissue adaptation is not fully understood. It is known to involve an increase in capillary and mitochondrial density and a decrease in muscle cell size, especially at very high altitudes. The result is a decrease in diffusion distance from the capillary to the mitochondria. Failure to undergo this complex series of events or individual variations in making these changes may lead to maladaptation and altitude illness.

CLINICAL SYNDROMES

THE SOJOURNER

If not enough time is allowed for adaptations, altitude illness can occur. For example, sudden ascent to 26,000 feet can cause death. However, a climber who takes weeks or months to arrive at that altitude on foot can work and function remarkably well. To minimize the risk of altitude illness, one should allow time to acclimatize. All altitude illnesses, from mild to severe, are probably a continuum. A unifying hypothesis is that hypoxia causes fluid to extravasate from the vascular to extravascular space. This process leads to tissue edema and accounts for neurologic and pulmonary symptoms. The initial leak may be in the brain and may cause increased intracerebral pressure and the symptoms of acute mountain sickness.

ACUTE MOUNTAIN SICKNESS

Presentation

Acute mountain sickness usually occurs within the first 12 to 72 hours of ascent above 2,500 m and may affect 25% to 40% of sojourners from low altitude who ascend rapidly. It is a mild form of altitude illness. Headache is the primary symptom. The headache may be mild or severe, constant or pounding, and may be accompanied by fatigue, lethargy, anorexia, nausea, and vomiting. Resting tachycardia, a sign of lack of acclimatization, decreased urine output, and fluid retention, signified by puffiness of hands and face, also may be present. Mild arterial oxygen desaturation greater than expected for the altitude and a widened alveolar to arterial oxygen difference are common. Periodic breathing at night and insomnia go hand in hand with acute mountain sickness. If one remains at that altitude, the symptoms usually abate in 24 to 48 hours and allow one to ascend. If symptoms do not subside, or if they worsen, one should descend before severe altitude illness ensues.

Treatment

A high index of suspicion and knowledge of the symptoms of acute mountain sickness allow one to avoid severe altitude illness and enjoy a sojourn to the mountains. Once acute mountain sickness is diagnosed, one should rest and not ascend higher until symptoms have improved. If symptoms do not abate or if they worsen, the patient must descend as far as necessary (more than 300 to 500 m) while he or she can still walk. Failure to do so can lead to severe altitude illness, inability to help oneself, and danger to colleagues.

Mild analgesics (aspirin, acetaminophen, and codeine) usually are effective in managing the symptoms of acute mountain sickness. If these measures do not work, other diagnoses or severe altitude illness should be considered. Acetazolamide is effective in preventing and controlling acute mountain sickness if taken during ascent (125 to 250 mg twice a day). The drug also may be taken when symptoms begin or before sleep. It prevents periodic breathing and decreases in arterial oxygen saturation during the night. The mechanism of action is not known but may be secondary to its role as a respiratory stimulant, mild diuretic, and carbonic anhydrase inhibitor—all of which may facilitate some of the normal mechanisms of acclimatization. A sojourner who has recurrent AMS should take acetazolamide prophylactically on ascent; otherwise, the drug should be carried as a treatment. Persons allergic to sulfa drugs should not take acetazolamide.

Dexamethasone, 4 mg by mouth every 6 hours, also is effective in controlling or preventing symptoms of mild to severe acute mountain sickness but does not aid acclimatization. It may convert a severely ill, nonambulatory patient into one who can descend and improve on his or her own. One should not, however, be lulled into false security, because relapses occur if the drug is stopped and descent is not undertaken. The drug is most appropriately used as a rescue drug if symptoms are worsening, especially in a remote environment. The mechanism of action of dexamethasone may be related to its effect on stabilization of the endothelium and prevention of tissue edema. Use of portable, inflatable hyperbaric bags also is effective if descent is not possible.

HIGH-ALTITUDE CEREBRAL EDEMA

High-altitude cerebral edema occurs in the presence of acute mountain sickness and usually includes a severe headache not relieved with analgesic, confusion, and truncal and gait ataxia; it can proceed to coma and death. Autopsy examinations demonstrate diffuse brain edema with microhemorrhages. Because all altitude illnesses have some neurogenic components, there is reason to believe that high-altitude cerebral edema is merely a worsening of acute mountain sickness. It is therefore important to be vigilant in all cases of acute mountain sickness. If definite neurologic signs appear, one must descend. Oxygen administration is helpful, and dexamethasone is effective in ameliorating symptoms so that the victim can descend. There should never be a delay in descent when high-altitude cerebral edema occurs unless severe weather or orthopedic trauma prevents descent.

HIGH-ALTITUDE PULMONARY EDEMA

High-altitude pulmonary edema is a severe and potentially fatal form of altitude illness. About 1% to 2% of sojourners above 10,000 feet (3,000 m) experience high-altitude pulmonary edema. High-altitude pulmonary edema was thought to be pneumonia or cardiac edema, but in the 1960s, subjects were studied and found to have normal pulmonary artery wedge pressures, which suggested that high-altitude pulmonary edema is a noncardiogenic form of pulmonary edema. Associated characteristics may include a blunted ventilatory response to high altitude, paradoxical fluid retention, and an accentuated pulmonary vascular response to hypoxia—all of which may lead to an increased pressure and stress on the pulmonary microvasculature and leakage into the interstitial and alveolar space. Examination of bronchoalveolar lavage fluid of persons with high-altitude pulmonary edema at 4,400 m on Mount McKinley showed very high concentrations of protein and cells similar to other forms of permeability pulmonary edema except that the cells were primarily alveolar macrophages rather than neutrophils. Because high pulmonary artery pressures appear to play a role in the development of high-altitude pulmonary edema, therapy that attenuates hypoxic pulmonary vasoconstriction, as with nifedipine, helps to prevent high-altitude pulmonary edema among susceptible subjects. Complete understanding of the underlying mechanism has not been achieved.

Dyspnea at rest and a dry cough accompanied by symptoms of acute mountain sickness begin 1 to 4 days after arrival at high altitude and evolve into severe dyspnea, confusion, worsening cough productive of pink frothy sputum, and death. These symptoms are accompanied by low-grade fever, tachypnea, tachycardia, and cyanosis. Varying degrees of neurologic dysfunction also may be present, underscoring the relation between high-altitude pulmonary edema and high-altitude cerebral edema. A chest radiograph shows diffuse bilateral infiltrates and a normal cardiac silhouette.

Slow ascent prevents high-altitude pulmonary edema, and early recognition of symptoms and descent are the best treatment. Patients with severe hypoxemia and illness usually recover within a couple of days of descent without apparent residual pulmonary dysfunction and can reascend after adequate acclimatization. Use of sedatives and hypnotic agents should be avoided, because respiratory depression worsens hypoxemia. Where medical care is available at moderate altitude, oxygen therapy for several days is adequate when arterial oxygen saturation can be raised to more than 90%. Patients can return home or to hotels with family or friends for observation and be seen daily by a physician until recovered. This approach is safe and economical for all but those with the most severe high-altitude pulmonary edema, who should be evacuated if possible. Nifedipine-XL (20 mg once or twice a day) should be used to prevent high-altitude pulmonary edema among susceptible persons who anticipate rapid ascent without time for adequate acclimatization. Diuretics, morphine, and nitroglycerin may have theoretic efficacy. All these drugs may have some beneficial effect on right-sided pressure but should not be used in the field. Unless severe weather or concomitant illness or trauma prevents descent, no one should die of high-altitude pulmonary edema.

OPHTHALMOLOGIC ABNORMALITIES

A number of visual symptoms have been reported, including transient blindness and blurring of vision, that may be caused by vascular spasm and clear without residual impairment. Retinal hemorrhage is common above 15,000 feet (4,500 m) but is usually asymptomatic unless it occurs over the macula. The hemorrhage resolves within 10 to 14 days. The underlying mechanism is not understood but may reflect microvascular leakage that occurs elsewhere, especially in the brain.

HIGH-ALTITUDE NATIVES

CHRONIC MOUNTAIN SICKNESS

The incidence of chronic mountain sickness is unknown. The illness is more prevalent in some high-altitude populations than in others. For example, it is more prevalent in the Andes and the North American Rocky Mountains and almost unheard of in Tibet. Chronic mountain sickness affects both highland natives and lowlanders who move to high altitude.

The clinical manifestations of chronic mountain sickness are similar to those that occur among lowlanders with chronic hypoxemia. The primary finding is excessive erythrocytosis in which hematocrit may reach 70% to 90%. Pulmonary hypertension, cor pulmonale, mental slowing, hypersomnolence, cyanosis, and plethora also are present. Patients have blunted ventilation, which may be a contributing factor to their accentuated hypoxemia. It is not clear whether this relative hypoventilation is a result of chronic high-altitude exposure or a contributing factor to the disease. Not all high-altitude natives with blunted ventilation have chronic mountain sickness.

Therapy for chronic mountain sickness requires reversal of the hypoxemia. Relocating to low altitude is ideal but often not practical. Most natives with chronic mountain sickness languish the remainder of their days, unrecognized as being ill. Oxygen therapy, especially at night, is helpful in reversing the syndrome but is often impractical and unavailable in remote mountain regions. Respiratory stimulants, such as acetazolamide, 125 mg twice a day, or medroxyprogesterone acetate, 20 mg three times a day, improve oxygen saturation when the patient is awake and reverse nocturnal periodic breathing and profound arterial oxygen desaturation. Phlebotomy is helpful as a temporary measure, especially to reverse the mental lassitude and decrease pulmonary vascular resistance.

REENTRY PULMONARY EDEMA

In North and South America, pulmonary edema occurs, especially among children and young adults, when high-altitude natives descend to low altitudes and then return to their high-altitude homes. The cause of this syndrome is not known but may be related to chronic hypertrophy of the pulmonary arteries, which become hyper-reactive on re-exposure to the hypoxic stress.

CLINICAL DISEASES AT HIGH ALTITUDE

Physicians should be aware of the detrimental effects that patients may undergo at high altitude. Although few data are available to document these effects, it is important to advise patients who live or who are going to high altitude, especially if they have pulmonary, cardiovascular, hematologic (e.g., sickle cell), or hypertensive disease or are pregnant. Patients with stable diseases cope with ascents and activities to moderate altitudes quite well. A better understanding of the adaptations and maladaptations to the hypoxic environment should allow the practitioners to help their patients make more judicious decisions.

LUNG DISEASE

Asthma

Although the cold, dry air of high altitude often is associated with greater airway reactivity, the scant literature that is available suggests that persons with asthma who live at high altitude or travel to high altitude do quite well. This may be because there are fewer allergens and less pollution in the high-altitude environment. Patients with asthma who ascend to high altitude should be advised about the potential risks and be armed with a spectrum of drugs, including bronchodilators and inhaled and oral steroids. Most studies of asthma among adults and children suggest that these agents are rarely necessary.

Chronic Obstructive Pulmonary Disease

Patients with chronic obstructive pulmonary disease (COPD) who live at high altitude have greater morbidity, and many of these patients migrate to lower altitudes as symptoms worsen. Patients with COPD who live at low altitude encounter environmental hypoxia with both air travel and more extended stays for recreation or family visits. With respect to air travel, patients who are hypoxemic and need oxygen therapy at low altitude and are not hypercapnic at low altitude should make arrangements for supplemental oxygen during the flight. Several studies have suggested ways to calculate the dose of oxygen, but these techniques usually are impractical and inaccurate; a reasonable estimate of an increase in usual oxygen dose is adequate. These patient should follow similar recommendations during a stay at high altitude because it is conceivable that several days of exaggerated hypoxemia can be potentially dangerous. Treatment of patients with chronic carbon dioxide retention, hypoxemia, and pulmonary hypertension is particularly problematic because too much oxygen may blunt their ventilation further and accentuate the manifestations of disease. Patients with COPD but without cardiac disease and not using oxygen therapy at low altitude should tolerate a flight of several hours or less.

Sleep Disorders

Little information is available regarding the effect of ascent to high altitude on patients with sleep disorders at low altitude. Anecdotal evidence suggests that the stimulus of hypoxia actually improves periodic breathing during sleep, but it is reasonable to have patients, particularly those with obstructive sleep apnea, continue their usual regimen.

CARDIOVASCULAR DISEASE

Systemic Hypertension

Upon acute exposure to high altitude, catecholamines increase proportionally and increase systemic blood pressure. Within a few days both catecholamines and blood pressure decrease toward sea level values. Among patients with pre-existing hypertension, the response is variable. For those with recalcitrant blood pressure going to higher altitude (3,000 m) the increase in blood pressure can become quite accentuated and potentially dangerous. Although data are scant and clinical guidelines in the literature are lacking, patients should be advised to continue their blood pressure medications and check their blood pressure every couple of days during their sojourn to high altitude. It may be necessary for them to increase their regimen to maintain acceptable blood pressures during more prolonged stays at high altitude.

Coronary Artery Disease

Evidence suggests that there may be a lower incidence of coronary artery disease among persons with long-time residence at high altitude. The reasons for such an association are not clear. The myocardium can withstand very low levels of oxygen, but theoretically the ambient hypoxia may unmask previously unknown coronary artery disease, turn angina to unstable disease, accentuate risk of myocardial infarction or sudden death, and provoke dysrhythmia. Studies to substantiate these possibilities do not exist. The threshold for angina among patients with coronary artery disease may be a lower level of exercise on acute ascent to high altitude, around 2,500 to 3,000 meters, but this finding does not preclude patients with stable angina from going to high altitude for recreation if moderate exercise is undertaken. Several studies with large cohorts of patients in the age range susceptible to myocardial infarction who were visitors to high-altitude resort areas or were trekkers to high altitude in Nepal did not show an increased prevalence of cardiac events. Clinicians must use clinical judgment in advising patients who want to go to high altitude. Except for those with unstable angina or difficult-to-manage dysrhythmias, there seems little additional risk to persons with pre-existing coronary artery disease or in those who have undergone coronary artery bypass surgery.

Pulmonary Vascular Disorders

Many times the symptoms of primary pulmonary hypertension are first realized during trips to moderate altitudes. Symptoms of dyspnea are sometimes quite striking. These patients should be counseled not to go to high altitude. Patients with pulmonary hypertension caused by chronic hypoxemic lung disease may be more susceptible to high-altitude pulmonary edema. The use of pulmonary vasodilators, such as nifedipine, might be indicated. Few studies have been performed to substantiate these conjectures.

Miscellaneous Disorders

Blood disorders such as sickle cell disease may be easily unmasked at even modest altitudes. It therefore is prudent to counsel patients with sickle cell disease or trait not to ascend even as high as 1,000 m. Little information is available on patients with cerebrovascular disease, epilepsy, or diabetes.

What clearly emerges from these cursory surveys is the need for good clinical studies to describe what happens to common medical problems among patients who live for many years at high altitude and among low-altitude residents who ascend to high altitude for recreation. This dearth of data is frustrating and begs for simple descriptive and epidemiologic studies of a number of diseases and long-term prospective studies to understand the underlying pathophysiologic processes so that clinicians can be better equipped to advise patients.

CHAPTER 385: ESSENTIAL POINTS OF THE HISTORY AND PHYSICAL EXAMINATION

MICHAEL E. HANLEY

[Medical History](#)
[Physical Examination of Patients with Respiratory Disease](#)

MEDICAL HISTORY

Most patients with respiratory disorders initially seek medical evaluation because they have signs or symptoms of respiratory illness or have an abnormality that is identified during routine health screening, evaluation of an unrelated medical problem, or epidemiologic surveys. A thorough and complete medical history is critical to the evaluation of all such disorders. Evaluation of abnormal but asymptomatic physical, laboratory, or radiographic findings requires a history of risk factors for pulmonary disease, including a thorough occupational, environmental, social including use of recreational and therapeutic drugs, and family history.

Patients with symptoms usually have one or more of the four cardinal respiratory symptoms of chest pain, cough with or without sputum production or hemoptysis, dyspnea, and wheezing. When evaluating symptoms, the clinician must ask the patient specific questions to elicit the character, chronology, severity, and, most important, pattern of the symptoms. Although the medical interview should be specific and detailed, the physician must avoid asking leading questions or questions that are too direct. Whenever possible, patients should be allowed to describe symptoms in their own words.

CHEST PAIN

Chest pain is one of the most common symptoms that prompt patients to seek medical assistance. Although the evaluation often focuses on whether the pain is caused by myocardial ischemia, pain localized to the thorax may originate from disease of any thoracic structure. It is crucial to have patients describe the pain in their own words. Diagnosis of the cause of pain, however, depends on identifying specific characteristics of the pain, including quality, location, radiation, severity, duration, frequency, and factors that precipitate, worsen, or relieve it. The differential diagnosis of chest pain is summarized in [Table 385.1](#).

Source	Common Characteristics
Ischemic heart disease	Precipitated by activity or ↑ cardiac demand Relieved by rest or vasodilators
Pericardial disease	Steady, substernal ↑ with swallowing or recumbency Relieved by sitting forward
Diseases of chest wall	Localized; ↑ with movement
Diseases of pleura	Pleuritic; often acute or crescendo pattern
Esophageal, upper GI, or subdiaphragmatic disease	Burning or achy; ↑ or ↓ with meals; relieved by antacids or H ₂ -antagonists.

TABLE 385.1. DIFFERENTIAL DIAGNOSIS OF CHEST PAIN

The quality and location of chest pain are related to the sensory innervation of the anatomic origin of the pain. In general, chest pain can be functionally classified into two main diagnostic categories: visceral cardiac and somatic pleuritic pain. The heart, pericardium, and mediastinal structures are innervated through autonomic pathways that travel through the vagus nerve. Patients with cardiac and mediastinal abnormalities perceive pain in a visceral rather than a somatic pattern. The pain usually is described as dull, heavy, constricting, or squeezing, a pressure sensation, or, if severe, crushing.

The intensity of cardiac pain ranges from mild to severe and has no value in identifying the underlying cause. Cardiac pain is central in location, usually substernal or epigastric, and radiates to either arm and the neck. Although chest pain that is lateral or precordial does not exclude myocardial ischemia, pain in this location usually indicates cardiac anxiety or a left anterior pleural or chest wall process. Classic angina pectoris from myocardial ischemia is caused by an imbalance between myocardial oxygen supply and demand. Angina pectoris is precipitated by any activity that increases cardiac demand or induces coronary arterial spasm, such as exertion, exposure to cold air, heavy meals, or emotional upset, and is relieved by rest and vasodilating medications. Persistent, intense pain of a cardiac quality that is not relieved by rest or vasodilating medications suggests a diagnosis of myocardial infarction. In myocardial infarction, the pain frequently is associated with sweating, palpitations, syncope, nausea, vomiting, and hypotension.

Pericardial pain has both cardiac and pleuritic quality because the adjacent visceral mediastinal and parietal chest wall pleura often are involved. Chest pain from pericarditis is a steady substernal pain worsened by breathing. The pain also typically increases with swallowing, hiccuping, or lying in a recumbent position, especially on the left side. It is improved by sitting or leaning forward and lying on the right side. When the diaphragmatic pleural pericardial surfaces are involved, the pain is referred to the shoulder blades or neck through the phrenic nerves. If pericarditis is suspected, it is important to evaluate for signs of abnormal cardiac hemodynamics due to cardiac tamponade. These include tachycardia, jugular venous distention, Kussmaul's sign (persistent or paradoxical increase of jugular venous distention during inspiration), paradoxical pulse, and hypotension. The presence of these signs warrants emergency evaluation and intervention, including echocardiography, right-sided heart catheterization, or pericardiocentesis.

The sensory innervation of the chest wall and diaphragmatic parietal pleura is through afferent fibers in the intercostal nerves. Disease that involves these structures typically manifests as an achy or sharp pain well localized to the involved area, usually is unilateral, and is worsened by torso or chest movement, such as coughing, sneezing, and deep breathing. The pain is ameliorated by shallow breathing or breath holding. Patients with pleuritic pain may report dyspnea because of a pain-induced increased awareness of breathing and may have evidence of chest wall splinting at physical examination. Pleuritic pain from inflammation or irritation of the diaphragmatic parietal pleura commonly radiates to the ipsilateral shoulder or side of the neck. Important additional clues in the evaluation of pleuritic chest pain are recent thoracic trauma or paroxysmal coughing, acuity of the pain, presence of systemic symptoms, and presence of localizing signs at physical examination. The speed of onset of pleurisy depends on the speed of development of the underlying disease.

Pain from pneumothorax, fractured ribs, or pulmonary embolism with lung ischemia or infarction develops suddenly. The intensity of the pain has a crescendo pattern in pulmonary embolism. Chest pain from acute infectious causes of pleurisy, such as viral epidemic pleurodynia, coxsackievirus B infection, or bacterial pneumonia, is slower but still rapid in onset and is characteristically associated with systemic inflammatory signs and symptoms, including fever, sweats, chills, myalgia, arthralgia, and malaise. Pain from chronic conditions, such as tuberculous pleuritis, asbestos-induced pleural disease, metastatic cancer, and occasionally anaerobic pleuropulmonary infection, has a more insidious onset.

Examination of the involved chest wall area and adjacent structures, including the lung and upper abdomen, may lead to a specific diagnosis. Point tenderness over a rib after trauma or a coughing paroxysm suggests a rib fracture. Point tenderness over one or more costochondral junctions, especially associated with localized warmth and erythema, may indicate costochondritis or infectious costal arthritis. The approach to pleuritic pain is discussed in [Chapter 358](#).

Esophageal, upper gastrointestinal, and subdiaphragmatic diseases often produce chest pain that can be mistaken for cardiac or lung disease. A primary abdominal process such as pancreatitis or cholecystitis should be considered in the differential diagnosis of lower chest pain or pleurisy, including pleural effusions of obscure causation. Esophagitis and esophageal spasm usually are associated with a history of heartburn, reflux, dysphagia, and odynophagia. If symptoms suggest an

esophageal origin, a trial antacid-antireflux regimen should be undertaken before a more expensive and invasive evaluation is initiated.

Diseases involving only lung parenchyma or visceral pleura, such as a solitary pulmonary nodule, usually are not painful because these structures lack pain fibers. The development of pain with such a condition suggests that the disease has spread outside the lung or that a second process exists.

COUGH

Coughing protects the lungs from injury and infection by clearing large bronchial airways of accumulated secretions and foreign material. The normal cough reflex is caused by afferent stimuli from cough receptors transmitted through sensory nerves to the central nervous system cough center and is mediated through motor nerves. Cough receptors are located throughout the respiratory tract and in extrapulmonary sites, including the pleura and pericardium, ear canals, paranasal sinuses, stomach, and diaphragm. Activation of the reflex occurs through receptor stimulation by inflammatory, mechanical, chemical, and thermal stimuli.

The most common causes of coughing are acute viral respiratory tract infections and smoking. Most patients with acute viral respiratory tract infections do not seek medical evaluation because their symptoms are self-limited and easily explained. A chronic cough is defined as a troublesome cough that lasts more than 3 weeks. The most common causes of chronic cough are tobacco-related chronic bronchitis, postnasal drip, occult asthma, and gastroesophageal reflux. Less common causes are pneumoconiosis, idiopathic interstitial lung disease such as sarcoidosis or idiopathic pulmonary fibrosis, bronchiectasis, bronchogenic carcinoma, drugs, chronic infection, and nonpulmonary disorders such as left ventricular failure, esophageal diverticula, and recurrent aspiration. The medical history suggests a specific diagnosis for 70% of patients with a chronic cough. Historical factors to be considered in the evaluation of a cough are shown in [Table 385.2](#).

Tobacco use
Recent change in pattern or character of cough
Presence and quantity of sputum production
Hemoptysis
Environmental and occupational exposure through inhalation
History of allergy or atopy
Nocturnal cough
Sinus symptoms
New drug exposure, especially to angiotensin-converting enzyme inhibitors and β -blocking agents
Substance abuse, especially of crack cocaine

TABLE 385.2. MEDICAL HISTORY FACTORS IN THE DIAGNOSIS OF CHRONIC COUGH

The evaluation of a cough among tobacco users is a challenge. Although all smokers with a cough should not be presumed to have only smoker's bronchitis, evaluating a cough for this population may lead to multiple unnecessary and expensive diagnostic tests. Full evaluation of chronic coughing among smokers should be considered when the cough is persistent and severe or if it is accompanied by a change in or development of sputum production, an increase in the frequency of coughing, hemoptysis, or constitutional symptoms such as weight loss and fatigue. The evaluation in this setting should focus on the diagnosis of chronic bronchitis, emphysema, or bronchogenic carcinoma.

A history of sputum production narrows the differential diagnosis of chronic cough to primary pulmonary conditions. Expectoration of sputum is caused by a combination of increased production of sputum by irritant stimulation of mucous glands and decreased mucociliary clearance. When patients have sputum production, the amount and quality of sputum should be characterized. This is best accomplished by giving the patient a specimen cup and collecting all sputum produced over 24 hours.

Sputum can be microscopically classified into five categories: clear and mucoid; purulent; putrid with three layers; rusty or blood-stained; and miscellaneous. Clear or mucoid sputum usually is caused by an irritative inhalant source, is not infected, and rarely requires antibiotic treatment. Purulent sputum suggests bacterial bronchitis or pneumonia and clinically mandates antibiotic therapy. Copious putrid sputum strongly indicates an anaerobic process such as a lung abscess or necrotizing pneumonia. Severe bronchiectasis commonly is associated with production of copious amounts of purulent sputum that classically settles into three layers: a mucous layer above, a watery layer in the middle, and purulent sediment below. Rusty or uniformly blood-stained sputum indicates the presence of red blood cells or hemoglobin. Cardiac causes and primary pulmonary inflammatory conditions should be considered. Two rare but characteristic types of sputum that suggest specific diagnoses are the clear, golden-yellow sputum that accompanies biliary tract-bronchial fistula and the copious, watery sputum that suggests alveolar cell carcinoma.

Cough accompanied by hemoptysis is a potential medical emergency and warrants immediate evaluation. Hemoptysis is expectoration of blood from the lower respiratory tract. When hemoptysis occurs, symptoms and signs of upper airway and gastrointestinal disease should be sought to exclude pseudo-hemoptysis (expectoration of blood from a source other than the lower respiratory tract, such as aspirated blood from epistaxis or upper gastrointestinal hemorrhage). Direct oral examination should be carefully performed, because a minor oral or gingival lesion may be overlooked. A simple maneuver to diagnose pseudo-hemoptysis in this situation is to collect an expectorated specimen of clear water that the patient has orally swished and gargled. Persistent fresh blood in the immediately expectorated specimen is highly confirmatory of pseudo-hemoptysis.

The differential diagnosis of hemoptysis depends on several factors, including the amount and duration of bleeding, the patient's age and smoking history, and accompanying symptoms such as weight loss, chest pain, and fever. It is important to measure the amount of blood in true hemoptysis. Massive hemoptysis is expectoration of more than 600 mL of blood in a 24-hour period. Expectoration of less than 600 mL, but more than blood streaking, is referred to as *frank* or *gross hemoptysis*. Scant hemoptysis is characterized by blood streaking of sputum.

Acute bronchitis is the most common cause of hemoptysis in the United States. Hemoptysis due to acute bronchitis resolves with antibiotic therapy and does not necessitate invasive evaluation other than chest radiography unless the hemoptysis persists despite use of antibiotics or if the radiographic findings are abnormal. Bronchogenic carcinoma is uncommon among nonsmokers and patients younger than 35 years. Patients with bronchogenic carcinoma usually also have a history of recent change in the severity and character of the cough and constitutional symptoms such as weight loss, fever, and anorexia.

Chronic coughing sometimes is caused by nonpulmonary disorders. If symptoms do not suggest a pulmonary source, additional questions should be asked to find a nonpulmonary or systemic chronic disease. The patient should be evaluated for evidence of heart disease that leads to pulmonary venous hypertension, such as cryptic mitral stenosis or left ventricular failure. Ear, nose, and throat disorders, including chronic sinusitis with postnasal drip, should not be overlooked. Symptoms of neurologic or gastrointestinal disease that leads to silent reflux and cryptic aspiration should be pursued. A useful test to detect aspiration is to watch the patient swallow a glass of water. Immediate coughing suggests aspiration. The rapidity and severity of the cough are directly related to the size and severity of aspiration. Evaluation of coughing is discussed in [Chapter 352](#).

DYSPNEA

Dyspnea is an awareness or perception of labored breathing. Most patients describe it as shortness of breath or breathlessness, but some describe a sensation of choking, tightness, or suffocation. If symptoms are sudden or severe, the patient may notice dyspnea at rest, but when dyspnea is mild or insidious, it is initially noticed only with considerable exertion.

The evaluation of patients with dyspnea should focus on quantifying the severity of shortness of breath, identifying the pattern of symptoms by determining the circumstances in which they occur, and searching for associated symptoms. Although quantifying the degree of dyspnea rarely leads to a specific diagnosis, it may yield clues to the cause and is valuable in monitoring the response to therapy and performing disability evaluations. Several issues should be considered when grading the degree of dyspnea. Does the severity of symptoms correlate with objective evidence of pulmonary disease, such as results of pulmonary function tests or chest radiographic findings? If it does not, there may be a second contributing process or an altogether new diagnosis. What is the tempo of illness? Are symptoms stable or slowly progressive? Dyspnea is graded according to the amount of exertion needed to produce symptoms. A simple scale recommended by the American

College of Chest Physicians is shown in [Table 385.3](#).

Grade	Description
I	No dyspnea with keeping pace with healthy persons of the same age and body build on level ground but shortness of breath on climbing hills or stairs
II	Can walk a mile at own pace without dyspnea but cannot keep pace with a healthy person on level ground
III	Shortness of breath on walking about 100 yards (90 m) or for a few minutes, even on level ground
IV	Shortness of breath on slight exertion, such as when dressing or talking

American College of Chest Physicians modification of British Medical Research Council Scale

TABLE 385.3. DYSPNEA SCALE

One of the most important clues in determining a specific cause of dyspnea is determining the pattern of symptoms and the circumstances in which it occurs. The diagnosis frequently focuses on differentiating left-sided heart disease with left ventricular dysfunction and elevated pulmonary venous pressure from a primary lung disease. Specific types of dyspnea such as paroxysmal nocturnal dyspnea (PND; dyspnea that awakens a patient from sleep) and orthopnea (dyspnea on assuming a supine position) strongly suggest a cardiac cause. However, PND-like symptoms also occur with nocturnal asthma, esophageal reflux with aspiration, and sudden “choking” from accumulated bronchopulmonary secretions obstructing large airways. Orthopnea also occasionally occurs among patients with chronic obstructive pulmonary disease, asthma, and neuromuscular disease. Additional history may help differentiate heart disease from primary pulmonary disease in these situations, and physical signs of left ventricular failure should be aggressively pursued. For example, although patients with cardiac PND may have a cough, the cough usually is dry and nonproductive. Patients with pulmonary-induced PND, however, have a productive cough and improvement in dyspnea with expectoration. Most patients with reflux and nocturnal aspiration also give a history of considerable heartburn. Nocturnal bronchial asthma causing PND may be accompanied by allergic or atopic clues and blood or sputum eosinophilia.

Other patterns of dyspnea suggest other diseases. Platypnea is the development or worsening of dyspnea after assuming an upright position. Although nonspecific, it often occurs among patients with pulmonary manifestations of chronic liver disease and patients with poor abdominal muscle tone. Sudden onset of dyspnea at rest may be associated with pulmonary emboli, gastric aspiration, or pneumothorax. A history of more severe dyspnea developing toward the end of the workday or work week with improvement during periods away from work suggests an occupational exposure. Seasonal variation or worsening after exercise or exposure to cold dry air or nonspecific irritants may indicate reactive airway disease. Because the cause of dyspnea is often a nonpulmonary condition, the physician must search for signs and symptoms of extrapulmonary disease, such as neuromuscular disease or hyperthyroidism.

The cause of dyspnea due to pulmonary disease usually can be accurately diagnosed with a careful history and physical examination, chest radiography, spirometry, and analysis of carbon monoxide–diffusing capacity or arterial blood gas measurements. If the results of this evaluation are normal or do not provide enough information for diagnosis and the symptoms are not considered psychogenic, a cardiopulmonary exercise test is warranted.

AUDIBLE RESPIRATORY SOUNDS

Some patients seek treatment with wheezing, stridor, or snoring. These abnormal respiratory sounds indicate abnormal turbulent airflow and increased airway resistance. Wheezes are high-pitched musical sounds generated by rapid passage of air through airways that are narrowed to the point of closure. Wheezes are generated by narrowing of either large or small airways. The quality of the wheeze does not differentiate the site of obstruction. Wheezes may occur in either phase of the respiratory cycle but tend to occur more commonly and are more prominent during expiration, when the airway caliber is smaller. Although wheezes are most commonly noticed by patients with acute asthma, wheezing may be produced by any cause of bronchial narrowing, including bronchospasm, mucosal edema and congestion, intraluminal accumulation of mucus, external airway compression, or dynamic airway narrowing or collapse. When the wheeze is localized to a specific site in the chest, focal obstruction of a larger bronchus by a neoplasm or foreign body should be considered.

Stridor is an especially harsh, loud musical sound of constant pitch. Although it may be heard throughout the respiratory cycle, it is most common during inspiration, when extrathoracic airways are typically narrowed. This sound is generated by critical obstruction of large airways, usually at the larynx but occasionally involving the trachea or a main stem bronchus. Stridor should be considered a medical emergency with the potential for complete airway obstruction and asphyxiation. Emergency airway evaluation with direct laryngoscopy and bronchoscopy and preparation for emergency establishment of an airway must be performed. All patients with stridor should be under constant direct observation and monitoring in an intensive care unit until the situation is resolved.

Snoring is a coarse sound generated in the nasopharynx, oropharynx, or hypopharynx during sleep. Snoring of oropharyngeal or hypopharyngeal origin is more likely to be pathologic than is snoring that is nasally produced. Snoring is more common among men than among women and should not be considered pathologic or in need of further medical evaluation unless the patient has additional clinical features of sleep-disordered breathing. These include otherwise unexplained pulmonary hypertension, cor pulmonale, polycythemia, severe morning headaches, excessive daytime somnolence or frank narcolepsy, intellectual deterioration, poor job performance, and personality changes (see [Chapter 382](#)).

OTHER MEDICAL HISTORY

Although most of the medical interview should focus on specific evaluation of the chief problem and present illness, important additional clues to the cause of the patient's pulmonary illness can be gathered from other aspects of the medical history. The most valuable of these include the history of previous illnesses and the social, family, occupational, and environmental histories. These parts of the medical history frequently are considered discrete components when the complete history is organized. However, when pertinent, these portions of the medical history are obtained during the characterization of the chief problem.

History of Previous Illnesses

Many chronic diseases follow cycles of remission and exacerbation. Symptoms often are caused by pulmonary complications of extrapulmonary disease. A thorough review of previous hospitalizations, medical evaluations, and other illnesses should be performed for all patients with pulmonary symptoms. This should include an inquiry about the existence of previous chest radiographs.

Social and Family History

A confidential inquiry regarding lifestyle and habits should be pursued, including sexual behavior, substance abuse, pet exposure, and hobbies. When necessary, the data obtained may require confirmation through interviews with family and friends. Clues to the diagnosis of atypical infection include travel to an area endemic for the infection, such as coccidioidomycosis, or a hobby that involves exposure to sites or animals that are vectors for the infectious agent. If the patient is immunosuppressed, the physician should ask about remote residence in endemic areas, because the infection may manifest as dissemination of a previously acquired but dormant infection.

Although genetically transmitted pulmonary diseases are uncommon, a family history of diseases such as cystic fibrosis or a α_1 -antitrypsin deficiency should be pursued when appropriate. The immediate family history is more helpful in identifying illness due to common exposures, especially infection. This should include a history of recent exposure to adults, children, or animals with known or suspected transmissible infections such as measles, chickenpox, influenza, tuberculosis, tularemia, Q fever, and psittacosis.

Occupational and Environmental History

Information about potential exposures through occupation or the environment is especially important in the evaluation of diffuse interstitial lung disease and asthma. General questions regarding changes in the severity of symptoms when exposed to or removed from various environments may provide a clue that the illness is environmentally mediated. Identification of specific agents that may contribute to illness requires specialized knowledge of workplace environments and may necessitate referral to an occupational medicine specialist. The occupational and environmental interview requires a detailed, systematic approach, because many exposure histories may be subtle or forgotten. Questionnaires that require patients to review systematically their employment record, hobbies and recreational activities, home environment, and other potential exposures are helpful.

PHYSICAL EXAMINATION OF PATIENTS WITH RESPIRATORY DISEASE

The ready availability and utility of chest radiography and the limitations of physical examination of the thorax have deemphasized physical examination of the chest. Many patients, however, such as those with asthma, have normal chest radiographs but significant findings at physical examination. Overdependence on chest radiographs, especially in monitoring, is wasteful and not cost-effective. Chest radiographs and physical examination supplement each other in the evaluation of chest abnormalities. The chest examination is not complete without review of a current, high-quality chest radiograph. Clinicians also need well-developed physical examination skills to diagnose pulmonary disease and to monitor the response to therapy.

DIRECT CHEST EXAMINATION

Because of the common association between pulmonary and cardiac disease, every evaluation for a chest disorder includes a thorough evaluation of the cardiovascular system. Details of this examination are described in [Chapter 63](#). The chest examination is based on the four basic skills of inspection, palpation, percussion, and auscultation. In general, palpation and percussion are the most helpful in confirming and clarifying the pathophysiologic mechanism associated with abnormal breath sounds detected at auscultation. Palpation also is useful in evaluating chest wall pain, swelling, or trauma. Palpation of subcutaneous crepitus is pathognomonic of subcutaneous emphysema and is always pathologic. Crepitus is most commonly found over the neck and upper chest or over sites of chest wall trauma. Subcutaneous emphysema is commonly associated with pneumothorax, pneumomediastinum, or laceration of the pharynx, esophagus, or large airway. The presence of crepitus should trigger a search for signs of these conditions.

Inspection can produce useful information about pulmonary symptoms. It includes assessment of respiratory distress, the presence of clubbing, and skin color and direct chest examination. The use of accessory muscles of respiration should be assessed, and the presence of plethora or cyanosis documented. Cyanosis is a bluish discoloration of the skin and mucous membranes associated with an increased percentage of reduced hemoglobin in the capillaries of those tissues. Central cyanosis, cyanosis occurring in both the skin and mucous membranes, suggests generalized arterial oxygen desaturation. Peripheral cyanosis, cyanosis localized to the skin, usually indicates marked tissue hypoperfusion. Clinical differentiation of one form from another often is difficult, and considerable arterial oxygen desaturation can occur in the absence of clinically detectable cyanosis. Measurement of arterial oxygen saturation by means of pulse oximetry or analysis of arterial blood gases should be considered for all patients with respiratory distress.

Although direct chest inspection should include assessment of the general shape, symmetry, and movement of the thorax, it is most valuable in evaluating the dynamics of breathing, especially for patients with respiratory distress. Of particular importance are the depth of tidal volume breaths and respiratory rate and pattern. Rapid, shallow breathing, especially with respiratory rates greater than 40 breaths per minute for adults, and paradoxical thoracic–upper abdominal movement (inward abdominal retraction during inspiration) often are associated with impending or frank respiratory collapse.

AUSCULTATION

The most useful physical examination technique applied to the chest is auscultation. Auscultation should be performed over the anterior, posterior, and midaxillary chest regions with careful comparison of the left and right hemithoraxes. The examiner must determine whether breath sounds are normal or abnormal and whether adventitial sounds are present. Normal breath sounds include tracheal, bronchial, bronchovesicular, and vesicular sounds. Determining whether breath sounds are abnormal requires assessment of the relative duration of each phase of the respiratory cycle and the intensity, pitch, and quality of the sounds. Evidence of increased transmission of breath sounds, such as detection of bronchial breath sounds at a site where vesicular sounds are expected, should alert the examiner to the existence of lung consolidation. Consolidation can be confirmed by means of detecting egophony in the involved area. Egophony is the increased transmission of voice-generated sounds through the chest. When spoken words are transmitted clearly and distinctly, egophony is characterized as either bronchophony (if the words were spoken) or whispered pectoriloquy (if the words were whispered).

Adventitial lung sounds are sounds that are not naturally associated with the breathing process. Adventitial sounds include rales, wheezes, rhonchi, and pleural rubs. Laennec originally referred to all adventitial lung sounds as *rales*, further categorizing them as sibilant, sonorous, or crepitant. In modern parlance, however, adventitial lung sounds are categorized as continuous or discontinuous on the basis of sound wave analysis. The term *rales* is restricted to discontinuous sounds characterized as crackly, short, explosive, and nonmusical, typically superimposed on the underlying breath sounds. Synonyms are *crackles* and *crepitation*. Rales, which may be further categorized as fine or coarse, are commonly heard in infiltrative lung disease and in conditions associated with increased airway secretions.

Continuous sounds include wheezes (sometimes called as *sibilant rhonchi*) and rhonchi. Wheezes have a high-pitched, sibilant quality; rhonchi are low in pitch and are sonorous. Wheezes and rhonchi typically are detected in diseases characterized by airway narrowing. Wheezes and rhonchi associated with mild degrees of airway narrowing may not be readily detectable during tidal volume breathing but can be accentuated by having the patient perform a cough or forced expiratory maneuver. The degree of airflow limitation can be accurately estimated at the bedside by means of grading the intensity of breath sounds. The examiner listens to the intensity of the breath sounds over six lung zones (upper anterior, midaxillary, and posterior bases) during repeated maximal inspiratory efforts by the patient. The intensity of the breath sounds is graded on a simple 5-point scale, 0 being absent sounds, 3+ normal, and 4+ louder than usual, normal. The total score (16 to 20 is normal, 6 to 10 severely abnormal) has an excellent correlation with forced expiratory volume in 1 second (FEV₁) measured during concomitant spirometry. An alternative is to use a simple peak flowmeter to estimate the degree of airflow limitation. Expiratory peak flow rates of 100, 200, 300, and 400 L per minute are roughly equal to FEV₁ of 1, 2, 3, and 4 L and breath sound intensities of 1, 2, 3, and 4+.

Pleural rubs are loud, coarse, evanescent sounds that typically have a rough or leathery quality. They usually are heard throughout the respiratory cycle but may be limited to one component of it. A pleural rub typically indicates a thickened pleura, usually caused by an inflammatory or neoplastic process.

EXTRATHORACIC EXAMINATION

Many respiratory diseases actually are multisystemic or generalized systemic processes and therefore often have extrathoracic features. Often the most critical part of the lung physical examination is careful attention to the evaluation of extrathoracic sites. On the first encounter with a patient with undiagnosed respiratory symptoms or disease, a complete physical examination is often performed by rote, not surprisingly with minimal return. As specific differential diagnoses are entertained and more diagnostic information is collected, experienced physicians have learned the value of returning to reexamine the patient for subtle new or previously missed signs and symptoms. The physician should be compulsive, comprehensive, and complete on the first encounter but should return to recheck the patient with a high index of suspicion for new disease or previously missed subtle abnormalities.

ACKNOWLEDGMENT

This chapter is an adaptation of the one written by Thomas A. Neff, M.D., for the second edition of this textbook. Dr. Neff was a professor of medicine in the pulmonary and critical care section of the University of Colorado School of Medicine for many years and was highly regarded for his skills as a clinician and his many contributions to the understanding of respiratory illness. He passed away in December 1994 and will be missed.

The purposes of this chapter are to outline the techniques available for imaging the chest, to review normal imaging anatomy, to illustrate the common radiographic signs of lung disease, and to describe the imaging approach to common clinical problems.

CHEST RADIOGRAPH

The chest radiograph is the first and often the only technique used in the patient with known or suspected lung disease. Radiographs must be obtained using a reproducible high-quality technique. Abnormalities are often simulated by an underexposed radiograph or by a radiograph with an inadequate inspiration. A reproducible inspiration close to total lung capacity can be ensured by having the patient breathe in, then breathe out as far as possible, and then breathe in as far as possible. Photo-timed exposure, with appropriate positioning of photocells, provides consistent radiographic density. Meticulous quality control of the film processor is also important.

If possible, the chest radiograph is obtained in the erect position with the patient's chest against the film cassette, so that the beam passes from back to front (posteroanterior, or PA). Because the heart is close to the front of the chest, it is less magnified on a PA radiograph than on an anteroposterior (AP) radiograph. AP radiographs are obtained in patients who are too sick to stand and in those who require portable radiographs. Lateral radiographs are obtained with the left side against the film cassette, which minimizes cardiac magnification.

NORMAL ANATOMY

FRONTAL CHEST RADIOGRAPH ([FIG. 386.1](#))

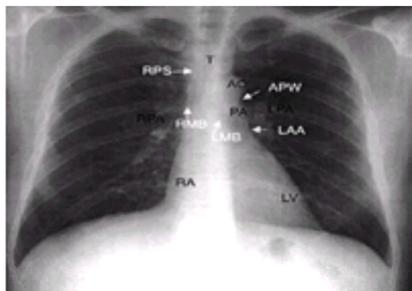

FIGURE 386.1. Normal anatomy on the frontal chest radiograph. T, trachea; RPS, right paratracheal stripe; Ao, aorta; APW, aortopulmonary window; PA, main pulmonary artery; LAA, left atrial appendage; RA, right atrium; LV, left ventricle.

The trachea is visible in the midline, inclining to the right at the level of the aortic arch. The right lung is immediately in contact with the right wall of the trachea, forming the right paratracheal line or stripe, which is usually less than 5 mm in thickness. The azygos vein is seen at the lower end of the right paratracheal line, as it arches over the right main bronchus. The left wall of trachea is separated from the left lung by the aortic arch and its branches.

Because the left pulmonary artery arches over the left main bronchus, the left hilum is usually higher than the right, and the left main bronchus is twice as long as the right. Both hila have concave lateral margins. The horizontal minor fissure is visible in the right lung, at the level of the hilum. The left hemidiaphragm is usually lower than the right.

The convex right heart border is formed by the right atrium. The left heart border begins at the convex aortic arch. The next convexity is due to the main pulmonary artery, and the concavity between the aortic arch and main pulmonary artery is called the aortopulmonary window. A concavity below the main pulmonary artery is occupied by the left atrial appendage. The remainder of the left heart border is formed by the left ventricle.

LATERAL CHEST RADIOGRAPH ([FIG. 386.2](#))

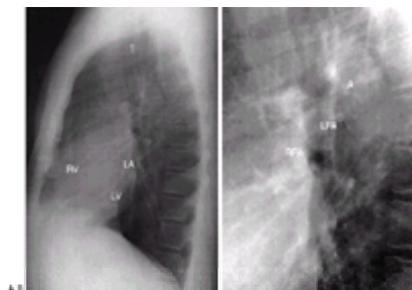

FIGURE 386.2. A, B: Normal anatomy on lateral chest radiograph, with detailed view of hila. T, trachea; RV, right ventricle; LV, left ventricle; LA, left atrium; RPA, oval composite shadow of right interlobar pulmonary artery and right superior pulmonary vein; LPA, left pulmonary artery, arching over the left main bronchus, parallel to aorta (A).

On the lateral radiograph, the useful landmarks are the trachea, the aortic arch, the heart, the sternum, and the spine. The upper two-thirds of the retrosternal space is usually clear, but it may be occupied by fat in obese patients, and it may be obscured by the patient's arms if they are insufficiently elevated. The major and minor

ADDITIONAL RADIOGRAPHIC TECHNIQUES

Expiration radiographs have traditionally been performed to detect pneumothorax but in fact are rarely indicated because inspiration views are equally sensitive for pneumothorax. They may sometimes be helpful in detecting air trapping due to large-airway obstruction. Decubitus views are helpful in showing mobile pleural effusions and in showing pneumothorax in supine patients. Lordotic views were commonly used to identify tuberculous lesions at the lung apices, but their value is declining with the decrease in prevalence of tuberculosis.

Fluoroscopy remains a useful technique for distinguishing between pulmonary nodules and extrapulmonary lesions, such as rib fractures, and for evaluating the movement of the diaphragm using a "sniff" test.

CT OF THE CHEST

The changing terminology of computed tomography requires some clarification. *Helical or spiral CT* is a technique by which the entire lung can be imaged as a three-dimensional dataset during one or two breath holds. It is the technique of choice for surveying the chest for nodules and other focal abnormalities. It is also useful for constructing images of airways or vessels in sagittal, coronal, or other planes. Contrast-enhanced helical CT is increasingly being used for direct visualization of emboli in the main, lobar, and segmental pulmonary arteries. Low-dose helical CT is being studied as a method for screening for lung cancer in high-risk individuals.

High-resolution CT (HRCT) is optimized to visualize fine detail within the lung, using thin sections (1 mm rather than 7 or 10 mm) and an edge-enhancing reconstruction algorithm. This technique is the primary method for diagnosis of bronchiectasis, and for diagnosis and characterization of infiltrative lung diseases and small-airway disease. Because the thin sections of HRCT are usually separated by 1 to 4 cm, this technique is not suitable for detecting lung nodules. However, a set of HRCT images obtained through a focal lung abnormality or nodule may help to characterize the abnormality.

Expiratory HRCT may be useful to detect air trapping in patients with emphysema, asthma, or small-airway disease.

Indications for administration of intravenous contrast during chest CT include visualization of the heart, aorta, hila, or pulmonary vessels, and characterization of lung nodules. Contrast is not usually indicated for evaluation of diffuse lung disease or for screening for metastases.

In general, the physician requesting a chest CT scan should not be too concerned about the details of chest CT technique. If the clinical question is clear from the requisition, the radiologist can usually determine the protocol and assess the need for intravenous contrast.

OTHER IMAGING MODALITIES

The clinical usefulness of magnetic resonance imaging (MRI) of the chest is limited. MRI of the aorta is used to evaluate dissection or aneurysm. MRI can help evaluate cardiac or paracardiac masses. MRI is more sensitive than CT for detection of chest wall invasion by tumor (particularly Pancoast tumor). Although magnetic resonance angiography of the pulmonary arteries may diagnose pulmonary emboli, it has been difficult to develop a robust technique for this purpose.

Nuclear imaging of the lung is primarily used to diagnose pulmonary embolism. Gallium imaging is occasionally used to help diagnose sarcoidosis. The use of ultrasonography of the chest is discussed below.

SOLITARY PULMONARY NODULE

Lung cancer is often first detected as an asymptomatic nodule on the chest radiograph. For this reason, solitary pulmonary nodules must never be ignored. Algorithm 1 (Fig. 386.6) shows that the most useful single test in the evaluation of a solitary pulmonary nodule is that of obtaining old films. Although nodules that have been stable for more than 2 years are likely to be benign, slow-growing lung cancers may take up to 5 years to develop. Other causes of noncalcified pulmonary nodules include noncalcified granulomas (due to tuberculosis or histoplasmosis), hamartomas, arteriovenous malformations, round pneumonia, and solitary metastasis. Hamartomas can often be recognized on CT by the presence of fat in the nodule. Arteriovenous malformations are identified by the presence of feeding or draining vessels. The technique of dynamic nodule CT is an important recent advance in the evaluation of the indeterminate solitary pulmonary nodule (Fig. 386.5). Nodules that fail to enhance by more than 15 Hounsfield CT units following a bolus of intravenous contrast are likely to be benign.

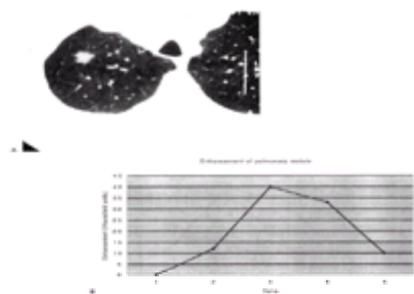

FIGURE 386.5. Solitary pulmonary nodule due to adenocarcinoma in a 62-year-old woman. **A:** Computed tomography shows solitary irregular pulmonary nodule, which was noncalcified. **B:** The nodule enhances by more than 15 Hounsfield units, indicating that it is not benign. Some inflammatory lesions may have a similar enhancement pattern.

FIGURE 386.6. The evaluation of a solitary pulmonary nodule.

STAGING OF LUNG CANCER

In a patient with suspected or confirmed lung cancer, algorithm 2 (Fig. 386.8) shows that CT scanning is currently the pivotal investigation (Fig. 386.7). Positron emission tomography scanning using ^{18}F -deoxyglucose to detect metabolically active tumor is emerging as a valuable test for detection of occult mediastinal and

distal metastasis, thereby distinguishing resectable from unresectable tumor with greater accuracy than CT. However, further clinical trials of this modality are required before can be introduced into clinical practice.

FIGURE 386.7. Computed tomography staging of lung cancer. Unenhanced chest computed tomogram in a 70-year-old man shows a 2.5-cm left upper lobe nodule with invasion of the chest wall (*white arrow*). There is a 2-cm lymph node (*black arrow*) in the aortopulmonary window lateral to the trachea. aa, ascending aorta; da, descending aorta. The radiologic staging of T3 N2 (stage IIIA) was confirmed histologically.

FIGURE 386.8. Approach to the patient with suspected or confirmed lung cancer.

DIFFUSE LUNG DISEASE

Asthma, probably the commonest diffuse lung disease, may be associated with radiologic evidence of airway wall thickening or hyperinflation, but the chest radiograph is otherwise normal. Acute exacerbations of asthma can be associated with pneumomediastinum, pneumothorax or atelectasis. Allergic bronchopulmonary aspergillosis, an uncommon complication of asthma, is associated with central bronchiectasis, best seen on CT.

Moderate or severe emphysema is diagnosed on the chest radiograph by the presence of hyperlucency and vascular obliteration. Smoking-related emphysema is most marked in the upper lobes, while emphysema related to α_1 -antitrypsin deficiency is more marked in the lower lobes. CT is more sensitive for detection of emphysema and can be used to classify emphysema into centrilobular, panlobular, and paraseptal patterns.

Table 386.1 and Algorithm 3 (Fig. 386.10) indicates how the chest radiograph and CT can be used to characterize infiltrative lung diseases. HRCT is significantly more accurate than chest radiography for disease characterization. HRCT can be used to identify certain diffuse diseases, such as idiopathic pulmonary fibrosis, lymphangiomyomatosis, pulmonary histiocytosis X, and sarcoidosis, with a high degree of accuracy. However, the HRCT appearance of individual patients should always be considered in association with the clinical features. If the radiologic pattern or the clinical presentation is atypical, then biopsy should always be performed.

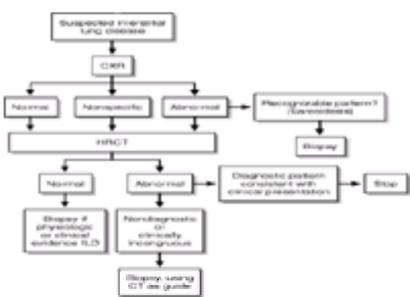

FIGURE 386.10. Imaging approach to characterization of infiltrative lung disease.

THROMBOEMBOLIC DISEASE (ALGORITHM 4, FIG. 386.11)

FIGURE 386.11. Imaging approach to thromboembolic disease.

The chest radiograph is usually abnormal, though nonspecific, in patients with pulmonary thromboembolism. The commonest abnormality is a decrease in lung

volumes, often associated with linear atelectasis. Wedge-shaped peripheral consolidation due to pulmonary infarction is substantially less common.

Ventilation–perfusion lung scanning is the traditional next step in the diagnostic pathway. A normal perfusion scan is associated with a very low likelihood of pulmonary embolism. A high-probability scan (Fig. 386.9) in patients with a high clinical suspicion for pulmonary embolism is associated with a 96% prevalence of pulmonary embolism. However, only 40% of patients with pulmonary embolism have high-probability scans. Most of the remaining patients have inconclusive scans and will require further investigation, such as ultrasonography of the lower extremity veins or pulmonary angiography. Ventilation–perfusion scanning is particularly difficult to interpret in patients with underlying pulmonary disease, and in these patients CT angiography is probably a better test. Ultrasonography of the lower extremities is most useful in patients whose symptoms are suggestive of deep venous thrombosis.

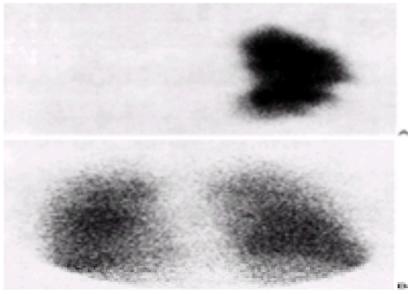

FIGURE 386.9. High probability lung scan in patient with suspected pulmonary embolism. **A:** Perfusion image (posterior view) obtained following intravenous administration of ^{99m}Tc -labeled macroalbumin particles shows absent perfusion in the left lung and multiple large defects in the right lung. **B:** Ventilation image obtained following inhalation of xenon 133 is near-normal.

Partly because of the lack of specificity of ventilation–perfusion scanning, CT angiography is emerging as an important diagnostic modality for pulmonary embolism. CT is excellent for diagnosis of embolism in the central pulmonary arteries (Fig. 386.12). Also, CT often identifies an alternative cause of the patient's symptoms. However, the lack of sensitivity of CT for detection of subsegmental emboli means that further diagnostic imaging is probably indicated to exclude embolism if the CT angiogram is normal. Pulmonary angiography remains the only modality that can definitively exclude pulmonary embolism.

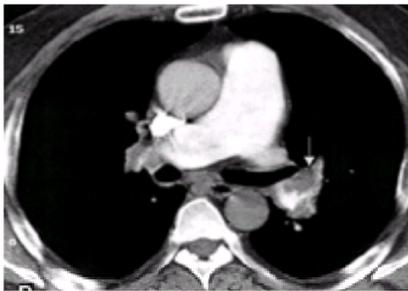

FIGURE 386.12. Acute pulmonary embolism on computed tomography (CT). Contrast-enhanced helical CT scan shows an irregular large thrombus in the dilated descending left pulmonary artery, extending into a segmental branch (arrow). The main pulmonary artery is mildly enlarged.

PLEURAL DISEASE

The earliest radiographic sign of pleural effusion is blunting of the costophrenic sulci. Since the costophrenic sulcus is deepest posteriorly, the lateral view is more useful than the frontal for detection of fluid. Decubitus imaging may be used to determine whether costophrenic blunting is due to pleural thickening or to mobile fluid. If there is more than 2 cm of mobile fluid along the chest wall on a decubitus radiograph, then blind thoracentesis is usually safe. If only a small amount of fluid is present, ultrasonographic guidance may be necessary.

A thin white line conforming to the expected shape of the pleura is the only specific radiologic sign of pneumothorax (Fig. 386.13). This line corresponds to the visceral pleura. Lung vessels are usually not visible outside the pleural line.

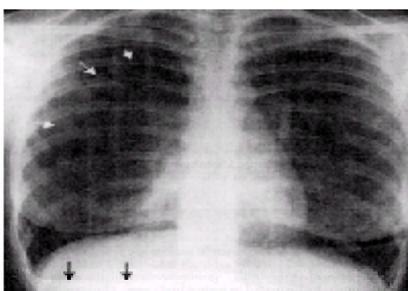

FIGURE 386.13. Spontaneous right hydropneumothorax in 25-year-old man. The pleural line is clearly visible (white arrows). An air–fluid level behind the diaphragm (black arrows) indicates that there is fluid as well as air in the right pleural space.

CHEST RADIOLOGY IN THE INTENSIVE CARE UNIT

The major roles of the chest radiograph in critically ill patients are to identify the positions of tubes and lines and to detect and follow pulmonary complications such as pneumonia, pulmonary edema, pneumothorax, and acute respiratory distress syndrome. Chest radiographs are indicated in these patients when a new tube or line is placed, or when there are clinical signs of deterioration, such as an increasing oxygen requirement. Routine daily chest radiographs are indicated only in the sickest patients.

Interpretation of radiographs in critical care patients is compromised by the fact that these are usually portable AP radiographs obtained in the supine position, often with an inadequate inspiration. Comparison of serial radiographs must take account of technical factors influencing radiographic appearances, including radiographic exposure, erect or supine positioning, depth of inspiration, and positive-pressure ventilation.

Pneumothorax and pleural effusions are more difficult to detect in the supine than in the erect position. In the supine patient, pneumothorax is usually anterobasal,

while pleural effusions layering posteriorly are evident as an increase in density superimposed on the lung. Decubitus imaging may be useful in detecting pneumothorax or effusion.

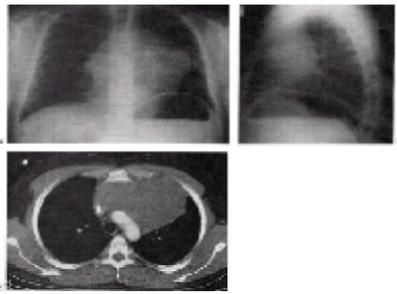

FIGURE 386.14. Anterior mediastinal mass in 25-year-old man. **A, B:** Posteroanterior and lateral chest radiographs show a mass in the anterior mediastinum. There is also a metastatic nodule in the left retrocardiac “miss area.” **C:** Computed tomography shows that the mass is composed of water density material. Biopsy confirmed germ cell tumor.

INTERVENTIONAL CHEST RADIOLOGY

Most pulmonary and mediastinal masses are amenable to image-guided transthoracic needle aspiration biopsy. These biopsies are usually performed using CT guidance, but ultrasonography or fluoroscopy may be useful in individual cases. The major complication of percutaneous needle biopsy is pneumothorax, which occurs in about 20% of cases but is usually self-limited, with chest tube drainage being required in only 5%. The risk of pneumothorax increases with the presence of emphysema, with increasing depth of the lesion, and with decreasing size of the lesion. CT can be most helpful in deciding whether to biopsy a mass bronchoscopically or percutaneously. If CT shows the mass to have an endobronchial component, or to have a bronchus leading directly to it (bronchus sign), then bronchoscopic biopsy is preferable, using the CT as a road map.

Imaging is increasingly used to guide diagnostic and therapeutic interventions. Ultrasonography is the ideal modality for guiding aspiration of pleural effusions. Ultrasonography excels at showing loculations and organization in a pleural collection. When ultrasonographic access is difficult, CT may be helpful. Image-guided placement of small-bore catheters is a viable alternative to surgical chest tubes for drainage of most pneumothoraces and fluid collections. Drainage of empyemas or complicated, loculated fluid collections can be enhanced by intrapleural administration of thrombolytics (streptokinase or urokinase). Pleurodesis may also be effectively accomplished using small-bore catheters.

[Screening Tests](#)
[Interpretation of Results](#)

In addition to testing lung function, pulmonary function tests assess other determinants of effective ventilation (e.g., upper airway patency, respiratory muscles, chemoreceptors). Our focus in this chapter is on those tests commonly used to assess pulmonary function with emphasis on what is required to maximize clinical usefulness.

PO₂, PCO₂, %SO₂ OF ARTERIAL BLOOD

Measurements of the PO₂ of arterial blood (PaO₂) are often useful for the detection of mild lung disease, especially when measured during exercise. Predicted values for PaO₂ decline with the normal changes of adult aging and must be adjusted for altitudes above sea level. The PaO₂ is also useful for following *changes* in lung function. However, relatively small changes in shunts (e.g., from localized atelectasis or an airway obstructed from secretions) can result in substantial changes in the PaO₂, which might be misinterpreted as changes in overall lung function.

The alveolar–arterial oxygen gradient, P(A-a) O₂, is less dependent on variations in ventilation than the PaO₂ and often is more useful for the detection of mild disease. The PAO₂ can be derived from the equation:

$$PAO_2 = P_{iO_2} - \frac{P_{aCO_2}}{R}$$

By assuming that alveolar equals arterial P CO₂; that the respiratory exchange ratio is 0.8, as in normal dietary conditions; and that water vapor pressure is 47 mm Hg, at sea level (760 mm Hg barometric pressure), PAO₂ = (760 – 47) (0.21) – PaCO₂/0.8 = 150 – 1.2 (PaCO₂).

Measurements of PaCO₂ are important for assessing the acid–base status and as indicators of the effectiveness of alveolar ventilation. Elevations of Pa CO₂ above the upper limit of normal (46 mm Hg) indicate that alveolar clearance of CO₂ is reduced and may be a valuable indicator of severe lung dysfunction. However, Pa CO₂ can also be elevated secondary to reduced central drive, including adaptive responses to excessive work of breathing and/or inspiratory muscle fatigue. Consequently, there is growing recognition that elevation of Pa CO₂, either at rest or during exercise, may not always be the bad prognostic sign it was once considered. Because of the large functional reserve of the lungs and the normal increase in ventilation in response to hypoxemia, elevation of Pa CO₂ is not a sensitive sign of mild lung disease.

Terminology regarding oxyhemoglobin saturation is frequently misused. Percent oxyhemoglobin (%Hb O₂) is defined as oxyhemoglobin expressed as a percentage of total hemoglobin. In contrast, percentage oxygen saturation (%S O₂) is oxyhemoglobin expressed as a percentage of hemoglobin available for oxygenation (the sum of deoxyhemoglobin and oxyhemoglobin). If a patient has an HbCO of 20%, a deoxyhemoglobin of 10%, and an HbO₂ of 70%, the %SO₂ would be 87.5% (70/80).

Pulse oximeters are devices with miniaturized sensors that attach to an ear or digit and estimate %Sa O₂ from measurements of changes in light absorption associated with systolic pulsations of blood flow. Because such devices respond within 60 seconds to changes in %Sa O₂, they are valuable noninvasive monitors of oxygenation during surgery and other procedures, in unstable patients in intensive care units, and for studies of sleep disorders. It is important to appreciate the limitations of this new technology. Because the 95% confidence interval for the accuracy of %Sa O₂ from most pulse oximeters is ±4%, and because of the shape of the oxyhemoglobin saturation curve, cutaneous oximeters have limited use for the detection of mild disease when compared with direct measurements of Pa O₂. Inherent inaccuracies in pulse oximeters also limit their use for other applications based on Pa O₂, such as prescription of home oxygen therapy. Their measurements are somewhat less accurate in the presence of carboxyhemoglobin and significantly less accurate with high levels of methemoglobin.

SPIROMETRY, FLOW–VOLUME CURVES

[Figure 387.1](#) illustrates relevant terminology and time and flow–volume curves from a normal subject. Although the development of equipment standards has improved the availability of spirometers with acceptable accuracy, attention to calibrations and other quality control steps are still important for acquiring clinically useful results.

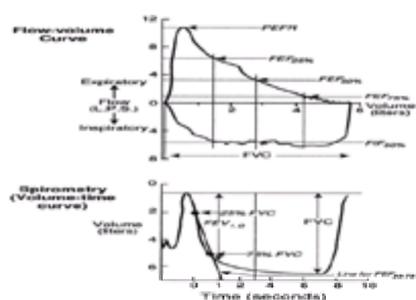

FIGURE 387.1. Flow–volume curve and spirometry tracing (volume–time curve) from a normal subject, with both curves from the same expiratory effort. FVC, forced vital capacity; FEV₁, forced expiratory volume in the first second of expiration; PEFr, peak expiratory flow rate. FEV_{25%}, forced expiratory flow rate at 25% VC. For this and other flows, the subscript indicates that the flow is measured at the volume expired, usually expressed as a percentage of the vital capacity.

With time tracings, the duration of the expiratory effort can be assessed. Flow–volume tracings offer easier visual assessments of changes of flow rates with repeat testing, appreciation of the relation between flow rates and expired volumes ([Fig. 387.1](#) and [Figure 387.2](#)), and recognition of patterns characteristic of localized and upper airway obstruction ([Fig. 387.3](#)).

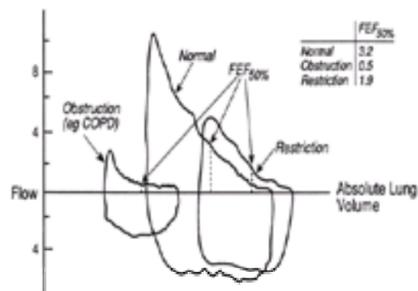

FIGURE 387.2. Examples of flow–volume curves in a patient with obstructive disease and a patient with restriction (diffuse interstitial fibrosis), as compared with a normal person. Volumes on the axis are absolute volumes to better demonstrate the relation of flows (e.g., $FEV_{50\%}$) to hyperinflation and restriction. COPD, chronic obstructive pulmonary disease; $FEV_{50\%}$, forced expiratory flow rate of 50%.

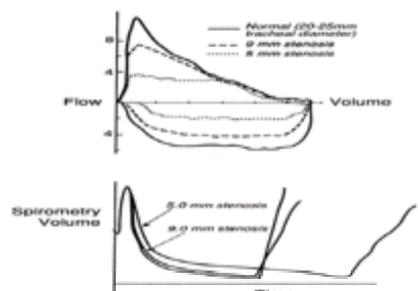

FIGURE 387.3. Effects of fixed obstruction of central airways (e.g., tracheal stenosis) on flow–volume curves. The 5-mm stenosis curve represents the characteristic flattened loop. The 9-mm-diameter stenosis (a 75% reduction in tracheal cross-sectional area) shows only a mild reduction in peak flows. Also notable for both examples of stenosis is the difficulty in recognizing the abnormalities from inspection of the volume vs time tracings.

The forced expiratory volume in 1 second (FEV_1) and the ratio of FEV_1 to the forced vital capacity (FVC) are the best parameters for the identification of patients with obstructive lung disease. Declines in FEV_1 with time is commonly used for assessing the rate of progression of obstructive lung disease; a normal decline in FEV_1 with aging of adults is 25 to 30 mL per year.

The FEV_1 -to-FVC ratio is useful when evaluating patients who have reductions of both the FVC and FEV_1 . A normal or high value for the ratio suggests that the FVC and FEV_1 are reduced because of a restrictive process rather than obstruction, whereas a low value indicates obstructive disease. For evaluating the progression of disease or responses to therapy, FEV_1 is more useful than the FEV_1 -to-FVC ratio. For example, bronchodilators may cause a greater increase in FVC than FEV_1 , causing a paradoxical decrease in the FEV_1 -to-FVC ratio.

Studies from the 1970s suggest that flow rates later in expiration (e.g., $FEF_{25\%-75\%}$, $FEF_{50\%}$) might be more useful than the FEV_1 for the identification of patients with early obstructive lung disease. However, several disadvantages of these flow rates limit their clinical usefulness, including larger variability on repeat testing, wider ranges of predicted values, and lack of evidence that isolated reductions in these flow rates (reductions when the FEV_1 is within normal limits) predict who develops clinically significant chronic obstructive pulmonary disease (COPD) in the future.

Reductions in expiratory flow rates must be interpreted with caution in patients with reduction of total lung capacity (TLC) because of the relation between lung volume and airway size. In [Figure 387.2](#), the volume axis of the flow–volume curves is expressed in terms of absolute lung volumes; although the loops from the patients with obstruction and restriction both have reduced values for $FEV_{50\%}$, if one compares flows at the same lung volumes, the restricted patient's $FEV_{50\%}$ is slightly above the value predicted from a normal patient.

[Figure 387.3](#) illustrates the changes in flow–volume loops from a fixed localized obstruction of the trachea. The classic configuration is a loop flattened in both inspiration and expiration, as observed in the curve representing a severe stenosis of 5-mm tracheal diameter. Less severe obstruction may cause a mild blunting of the peak expiratory flow rates, a pattern difficult to distinguish from normal. Although a flattened flow–volume curve is a specific sign of localized central airway obstruction, it is not sensitive and its absence does not rule out significant localized obstruction of central airways. Variable intrathoracic obstruction, as seen with tracheomalacia where luminal diameters increase with inspiration and decrease during expiration, produce curves that may be difficult to distinguish from loops that are suggestive of COPD. Variable extrathoracic airway obstruction (e.g., paralyzed vocal cords) results in reductions in maximal inspiratory flows with normal maximal expiratory flows. (This picture is, however, most commonly artifactual and the result of an inadequate inspiratory effort or, occasionally, inspiratory muscle weakness).

RESPONSE TO BRONCHODILATORS

Testing the response to bronchodilators seldom requires more than repeat measurements of spirometry 15 to 30 minutes after inhalation of a bronchodilator. An increase in FEV_1 of at least 12% and 200 mL is a standard criterion of response. The absence of an acute response, however, does not obviate the need for a clinical trial of bronchodilator therapy. Testing bronchodilator response is frequently not indicated; clinicians should carefully consider when it is necessary.

BRONCHIAL CHALLENGE

A decrease in FEV_1 of 20% or more after low doses of inhaled methacholine or histamine is common in patients with asthma and is a useful test of bronchial hyperresponsiveness (see [Chapter 363](#)). Responses to higher doses can also occur in patients with allergic rhinitis, chronic bronchitis, and congestive heart failure. Inhalation challenges using specific antigens can be useful in confirming that a suspected inhalant is the cause of lung dysfunction.

LUNG VOLUMES

Lung volume measurements can be useful for evaluating patients with restrictive or obstructive lung diseases. Restrictive lung disease is defined physiologically as a reduction in TLC. Obstructive disease is a disorder with reduced maximal inspiratory or expiratory flow rates, which is frequently accompanied by hyperinflation of residual volume (RV), functional residual capacity (FRC), and sometimes TLC. [Figure 387.3](#) illustrates that both obstructive and restrictive diseases can cause reductions of vital capacity (VC) of similar magnitude; the measurements of TLC distinguish the two processes. If spirometry shows a reduced FVC, but no reduction in the FEV_1 -to-FVC ratio or other flows (e.g., $FEF_{25-75\%}$), it is reasonable to assume that the FVC is reduced because of restrictive disease even in the absence of measurements of TLC. However, if the FEV_1 -to-FVC ratio is reduced without measurements of TLC, one cannot determine whether the VC is reduced as a result of the obstructive disease or restrictive disease superimposed on obstruction.

In clinical practice, absolute lung volumes (TLC, FRC, and RV) can be measured by one of three techniques: gas dilution or washout, body plethysmography, or surface measurements of thoracic borders on conventional posteroanterior and lateral chest radiographs. All three techniques give comparable results in normal

subjects, but the results can differ in patients with disease.

Helium dilution or nitrogen washout techniques are the lung volume techniques most commonly available, but they may underestimate volumes in patients with obstructive airway or bullous diseases because of impaired communication between proximal airways and distal airspaces. Body plethysmography can measure lung volumes accurately in such patients but requires equipment and levels of technical expertise that are not available in many hospitals. The accuracy of radiographic TLC measurements (15% or greater) limits their clinical usefulness in individual patients, except when determining changes in volumes from serial radiographs.

Accurate measurements of RV, FRC, and TLC give a better appreciation of the impressive hyperinflation of lung volumes that can occur in severe obstructive lung disease (Fig. 387.4). Measurements of TLC facilitate recognition of restrictive processes superimposed on obstructive disease and increase the detection of mild obstructive disease in some patients.

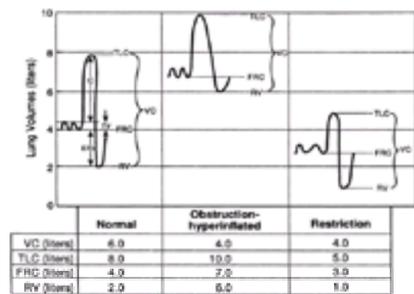

FIGURE 387.4. Absolute lung volumes in a normal person, a patient with hyperinflation secondary to obstructive airways disease, and a patient with restrictive lung disease. VC, vital capacity (the volume expired from a maximal inspiration); TLC, total lung capacity (to full expiration); RV, residual volume; FRC, functional residual capacity (volume at end of a normal tidal breath); IC, inspiratory capacity; TV, tidal volume; ERV, expiratory reserve volume.

MAXIMAL INSPIRATORY PRESSURES

Maximal inspiratory pressures (MIP) is more specific for neuromuscular disease than reductions in VC and is useful for identifying patients weanable from mechanical ventilation. MIP may also be decreased by severe hyperinflation, electrolyte derangements, or nutrition deficiencies. The wide range of predictive values limits the sensitivity of these tests. Tests for the early recognition of respiratory muscle fatigue, a significant determinant of dyspnea, are complex and available only in specialized laboratories.

DIFFUSING CAPACITY OF CARBON MONOXIDE

Although the diffusing capacity of carbon monoxide (DLCO) assesses transfer of gas by diffusion from the alveoli to the pulmonary capillaries, additional factors (e.g., hemoglobin concentration, distribution of ventilation and perfusion, lung volumes) affect the uptake of carbon monoxide in this test; as a result, many clinicians prefer to call this test the transfer factor for carbon monoxide. Nonetheless, experience has shown DLCO to be a useful clinical test.

The single-breath DLCO is measured from differences in inspired and expired CO concentrations after inspiring 0.3% CO and 10 seconds of breath holding; a tracer gas, such as helium, is included to correct for the dilution due to the RV. DLCO measurements under rebreathing and steady-state conditions are not widely used clinically. Observed interlaboratory differences for DLCO values of up to 40% have been attributed to differences in testing techniques. Despite the availability of standardized methodologies of testing, differences between published reference values for DLCO can be substantial (more than 30%) and necessitate confirmation that the predicted values used are appropriate for specific testing systems.

The DLCO is increased in pulmonary hemorrhage, polycythemia, and some cases of asthma or early congestive heart failure. The DLCO is frequently decreased in severe anemia, interstitial diseases, emphysema, congestive heart failure, and pulmonary vascular diseases (e.g., emboli). Although the DLCO is often the most sensitive standard pulmonary function test for detecting early interstitial or pulmonary vascular disease, a normal test does not rule out these disorders. Although nonspecific, the DLCO is a reasonable early test for the evaluation of a patient complaining of dyspnea.

EXERCISE TESTING

Spirometry before and after exercise identifies exercise-induced asthma. Observing simple tests of exercise capacity (e.g., the distance walked in 12 minutes) often clarifies the specific symptoms that limit exercise and the severity of exercise limitation and dyspnea.

Measurement of exercise PaO₂ and PaCO₂ detects dysfunction not present at rest and identifies the need for ambulatory oxygen supplementation. Increased physiologic dead space (VDS) as measured by the VDS-to-VT ratio can be a sensitive but nonspecific indicator of lung dysfunction during exercise. Increases in PaCO₂ during exercise may reflect limited lung reserve but can also reflect alterations in ventilatory drive. Oxygen uptake during maximal exercise (V_{O₂max}), a measure of maximal work, may be useful in assessing patients being considered for disability compensation, cardiac surgery, resectional lung surgery, or heart or lung transplantation. Assessments of changes in FRC and flow limitation of tidal volumes during exercise can identify causes of dyspnea not detected during conventional testing but are currently available in relatively few centers.

OTHER TESTS

Tests for small-airway disease (e.g., closing volume, flow-volume curves before and after inhalation of helium-oxygen mixtures, and frequency dependence of compliance) now play a limited role in clinical practice because they do not identify those patients whose airway disease will progress to disabling disease. Tests of distribution of ventilation (e.g., from multiple-breath nitrogen washout measurements of lung volumes) may be helpful in identifying patients with mild obstructive airway disease. Other specialized tests (e.g., physiologic dead space, airway resistance, lung compliance, tests of control of ventilation) have clinical applications but are often available only in specialized tertiary laboratories, such as at centers involved with lung volume reduction surgery.

SCREENING TESTS

The use of pulmonary function tests to screen for early airway disease is not recommended because there is no evidence that earlier therapy has an effect on long-range outcome. However, when appropriately utilized, screening can be useful for persons facing future occupational exposure to noxious inhalants, for the preoperative evaluation of selected patients, and for patients undergoing therapy that could cause pulmonary dysfunction (e.g., therapy with bleomycin).

INTERPRETATION OF RESULTS

Few medical tests are as dependent on patient cooperation as many tests of pulmonary function. Reductions of VC, TLC, or FEV₁ can readily be caused by inadequate patient effort or a patient's poor understanding of the ventilatory maneuvers required. Test reports should always be reviewed for comments regarding such factors that might influence their validity. Additional clues may be the reproducibility of duplicate maneuvers and whether the actual tracings are consistent with adequate effort.

After confirming that the tests were performed adequately and that the predicted values are appropriate for the specific patient being studied, the interpretation should

address the following four basic questions:

- Is the test normal?
- Does the pattern of abnormalities suggest a specific category of disease?
- What is the severity of disease?
- What changes have been observed since previous tests?

Is the Test Normal?

Normal values for most pulmonary function tests should be adjusted for relevant determinants (age, height, race, and sex). If predicted values of FVC, FEV₁, and TLC from studies of white subjects are used for black or Asian patients, they should be reduced by 12%, or prediction equations specific for Asian and blacks can be used. For spirometry and most pulmonary function tests, predicted values from commonly used published studies are reasonably comparable. For other tests (e.g., DLCO, MIP), predicted values may differ substantially, most likely because of differences in testing methodologies and possibly also from differences in the subjects tested. Until standardization of testing methodologies is sufficiently widespread to allow standardized prediction equations appropriate for all laboratories, the adequacy of prediction equations (and testing methodologies) is best confirmed by testing disease-free subjects representative of a hospital's patient population.

For most pulmonary function tests, results from normal subjects fall in a gaussian distribution that allows prediction of limits of normal from the predicted value and the standard deviation of the predicted values for that specific patient. For nongaussian distributions, limits of normal can be defined by analysis of percentiles of the study population. The 95% confidence limits for the range of normal values are determined by a 2-tailed *t* test; 2.5% of a normal population fall below the lower limit of normal. In most cases, however, disease only causes changes in one direction (e.g., reduced FEV₁ in COPD). In such situations, it is more appropriate to define only the lower limit of normal by a 1-tailed *t* test; 5% of a normal population is expected to have values below this limit.

Caution must be used in interpreting results that are near the limits of normal. As illustrated in Fig. 387.5, the 95% lower limit of normal for FEV₁ would be a relatively good criterion for identifying patients with severe COPD because there is relatively little overlap with normal subjects. In contrast, because of the overlap in FEV₁ between patients with mild COPD and normal subjects, over 30% of a population of patients with mild COPD may have FEV₁ greater than the lower limit of normal. If a patient's result is just above the lower limits of normal (e.g., 78% of predicted), it would be misleading to conclude that the patient is normal—the result could represent a low normal and could also represent mild COPD. Table 387.1 illustrates how interpretations can be worded to reflect this overlap of mild dysfunction and limits of normalcy.

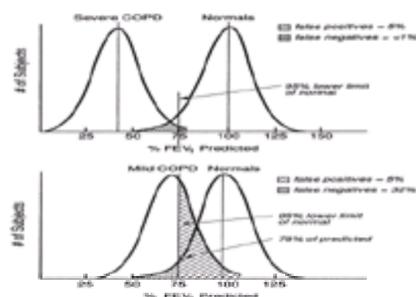

FIGURE 387.5. Comparison of distribution of FEV₁ values in a sample of normal adults and a sample of patients with severe COPD. In contrast to the top graph, in the bottom graph the sample of patients with mild COPD (mean FEV₁ = 68% of predicted) shows considerable overlap with a normal population. More than 30% of patients with mild disease are falsely labeled as normal, using the conventional lower limit of normal ($\alpha = .05$). FEV₁, forced expiratory volume in the first second of expiration; COPD, chronic obstructive pulmonary disease.

Interpretation	TLC, Four- Quartile (% of Predicted)	FEV ₁ , Four- Quartile (% of Predicted)
Within normal limits	>90	>90
Within normal limits but is a low-normal result (about one-third reduction) (Obstruction)	80-90	LLN-90
Below limits of normal, most likely mild restriction (Obstruction); small chance this is a variant of normal	70-80	70-LLN
Moderately severe restriction (Obstruction)	60-70	60-70
Severely severe restriction (Obstruction)	50-60	50-60
Severe restriction (Obstruction)	<50	<50

TLC, total lung capacity; FEV₁, forced expiratory volume in 1 second; LLN, lower limit of normal.

 Reference Values and Interpretive Strategies. Am Rev Respir Dis 1991;144:1242-1258.

TABLE 387.1. INTERPRETATION OF SEVERITY OF RESTRICTIVE AND OBSTRUCTIVE LUNG DISEASE (BASED ON PHYSIOLOGIC MEASUREMENTS OF TLC AND FEV₁)

A second important consideration regarding limits of normal is that they do not predict the probability of disease but rather the probability that the value would occur in a sample of normal subjects. To predict the probability of disease, one would need to know both the distribution of values in a sample of patients with disease and the prevalence of disease in the patients being tested—information that is seldom available. If an FEV₁ of 78% of predicted (Fig. 387.5) was from an asymptomatic student in a screening survey, the probability is higher that the subject is normal than it would be if the result was from a clinic patient with complaints of wheezing.

Does the Dysfunction Suggest a Specific Category of Disease?

The symptom that usually leads to an assessment of lung function is dyspnea, a ubiquitous symptom with a complex differential diagnosis. Although it is rare that pulmonary function testing indicates a specific diagnosis, the results frequently suggest a category of diseases that substantially narrows the differential diagnosis.

Lung dysfunction leading to dyspnea can be divided into three basic physiologic categories: obstructive, restrictive, and vascular. Patients with obstructive lung disease are identified from reductions of flow rates during maximal inspiration and expiration. Then, based on additional clinical information, the disease can be subdivided into the following subcategories: localized obstruction (e.g., tracheal stenosis), asthma, chronic bronchitis, emphysema, and other diseases causing obstruction of small airways such as bronchiolitis.

Restrictive lung diseases are characterized physiologically by a reduction in TLC. This broad category can then be subdivided into pleural diseases; alveolar filling processes; interstitial diseases; neuromuscular involvement of respiratory muscles; and thoracic cage abnormalities, which include intra-abdominal processes such as pregnancy or tense ascites as well as chest wall problems such as scoliosis.

Diseases involving the pulmonary vascular bed (e.g., emboli, vasculitis) do not result in patterns of gas exchange or ventilatory dysfunction specific for these disorders. Instead, they are suggested from pulmonary function tests by their typical abnormalities (reduced Pa O₂ at rest or during exercise, reduced DLCO, increased VDS-to-VT ratio) in the absence of evidence of other lung diseases.

How Severe Is the Disease?

[Table 387.1](#) provides a guideline for interpreting the severity of dysfunction for both restrictive and obstructive lung disease based on measurements of TLC and FEV₁, respectively. Such guidelines are, however, somewhat arbitrary and may not meaningfully reflect the severity of the disease process in individual patients. For example, if a patient had a high-normal TLC of 115% of that predicted before developing pulmonary fibrosis, a decrease in the TLC to 72% of that predicted could represent much more severe disease than if the healthy baseline value was 84% of that predicted.

Assigning a patient's disease to somewhat simplistic categories of severity may be much less useful clinically than using physiologic data to answer more meaningful questions. Such questions include the following: What is the estimated 5-year survival rate if the patient is not treated? Is the severity of airway obstruction consistent with the patient's PaCO₂ of 55 mm Hg? What is the risk of lung resection in this patient?

Are There Significant Changes Since Previous Testing?

When interpreting serial studies, consideration must be given to possible interlaboratory differences, normal variability on repeat testing, and the effects of growth or aging (which, ideally, should be based on cross-sectional rather than longitudinal studies).

CHAPTER 388: HEMODYNAMIC AND RESPIRATORY MONITORING IN CRITICAL CARE

BARBARA A. COCKRILL

[Monitoring Hemodynamic Pressures](#)
[Monitoring Ventilation](#)
[Monitoring Oxygen Exchange](#)

Critically ill patients often suffer from derangements in the cardiovascular and respiratory systems. The field of critical care has developed in large part because of the relatively recent ability of the clinician to monitor and intervene in these derangements. This chapter will discuss monitoring techniques frequently used in critical care medicine. The first section discusses hemodynamic pressure measurements, the second covers ventilation and carbon dioxide exchange, and the third discusses monitoring parameters of oxygenation.

MONITORING HEMODYNAMIC PRESSURES

ARTERIAL PRESSURE

All patients in the intensive care unit (ICU) should have frequent assessment of peripheral blood pressure. For many, an automated blood pressure cuff, which automatically inflates at regular intervals, is sufficient. The cuff is placed on the upper arm, and pressure is recorded digitally on a screen.

Placement of an intra-arterial catheter for invasive monitoring of peripheral blood pressure is indicated for patients with the potential for rapid changes in hemodynamic status, those in whom vasoactive drugs are being used, or in patients with respiratory failure who need frequent blood gas analysis. The most common site for an arterial line is the radial artery. This site is easily accessible, relatively comfortable for the patient, and carries a low risk of ischemic injury. Before cannulating a radial artery, an Allen test should be performed to confirm adequate collateral flow via the ulnar artery. The examiner manually compresses both arteries until the patient's hand becomes pale. Pressure on the ulnar artery is released: the hand should flush pink within 5 to 7 seconds, indicating adequate perfusion from the ulnar artery. If not, another site should be used for the arterial access. If the Allen test has been properly performed, the risk of ischemic damage to the hand is low. Other potential sites include the ulnar, brachial, femoral, and dorsalis pedis arteries. The contour of the arterial waveform changes depending on the site of measurement ([Fig. 388.1](#)). At sites more distal to the aorta the systolic pressure will be higher and the diastolic pressure lower; however, the *mean* arterial blood pressure (MAP) is essentially constant. Systolic pressure in the dorsal pedis artery may be as much as 25 mm Hg higher than that recorded from the radial artery.

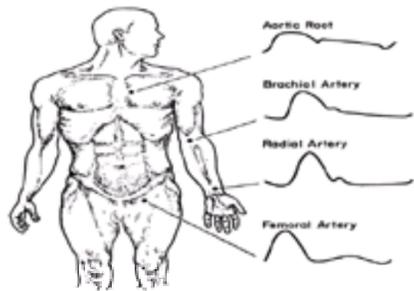

FIGURE 388.1. The arterial waveform recorded from different parts of the arterial tree. (From Marino PL. *The ICU book*. Philadelphia: Lea & Febiger 1991:91, with permission.)

Inaccurate transmission of pressures due to “overdamping” is a frequent pitfall in pressure monitoring. Overdamping results in a waveform that is blunted: systolic pressure appears lower than the actual pressure, and diastolic appears higher. The presence of air bubbles in the pressure tubing is the most common cause. Because the air is compressible, the bubble will “cushion” the transmission of pressure. The mean pressure is still accurate, but systolic hypertension and/or diastolic hypotension will be missed. The latter becomes critically important for patients with myocardial hypoperfusion. The left ventricle is primarily perfused during diastole; isolated diastolic hypotension may result in cardiac ischemia.

Local hemorrhage, infection, and thrombosis are all potentially serious complications of arterial catheters. Hemorrhage is best controlled with local compression as most sites are superficial. The risk of bacteremia with arterial catheters is roughly 4% in large series, although local colonization rates are higher. Risk factors for infection include (a) placement by surgical cut-down (ninefold increase); (b) local inflammation; and (c) a longer duration of cannulation. A catheter should not be placed through inflamed skin and should be removed as soon as it is no longer needed. In most studies, the infection rate is similar for femoral lines as compared with radial lines.

The incidence of clinically significant arterial occlusion is low (less than 1% in large series), although radiographic occlusion is present in 25%. Risk factors for ischemia include (a) a large-bore cannula; (b) systemic hypotension; (c) severe peripheral vascular disease; and (d) the use of systemic vasopressor agents. An 18-gauge catheter is associated with a fourfold increase in radial artery occlusion, as compared with a 20-gauge catheter. It is recommended that a 20-gauge line be used, especially in a smaller individual. Patients with vasospastic disease, such as severe Raynaud's phenomenon, may also be at increased risk and must be monitored closely.

PULMONARY ARTERY CATHETERS

Pulmonary artery (PA) or Swan–Ganz catheters are long, flow-directed, balloon-tipped catheters that are inserted via the central venous circulation through the right heart and into the PA. Most catheters also have a thermistor at the distal end to allow the measurement of thermodilution cardiac output. Pulmonary vascular resistance (PVR) and systemic vascular resistance (SVR) are derived from the measured pressure and cardiac output values. Mixed venous blood from the pulmonary artery may also be obtained.

Clinical Indications

In complicated critically ill patients, the hemodynamic profile is difficult to assess by clinical examination alone. In one study, clinicians accurately predicted the hemodynamic profile less than 50% of the time in patients who subsequently had PA catheters inserted. Furthermore, the information gained from PA monitoring frequently resulted in a change in therapy. The situations in which a PA catheter may be useful include (a) hypotension despite adequate fluid resuscitation; (b) pulmonary edema unresponsive to empirical diuresis; (c) pulmonary edema associated with hypotension and/or pulmonary hypertension; and (d) respiratory failure in which high levels of positive end-expiratory pressure (PEEP) are required. The information gained from a PA catheter is probably most helpful in balancing two often opposing goals: (a) minimizing pulmonary venous pressure and edema; and (b) optimizing left-heart filling pressures.

The subclavian and internal jugular veins are the most common insertion sites. The subclavian is more comfortable for the patient but carries an increased risk of pneumothorax (1% to 2%) and bleeding (because the subclavian artery is not compressible). The internal jugular route is preferred in patients with hyperinflation or on mechanical ventilation due to the lower incidence of pneumothorax.

The pressure tracing should be continuously displayed and recorded during insertion to allow complete analysis ([Fig. 388.2](#)). The catheter is advanced through the

right heart into the PA until the balloon lodges in a smaller branch and the typical “wedge” tracing appears. Once the balloon is wedged, a static column of blood develops between the catheter tip and the next junction between flowing and nonflowing blood: the junction or “J” point ([Fig. 388.3](#)). Because of the static column of blood, the pressure measured at the catheter tip (pulmonary artery occlusion pressure, PAOP) is equal to the pressure at the J point. The J point is usually at the level of the pulmonary veins. Under normal circumstances, the PAOP accurately reflects left ventricular end-diastolic pressure (LVEDP) because there is no obstruction between the pulmonary veins and the left ventricle at end diastole when the pulmonary veins and mitral valve are normal. Thus, the PAOP is equal to the J-point pressure, which is equal to the LVEDP.

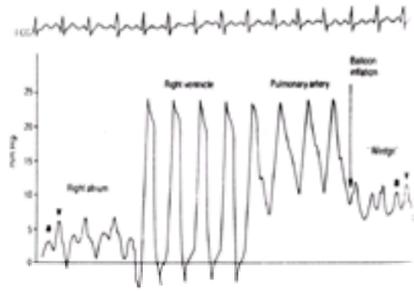

FIGURE 388.2. The normal pressures and waveforms demonstrated on insertion of a pulmonary artery (PA) catheter are shown. The appearance of respiratory variation indicates that the catheter has entered the thorax. The balloon is then inflated, and blood flow directs the catheter through the right heart and into the PA. The right atrial pressure waveform shows characteristic a and v waves. As the catheter enters the right ventricle (RV), systolic pressure rises and diastolic pressure is unchanged due to the low resistance to flow through the tricuspid valve. When the catheter traverses the pulmonary valve, systolic pressure is relatively constant and the diastolic pressure rises. It is not unusual to observe a small (less than 5 mm) decrease in systolic pressure between the RV and PA (PA), especially in high-flow states. Normally there is a small difference (less than 5 mm Hg) between PA_{dia} and left atrial pressure (LA). The pulmonary capillary bed has tremendous reserve, so that increases in flow are not associated with an increase in resistance. When there is occlusion or loss of the pulmonary capillary bed and an elevation in pulmonary vascular resistance, the PA_{dia} may exceed LA significantly. The wedge tracing shows a and v waves, which are transmitted from the left atrium. The v wave occurs after the T wave on a simultaneously recorded electrocardiogram (see text). Pulmonary and systemic vascular resistance (PVR and SVR) are calculated using the cardiac output (CO): $PVR = (PA_{mean} - PAOP)/CO$; $SVR = (MAP - RA)/CO$. (From Mathay MA. Invasive hemodynamic monitoring in critically ill patients. *Clin Chest Med* 1983;4:233, with permission.)

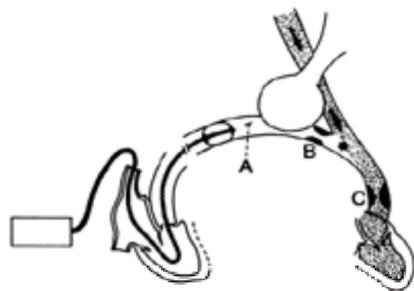

FIGURE 388.3. Definition of the pulmonary artery occlusion pressure (PAOP). The PAOP measured at point A is nearly identical to the pressure at the junction of static and flowing venous blood (J point, *). This site is generally in a pulmonary vein of equal size to the artery that has been occluded. The PAOP will not be influenced by partial occlusions of the static column (B), as would be seen in the rare disorder pulmonary veno-occlusive disease. However, obstructions (C) downstream of the junction point dissipate pressure, causing PAOP to significantly exceed the mean left atrial pressure, as is seen in an obstructing left atrial myxoma or mitral stenosis. (From Marini JJ, Wheeler AP. *Critical care medicine: the essentials*. Baltimore: Williams & Wilkins, 1989:17, with permission.)

In a number of conditions, the PAOP does not accurately reflect the LVEDP ([Fig. 388.3](#)). The easiest circumstance to understand is that of mitral stenosis. In the presence of mitral stenosis, the pressure at the J point is higher than LVEDP due to obstruction to blood flow at the mitral valve. The pressure in the left atrium (LA) is accurately measured in mitral stenosis. Pulmonary edema may be present in mitral stenosis due to elevated pulmonary capillary pressures up-stream from the site of obstruction. If the obstruction to flow is distal to the J point but proximal to the LA (such as with an obstructing left atrial myxoma), the PAOP will be higher than both the LA pressure and the LVEDP.

The term pulmonary capillary wedge pressure (PCWP) is often used interchangeably with PAOP and is so much part of medical jargon that it is likely to prevail. Note that pulmonary *capillary* wedge pressure is not correct in that the occlusion pressure reflects pulmonary capillary pressure only when the catheter is wedged. Once the balloon is deflated and flow continues through the pulmonary capillaries, the actual capillary pressure (and tendency for edema formation) may be higher. This is why patients with pulmonary veno-occlusive disease (a rare disorder characterized by obstruction at the site of the pulmonary venules) will have pulmonary edema with a normal PAOP ([Fig. 388.3](#)).

The use of positive-pressure mechanical ventilation may also affect the accuracy of PAOP measurement. The lung can be divided into three zones based on the relative pressures of the pulmonary arteries, pulmonary veins, and the alveoli. Note that the PAOP reflects the J-point pressure only if the catheter is in zone III ([Fig. 388.4](#)). If the catheter enters zone I or II (alveolar pressure less than pulmonary venous pressure), when the balloon is up and the catheter is wedged, the pulmonary capillary pressure is equal to the pulmonary venous pressure, and the capillaries will therefore be compressed by alveolar pressure. Thus, alveolar pressure will be measured, not the downstream J-point pressure. Most of the lung is under zone III conditions in the supine patient, and most of the blood flows through zone III. During insertion, the PA catheter position is directed by the flow of blood. It is therefore uncommon for a catheter to enter zone I or II initially. However, in a critically ill patient, a zone III position may be converted to a zone II position. This most commonly occurs if a patient has been markedly diuresed (PA pressure has decreased) or if a patient has had a marked increase in PEEP (alveolar pressure has increased).

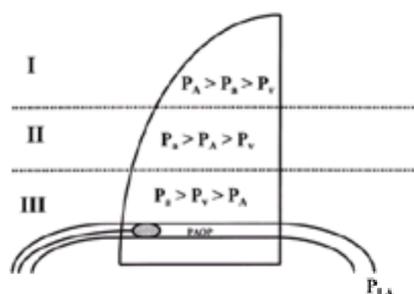

FIGURE 388.4. The lung is partitioned into three zones based on the relationship between the alveolar pressure (P_A), the mean pulmonary arterial pressure (P_a), and the pulmonary venous pressure (P_v). The pulmonary artery occlusion pressure (PAOP) is an accurate measurement of the downstream left atrial pressure (P_{LA}) only when P_v exceeds P_A (zone III). (Adapted from Marino PL. *The ICU book*. Philadelphia: Lea & Febiger, 1991:125, with permission.)

Respiratory changes in intrathoracic pressure may also affect hemodynamic pressure measurements. Pleural pressure, and therefore juxtacardiac pressure, changes with respiration. The PAOP is least affected by respiration at end expiration and therefore should be measured at this point. During spontaneous breathing, the intrathoracic pressure is negative on inspiration, and end expiration is at the high spot on the tracing. In contrast, for patients on positive pressure ventilation, end expiration is represented at the low spot on the tracing.

By definition, PEEP applies positive pressure at end expiration. In compliant lungs this pressure will be transmitted and raise pleural and juxtacardiac pressure at end expiration, and therefore could be reflected in the measured PAOP. However, in clinical practice it is unusual for transmitted PEEP to account a large part of the measured PAOP. With less than 10 cm PEEP transmission is not clinically significant. In general, only patients with low pulmonary compliance require high levels of PEEP, and in this case typically 25% or less of PEEP is transmitted. Furthermore, it must be remembered that PEEP is measured in centimeters of H₂O and PAOP in millimeters of Hg. Fourteen cm H₂O approximately equals 10 mm Hg. This means that on 14 cm of PEEP the typical pressure that may be reflected in the PAOP would be 0.25 × 10 mm Hg = 2.5 mm Hg. A PEEP trial is helpful when high levels (more than 12 cm) are used.

Complications

The complications of PA catheters can be divided into complications of insertion and those associated with an indwelling line. Pneumothorax and infection are complications common to any central line. Because the PA catheter traverses the right heart, arrhythmias may develop but usually are transient. All patients must have a continuous ECG monitor during insertion and while the PA catheter is in place. Premature atrial and ventricular complexes are generally well tolerated, but ventricular tachycardia requiring countershock does occur. Right bundle-branch block develops in a small percentage of patients, and anyone with a preexisting left bundle-branch block should have an external or temporary internal pacemaker in place prior to insertion.

Pulmonary infarction is a serious complication of PA catheters. The risk is increased in patients with poor cardiac output. The risk is reduced by minimizing the time in the wedge position and keeping the catheter from migrating too distally. Daily chest roentgenograms are necessary to check catheter position. The tip of the catheter should be within the shadow of the pulmonary artery. The full 1.5 cm³ of air should be required for balloon inflation to obtain the wedge, and inflation should always be done slowly.

The most devastating complication is pulmonary artery rupture, which has a 75% mortality in some series. Pulmonary hypertension and anticoagulation are the major risk factors, but above-noted factors associated with infarction are also associated with rupture. A contained perforation must be considered in any patient who develops hemoptysis with a pulmonary artery line in place. A contrast chest computed tomography scan will demonstrate a pseudoaneurysm in patients with a contained rupture, which requires radiographically directed embolization or surgery.

THERMODILUTION CARDIAC OUTPUT

Another important function of a PA catheter is to provide thermodilution cardiac output measurements. Cool saline (iced or room temperature) is injected via the catheter into the right atrium where it mixes with and cools the blood. As the cooler blood (and saline) is pumped through the heart and enters the PA, the change in temperature caused by injection of saline will be detected by the thermistor at the distal tip of the catheter. A high cardiac output will cause a rapid change in temperature, as the injectate is rapidly pumped past the thermistor; a low cardiac output will cause a slower change in temperature. The cardiac output is inversely proportional to the area under the curve of the plotted temperature change ([Fig. 388.5](#)).

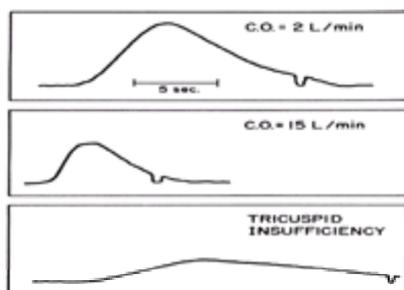

FIGURE 388.5. Thermodilution curves for low cardiac output (*upper*), high cardiac output (*middle*), and tricuspid valve insufficiency (*lower*). (From Marino PL. *The ICU book*. Philadelphia: Lea & Febiger, 1991:125, with permission.)

Does the PA catheter help us to treat patients more effectively? Despite the widespread use of the PA catheter and its substantial cost, data to confirm that the procedure is beneficial to patients are lacking. In fact, some recent studies (all observational in design) have suggested that the use of the PA catheter is associated with increased mortality. A large prospective cohort study that examined the association between right heart catheterization in the first 24 hours of care in the ICU and subsequent survival found a significantly increased 30-day mortality in patients who underwent right heart catheterization. The differences could not be explained by any measure of severity of illness (propensity score, APACHE III score). The following explanations have been suggested for the following sobering results:

- PA catheterization may be a marker for an aggressive or invasive style of care that may be associated with a higher mortality rate.
- The information gained from PA catheterization may have been misunderstood or misused.
- The therapy selected on the basis of the information provided by PA catheterization may lead to a higher mortality.
- The study may not have adjusted for a confounding variable.

This study reinitiated a long-standing debate about the risk: benefit ratio of PA catheters. The American Thoracic Society, the Society of Critical Care Medicine, the American Association of Critical Care Nurses, the American College of Chest Physicians, and the European Society of Intensive Care Medicine have issued a consensus statement with the following recommendations:

There is currently no indication for a moratorium on the use of PA catheters. Prospective randomized trials of PA catheters are indicated, ethical, and appropriate. The decision to insert a PA catheter should continue to be based on the specific clinical circumstances of a given patient.

MONITORING VENTILATION

MECHANICS OF VENTILATION

During normal spontaneous respiration, negative pressure is generated by contraction of the diaphragm, while the intercostals stabilize the rib cage. Exhalation is passive, relying on the intrinsic elastic recoil of the lungs. During respiratory distress, both inspiratory and expiratory accessory muscles are recruited, and exhalation becomes active. In the mechanically ventilated patient, positive inspiratory pressure is generated by the ventilator, and exhalation is either passive or active depending on the patient. Negative-pressure mechanical ventilators, such as the iron lung, are rare in current clinical use.

The most basic form of respiratory monitoring is simple observation. Patients in respiratory distress usually assume a breathing pattern of a rapid rate and small tidal volume (VT). In the setting of diaphragmatic weakness or fatigue, the patient may also develop *abdominal paradox*. This refers to the inward motion of the abdomen on inspiration, and occurs because the diaphragm is not moving normally on inspiration. The term *respiratory alternans* describes the patient who is alternating between a normal pattern (abdomen moves down and out on inspiration) and abdominal paradox. Both of these patterns may be a sign of fatigue and impending

hypercapnic respiratory failure.

A maximal inspiratory pressure (MIP) measurement is direct assessment inspiratory muscle strength. This is measured having the patient maximally inspire against an occluded airway. For intubated patients who are unable to cooperate, the endotracheal tube is occluded for 20 seconds or 10 inspiratory efforts, and the maximum force generated is recorded. The MIP is useful for following patients with neuromuscular disease, such as myasthenia gravis, to assess the need for mechanical ventilation, and for patients weaning from the ventilator to assess readiness for discontinuation of mechanical ventilation. The patient who cannot generate an inspiratory force of -20 cm H₂O or less is unlikely to be able to breathe without mechanical support. A single value which is more negative than -20 cm H₂O is not a definite indicator of successful weaning. The MIP measures strength, not endurance; the patient with a very high respiratory load may be unable to sustain adequate ventilation over a long period.

COMPLIANCE

The compliance of the respiratory system (C_{rs}) is a measure of the pressure needed to inflate the lungs and chest wall with a given volume of gas. Intuitively, compliance can be considered as the relative “stiffness” of the respiratory system. Compliance is calculated as change in volume divided by the change in pressure:

$$C_{rs} = \Delta V / \Delta P$$

Static compliance (C_{stat}) is a measure of the airway pressure required to hold the lungs and chest wall inflated at a given V_T. It is determined by stopping flow at end inspiration, allowing a short period for equilibration, and measuring the pressure at the airway (plateau pressure). Because it is measured during a no-flow state, airway resistance does not influence C_{stat}. When using C_{stat} clinically, it is assumed that the contribution from the chest wall is fairly constant. In ICU patients, however, chest wall compliance may be variable due to level of sedation, surgery, pain, abdominal distention, respiratory muscle contraction, chest wall edema, and the use of paralytic drugs. Therefore, while determination of the C_{stat} is a useful parameter, changes do not necessarily indicate a change in the status of the pulmonary parenchyma, and the rest of the clinical picture must be considered.

AIRWAY PRESSURE AND LUNG VOLUMES

The airway pressure parameters that are most important to monitor depend on the mode of ventilation being used. A few points deserve emphasis. There are two basic modes in clinical use: pressure-limited and volume-limited.

During pressure-limited ventilation, the ventilator delivers a set inspiratory pressure. In this case, the tidal volume is the dependent variable. Therefore, changes in respiratory status will be reflected in the tidal volume. The inspiratory pressure will be unchanged because it is set by the ventilator. There are many determinants of the tidal volume, including set pressure level, C_{rs}, inspiratory time, and inspiratory flow rate. Monitoring the tidal volume for a patient on pressure-limited ventilation will provide immediate clues to changes in the respiratory status.

During volume-limited ventilation, the ventilator delivers a set tidal volume. The inspiratory pressure is determined by the airways resistance, C_{rs}, V_T, and the inspiratory flow rate. Peak inspiratory pressure (PIP) is a key parameter to follow in patients on volume-limited ventilation because nonaltered ventilator settings are an indicator of airways resistance and lung compliance. High PIP is associated with barotrauma (including pneumothorax and pneumomediastinum) and overdistention (which causes ongoing pulmonary parenchymal injury). A sudden increase in PIP must be investigated. Comparison of the peak and plateau pressures can provide a clue to the etiology. If plateau pressure is unchanged from baseline (or significantly less than peak), then an increase in airways resistance from bronchospasm, retained secretions, or a kink in ventilator tubing is the major culprit. If plateau pressure is also increased, then atelectasis, pneumothorax, or a right main-stem intubation are possible, as are causes of acute decreases in lung compliance such as congestive heart failure.

DEAD SPACE

The partial pressure of carbon dioxide (CO₂) in the arterial blood (P_aCO₂) is determined by the balance between CO₂ production (V̇CO₂) and CO₂ elimination by the lungs. The amount of CO₂ excreted by the lungs is dependent on the alveolar ventilation (V̇_A). Thus:

$$P_{aCO_2} = \dot{V}CO_2 / \dot{V}_A$$

Not all of the gas that enters the lungs is active in the exchange of carbon dioxide and oxygen. The tidal volume can be divided into two components: that which participates in gas exchange (V̇_A) and that which does not (dead space ventilation, V̇_{DS}). That is:

$$V_T = \dot{V}_{DS} + \dot{V}_A$$

The alveolar ventilation is the volume of gas that is in contact with pulmonary capillary blood and is active in gas exchange. Dead space ventilation includes the volume that is in the conducting airways (anatomical dead space) and in alveoli that are not perfused by capillary blood (alveolar dead space). If the fraction of ventilation that goes to dead space (V̇_{DS}/V_T) increases, then the total minute ventilation (V̇_E) must increase in order to maintain the same V̇_A (and P_aCO₂). This ratio increases in patients on positive-pressure mechanical ventilation but is overcome by increasing total ventilation. The fraction of ventilation that goes to dead space can be approximated as follows:

$$\dot{V}_{DS} / V_T = (P_{aCO_2} - P_{ECO_2}) / P_{aCO_2}$$

where P_{ECO₂} is the partial pressure of CO₂ in mixed expired gas. This determination requires collection of expired gas and measurement of CO₂, which is time consuming, expensive, and technically difficult. For patients on mechanical ventilation, V̇_{DS}/V_T can be approximated. The condensate in the expiratory circuit trap is constantly exposed to expired gas; therefore the partial pressure of CO₂ of the fluid is the same as that of the expired gas. Thus determination of the P_{CO₂} in the fluid will give an estimate of the P_{ECO₂}. This is done by simply obtaining a “blood gas” analysis on the fluid. Care should be taken to use fresh water, allow equilibration for 5 minutes, and collect the fluid anaerobically. If water that has been sitting in the tap is used, bacterial contamination may cause an artificially high P_{CO₂}, and thus dead space will be underestimated. If exposed to room air, the fluid P_{CO₂} will be artificially low. Dead space is a useful parameter to evaluate in mechanically ventilated patients with respiratory failure. A patient with a dead space ratio of more than 0.6 will generally not be able to sustain the high V̇_E required to wean successfully from mechanical ventilation. (For a more complete discussion of ventilation, see [Chapter 10](#).)

MONITORING OXYGEN EXCHANGE

OXIMETRY

The pulse oximeter is an electronic monitoring device that allows noninvasive assessment of hemoglobin saturation. The oximeter transmits two wavelengths of light through pulsating tissue via a probe that usually is applied to the finger or ear lobe. By comparing the light absorption at the two wavelengths, the degree to which hemoglobin is saturated (SaO₂) can be determined. The four common hemoglobin species are oxyhemoglobin, reduced hemoglobin, carboxyhemoglobin, and methemoglobin. The pulse oximeter, which emits only two wavelengths of light, does not detect carboxyhemoglobin or methemoglobin. This is especially important to consider in the emergency room setting and for patients with smoke inhalation injury. Hemoglobin molecules with CO at the binding sites may register as “saturated” hemoglobin and thus will give a falsely elevated SaO₂. Methemoglobin may also cause inaccuracies. Some drugs, especially nitrates and inhaled nitric oxide, may elevate methemoglobin. The hallmark of methemoglobinemia is cyanosis despite apparently adequate arterial oxygen levels. If carboxyhemoglobinemia or methemoglobinemia is suspected, blood should be analyzed on a co-oximeter. This device can accurately measure hemoglobin, oxyhemoglobin, carboxyhemoglobin,

and methemoglobin.

Pulse oximetry is very useful for monitoring trends in individual patients. It has pitfalls and does not replace arterial blood gas determinations. The reading is accurate at ± 4 percentage points if the saturation is above 75%, but the accuracy decreases at saturations below 75%. The oximeter uses the difference between systolic and diastolic values to factor out the absorption due to tissues; in low perfusion states, a lack of pulse differential may lead to incorrect values. If a good pulse tracing is not obtained, the reading should not be considered accurate. Darkly pigmented skin may also cause inaccuracies: one study found that when titrating oxygen therapy a higher pulse oximetry saturation target is needed (more than 95%) in black individuals. Other factors that may cause an incorrect saturation determination include the use of intravascular dyes such as methylene blue and indocyanine green, high levels of ambient light, and dark-colored nail polish. The oximeter may be inaccurate by four percentage points or more under the best circumstances. In addition, the pulse oximeter gives no information regarding Pa CO₂. Hypoventilation and hypercarbia are often present without coexisting falls in Sa O₂.

BLOOD GAS ANALYSIS

A blood gas refers to the measurement of the partial pressures of oxygen (Pa O₂), carbon dioxide (PaCO₂), and pH. Blood gases may be monitored either by a single sample drawn via needle puncture, or by drawing from an indwelling arterial catheter. Specimens drawn from a catheter more accurately reflect the steady-state blood gas because the patient is less likely to experience an acute change in breathing patterns as with an arterial puncture.

To ensure a steady state, arterial blood gases should be drawn after at least 10 minutes on a stable inspired oxygen (Fi O₂), and more time may be required in patients with severe lung disease. Specimens are placed on ice and analyzed within 30 minutes. Leaving a blood sample at room temperature or a delay in analysis may lead to falsely low values of PaO₂ and/or falsely high values of PaCO₂, because leukocytes in the blood continue to be metabolically active, consuming oxygen and producing carbon dioxide. In the presence of very high leukocyte (more than 100,000 K) counts, falsely low Pa O₂ is common because of the rapid oxygen consumption by the leukocytes ("leukocyte larceny"). In this case, samples must be run immediately in order to obtain an accurate Pa O₂. In cases of marginal oxygenation, recognition of the patient's positional effects on oxygenation may help with management.

ALVEOLAR/ARTERIAL OXYGEN GRADIENT

The alveolar/arterial gradient [P(A-a) O₂] refers to the difference between alveolar and arterial oxygen, and quantifies the efficiency of transfer of oxygen from alveoli to blood. In order to determine the gradient, the partial pressure of oxygen in the alveoli (P AO₂) is calculated from the modified alveolar gas equation. On room air at sea level, this equation simplifies to

$$PAO_2 = 150 - 1.25(PaCO_2)$$

The P(A-a)O₂ gradient is calculated by subtracting the measured Pa O₂ obtained by blood gas from the *derived* value for PAO₂. The P(A-a)O₂ calculation takes alveolar CO₂ partial pressure into account and therefore is most useful in distinguishing hypoxia due to hypercarbia from hypoxia due to other causes. Patients with hypoxia due to hypercarbia will still have a normal P(A-a) O₂. On room air the normal value is less than 10 mm Hg. Because the normal P(A-a) O₂ is effected by increasing Fi O₂ and changes in mixed venous oxygen saturation, it is much less helpful in patients on supplemental oxygen. The Pa O₂/Fi O₂ ratio is also a commonly used index in critical care, but it is influenced by changes in Fi O₂ and is therefore imprecise.

SHUNT FRACTION

The shunt fraction (\dot{Q}_s/\dot{Q}_t) is the fraction of the systemic cardiac output (\dot{Q}_t) that reaches the arterial circulation without exposure to alveolar oxygen. The oxygen content of shunted blood is therefore equal to that of mixed venous blood. In normals, \dot{Q}_s/\dot{Q}_t is less than 5% and comprises venous return to the left atrium from bronchial, pleural, and thebesian veins. Determination of shunt fraction is a useful exercise in the hypoxic ICU patient. Hypoxia due to large shunt fractions (more than 25%) is unresponsive to increases in Fi O₂; therefore, the presence of a large shunt should encourage the clinician to decrease Fi O₂ to levels below the toxic range. Elevated levels should also alert the clinician to search for intracardiac shunts and/or pulmonary arteriovenous malformations. Right to left shunting may develop through the patent foramen in the setting of severe pulmonary hypertension and elevated right-sided pressures. Efforts to decrease the elevated right-sided pressures or, occasionally, to increase the left heart pressures may be useful in decreasing the degree of shunt. Approximately 30% of adults have a probe patent foramen ovale.

Most patients in the ICU are hypoxic due to a combination of ventilation-perfusion (\dot{V}/\dot{Q}) mismatching and shunt, and occasionally a low mixed venous oxygen. In order to determine the "true" shunt, blood gases must be drawn while the patient is breathing 100% oxygen, or areas of \dot{V}/\dot{Q} mismatching will also contribute to the hypoxia. Fifteen minutes of 100% Fi O₂ must be allowed prior to drawing arterial and mixed venous blood gases. If inhalation of 100% O₂ is prolonged, absorption atelectasis will develop, further contributing to the shunt fraction. The shunt fraction is calculated as follows:

$$\dot{Q}_s/\dot{Q}_t = (C_c'CO_2 - CaO_2)/(C_c'CO_2 - CvO_2)$$

where CaO₂ is the oxygen content of arterial blood, CvO₂ is the oxygen content of mixed venous blood, and Cc'O₂ is the oxygen content of end-capillary blood in the lungs. End-capillary blood is assumed to have a P O₂ equal to that of PAO₂ (calculated with the alveolar gas equation), and the saturation is determined by the oxygen dissociation curve.

OXYGEN CONTENT

The oxygen content of blood refers to the total amount of oxygen in the blood and is composed of oxygen that is dissolved in the plasma and oxygen that is bound to hemoglobin. The partial pressure of oxygen (PaO₂) reflects the amount dissolved in plasma. The amount of oxygen bound to hemoglobin is typically quantified as the percentage of hemoglobin that is saturated with oxygen (SaO₂). The formula for arterial oxygen content is as follows (amount dissolved + amount bound to hemoglobin):

$$CaO_2 \text{ (mL/dL)} = (0.003 \times PaO_2) + 1.39 \times [Hb] \times SaO_2$$

Factors that lead to fewer binding sites on hemoglobin molecules include anemia and binding by substances that have a higher affinity for hemoglobin than oxygen, such as carbon monoxide. The affinity of hemoglobin for oxygen is decreased with abnormal hemoglobins and by the factors associated with shifting the oxyhemoglobin dissociation curve to the left ([Fig. 388.6](#)). Note that when the number of binding sites on hemoglobin is decreased, it follows that the oxygen content will be decreased even if the hemoglobin saturation is normal!

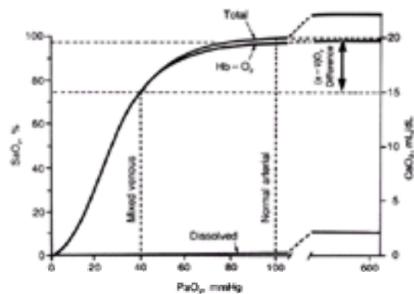

FIGURE 388.6. The oxyhemoglobin dissociation curve, relating the partial pressure of oxygen (O_2) in systemic arterial blood (PaO_2), in millimeters of mercury, to systemic arterial saturation (SaO_2), in percent, and to the O_2 content of systemic arterial blood (CaO_2), in milliliters per deciliter of blood. A normal hemoglobin (Hb) concentration of 15 g per deciliter is assumed, as is an unshifted dissociation curve. The curve descends steeply below PaO_2 values of 50 to 60 mm Hg, indicating severely reduced O_2 -carrying capacity by Hb below this PaO_2 . The lower line represents O_2 bound to Hb plus O_2 dissolved. Dissolved O_2 contributes little to CaO_2 at a PaO_2 in the normal range. (From Luce JM, Tyler ML, Pierson DJ. *Intensive respiratory care*. Philadelphia: WB Saunders, 1984:26, with permission.)

OXYGEN DELIVERY

Two components are involved in providing delivery of oxygen to the tissues: arterial oxygen content and cardiac output (\dot{Q}). The oxygen delivery (DO_2) is equal to the arterial oxygen content multiplied by the cardiac output:

$$DO_2 = CaO_2 \times \dot{Q}$$

When oxygen demand is increased, the normal response is an increase in cardiac output. With further stress, the tissues increase oxygen extraction such that the oxygen content of mixed venous blood decreases. The normal arterial content is approximately 20 mL O_2 per 100 mL of blood, and the resting difference between arterial and venous oxygen content is approximately 5 mL per 100 mL (Fig. 388.6). Therefore, the extraction ratio is 25%; only one-fourth of the total oxygen that is delivered is actually taken up by the tissue. This ratio rises when more oxygen is extracted peripherally, and consequently the oxygen content of mixed venous blood (CvO_2) falls. In most clinical situations, low-oxygen mixed venous content is a reliable indicator that the extraction ratio is increased and oxygen delivery is inadequate. This can be confirmed by measuring lactic acid: an increase in lactic acid provides clear evidence that cells are not receiving enough oxygen to maintain aerobic metabolism. In this setting, clinical interventions to increase oxygen delivery, either through increases in oxygen content or cardiac output, are reasonable. In sepsis, however, there may be a peripheral defect in cellular oxygen utilization such that lactic acid will be produced even if sufficient oxygen is being delivered. In this setting the CvO_2 will not be low; adequate oxygen is being delivered but the tissues are unable to use it.

MIXED VENOUS OXYGEN

The normal value for mixed venous oxygen saturation (SvO_2) is about 75%. Values below this level indicate that O_2 delivery is not keeping up with O_2 demand. Continuous monitoring of SvO_2 may allow the early detection of changes in this balance—especially when associated with an increased lactic acid level. SvO_2 influences SaO_2 when there is a high degree of shunt or \dot{V}/\dot{Q} mismatch. Thus a fall in SaO_2 should not be immediately attributed to changes in pulmonary function, as the determinants of SvO_2 may also be contributing.

Some PA lines are equipped with an oximeter for continuous monitoring; otherwise a sample drawn from the PA is needed for measurement of SvO_2 . The sample is drawn slowly with the balloon down from the distal port of the catheter after an initial 3 cm³ has been discarded. If blood is drawn too rapidly or if the catheter is too distal, the sample will be contaminated by pulmonary capillary blood and therefore overestimate the mixed venous oxygenation.

Decreased SvO_2 has been associated with increased mortality in acute myocardial infarction and shock. In sepsis and acute respiratory distress syndrome, however, the SvO_2 may remain increased despite serious tissue hypoxemia due to a cellular defect in oxygen uptake. There is controversy regarding the value of continuous monitoring of mixed venous blood. Currently, the best use of continuous SvO_2 monitoring is as an early warning to prompt investigation of changes (i.e., cardiac output, oxygen demand).

CHAPTER 389: DIAGNOSTIC PROCEDURES IN PULMONARY AND CRITICAL CARE MEDICINE

SUZETTE GAROFANO AND DIANE E. STOVER

[Diagnostic Procedures in Pulmonary and Critical Care Medicine](#)
[Evaluation of the Lung Parenchyma and Airways](#)
[Evaluation of Pleural Effusions](#)
[Cervical Mediastinoscopy and Anterior Mediastinotomy](#)

DIAGNOSTIC PROCEDURES IN PULMONARY AND CRITICAL CARE MEDICINE

A wide variety of noninvasive and invasive procedures are useful in the diagnosis of diseases affecting the respiratory tract. A knowledge of these procedures, their indications, complications, and limitations is essential for formulating a rational approach to the evaluation of patients with pulmonary disease. Chest imaging, pulmonary function testing, and hemodynamic and respiratory monitoring in the critically ill patient are covered in other chapters (see [Chapter 386](#), [Chapter 387](#) and [Chapter 388](#)). The remaining most common diagnostic procedures are discussed in this chapter.

EVALUATION OF THE LUNG PARENCHYMA AND AIRWAYS

SPUTUM EXAMINATION

Examination and culture of expectorated sputum is usually the first step in evaluating patients with pulmonary symptoms or chest roentgenographic abnormalities. The proper collection and handling of the specimen is essential to maximize diagnostic yield, especially if a bacterial pneumonia is suspected. Because sputum specimens are contaminated by upper airway–colonizing organisms, examination of expectorated sputum may not accurately reflect lower respiratory pathogens, especially in patients with bacterial pneumonia. This is less of a problem in the diagnosis of malignancies or infections caused by organisms that do not normally colonize the oropharynx, such as *Mycobacterium tuberculosis* and *Pneumocystis carinii*. To minimize oropharyngeal contamination, patients should be instructed to first rinse their mouths or brush their teeth. They should cough deeply and expectorate directly into a sterile, leak-proof container. The specimen should be transported immediately to the microbiology laboratory. In cases of suspected tuberculosis, three fresh morning specimens should be collected for the best diagnostic yield.

The gross characteristics of the sputum specimen may suggest specific diagnoses. Copious purulent sputum is generally suggestive of pyogenic bacterial infection. However, a purulent appearance may be caused by any inflammatory process, including asthma caused by the presence of numerous eosinophils. Pneumococcal infection has classically been described to produce rusty sputum. Dark red currant jelly sputum has been associated with *Klebsiella pneumoniae*. Foul-smelling sputum suggests the presence of an anaerobic or mixed anaerobic and aerobic bacterial infection. Hemoptysis is a nonspecific finding that is often associated with bronchitis or pneumonia; however, it should raise the suspicion of an underlying malignancy, especially if signs and symptoms of an infection are lacking.

Gram's stain of the sputum can be used to assess the quality of the specimen and should be performed on all specimens obtained from patients with a suspected bacterial pneumonia. A specimen is considered satisfactory if fewer than 10 squamous epithelial cells per low-power field are seen. In patients with a suspected bacterial pneumonia, more than 25 polymorphonuclear cells per low-power field and the presence of elastin fibers on KOH wet mount of the specimen are supportive evidence that the specimen originated from the lower respiratory tract. However, one should not exclude the possibility of oropharyngeal contamination. An unsatisfactory specimen should not be submitted for bacterial culture.

Because of difficulties in performing and interpreting the sputum Gram stain and problems with oropharyngeal contamination, the value of the Gram stain in the initial evaluation of a patient with pneumonia has recently been questioned. Yet most authorities agree that, when examined by someone with experience, a properly performed Gram stain on a good-quality specimen with a predominant intracellular organism is useful in suggesting the likely diagnosis and guiding initial antibiotic choice while awaiting culture results. Likewise, in a febrile patient with a pulmonary infiltrate, Gram's stain of a satisfactory specimen without a predominant organism may indicate an atypical bacterial infection, such as *Mycoplasma*, *Legionella*, or *Chlamydia*, or a viral process.

The diagnostic usefulness of a sputum specimen may be maximized by a variety of special staining and immunologic techniques. Direct staining of sputum can be diagnostic for several infectious processes ([Table 389.1](#)). Acid-fast stains of expectorated sputum are frequently positive for tuberculosis. In early, noncavitary disease, sputum smears reveal acid-fast bacilli in 20% to 40% of cases, with up to 95% yield in cases of advanced cavitary disease. The direct fluorescent antibody stain is a rapid method of identifying *Legionella* species in sputum. The sensitivity of the direct fluorescent antibody stain has been reported to range from 30% to 70%, with a specificity of approximately 95%. The polymerase chain reaction and DNA probes are newer techniques currently being developed for the rapid, sensitive, and specific diagnosis of infections, especially those caused by organisms that may not be detected by direct microscopic examination or are slow-growing in culture. Early studies using polymerase chain reaction probe for the diagnosis of *M. tuberculosis* infection report sensitivities equal to or greater than culture, ranging from 39% to 100% and specificities of more than 90%.

Pathogen	Stain
Fungi	Grocott-Gomori methenamine-silver
<i>Legionella</i>	Direct fluorescent antibody
<i>Mycobacterium tuberculosis</i>	Acid-fast stain
<i>Nocardia</i>	Modified acid-fast stain
<i>Pneumocystis carinii</i>	Toluidine blue O Grocott-Gomori methenamine-silver
Viruses:	Weigert-Gram Giemsa Fluorescent monoclonal antibody
Respiratory syncytial virus	Fluorescent monoclonal antibody
Influenza	
Parainfluenza	
Adenovirus	

TABLE 389.1. RESPIRATORY PATHOGENS THAT MAY BE DETECTED BY DIRECT STANNING OF EXPECTORATED SPUTUM

If a spontaneously expectorated sputum cannot be obtained, sputum induction using nebulized hypertonic (3%) saline may be useful. Sputum induction has been of value in diagnosing *P. carinii* pneumonia in patients with AIDS. The sensitivity of stained induced specimens in this population ranges from 55% to 92%, the highest yields obtained with the use of immunofluorescent monoclonal antibodies. The diagnostic use of sputum induction for other infectious processes or malignancies is not known, but it probably should be performed in those circumstances if patients cannot provide a satisfactory specimen spontaneously.

Cytologic examination of sputum should be performed when malignancy is suspected. The diagnostic yield of cytologic examination ranges from 50% to 90%. Recovery rates can be improved by sending multiple early-morning specimens. Yield improves sequentially when sending up to five specimens. Recent studies suggest that overexpression by sputum cells of the protein heterogeneous nuclear ribonucleoprotein A2/B2 may be a marker of lung carcinoma. Examination of expectorated sputum samples for this protein by monoclonal antibody staining may be a potentially useful means for detecting preclinical lung cancer. These studies are preliminary, and the sensitivity and specificity of this technique for the early detection of lung cancer are not known.

TRANSTRACHEAL ASPIRATE

Transtracheal aspirate is a technique used to obtain specimens from the lower respiratory tract for microbiologic examination without contamination by oropharyngeal flora. In this technique, a plastic catheter is passed through the cricothyroid membrane into the trachea. As the patient coughs, a specimen is aspirated into an

attached syringe.

False-negative results of bacterial cultures are rare using this technique unless the patient is receiving concurrent antibiotic therapy. However, a significant false-positive rate may occur in patients with chronic respiratory diseases such as chronic bronchitis, bronchiectasis, bronchogenic carcinoma, and symptomatic asthma who may have bacterial colonization of the lower respiratory tract without true infection. The risk of serious complications, including hemorrhage, worsening hypoxemia, and, rarely, death, has also limited the usefulness of this technique.

BRONCHOSCOPY

Since its introduction in the late 1960s, flexible fiberoptic bronchoscopy (FOB) has become one of the most commonly used diagnostic tools in pulmonary medicine. FOB allows direct visualization of the tracheobronchial tree and sampling of the lower respiratory tract and lung parenchyma for microbiologic, cytologic, and pathologic evaluation.

Flexible fiberoptic bronchoscopy can be performed on inpatients, outpatients, and mechanically ventilated patients. Although bronchoscopy may be performed comfortably without premedication in some patients, most commonly some combination of parenteral atropine and an analgesic or benzodiazepine is administered. After the application of topical anesthesia to the upper airway mucosa, the bronchoscope is passed through the nose or mouth and then through the vocal cords into the trachea. After inspection of the tracheobronchial tree, a variety of attendant procedures may be performed. Bronchial washings are obtained by instilling small amounts of saline into the airway and suctioning back the saline. Bronchial and transbronchial brushings are obtained by inserting a small brush through the bronchoscope and moving it back and forth over an endobronchial lesion or by advancing the brush into the lung parenchyma, entrapping fragments of tissue between the bristles. The specimens are then transferred onto a glass slide for cytologic and microbiologic evaluation. Bronchoalveolar lavage (BAL) is performed by wedging the bronchoscope into a subsegmental bronchus, usually in the lingula or right middle lobe. Aliquots of saline (30 to 60 mL) are instilled through the bronchoscope and then gently aspirated back into a syringe or suction trap. Approximately 40% to 60% of the infused fluid is recovered. Bronchial biopsies can be performed under direct vision of lesions that are endoscopically visible. Transbronchial biopsies (TBBs) of the lung parenchyma are usually performed under fluoroscopic guidance. Transbronchial needle aspiration (TBNA) allows tissue sampling from the lung parenchyma as well as paratracheal, hilar, and subcarinal lymph nodes.

The protected specimen brush and protected BAL are two techniques developed in an attempt to improve the diagnosis of bacterial pneumonia, especially nosocomial or ventilator-associated pneumonia. Specimens are obtained from the lower respiratory tract, without upper airway contamination, through protected, sealed catheters advanced through the bronchoscope into the distal bronchial tree. These techniques have been found to be useful in diagnosing bacterial infections in the absence of concurrent antibiotic therapy when quantitative bacterial culture thresholds of more than 10³ colony-forming units per milliliter for protected specimen brush and more than 10⁴ colony-forming units per milliliter for protected BAL are used.

Flexible FOB has a wide variety of diagnostic and therapeutic applications. Some of the most common uses are listed in [Table 389.2](#). FOB is very useful in the diagnosis of bronchogenic carcinoma. A diagnostic yield of 95% has been reported with biopsy and brushings of endobronchial lesions. The diagnosis of lung carcinoma can be made in approximately 80% of cases that present as parenchymal masses larger than 2 cm. BAL has recently been reported to be valuable in diagnosing peripheral primary lung carcinomas, revealing malignant cells in up to 64% of cases. The diagnostic yield was higher with larger lesions and with bronchoalveolar carcinoma cell type.

Diagnostic
Abnormal chest radiograph
Atelectasis
Interstitial lung disease
Cavitary lesion
Diffuse infiltrates in the immunocompromised host
Suspected bronchogenic carcinoma
Staging of bronchogenic carcinoma
Cough
Hemoptysis
Suspected tracheobronchial foreign body
Wheeze and stridor
Assessment of endotracheal tube position

Therapeutic
Removal of tracheobronchial foreign body, retained secretions, or mucous plugs
Control of massive hemoptysis
Treatment of endobronchial neoplasms
Laser therapy
Brachytherapy
Photodynamic therapy
Tracheobronchial stent placement
Therapeutic lavage in pulmonary alveolar proteinosis
Insertion of endobronchial tubes

TABLE 389.2. INDICATIONS FOR BRONCHOSCOPY

The major clinical application for TBNA is to obtain mediastinal or hilar lymph node tissue for the diagnosis and staging of lung cancer. The sensitivity of TBNA for this indication has been reported to range for 50% to 80% with the specificity approaching 100%. TBNA may also be useful for the diagnosis of granulomatous diseases associated with intrathoracic adenopathy. TBNA has been found to have a yield of up to 90% for the diagnosis of sarcoidosis. A recent study found TBNA to be particularly useful for the diagnosis of mycobacterial infection in HIV-positive patients. TBNA established the diagnosis of mycobacterial disease in 87% of patients and was the only positive bronchoscopic specimen in 48% of cases.

Fluorescent bronchoscopy using a device termed the lung-imaging fluorescent endoscopy (LIFE) bronchoscope is a recently introduced technique to detect small, superficial endobronchial precancerous and carcinoma-in-situ lesions that are not readily visible with conventional bronchoscopy. This technique is based on differences in autofluorescence patterns between premalignant and malignant tissue and normal bronchial tissue. In one study, the use of LIFE bronchoscopy improved the detection of carcinoma in situ from 40% with conventional bronchoscopy to 91%. The ultimate role for this technique in the surveillance, diagnosis, and treatment of early carcinoma remains to be determined.

BAL can be diagnostic in several infectious processes ([Table 389.3](#)). The isolation of other organisms, such as cytomegalovirus and *Aspergillus*, in susceptible hosts with compatible clinical presentations can be considered diagnostic for invasive pulmonary infection. BAL can also be diagnostic for a few noninfectious processes, whereas several others can be presumptively diagnosed in the proper clinical setting ([Table 389.4](#)).

<i>Pneumocystis carinii</i>	<i>Histoplasma</i>
<i>Mycobacterium tuberculosis</i>	<i>Toxoplasma</i>
<i>Nocardia</i>	<i>Strongyloides</i>
<i>Mycoplasma</i>	Influenza
<i>Legionella</i>	Respiratory syncytial virus

TABLE 389.3. PATHOGENS IN WHICH ISOLATION FROM BRONCHOALVEOLAR LAVAGE IS DIAGNOSTIC FOR INFECTION

Diagnosis	BAL Findings
Malignancy	Neoplastic cells
Pulmonary alveolar proteinosis	Opaque, milky BAL fluid Periodic acid-Schiff staining Lamellar structures on electron microscopy
Eosinophilic granuloma	Langerhans cells Birbeck's granules on electron microscopy OR16 monoclonal antibody staining
Asbestos exposure	Asbestos bodies
Pulmonary hemorrhage*	Hemosiderin-laden macrophages
Sarcoidosis*	Noncaseating granuloma
Lipid pneumonia*	Fat globules in macrophages
Eosinophilic pneumonia*	Increased percentage of eosinophils
Amiodarone exposure or toxicity*	Large macrophages with lamellar inclusion bodies

* Suggested diagnosis in the proper clinical setting.
BAL, bronchoalveolar lavage.

TABLE 389.4. BRONCHOALVEOLAR LAVAGE ANALYSIS OF NONINFECTIOUS PROCESSES

The diagnostic accuracy of FOB with or without TBB for diffuse lung disease of noninfectious etiologic process varies with the underlying disease process. Sarcoidosis can be diagnosed in a majority of cases, but the sensitivity of FOB for other disorders, such as eosinophilic granuloma, pulmonary alveolar proteinosis, and bronchiolitis obliterans with organizing pneumonia, may be low. FOB should be the initial invasive diagnostic procedure performed in most cases of diffuse lung diseases to exclude an infectious process or sarcoid, but a surgical procedure may be required for a definitive diagnosis.

Fiberoptic bronchoscopy has become an invaluable tool in the evaluation of diffuse pulmonary infiltrates in the immunocompromised host. Bronchoscopy with BAL and TBB has been reported to have about 90% sensitivity for the diagnosis of an infectious process in this setting, with an overall diagnostic yield of 70%. Bronchoscopy has a particularly high yield for *P. carinii* pneumonia; 94% in non-AIDS-immunocompromised patients with bilateral BAL and close to 100% in patients with AIDS if both BAL and TBB are performed. BAL is also an excellent technique for the diagnosis of cytomegalovirus pneumonia in bone marrow transplant recipients with a sensitivity of more than 90% when stained with immunofluorescent cytomegalovirus monoclonal antibodies.

Rigid bronchoscopy that uses a large-diameter, straight metal tube is less frequently performed. In comparison with flexible FOB, rigid bronchoscopy usually requires general anesthesia and allows good visualization of only the lobar bronchi. It remains the procedure of choice in several clinical settings, however, including foreign-body retrieval, massive hemoptysis, and dilatation of tracheobronchial stenosis.

Fiberoptic bronchoscopy is a safe and well-tolerated procedure. Major complication rates range from 0.08% to 5% and mortality rates from 0.01% to 0.5%. The most serious complications are respiratory depression and hypotension caused by excessive sedation, laryngospasm, bronchospasm (especially in patients with a history of bronchospasm), hypoxemia, and pneumothorax and bleeding following biopsy procedures. Postbronchoscopy fever may occur in approximately 25% of patients and usually follows BAL. It is generally self-limited and not associated with infection. Flexible FOB carries an extremely low risk of bacteremia, and prophylaxis with antibiotics is not routinely recommended, even in the immunocompromised host. In contrast, bacteremia has been documented following rigid bronchoscopy, and prophylactic antibiotics are recommended in patients at risk for bacterial endocarditis. Transient radiographic abnormalities may occur in the area where BAL was performed.

In general, an oxygen tension of at least 75 mm Hg on 50% or less supplemental oxygen should be present before proceeding with FOB. The P_{O_2} may decrease by up to 25 mm Hg during the procedure. All patients should be continuously monitored by pulse oximetry and receive supplemental oxygen. The procedure should be terminated if a PO_2 of at least 60 mm Hg and an oxygen saturation of 90% cannot be maintained. Any further decrease in the P_{O_2} may lead to severe hypoxemia because of the location of this value near the steep portion of the oxyhemoglobin dissociation curve.

Fiberoptic bronchoscopy is absolutely contraindicated without intubation in the presence of bilateral vocal cord paralysis because of the potential for complete occlusion of the airway. Other contraindications to FOB include inability of the patient to cooperate with the procedure, hemodynamic instability, recent myocardial infarction or unstable angina, and severe uncorrectable coagulopathy. Biopsy procedures should not be performed with a platelet count below 50,000 per millimeter. Bleeding complications during FOB with BAL are rare even, with platelet counts of fewer than 50,000 per millimeter.

TRANSTHORACIC NEEDLE ASPIRATION

Transthoracic needle aspiration (TTNA) is an important means of diagnosing thoracic and mediastinal disease. The procedure may be performed on an outpatient basis. Sedation is usually not required. The lesion for biopsy is localized using either fluoroscopy or computed tomography (CT) scan. The patient is appropriately positioned; local anesthesia is administered to the skin, subcutaneous tissue, and parietal pleura. The needle is advanced into the lesion under fluoroscopic or CT guidance. The specimen is aspirated into a syringe attached to the needle. It is often useful to have a cytologist present during the procedure to assess whether diagnostic material has been obtained or a second needle pass is required. Stains and culture of the aspirated material should be obtained if clinically indicated. Newer types of needles allow procurement of core specimens of tissue for histologic examination as well. A chest radiograph is usually performed immediately after the procedure and 2 to 4 hours later to detect the presence of a pneumothorax.

TTNA is indicated in the diagnosis of pulmonary nodules, especially if peripheral and smaller than 2 cm. In this setting, the diagnostic yield for TTNA is higher than for FOB. Other indications for TTNA include the diagnosis of central (hilar and mediastinal) masses and pleural-based masses and the diagnosis of suspected infectious processes, especially if bronchoscopy has failed to reveal a definitive diagnosis and the lesion is localized or nodular. TTNA is generally not useful in the diagnosis of diffuse or interstitial lung diseases; such processes tend to involve the lung parenchyma in a patchy manner in varying stages of evolution and require pathologic examination of larger tissue specimens for diagnosis.

The sensitivity of TTNA for the diagnosis of malignancy is high, ranging from 64% to 97%. False-positive results for malignancy are extremely low. The diagnostic yield for infections ranges from 40% to 90%, with the higher yields reported for nonbacterial processes. A negative result or specific nonmalignant diagnosis, such as hamartoma, amyloid, granulomatous disease, or infection, is made in approximately 5% to 25% of patients undergoing this procedure. However, such findings do not necessarily exclude the possibility of malignancy. If the clinical suspicion for malignancy is great, the decision must be made as to whether to repeat the TTNA, which yields a diagnosis in 35% to 40% of cases, or proceed to a surgical procedure. Some physicians recommend surgery as the initial procedure of choice if the clinical presentation is highly suggestive of malignancy and the patient is an acceptable surgical candidate. If the clinical picture is consistent with a benign process, the patient may be followed closely with serial chest radiographs.

The most common complication of TTNA is pneumothorax, which occurs in 10% to 37% of procedures. Chest tube placement is required in less than 50% of such cases. The risk of pneumothorax appears to increase with an increasing number of needle passes, increased depth of the lesion, presence of cavitation, advanced patient age, and underlying chronic obstructive pulmonary disease or bullous disease. Other, less common complications include hemoptysis, which is usually self-limited; intraparenchymal hemorrhage; venous air embolism; subcutaneous emphysema; and hemopericardium with tamponade when lesions are located near the pulmonary artery. Reports of tumor seeding of the needle tract exist but are exceedingly rare. Reported mortality rates of this procedure are less than 0.2%.

Contraindications to performing TTNA include an uncooperative patient or excessive coughing, uncorrectable coagulopathy, thrombocytopenia with platelet counts less than 50,000 per millimeter, and hydatid cyst. Relative contraindications include severe emphysema, previous pneumonectomy, pulmonary artery hypertension, mechanical ventilation, and suspected vascular lesion. However, TTNA has been performed safely in patients with these conditions.

THORACOSCOPY

The technique of thoracoscopy (pleuroscopy) was introduced in the early 1900s and used primarily for the lysis of pleural adhesions to create a pneumothorax for the treatment of tuberculosis. With the advent of antituberculosis therapy, thoracoscopy became rarely used, except for the diagnosis of pleural diseases and pleurodesis of malignant effusions. With recent technical advances in video imaging and endoscopic instrumentation, video-assisted thoracoscopic surgery (VATS) has rapidly emerged as a technique with many potential diagnostic and therapeutic applications.

VATS requires general anesthesia and endotracheal intubation. In contrast to simple thoracoscopy, VATS requires single-lung ventilation with collapse of the lung to

be examined. The patient is placed in the lateral decubitus position and a video thoracoscope is introduced through a 1-inch incision. Images are projected on a video monitor. Various instruments for dissection, resection, and stapling of the lung parenchyma, as well as for talc insufflation for pleurodesis, are introduced through two or three additional small incision sites. At the end of the procedure, a chest tube is inserted in one of the sites and the other sites are closed.

Using this technique, the surgeon can visualize the entire pleural space and parenchymal surface. A large number of potential indications for VATS has been advanced, but the currently accepted applications in the management of pleuropulmonary diseases are listed in [Table 389.5](#). Thoracoscopy (simple or VATS) remains a very effective means of diagnosing and managing pleural diseases. The vast majority of undiagnosed exudative pleural effusions can be diagnosed using thoracoscopy. Pleurodesis of malignant effusions with talc insufflation is effective in 85% to 90% of cases using thoracoscopic techniques. Pleurodesis is less successful when using other sclerosing agents such as tetracycline or bleomycin.

Diagnostic

Evaluation of undiagnosed exudative pleural effusions
Diagnosis of indeterminate pulmonary nodules
Lung biopsy in diffuse lung disease
Biopsy of pleural-based or peripheral lung masses
Biopsy of mediastinal nodes or masses

Therapeutic

Pleurodesis of malignant pleural effusion
Treatment of spontaneous pneumothorax
Resection of pulmonary metastases
Thoracic sympathectomy

TABLE 389.5. INDICATIONS FOR VIDEO-ASSISTED THORACOSCOPIC SURGERY

At what point thoracoscopy should be considered in the evaluation of patients with pulmonary nodules or diffuse lung disease is a more controversial issue. Many physicians either proceed directly to thoracoscopy or follow a nondiagnostic TTNA with thoracoscopy when evaluating an indeterminate pulmonary nodule, especially if the index of suspicion is high for malignancy. If a malignancy is detected at the time of thoracoscopy, the patient should undergo proper staging and thoracotomy with definitive resection (lobectomy or pneumonectomy), unless he or she is unable to tolerate an extensive resection because of underlying pulmonary compromise or is inoperable for another reason.

VATS may supplant open-lung biopsy (OLB) as the method of choice for the definitive diagnosis of diffuse lung disease when less invasive techniques have failed to determine a cause. Few studies directly comparing VATS and OLB exist, but VATS appears to be of equal diagnostic accuracy (more than 90%). VATS is less invasive than standard thoracotomy and results in less postoperative morbidity. Respiratory compromise, pain, length of time for which chest tube drainage is required, and length of hospital stay are all reduced following VATS, compared with thoracotomy.

Preliminary studies indicate that VATS can be performed safely in thrombocytopenic immunocompromised patients to establish the diagnosis of a variety of infectious and noninfectious diseases. VATS has been reported to have a diagnostic yield of up to 100% in the immunocompromised patient population, with postoperative morbidity comparable to that of conventional OLB.

Lesions located deep within the lung parenchyma or in the hilum, upper mediastinum, or posterior paravertebral area are frequently not amenable to biopsy or resection by VATS. VATS cannot be performed in the presence of dense pleural scarring or severe coagulopathy. Patients who require mechanical ventilation or have severe pulmonary compromise are usually not candidates for VATS because they often cannot tolerate single-lung ventilation.

OPEN-LUNG BIOPSY

Open-lung biopsy has been considered the most reliable procedure for obtaining lung tissue for examination, with an overall diagnostic accuracy of more than 90%. It is performed under general anesthesia. Usually biopsies are taken through a small, anterior intercostal incision. In diffuse lung processes, lung specimens are typically obtained from the anteriorly located right middle lobe or lingula. It is important that both normal-appearing and abnormal-appearing lungs are biopsied because severely affected, fibrotic regions may be of little diagnostic use. For lesions localized laterally or posteriorly, a full posterolateral thoracotomy incision may be required.

Complications from OLB occur infrequently (7%) and include bleeding, infection, and problems related to general anesthesia. Mortality rates range from 0.5% to 1.8%. There are relatively few absolute contraindications to performing an OLB, but they do include hemodynamic instability and severe coagulopathy that cannot be corrected by blood product support.

OLB has historically been performed after less invasive procedures have been exhausted or when a rapidly deteriorating clinical picture mandates that a definitive diagnosis be expediently obtained. More studies are required that directly compare the diagnostic accuracy of OLB with that of VATS, particularly in the patient who is immunocompromised. The less invasive VATS may ultimately replace OLB as the diagnostic procedure of choice when surgical intervention is necessary for the diagnosis of parenchymal lung disease.

EVALUATION OF PLEURAL EFFUSIONS

THORACENTESIS

Thoracentesis is the most commonly performed procedure to diagnose and manage pleural effusions. A thoracentesis should be performed in most cases of an undiagnosed pleural effusion. In certain circumstances, such as obvious congestive heart failure, following thoracic or abdominal surgery, or following the postpartum period, pleural effusions are common and thoracentesis generally is not necessary if the clinical picture is typical. A thoracentesis may be performed therapeutically for relief of dyspnea in patients with large effusions.

Before a thoracentesis can be performed, lateral decubitus chest radiographs should be obtained. If the pleural effusion is freely layering and the distance between the inner chest wall and the outer lung on the decubitus film is more than 10 mm, ample fluid is present to support the safe performance of a thoracentesis. If there is a small amount of fluid or the fluid does not freely layer, ultrasonography of the chest should be performed prior to thoracentesis for fluid localization or guidance during the procedure.

The patient should be sitting upright with arms resting on a bedside table and his or her back relatively straight to maximize layering of the pleural effusion posteriorly. The site of needle insertion is identified by locating the point at which dullness to percussion or decreased tactile fremitus occurs because this indicates the superior border of the effusion. The thoracentesis should be performed posterolaterally, one interspace below this point. The area is cleansed with an antiseptic solution and a sterile field created. The skin is anesthetized using a small (25-gauge) needle. A larger 22-gauge needle is then used to anesthetize the periosteum of the underlying rib and moved over its superior aspect to avoid the neurovascular bundle running along the inferior rib border. The needle is slowly advanced toward the pleural space with aspiration followed by injection of small amounts of anesthesia every few millimeters. Once pleural fluid is aspirated, the needle is withdrawn. Then another needle, attached to a 60-mL syringe, is advanced over the same path as the anesthetic needle and a sample of the pleural fluid is aspirated into the syringe. For a therapeutic thoracentesis, a plastic catheter that threads over or through the needle may be advanced into the pleural space. The needle is then withdrawn and the catheter attached to a drainage bag or vacuum bottle. Following the procedure, an expiratory chest radiograph should be obtained to check for the presence of a pneumothorax.

The gross features of the pleural fluid should be noted. A putrid odor is suggestive of an anaerobic infection. Frank pus indicates the presence of an empyema. A grossly bloody effusion with a hematocrit of more than 50% of the peripheral value is consistent with a hemothorax. Milky-appearing fluid may be caused by a chylous

or pseudochylous effusion.

Analysis of pleural fluid of unknown cause should consist of a protein and lactate dehydrogenase (LDH) determination, glucose level, pH, cell count, cytologic examination, and Gram's stain with culture. Determining whether the pleural fluid is a transudate or an exudate is useful in formulating a differential diagnosis. An exudative pleural effusion meets one of following criteria set forth by Light and colleagues: pleural fluid protein/serum protein more than 0.5, pleural fluid LDH/serum LDH more than 0.6, pleural fluid LDH more than two-thirds of the upper limit of normal for the serum LDH. The pleural effusion is transudative if none of the above criteria is met. Several recent studies have proposed other laboratory values to identify exudative pleural effusions. The parameters include cholesterol more than 55 mg per deciliter, pleural fluid bilirubin/serum bilirubin 0.6 or more, and serum and pleural fluid albumin gradient less than 1.2 g per deciliter. However, none of these values has been found to be more accurate than the LDH and protein criteria.

A transudative pleural effusion may be caused by a limited number of disorders. The most common cause is congestive heart failure. Pleural effusions caused by congestive heart failure are usually right-sided or bilateral. About 25% of pleural effusions secondary to pulmonary emboli are transudative. The differential diagnosis of an exudative pleural effusion is much more extensive. Some of the more common causes are listed in [Table 389.6](#). Other pleural fluid values that may aid in narrowing the diagnostic possibilities of an exudative effusion are listed in [Table 389.7](#). (See [Chapter 358](#) for a more detailed discussion of laboratory evaluation of pleural effusion fluid.)

Transudates
Congestive heart failure
Pericardial disease
Cirrhosis
Nephrotic syndrome
Myxedema
Atelectasis
Pulmonary embolism
Exudates
Malignancy
Infection
Pulmonary embolism
Pancreatitis and other pancreatic diseases
Esophageal perforation
Postabdominal surgery
Intra-abdominal abscess
Splenic infarct/hematoma
Collagen vascular disease
Rheumatoid arthritis
Systemic lupus erythematosus
Drug- or radiation-induced
Asbestos exposure (benign effusion)
Sarcoid

TABLE 389.6. DIFFERENTIAL DIAGNOSIS OF PLEURAL EFFUSIONS

Effusion Fluid	Differential Diagnosis
Low protein	Heart failure, liver disease, renal disease, nephrotic syndrome, myxedema, cirrhosis, pericardial disease, pulmonary embolism, atelectasis
High protein	Malignancy, infection, pulmonary embolism, pancreatitis, esophageal perforation, postabdominal surgery, intra-abdominal abscess, splenic infarct/hematoma, collagen vascular disease, rheumatoid arthritis, systemic lupus erythematosus, drug- or radiation-induced, asbestos exposure, sarcoid
Low LDH	Heart failure, liver disease, renal disease, nephrotic syndrome, myxedema, cirrhosis, pericardial disease, pulmonary embolism, atelectasis
High LDH	Malignancy, infection, pulmonary embolism, pancreatitis, esophageal perforation, postabdominal surgery, intra-abdominal abscess, splenic infarct/hematoma, collagen vascular disease, rheumatoid arthritis, systemic lupus erythematosus, drug- or radiation-induced, asbestos exposure, sarcoid
Low glucose	Infection, malignancy, rheumatoid arthritis, systemic lupus erythematosus, drug- or radiation-induced, asbestos exposure, sarcoid
High glucose	Heart failure, liver disease, renal disease, nephrotic syndrome, myxedema, cirrhosis, pericardial disease, pulmonary embolism, atelectasis
Low pH	Infection, malignancy, rheumatoid arthritis, systemic lupus erythematosus, drug- or radiation-induced, asbestos exposure, sarcoid
High pH	Heart failure, liver disease, renal disease, nephrotic syndrome, myxedema, cirrhosis, pericardial disease, pulmonary embolism, atelectasis
Low cholesterol	Heart failure, liver disease, renal disease, nephrotic syndrome, myxedema, cirrhosis, pericardial disease, pulmonary embolism, atelectasis
High cholesterol	Malignancy, infection, pulmonary embolism, pancreatitis, esophageal perforation, postabdominal surgery, intra-abdominal abscess, splenic infarct/hematoma, collagen vascular disease, rheumatoid arthritis, systemic lupus erythematosus, drug- or radiation-induced, asbestos exposure, sarcoid

TABLE 389.7. DIFFERENTIAL DIAGNOSIS OF EXUDATIVE PLEURAL EFFUSIONS

Three of the most common causes of an exudative pleural effusion are a parapneumonic effusion, malignancy, and tuberculosis. Parapneumonic effusions should be analyzed to determine the need for chest tube placement. An empyema (frank pus in the pleural space) or the presence of organisms on Gram's stain of the fluid requires immediate drainage. A complicated pleural effusion has been defined as one that does not resolve with antibiotic therapy alone and requires chest tube drainage either for control of infection or to prevent the development of a fibrothorax. The criteria used to determine whether a parapneumonic effusion requires chest tube drainage include presence of loculation, pH less than 7.10, glucose less than 40, or LDH more than 1,000, or any combination of the latter three factors. If the initial pH is between 7.10 and 7.20, the thoracentesis should be repeated in 12 to 24 hours.

Pleural fluid cytologic examination can provide a diagnosis of malignancy in 54% to 63% of cases. Obtaining a second and third sample for cytologic examination increases the yield to 72% and 77%, respectively.

Acid-fast smears of the pleural fluid yield a diagnosis of tuberculosis in less than 10% of cases. Pleural fluid cultures identify tuberculosis in 13% to 75% of patients. An elevated adenosine deaminase level of more than 70 units per liter has been reported to be diagnostic of tuberculous pleuritis. The presence of more than 5% mesothelial cells in the pleural fluid virtually excludes the possibility of tuberculosis; their absence, however, is not specific for tuberculosis.

The most common complication of thoracentesis is pneumothorax, which occurs in approximately 10% of procedures. Most pneumothoraxes do not require chest tube insertion. Vasovagal reactions may occur, and some physicians routinely administer atropine before the procedure to reduce vagal tone. Reexpansion pulmonary edema has been described after removal of large amounts of fluid. It is recommended that no more than 1.0 to 1.5 L of fluid be removed at one sitting. Data regarding the mechanism by which reexpansion pulmonary edema develops are inconclusive. Some have speculated that its development is related to increasing negative pleural pressures generated during the procedure and that draining large volumes of fluid can be accomplished safely if the pleural pressure can be monitored and maintained at more than -20 cm H₂O. Reexpansion pulmonary edema usually develops in the ipsilateral lung but may involve the contralateral lung as well. Other more serious but rarely occurring complications include laceration of the intercostal artery, splenic rupture, and air embolism.

There are few contraindications to performing a thoracentesis, and the decision to proceed must be guided by the clinical circumstances. Relative contraindications include severe coagulopathy, small volume of fluid, mechanical ventilation, and cutaneous infection at the site of needle entry.

PLEURAL BIOPSY

A percutaneous pleural biopsy is indicated for further evaluation of an undiagnosed exudative pleural effusion. A pleural biopsy is performed in a manner similar to that of a thoracentesis. Special larger bore needles (Abrams and Cope) designed with a hook and cutting edge are used to ensnare the parietal pleura. Contraindications and complications of the procedure are essentially the same as those for a thoracentesis.

Pleural biopsy is most useful in establishing the diagnosis of tuberculosis and malignancy. Histologic examination and culture of pleural biopsy specimens provide the diagnosis of tuberculosis in more than 75% of patients. The addition of pleural biopsy histology and culture to pleural fluid studies increases the diagnostic yield for tuberculous pleuritis to approximately 90%. If tuberculosis is highly suspected, pleural biopsy should be performed at the time of initial thoracentesis.

Pleural biopsy is less useful than pleural fluid cytology in the diagnosis of malignancy. Biopsy reveals malignancy in 40% to 50% of cases but is rarely the sole positive result. Adding pleural biopsy to pleural fluid cytology increases the diagnostic yield by only 7%. Although opinions vary, if a malignant pleural effusion is suspected, pleural biopsy may be performed either at the time of the initial thoracentesis or on repeat thoracentesis if the results of the first are nondiagnostic.

An exudative pleural effusion that remains undiagnosed after two to three thoracenteses and a pleural biopsy presents a clinical dilemma. In patients with underlying lung parenchymal abnormalities on chest radiograph or CT scan, a bronchoscopy should be the next diagnostic procedure attempted. It has been suggested that a conservative approach be considered in patients in whom a low index of suspicion for tuberculosis or malignancy exists if the following criteria are met: clinical

stability, no weight loss, negative purified protein derivative, afebrile, less than 95% lymphocytes in the pleural fluid, and an effusion size less than 50% of the hemithorax. If a patient does not meet these criteria, a more aggressive evaluation is warranted. Thoracoscopy, as described previously, is usually selected as the next diagnostic procedure; it reveals the cause of the effusion in approximately 90% of cases. Lymphoma and malignant mesothelioma are the most common causes of pleural effusions that remain undiagnosed even after surgical evaluation.

CERVICAL MEDIASTINOSCOPY AND ANTERIOR MEDIASTINOTOMY

Cervical mediastinoscopy and anterior mediastinotomy are complementary procedures that allow evaluation of mediastinal structures. These procedures are most commonly performed for staging of mediastinal lymph nodes in patients with non-small cell lung carcinoma prior to thoracotomy. Other indications include biopsy of enlarged mediastinal lymph nodes in patients suspected of having lymphoma, granulomatous disorders, infections, or mediastinal malignancies; drainage of mediastinal cysts; and staging of patients with esophageal carcinoma.

Both procedures require general anesthesia. Cervical mediastinoscopy is performed through a small incision in the suprasternal notch. The pretracheal fascia is opened and blunt dissection continued anteriorly and laterally to the trachea, extending distally to the carina. A lighted mediastinoscope is advanced through the created space. Paratracheal, superior tracheobronchial, azygous, and anterior subcarinal lymph nodes are accessible through this approach. An anterior mediastinotomy (Chamberlain's procedure) is usually performed through a 3- to 5-cm incision in the second intercostal space just lateral to the sternum. This procedure is preferred by some surgeons in patients with lung carcinomas located in left upper lobe because it allows access to anterior mediastinal and aortopulmonary lymph nodes, which are common sites of metastases from such lesions.

Whether these procedures should be performed in all patients with non-small cell carcinoma before thoracotomy is controversial. CT evaluation of the mediastinum has about an 80% sensitivity and specificity for detecting nodal metastases using a node size threshold of more than 1 cm. Most surgeons reserve mediastinoscopy and mediastinotomy for those patients with radiographic evidence of lymph node enlargement, as well as for those with centrally located tumors and large locally advanced tumors.

Major complications occur in less than 1% of procedures. The principal risk is of hemorrhage caused by injury or inadvertent biopsy of one of the intrathoracic vessels. Less common complications include vocal cord paralysis from recurrent laryngeal nerve injury and chylothorax following injury to the thoracic duct.

Severe bleeding diathesis and inability to tolerate general anesthesia are the major contraindications to the performance of these procedures. Relative contraindications include the superior vena cava syndrome, because vessel engorgement may increase the risk of significant bleeding, and previous mediastinal procedures including tracheostomy and mediastinal irradiation, which cause scarring and obliteration of mediastinal fascial planes.

CHAPTER 390: RESPIRATORY THERAPY TECHNIQUES

CAROLYN H. WELSH

- [Supplemental Oxygen Therapy](#)
- [Artificial Airways](#)
- [Mechanical Ventilation](#)
- [Noninvasive Positive-Pressure Ventilation](#)
- [Other Respiratory Therapy Techniques](#)
- [Airway Suctioning](#)
- [Humidity and Aerosol Therapy](#)
- [Medication Via Aerosol Therapy](#)

Respiratory therapy is a specialty in which trained practitioners operate under medical guidance to provide evaluation and treatment of persons with cardiopulmonary disease. Most respiratory therapy techniques and devices are designed and used to achieve one or more of the following goals: to improve oxygenation, to increase ventilation, to expand lung volume, or to clear secretions. Other techniques involve delivery of medications via the airway for treatment of respiratory and systemic diseases. Respiratory therapy techniques are used not only in intensive care units but also on hospital wards, clinics, and at home. Recently, practice guidelines have been developed by the National Board for Respiratory Care to enhance standard high-quality respiratory care practice throughout the United States. Some techniques are supported by good-outcome data, whereas others, such as humidification, are often used based on tradition rather than proof of benefit. Where outcome data are available, they are provided in this chapter. If information on relative cost is available, it is also provided.

SUPPLEMENTAL OXYGEN THERAPY

Oxygen therapy has been used extensively during the past 20 years, on the basis of information provided by the Nocturnal Oxygen Therapy Trial and the British Medical Research Council studies. Both these trials demonstrated that for hypoxemic patients, longer use of oxygen each day significantly prolongs survival. Current criteria for supplemental oxygen use in hypoxemic patients include a low Pa O₂ (less than 50 to 55 mm Hg), or an oxygen saturation less than or equal to 85%. When PaO₂ is in the 55 to 60 mm Hg range, long-term oxygen therapy is also warranted if there is clinical evidence of right-heart failure, as demonstrated by jugular venous distention, a right-sided S₃ gallop, pedal edema, erythrocytosis, or electrocardiographic manifestations such as P pulmonale, right axis deviation, and right ventricular hypertrophy. Methods for oxygen delivery are listed in [Table 390.1](#). The choice of oxygen delivery technique and device is based on both the severity of hypoxemia and patient comfort.

Characteristic	Oxygen Administration Device				
	Nasal Cannula	Venturi Mask	Simple Face Mask	Non-Rebreathing Mask	Endotracheal or Tracheostomy Tube
Flow range	1-6 L/min	3-10 L/min	1-10 L/min*	10-100% O ₂	21-100% O ₂
Effective delivery range	15-40% FiO ₂	24% 20% 24% O ₂ , etc. Variable, up to ordered FiO ₂	Variable, up to 30-40% O ₂ **	Highly variable, up to 70-80% O ₂ **	21-100% O ₂ **
Actual delivered FiO ₂ (room air)	21%	21%	21%	21%	21%†
Humidification and heating required?	No	No	No	No	No
Continuity of flow to patient?	++	+	+	+	+++††
Impedance or discomfort to patient	+	++	++	+++	+++

*May be as high as 100 L/min when high-flow generator is used.
 **This is known but usually variable.
 †Room air, depending on amount of room air is entrained, which is increased by high minute ventilation, poor mask fit, agitation, and so on.
 ††Some cannot avoid essentially including (downstream) extension tube to prevent high inspiratory embolism of room air.
 ‡In low humidity environments, some patients are more comfortable with added humidity when flows exceed 6 L/min. No, Nozzle humidifier system.

TABLE 390.1. CHARACTERISTICS OF OXYGEN ADMINISTRATION DEVICES

For either the hospitalized or home patient, oxygen orders should specify a delivery method, flow rate or Fi O₂, and duration of therapy during a 24-hour cycle. Oxygen may be prescribed, as needed, for nocturnal use only, for use with exercise, or for 24 hours per day. Monitoring to assess safety and efficacy can be performed using a finger oximeter, and flow rate can be appropriately titrated. For the acutely ill patient, the lack of a carbon dioxide tension (Pa CO₂) measurement from an oximeter limits its usefulness. The acutely ill patient generally requires the full arterial blood gas (ABG) analysis, which measures pH, Pa CO₂, PaO₂, calculated bicarbonate, base excess and oxygen saturation. The additional acid–base information from the ABG aids in the assessment of respiratory fatigue and a potential decision to intubate. An arterial blood gas specimen should also be taken after starting oxygen therapy in a CO₂-retaining patient to check for worsening hypercarbia and 20 to 30 minutes after starting mechanical ventilation to assess the impact of treatment on oxygenation and acid–base status.

Gas enriched in oxygen can be supplied in one of three ways for home use: by concentrator, tank, or compressed liquid. Concentrators purify oxygen from the atmosphere and require a functioning electrical power source. Cylindrical tanks of compressed gas can be delivered to the home for stationary or portable use. These are heavy and have the potential to explode with decompression. A third source, liquid oxygen, can be supplied in a large reservoir with light-weight portable tanks filled from this stationary source. In general, the liquid is lighter to carry and thus often preferred, but it is also considerably more expensive.

To conserve oxygen supply from either a tank or a liquid system, a trigger or demand valve can be inserted in-line, which limits release of oxygen to the inspiratory phase of the breathing cycle. Duration of portable supplies can be doubled or tripled with use of this valve. To increase the F IO₂ for a patient chronically requiring high flow rates, a small reservoir can be attached in-line with the oxygen tubing so that less room air is entrained with a breath and the actual F IO₂ reaching the pharynx is higher. On rare occasions, transtracheal oxygen delivery may be useful to increase the Pa O₂ to an acceptable level, or to improve acceptability of oxygen therapy to a patient by improving cosmetic appeal or lessening nasal irritation or sinus symptoms. Good outcome data are lacking to support the superiority of transtracheal oxygen over other methods of delivery.

Oxygen is not only expensive; it is also potentially hazardous. Severe hypoxemia in a patient must be addressed immediately. However, for the chronic obstructive lung disease (COPD) patient, overly vigorous treatment with oxygen may lead to progressive hypoventilation from suppression of the hypoxic respiratory drive and induce respiratory acidosis. Therefore, it is important to start therapy with the lowest flow of oxygen needed and proceed cautiously. Such patients cannot be given oxygen and then left in an unmonitored situation but must be observed for overt or insidious onset of respiratory acidosis. Supplemental oxygen is said to lead to parenchymal oxygen toxicity, but actual clinical relevance of oxygen toxicity is unclear and its incidence is probably overestimated.

ARTIFICIAL AIRWAYS

An endotracheal tube is inserted in the nose or mouth to facilitate mechanical ventilation in the treatment of acute respiratory failure. Other indications for intubation are to relieve upper airway obstruction, to allow removal of excessive secretions by suction catheter, and to protect the airways from aspiration of gastric contents. Unfortunately, intubation fails to completely protect a patient from aspiration. To minimize the risk of aspiration, patients should be kept in a semi-upright position while intubated. Use of a large tube will decrease the work of breathing during ventilator weaning. An additional choice is that of tube insertion site. Orotracheal tubes move around more in the mouth and are less well tolerated by the patient. Nasotracheal tubes are both more comfortable and smaller, but they are associated with a higher incidence of sinusitis. Because of the perceived risk of sinusitis, nasotracheal tubes are now being used less often.

Tracheostomy has been advocated at an early time point after endotracheal intubation for the patient needing long-term ventilation, with the premise that tracheostomy leads to fewer complications than the endotracheal tube and shortens the duration of ventilation. The lower number of complications is not well documented, although patient comfort is said to be improved with tracheostomy placement. The timing of tracheostomy is thus a clinical decision. Clinical practice varies, with tracheostomy performed 2 to 6 weeks after the initial intubation.

Complications of endotracheal intubation and tracheostomy include aspiration, lower respiratory tract infection, bleeding from erosions induced by the tube or a suction catheter, sinusitis, intraluminal scar formation that narrows the trachea, or tracheal collapse. It is important to remove these tubes as soon as they are no longer needed in order to minimize such side effects.

Similar to its use for obstruction in the vascular bed, stent placement in an airway or balloon dilatation of the airway can be tried to relieve significant airway obstruction or collapse in the trachea or large bronchi. Conditions that may merit this treatment include post-transplantation or postirradiation bronchial stenosis, bronchomalacia, malignant obstruction of large airways, respiratory–esophageal fistula, or congenital tracheobronchomegaly.

MECHANICAL VENTILATION

Mechanical ventilation is initiated most often for patients who fail to ventilate adequately due to conditions such as drug overdose, operative anesthetics, neuromuscular disease, or asthma and COPD exacerbations. In this setting, PaCO₂ is acutely elevated such that the pH falls to less than 7.20 to 7.25. The second major category of patients who merit mechanical ventilation comprises primarily hypoxemic patients who may have a condition such as pneumonia, aspiration, cardiogenic pulmonary edema, or acute respiratory distress syndrome (ARDS) and need ventilation mainly to support oxygenation. Often, mechanical ventilation is required when P(A-a)O₂ is more than 350 mm Hg while the patient is receiving 100% oxygen. Some persons may also require ventilation if they are experiencing excessive work of breathing.

Mechanical ventilation through an endotracheal tube delivers positive pressure during inspiration and expiration, in contrast to normal breathing whereby inspiration is accompanied by negative intrathoracic pressure. Standard ventilation is most often volume-limited where a preset volume of air is delivered to the patient (volume-controlled, pressure- or time-cycled), but it can also be pressure-limited, whereby the tidal volume is determined by a preset pressure and the volume varies with chest wall and lung compliance (pressure-controlled, volume- or time-cycled). Several different means of delivering ventilation to a patient are available; these are called *modes* (Table 390.2). Frequently used modes of volume-limited ventilation include assist control (AC) and synchronized intermittent mandatory ventilation (SIMV). Most ventilation is accomplished using one of these two modes. AC may result in higher ventilation because each initiated breath is a full tidal volume but usually induces a lower work of breathing. SIMV generates less alkalosis but induces a higher work of breathing. Frequently used pressure-limited modes are pressure support ventilation (PSV), where pressure support is given only during the inspiratory phase with spontaneous breathing, and pressure control where pressure truly limits ventilation. PSV heightens patient–ventilator synchrony but relies on an intact drive; therefore, it should not be used for patients who require high-level sedation. It is, however, a well-tolerated and commonly used mode of weaning. Pressure control is most often implemented for the severely hypoxemic patient. The concept that barotrauma is induced by high volumes or large swings in intra-alveolar pressure, and the fact that this is deleterious favors use of this mode for the complicated ARDS, trauma, or sepsis patient.

Type	Mode	Description
Volume-controlled	Assist control (AC)	Each initiated breath is a full tidal volume but usually induces a lower work of breathing.
	Synchronized intermittent mandatory ventilation (SIMV)	Generates less alkalosis but induces a higher work of breathing.
	Pressure support ventilation (PSV)	Pressure support is given only during the inspiratory phase with spontaneous breathing.
	Pressure control	Pressure truly limits ventilation.
Pressure-controlled	Pressure support ventilation (PSV)	Heightens patient–ventilator synchrony but relies on an intact drive.
	Pressure control	Most often implemented for the severely hypoxemic patient.
Pressure support	Pressure support ventilation (PSV)	Heightens patient–ventilator synchrony but relies on an intact drive.
	Pressure control	Most often implemented for the severely hypoxemic patient.

TABLE 390.2. TYPES AND MODES OF MECHANICAL VENTILATION

Initial ventilator settings are chosen to minimize peak and mean airway pressures while delivering adequate oxygen. This may often be accomplished with volume-cycled ventilation using a tidal volume of 6 to 8 mL per kilogram (400 to 600 cm³ for the average adult), a respiratory rate of 10 to 20, and an FIO₂ of 100%, with either an AC or an SIMV mode. Initial settings, including flow rate, are adjusted to keep peak airway pressure below 35 to 40 cm H₂O. The aim is also to improve patient synchrony with the ventilator and to decrease the work of breathing (the energy expended to breathe). Increased availability of microprocessor technology on ventilators has been helpful in achieving these goals.

Complications from mechanical ventilation and endotracheal intubation are common. This realization led to recent attempts to switch to noninvasive ventilation whenever possible. Positive-pressure ventilation may adversely affect every organ system. The most important complications are barotrauma, hemodynamic compromise, and nosocomial infection. Barotrauma results from overdistention of alveoli under positive pressure, with pneumothorax being one common manifestation. The alveoli can rupture, forcing gas into adjacent interstitium, with subsequent tracking into the pleural space, mediastinum, or peritoneum as well as into vessels, which may cause air emboli. Keeping peak pressures as low as possible, below 35 to 40 cm H₂O, minimizes this complication. In general, application of positive-pressure ventilation decreases venous return to the heart and thus lowers cardiac output, which may lead to hypotension and impaired oxygen delivery. Persistent hypotension can worsen renal and other organ function, thus escalating multiorgan failure. The third major complication, nosocomial infection (especially ventilator-associated pneumonia), remains a common problem for as many as 10% to 15% of ventilated patients.

Since there is a potential for oxygen toxicity on FiO₂ of 60% or greater, the lowest necessary FIO₂ should be selected. To lower the FIO₂, positive end-expiratory pressure (PEEP) can be used. PEEP works by increasing the lung volume, thereby opening collapsed alveoli and improving ventilation/perfusion matching. Potential problems with PEEP are an increased likelihood of barotrauma and hypotension, similar to that of positive-pressure ventilation itself.

Auto-PEEP, or intrinsic PEEP, is the development of hyperinflation within the alveolus during mechanical ventilation. It should be routinely monitored in ventilated patients. It is caused by the ventilator delivery of positive-pressure breaths before complete exhalation of the previous breath has occurred. It is most common in conditions with a high minute ventilation (amount of air breathed per minute), such as in ARDS and in diseases of airflow limitation (asthma and COPD). Since the ventilator manometer will not register auto-PEEP, detection involves occlusion of the expiratory port at end exhalation, allowing equilibration of the airway and circuit pressure. The complications of auto-PEEP are similar to those of applied PEEP: diminished cardiac output and actual hypotension, increased intracranial pressure, increased risk of barotrauma, and inaccurate pulmonary artery catheter measurements, including false elevation of the wedge pressure which may lead to inappropriate fluid and vasopressor management. Strategies to reduce auto-PEEP include use of a large-bore endotracheal tube, slowing of respiratory rate, lowering of minute ventilation, increasing of inspiratory flow rates and thereby allowing for more exhalation time, use of bronchodilators if appropriate, sedation, paralysis, and addition of PEEP equivalent to the original auto-PEEP.

There are many ways to wean a patient from the ventilator. The first task for the clinician is to assess the patient's readiness to wean with spontaneous ventilatory parameters or the even more useful rapid shallow breathing index (Table 390.3). The rapid shallow breathing index can distinguish persons with a high likelihood of weaning failure. It is the ratio of breaths per minute to tidal volume for a spontaneously breathing patient. If a patient breathing spontaneously has an index greater than 100 breaths per minute per liter, the chance of weaning success is negligible. The observation of excessive accessory muscle use and paradoxical breathing during weaning is a useful physical examination adjunct to assessment of high likelihood of weaning failure.

Step	Criteria
1	Spontaneous tidal volume > 10 mL/kg
2	Spontaneous respiratory rate < 30 breaths/min
3	Spontaneous PEEP > 5 cm H ₂ O
4	Spontaneous FiO ₂ < 0.5
5	Spontaneous PaO ₂ > 60 mmHg
6	Spontaneous PaCO ₂ < 50 mmHg
7	Spontaneous pH > 7.35
8	Spontaneous SaO ₂ > 90%
9	Spontaneous RR < 30 breaths/min
10	Spontaneous tidal volume > 10 mL/kg
11	Spontaneous PEEP > 5 cm H ₂ O
12	Spontaneous FiO ₂ < 0.5
13	Spontaneous PaO ₂ > 60 mmHg
14	Spontaneous PaCO ₂ < 50 mmHg
15	Spontaneous pH > 7.35
16	Spontaneous SaO ₂ > 90%
17	Spontaneous RR < 30 breaths/min
18	Spontaneous tidal volume > 10 mL/kg
19	Spontaneous PEEP > 5 cm H ₂ O
20	Spontaneous FiO ₂ < 0.5
21	Spontaneous PaO ₂ > 60 mmHg
22	Spontaneous PaCO ₂ < 50 mmHg
23	Spontaneous pH > 7.35
24	Spontaneous SaO ₂ > 90%
25	Spontaneous RR < 30 breaths/min
26	Spontaneous tidal volume > 10 mL/kg
27	Spontaneous PEEP > 5 cm H ₂ O
28	Spontaneous FiO ₂ < 0.5
29	Spontaneous PaO ₂ > 60 mmHg
30	Spontaneous PaCO ₂ < 50 mmHg
31	Spontaneous pH > 7.35
32	Spontaneous SaO ₂ > 90%
33	Spontaneous RR < 30 breaths/min
34	Spontaneous tidal volume > 10 mL/kg
35	Spontaneous PEEP > 5 cm H ₂ O
36	Spontaneous FiO ₂ < 0.5
37	Spontaneous PaO ₂ > 60 mmHg
38	Spontaneous PaCO ₂ < 50 mmHg
39	Spontaneous pH > 7.35
40	Spontaneous SaO ₂ > 90%
41	Spontaneous RR < 30 breaths/min
42	Spontaneous tidal volume > 10 mL/kg
43	Spontaneous PEEP > 5 cm H ₂ O
44	Spontaneous FiO ₂ < 0.5
45	Spontaneous PaO ₂ > 60 mmHg
46	Spontaneous PaCO ₂ < 50 mmHg
47	Spontaneous pH > 7.35
48	Spontaneous SaO ₂ > 90%
49	Spontaneous RR < 30 breaths/min
50	Spontaneous tidal volume > 10 mL/kg
51	Spontaneous PEEP > 5 cm H ₂ O
52	Spontaneous FiO ₂ < 0.5
53	Spontaneous PaO ₂ > 60 mmHg
54	Spontaneous PaCO ₂ < 50 mmHg
55	Spontaneous pH > 7.35
56	Spontaneous SaO ₂ > 90%
57	Spontaneous RR < 30 breaths/min
58	Spontaneous tidal volume > 10 mL/kg
59	Spontaneous PEEP > 5 cm H ₂ O
60	Spontaneous FiO ₂ < 0.5
61	Spontaneous PaO ₂ > 60 mmHg
62	Spontaneous PaCO ₂ < 50 mmHg
63	Spontaneous pH > 7.35
64	Spontaneous SaO ₂ > 90%
65	Spontaneous RR < 30 breaths/min
66	Spontaneous tidal volume > 10 mL/kg
67	Spontaneous PEEP > 5 cm H ₂ O
68	Spontaneous FiO ₂ < 0.5
69	Spontaneous PaO ₂ > 60 mmHg
70	Spontaneous PaCO ₂ < 50 mmHg
71	Spontaneous pH > 7.35
72	Spontaneous SaO ₂ > 90%
73	Spontaneous RR < 30 breaths/min
74	Spontaneous tidal volume > 10 mL/kg
75	Spontaneous PEEP > 5 cm H ₂ O
76	Spontaneous FiO ₂ < 0.5
77	Spontaneous PaO ₂ > 60 mmHg
78	Spontaneous PaCO ₂ < 50 mmHg
79	Spontaneous pH > 7.35
80	Spontaneous SaO ₂ > 90%
81	Spontaneous RR < 30 breaths/min
82	Spontaneous tidal volume > 10 mL/kg
83	Spontaneous PEEP > 5 cm H ₂ O
84	Spontaneous FiO ₂ < 0.5
85	Spontaneous PaO ₂ > 60 mmHg
86	Spontaneous PaCO ₂ < 50 mmHg
87	Spontaneous pH > 7.35
88	Spontaneous SaO ₂ > 90%
89	Spontaneous RR < 30 breaths/min
90	Spontaneous tidal volume > 10 mL/kg
91	Spontaneous PEEP > 5 cm H ₂ O
92	Spontaneous FiO ₂ < 0.5
93	Spontaneous PaO ₂ > 60 mmHg
94	Spontaneous PaCO ₂ < 50 mmHg
95	Spontaneous pH > 7.35
96	Spontaneous SaO ₂ > 90%
97	Spontaneous RR < 30 breaths/min
98	Spontaneous tidal volume > 10 mL/kg
99	Spontaneous PEEP > 5 cm H ₂ O
100	Spontaneous FiO ₂ < 0.5

TABLE 390.3. WEANING FROM MECHANICAL VENTILATION

There are several choices of weaning technique. A routine healthy postoperative patient may need little or no weaning from mechanical ventilation. For the patient in whom success is less certain, initial weaning choice may be either with a T piece, whereby a patient's endotracheal tube is connected to oxygen but separate from ventilator circuit; with sequentially diminishing levels of pressure support and assessment of tidal volume adequacy; or with lowering of SIMV breaths from 10 to 12 L per minute to less than 1 L per minute. Favored type of wean varies. Randomized trials indicated that both pressure support ventilation (PSV) and daily T-piece trials are good options for weaning. In general, patients will wean from mechanical ventilation as the underlying medical conditions that precipitated the need for starting ventilation resolve.

NONINVASIVE POSITIVE-PRESSURE VENTILATION

Noninvasive positive-pressure ventilation (NIPPV) consists of mask delivery of air or oxygen under positive pressure, but it is otherwise similar to standard mechanical ventilation by an endotracheal tube. This technique is advocated in acute respiratory failure to avoid the complications of endotracheal intubation and mechanical ventilation, particularly those of nosocomial infections. During the past few years, NIPPV use has risen in hospitalized patients in three settings: (a) treatment of acute respiratory failure, especially respiratory failure due to chronic obstructive lung disease exacerbations; (b) weaning; and (c) postoperative support of ventilation. There is some evidence that NIPPV shortens the length of ICU stay, and a recent meta-analysis of seven randomized controlled trials showed that use of NIPPV decreased the need for endotracheal intubation and improved survival in persons with respiratory failure due to acute exacerbations of COPD. In addition, the use of early extubation with subsequent noninvasive ventilation weans in acute respiratory failure/COPD decreased weaning times, diminished nosocomial pneumonia, and improved 60-day survival. For chronic home use, patients may receive nocturnal positive-pressure ventilation either for chronic respiratory failure due to neuromuscular disease or for obstructive sleep apnea therapy where treatment increases upper airway pressure, keeps the airway patent, and prevents apneas.

NIPPV can be delivered as either continuous positive airway pressure (CPAP) or bilevel positive airway pressure (Bi-PAP). CPAP is the application of positive pressure at one level throughout the respiratory cycle. Bi-PAP consists of separately set inspiratory and expiratory pressures, with the difference between these two set pressures being a driving pressure for ventilation. Bi-PAP can be administered with or without time-cycled breaths, similar to standard mechanical ventilation. Use of either of these methods of NIPPV may be achieved via nasal mask or full-face mask, and oxygen can be administered simultaneously. The importance of coaching and talking patients through the setup and implementation of NIPPV cannot be overemphasized. If a patient cannot cooperate, the success rate of this therapy drops dramatically. Mask fit is especially important to the success of this therapy. Initiation of this technique is time consuming for therapists, nurses, and doctors, which has limited its use in some settings (e.g., emergency room).

OTHER RESPIRATORY THERAPY TECHNIQUES

Two goals of treatment underlie many of the standard respiratory therapy techniques: removal of secretions and expansion of lung volume to diminish atelectasis. Both of these goals may lead to improved oxygenation and reduced infection rates. Therapies that address these two objectives are interrelated. Sputum removal may be a particularly important strategy for the patient with bronchiectasis or chronic bronchitis. Chest physiotherapy, renamed postural drainage therapy (PDT) in the recently published National Board for Respiratory Care practice guidelines, includes techniques of postural drainage, chest wall percussion and vibration, coughing, suctioning, breathing exercises, and patient mobilization. These sputum removal techniques are listed in [Table 390.4](#). Although postural drainage is thought to be an important component of PDT, measurement of efficacy of PDT is difficult as there is little standardization of protocols and published studies include only small numbers of patients. Cook and colleagues undertook comparison of several PDT techniques with a meta-analysis to address efficacy and cost containment. Despite use of percussion and vibration techniques for many years, there is little evidence to support their use. Additionally, they are labor-intensive, requiring a trained therapist to assist the patient. Ultrasonic therapy is similarly labor-intensive without proven efficacy beyond other PDT techniques. Use of a flutter valve during exhalation induces oscillations in pressure and flow, which vibrate the airway walls and loosen mucus. This has received much recent attention, as has the ThAirapy vest, a new device that allows a patient to self-administer high-frequency chest compressions. The advantages of the flutter valve and the vest are the capacity for self-administration and the resulting lower associated personnel cost. Mucolytic drugs, such as acetylcysteine or rDNAse delivered into the airway, may also enhance secretion removal, although survival efficacy is unproven.

Technique	Indication
Postural drainage	Chronic bronchitis, bronchiectasis, pneumonia
Chest wall percussion	Chronic bronchitis, bronchiectasis, pneumonia
Vibration	Chronic bronchitis, bronchiectasis, pneumonia
Coughing	Chronic bronchitis, bronchiectasis, pneumonia
Suctioning	Chronic bronchitis, bronchiectasis, pneumonia
Breathing exercises	Chronic bronchitis, bronchiectasis, pneumonia
Patient mobilization	Chronic bronchitis, bronchiectasis, pneumonia
Flutter valve	Chronic bronchitis, bronchiectasis, pneumonia
ThAirapy vest	Chronic bronchitis, bronchiectasis, pneumonia
Mucolytic drugs	Chronic bronchitis, bronchiectasis, pneumonia

TABLE 390.4. RESPIRATORY THERAPY TECHNIQUES

Techniques to increase lung expansion are also listed in [Table 390.4](#). These, in addition to postural drainage itself, are thought to be the major useful components of chest physiotherapy. The huff or forced expiratory technique (FET) is controlled diaphragmatic breathing interspersed with forced expirations from mid- to low-lung volume. It is more effective than either manual techniques or intermittent positive-pressure breathing (IPPB) to increase sputum production in cystic fibrosis patients. Since after initial instruction it involves using the efforts of the patient only, rather than the services of an additional therapist, it is time- and cost-effective for many patients. Positive expiratory pressure (PEP) therapy uses exhalation through a fixed-orifice resistor at an expiratory pressure of 10 to 20 cm H₂O. PEP splints airways open so that the patient can expectorate secretions using the huff technique. It is simple to use, and is an inexpensive way to remove secretions and expand lungs. In cystic fibrosis patients, PEP mask breathing with FET was compared both to postural drainage and FET and to exercise bicycle and FET. All were effective in sputum removal.

Patient mobilization and exercise are important not only for sputum removal in the chronically infected patient but also for avoidance of postoperative atelectasis. Intermittent positive-pressure breathing, incentive spirometry, and CPAP have all been shown to reduce postoperative atelectasis. Supplemental oxygen therapy should not be interrupted to deliver these treatments.

Undesirable effects of PDT and related procedures include hypoxemia, pain, dehiscence of wounds, arrhythmias, or displacement of lines, endotracheal tubes, and chest tubes. Pain can be assessed and pretreated with analgesia. When chest physiotherapy is poorly tolerated or accompanied by pain, patient compliance

diminishes to about 40%.

AIRWAY SUCTIONING

Suctioning with a catheter through the nose, mouth, or endotracheal or tracheostomy tube is another therapy implemented to remove secretions from the airways. Its use should be limited to situations where the patient is mechanically ventilated or where other physiotherapy modes to remove secretions have been ineffective. Secondary goals of suctioning include improving oxygenation and lowering the work of breathing. All patients on ventilators whose upper airways are bypassed with an endotracheal tube undergo routine suctioning. Patients may also need suctioning if they are producing copious secretions due to bronchiectasis or pneumonia, where the secretions cannot be mobilized with less invasive techniques, such as a cough or a forced breathing maneuver. If a patient is bleeding or vomiting, or has lost the cough reflex due to underlying neurologic disease, sedatives, overdose, or stroke, intermittent suctioning is often indicated.

A rigid suction catheter is used for removal of oral secretions and a flexible catheter is used for airway suctioning to avoid airway trauma and abrasions. The airway catheter is inserted using sterile technique to minimize the risk of nosocomial pneumonia. Normal saline instillation before suctioning is practiced routinely for ventilated patients, without much data to suggest its benefit. Some hospitals have recently implemented suctioning without normal saline unless secretions are too viscous. Complications of suctioning include hypoxemia, arrhythmias, and hemodynamic instability. A closed-system, in-line suction catheter is frequently placed into mechanical ventilator circuits to minimize these complications and to reduce the aerosol spread of infectious particles into the atmosphere.

HUMIDITY AND AEROSOL THERAPY

Humidity is delivered to the airways for several theoretical reasons, mostly to avoid excessive drying when the glottis and upper airway are bypassed, as happens with endotracheal or tracheostomy tube placement. Humidity may also improve mucus transport or provide passive heating for a hypothermic patient. Humidification therapy is most commonly used for mechanically ventilated patients, but whether there is benefit from humidity alone in any other situation is unclear. Two categories of humidification devices are available for the ventilated patient; a heat moisture exchanger, which allows passive heat production and high flow, and a heated humidifier, such as a cascade or the bubble-through-wick apparatus. Potential complications and relative cost in part decide the choice of device. Heat moisture exchangers have the potential for high airway resistance, which may hamper weaning for a patient with underlying respiratory disease. In contrast, heated humidifiers are easily colonized with bacteria, may also develop high resistance from the pooled condensate in the circuit, and can burn airway mucosa if the heater malfunctions.

MEDICATION VIA AEROSOL THERAPY

The medications that can be administered by aerosol therapy are numerous and the list is growing. These include bronchodilators, anti-inflammatory medications, corticosteroids, morphine, topical anesthetics, mucolytic agents, insulin, other hormones, epinephrine, antibiotics, and antiviral therapy. Many of these can also be given by mouth or vein. Reasons to choose an inhaled method of delivery include better penetration of a drug delivered by the aerosol route to the site of action, often the lungs or airways. In addition, some medications may be given by aerosol on an emergency basis, even in the absence of intravenous access.

Three types of devices are used for aerosolized medication delivery: a small-volume nebulizer, a metered-dose inhaler, or a dry-powder inhaler. The small-volume nebulizer requires a higher dose of drug than the metered-dose inhaler and is correspondingly more costly. Its major benefit is that less mastery of technique is required for successful delivery of medications. Years of emergency room visits and home use for persons with asthma and COPD exacerbations have convinced patients that nebulizers are superior to metered-dose inhalers. Despite this bias, data of Mandelberg et al. suggest that metered-dose inhalers are subjectively and objectively comparable, if not superior, for emergency room therapy and perhaps even ventilator use when used correctly.

Most anticholinergic agents, β -agonists, and anti-inflammatory therapy for asthma can be delivered with a metered-dose inhaler. The importance of good technique cannot be overestimated. Components of delivery include the following steps: inversion and shaking of the canister, normal exhalation, an activation push starting halfway through inhalation, and sustaining of a breath-hold for 4 to 10 seconds. Problems with technique happen at each step. Patients routinely misuse metered-dose inhalers and thus limit the efficacy of medication. At most, 10% of the solution is delivered to the lungs; however, doses are usually tenfold lower than for the nebulizer devices, since less drug is deposited in the large airways. For the elderly and the young infant, hand-mouth coordination is more difficult and the inhaler is often activated improperly, resulting in inadequate medication delivery. Use of a spacer attached to the inhaler, either 6 inches of ventilator tubing or a specially designed chamber device, improves drug delivery to the lungs. For arthritic adults, special adapters improve the ability to initiate dispensation. Dry-powder inhaler delivery systems are under development to meet the federal mandate to minimize fluorocarbon release into the atmosphere and avoid ozone depletion. In contrast to the metered-dose inhaler, these devices are easy to use; however, they are not available for ventilator attachment.

CHAPTER 391: LUNG TRANSPLANTATION

ROBERT M. KOTLOFF

[Current Trends in Transplant Activity](#)
[Indications](#)
[Timing of Referral](#)
[Patient Selection](#)
[Donor Selection and Organ Allocation](#)
[Available Surgical Techniques](#)
[Routine Post-Transplantation Management](#)
[Outcomes](#)
[Complications](#)

Human lung transplantation was first attempted in 1963, but it was not until two decades later that extended survival was achieved. Further refinements in patient selection, surgical technique, and postoperative care have since facilitated the successful application of lung transplantation to a wide variety of advanced disorders of the airways, lung parenchyma, and pulmonary vasculature. There has been a marked proliferation of lung transplant centers worldwide, and as of 1999 more than 9,000 procedures had been performed.

Although lung transplantation has assumed an important role in the therapeutic approach to select patients with advanced lung disease, several serious problems remain that limit its efficacy. There is a severe shortage of suitable donor organs at a level that is increasingly insufficient to meet current demands. Immunosuppressive therapy is associated with a number of troubling side effects, most notably a significant risk of infection and malignancy. Rejection occurs frequently and continually threatens organ function. Though lung transplantation offers the prospect of improved quality of life, long-term survival remains an elusive goal, with less than half of recipients living beyond 5 years. To optimize outcomes in the face of these shortcomings, it is essential that candidates be selected judiciously and that care of recipients be rendered in a meticulous and vigilant fashion.

CURRENT TRENDS IN TRANSPLANT ACTIVITY

Following the initial technical successes of the 1980s, the field of lung transplantation realized tremendous growth in both the number of procedures performed and the number of candidates listed ([Fig. 391.1](#)). Over the past several years, however, lung transplant activity in the United States has leveled off at an approximate rate of 800 to 900 procedures annually, representing one-third the volume of heart transplants and one-fourth the volume of liver transplants performed. This limitation reflects a fixed cadaveric organ donor pool, accentuated by the fact that only 15% of cadaveric donors have lungs suitable for harvest. As a result of the current donor constraints, the number of registered candidates now exceeds the annual number of procedures by threefold ([Fig. 391.1](#)), the median waiting time has escalated to 18 months, and an increasing number of candidates are dying on the waiting list.

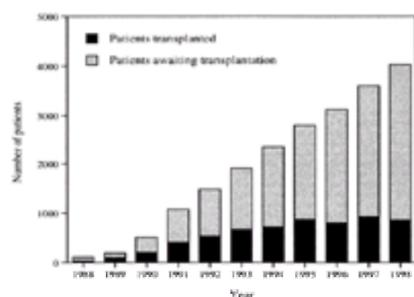

FIGURE 391.1. Lung transplantation–related activity in the United States between 1988 and 1998. There is a widening discrepancy between the number of patients awaiting transplantation and the number of procedures performed annually. (Data from the United Network for Organ Sharing U.S. Scientific Registry.)

INDICATIONS

The range of diseases amenable to transplantation is broad. Chronic obstructive pulmonary disease (including α_1 -antitrypsin deficiency) represents the most common indication, accounting for approximately 40% of all procedures. Other established indications are idiopathic pulmonary fibrosis, primary pulmonary hypertension, Eisenmenger's syndrome, and cystic fibrosis. Less common disorders for which transplantation has been successfully applied include lymphangioleiomyomatosis, eosinophilic granuloma, bronchiectasis unrelated to cystic fibrosis, and pulmonary fibrosis due to radiation or drugs. Transplantation of patients with lung disease due to a systemic process remains controversial. In this regard, reports of frequent disease recurrence in patients with sarcoidosis and of extrapulmonary complications in patients with collagen vascular disease have raised concern about the suitability of such patients for transplantation. Nonetheless, short-term functional outcomes and survival following transplantation are comparable to those of other patient populations, and most centers are willing to offer transplantation to carefully selected patients without significant extrapulmonary organ dysfunction.

TIMING OF REFERRAL

Several considerations impact on the timing of referral for lung transplantation. The inherent risks of transplantation, including a 50% mortality rate by 5 years, dictate that this option be reserved for patients with advanced, life-threatening disease for which alternative therapies are unavailable or unsuccessful. On the other hand, patients who have progressed to a stage of profound debility are poor candidates at high risk for perioperative morbidity and mortality and for inferior functional recovery. Thus, patients should be referred during the “transplant window” when they are sufficiently ill to warrant the risks of transplantation but not so ill as to compromise the likelihood of a successful outcome. An additional factor that must be considered is an anticipated waiting time of 12 to 24 months at most centers, during which the patient must remain functionally suitable for transplantation.

Disease-specific guidelines for timely referral and listing of patients, based on available prognostic indexes, are listed in [Table 391.1](#). The patient's perception of an unacceptably poor quality of life is an important additional factor to consider but should not serve as the sole justification for referral of a patient whose disease is not deemed to be at a life-threatening stage. The imprecise nature of predictive indexes must be acknowledged, particularly with respect to chronic obstructive pulmonary disease and Eisenmenger's syndrome, which tend to follow highly variable and often protracted courses even in the advanced stages. In contrast, idiopathic pulmonary fibrosis is usually a rapidly progressive and highly lethal disease without effective medical treatment; early referral of such patients for transplantation is prudent. The availability of continuous intravenous prostacyclin for treatment of primary pulmonary hypertension has influenced the timing of transplantation for this group of patients. The use of prostacyclin has been associated with improvement in hemodynamics, exercise tolerance, and survival. While previously viewed as a “bridge” to transplantation, this therapeutic modality can actually obviate the need for transplantation for those patients who demonstrate a dramatic and sustained response.

Chronic Obstructive Pulmonary Disease

- Postbronchodilator forced expiratory volume in 1 second (FEV₁) < 25% of predicted and/or presence of air pulmonary and/or Pco₂ > 55 mm Hg

Idiopathic Pulmonary Fibrosis

- Symptomatic, progressive disease unresponsive to medical therapy
- Vital capacity below 60-70% of predicted
- Resting or exercise oxygen desaturation

Cystic Fibrosis

- FEV₁ < 30% of predicted, or rapidly declining lung function if FEV₁ < 30%
- Females and patients < 18 years of age have a poorer prognosis; consider earlier referral

Primary Pulmonary Hypertension

- New York Heart Association functional class III or IV despite optimal medical therapy (including intravenous prostacyclin)
- Parameters portending a high risk of death include mean pulmonary arterial pressure > 55 mm Hg, mean right atrial pressure > 15 mm Hg, and cardiac index < 2 L/min/m²

Eisenmenger's Syndrome

- New York Heart Association functional class III or IV despite optimal medical therapy

Adapted from Murray H, Port R, Estenne M, et al. International guidelines for the selection of lung transplant candidates. J Heart Lung Transplant 1998;17:705-5

TABLE 391.1. DISEASE-SPECIFIC GUIDELINES FOR LISTING FOR LUNG TRANSPLANTATION

PATIENT SELECTION

Selection criteria are necessarily stringent in order to maximize the likelihood of successful outcomes. Indiscriminate transplantation of poor candidates willing to accept any degree of risk cannot be justified in the face of current severe organ shortages. Recommended selection criteria are listed in [Table 391.2](#). The scarcity of organs and the somewhat inferior outcomes achieved with increasing age have prompted the establishment of recommended age cutoffs: 55 years for heart–lung, 60 years for bilateral lung, and 65 years for single-lung transplantation. Candidates should be functionally disabled (New York Heart Association class III or IV) but still ambulatory and able to participate in preoperative pulmonary rehabilitation. They should be free of significant extrapulmonary end-organ dysfunction. In particular, renal function must be normal or only mildly impaired since the chronic use of cyclosporine or tacrolimus following transplantation invariably causes significant renal insufficiency. Adequate hepatic function is necessary to minimize the risk of postoperative bleeding, liver failure, and drug toxicity. This issue has been most closely examined in patients with pulmonary hypertension and passive hepatic congestion, for whom a preoperative bilirubin level exceeding 2.1 mg per deciliter is associated with an early post-transplantation mortality rate approaching 60%, as compared to 16% for those with normal bilirubin levels. Severe left ventricular dysfunction or extensive coronary artery disease contraindicates isolated lung transplantation but warrants consideration of heart–lung transplantation for younger candidates. Other absolute contraindications include active infection with HIV or hepatitis B virus infection with hepatitis C virus with evidence of significant liver damage; active or recent cigarette smoking, drug abuse, or alcohol abuse; and extremes of weight. Current or recent history of malignancy (other than skin cancer) is also considered an absolute contraindication, though there have been several recent attempts to utilize lung transplantation with curative intent for patients with bronchoalveolar cell carcinoma restricted to the lungs. The risk posed by other chronic medical conditions, such as diabetes mellitus, hypertension, osteoporosis, and limited coronary artery disease, must be assessed individually based on severity of disease, presence of end-organ damage, and ease of control with standard therapies.

Preoperative Selection Criteria

- Age < 55 years
- Negative for HIV antibody and hepatitis B surface antigen
- No active or recent history of malignancy (excluding localized squamous or basal cell skin cancer, localized cervical cancer, and primary brain tumors with low metastatic potential)
- Cigarette smoking history of < 20 pack-years
- No history of significant chronic lung disease
- No prior thoracic surgery on side of harvest
- Absence of significant chest trauma
- No evidence for aspiration or sepsis
- Clear chest radiograph
- Pao₂ > 300 mm Hg on Fio₂ 1.0, PEEP 5 cm H₂O
- Absence of purulent secretions or gastric contents at bronchoscopy

Adapted from Murray H, Port R, Estenne M, et al. International guidelines for the selection of lung transplant candidates. J Heart Lung Transplant 1998;17:705-5

TABLE 391.2. GENERAL GUIDELINES FOR TRANSPLANT REAPIENT SELECTION

Selection criteria have been liberalized in several important areas. Preoperative corticosteroid therapy was once considered an absolute contraindication as it was believed to impair healing of the bronchial anastomosis. Refinement in the surgical handling of this precarious anastomosis now permits transplantation to be safely performed in patients maintained on moderate doses of steroids. Prior thoracic surgery or pleurodesis renders the native lung more difficult to explant and increases the risk of perioperative bleeding, particularly when cardiopulmonary bypass is required, but does not contraindicate transplantation in most instances. As discussed previously, transplantation of carefully selected patients with active collagen vascular disease is now considered appropriate by many centers as long as there are no major extrathoracic manifestations that could compromise outcomes. Perhaps most controversial is the transplantation of mechanically ventilated patients. In the absence of an allocation system that preferentially diverts lungs to patients with respiratory failure, expeditious transplantation is feasible only for those patients whose accrued time places them at the top of the waiting list. In these circumstances, some centers are willing to offer transplantation until the time that progressive debility or superimposed complications necessitate deactivation of the ventilator-dependent patient. Although successful outcomes have been reported, preoperative mechanical ventilation is associated with an increased likelihood of death in the first post-transplantation year.

The presence of chronic infection of the airways and sinuses poses unique risks for patients with cystic fibrosis. In general, however, the incidence of post-transplantation infection in the cystic fibrosis population is similar to that of other groups. Some centers exclude patients harboring pan-resistant *Pseudomonas aeruginosa*, but recent evidence demonstrating similar infection rates and survival compared to patients colonized with sensitive strains has challenged this policy. The experience with *Burkholderia cepacia* has been much more ominous. This organism is intrinsically resistant to available classes of antibiotics and has a propensity to reemerge in the post-transplantation period as a cause of life-threatening infections. Because of its association with inferior survival rates, an increasing number of centers consider preoperative colonization with *B. cepacia* to be an absolute contraindication to transplantation. Colonization of the respiratory tract with *Aspergillus* organisms, while common among cystic fibrosis patients, does not appear to portend an increased risk of post-transplantation infection. Exclusion of patients on the basis of positive preoperative cultures is therefore not justified. Furthermore, the merits of attempting to eradicate the organism prior to transplantation, a strategy advocated by some programs, remain uncertain.

DONOR SELECTION AND ORGAN ALLOCATION

In addition to meeting strict criteria for declaration of brain death, cadaveric lung donors are selected on the basis of established guidelines ([Table 391.3](#)). Unfortunately, the lungs are a particularly fragile organ in the brain-dead patient and are frequently compromised by volume overload, contusion, aspiration of gastric contents, or pneumonia. The extreme scarcity of organs has prompted some programs to liberalize selection criteria to include older donors, more extensive smoking histories (in the absence of significant smoking-related lung disease), and contralateral organ harvest in the setting of a unilateral pneumonia or contusion.

Age < 55 years
Negative for HIV antibody and hepatitis B surface antigen
No active or recent history of malignancy (excluding localized squamous or basal cell skin cancer, localized cervical cancer, and primary brain tumors with low metastatic potential)
Cigarette smoking history of < 20 pack-years
No history of significant chronic lung disease
No prior thoracic surgery on side of harvest
Absence of significant chest trauma
No evidence for aspiration or sepsis
Clear chest radiograph
Pao₂ > 300 mm Hg on Fio₂ 1.0, PEEP 5 cm H₂O
Absence of purulent secretions or gastric contents at bronchoscopy

Fio₂, partial pressure of oxygen, arterial; Fio₂, fraction of inspired oxygen; PEEP, positive end-expiratory pressure.

OUTCOMES

SURVIVAL

The Registry of the International Society for Heart and Lung Transplantation contains data on more than 8,000 patients from 150 centers worldwide who have undergone lung transplantation since 1985. Actuarial survival rates for this large cohort are 71% at 1 year, 55% at 3 years, 43% at 5 years, and 32% at 7 years, with a median survival of 3.8 years. Collective survival rates have not improved substantially since 1991 and remain inferior to those achieved with liver and heart transplantation, for which 5-year actuarial survival approximates 70%. Long-term survival following bilateral lung transplantation is moderately superior to that following single lung transplantation. Older recipients (55 years and older) have inferior long-term survival rates compared to their younger counterparts.

Mortality is highest during the first year, with primary graft failure and infection representing the most common causes of deaths. Factors portending an increased risk of early death include ventilator dependence prior to transplantation, an underlying diagnosis other than emphysema, and advanced recipient or donor age. Beyond the first year, attrition slows to an annual rate of approximately 5% to 10%. Most late deaths are attributable to the development of bronchiolitis obliterans, the lethal effects of which are due to both progressive respiratory failure and to an increased susceptibility to infection.

PULMONARY FUNCTION

The peak effect of lung transplantation on pulmonary function parameters is usually not realized until 3 to 6 months following the procedure, at which time the adverse impact of such factors as postoperative pain, weakness, altered chest wall mechanics, and reimplantation lung injury has dissipated. Complete normalization of pulmonary function is the anticipated result of bilateral lung transplantation. Following single-lung transplantation for chronic obstructive pulmonary disease, the FEV₁ increases several fold to a level of approximately 50% to 60% of the predicted normal value. Similarly, single-lung transplantation for pulmonary fibrosis results in marked but incomplete improvement in lung volumes, with persistence of a mild restrictive pattern.

Transplantation also leads to correction of gas exchange abnormalities. Oxygenation improves rapidly, permitting the majority of patients to be weaned from supplemental oxygen within the first week. Hypercapnia may take longer to resolve due to lingering abnormalities in the ventilatory response to CO₂.

EXERCISE CAPACITY

Exercise tolerance improves sufficiently to permit the majority of transplant recipients to resume an active lifestyle. Although free of limitations to usual activity, transplant recipients demonstrate a characteristic reduction in peak exercise performance as assessed by cardiopulmonary exercise testing. Specifically, patients typically achieve a maximum oxygen consumption at peak exercise of only 40% to 60% of that predicted, despite a normal ventilatory response, maintenance of normal oxygenation, and essentially normal cardiac response. Suboptimal exercise performance persists in subjects tested as late as 1 to 2 years following transplantation. Despite the greater magnitude of improvement in pulmonary function associated with the bilateral procedure, there is no significant difference in peak exercise performance between single and bilateral lung transplant recipients. Emerging evidence suggests that the limitation to exercise may be due to skeletal muscle dysfunction caused by cyclosporine-induced impairment in mitochondrial respiration.

HEMODYNAMICS

When performed in patients with pulmonary hypertension, both single and bilateral lung transplantation lead to immediate and sustained normalization of pulmonary arterial pressure and enhanced cardiac output. In response to a decrease in afterload, right ventricular performance gradually normalizes in the majority of patients. A threshold of right ventricular dysfunction, below which recovery will not occur, has yet to be defined.

COMPLICATIONS

PRIMARY GRAFT FAILURE

Primary graft failure describes a severe form of acute allograft dysfunction that appears within the first hours to days following transplantation and is presumed to represent a manifestation of ischemia–reperfusion injury. Histologically, a pattern of diffuse alveolar damage is seen, identical to that associated with acute respiratory distress syndrome. The incidence of this complication varies from 15% to 35% in contemporary clinical series. The diagnosis rests on the presence within 72 hours of transplantation of widespread radiographic infiltrates and impaired oxygenation, and the exclusion of other causes of early graft dysfunction such as volume overload, pneumonia, rejection, and pulmonary venous outflow obstruction. Treatment is supportive, relying on conventional mechanical ventilatory techniques as well as on the use of such adjunct measures as nitric oxide, independent lung ventilation, and extracorporeal life support for those who cannot be otherwise stabilized. With mortality rates of up to 60%, primary graft failure ranks second only to infection as a leading cause of early deaths among transplant recipients. Recovery in survivors is often protracted and incomplete, though attainment of normal lung function and exercise tolerance is possible. Results of emergent retransplantation in this setting have been poor.

AIRWAY COMPLICATIONS

With implantation of the allograft, no attempt is routinely made to reestablish the bronchial arterial circulation. As a result, the donor bronchus is precariously dependent on retrograde blood flow through low-pressure pulmonary venous to bronchial vascular collaterals, placing it at risk for ischemic injury. Because dehiscence of the airway was initially a common sequela, techniques have evolved to buttress the bronchial anastomosis and provide a nurturing blood supply. A telescoping technique is currently employed that intussuscepts donor and recipient bronchi, overlapping by one to two cartilaginous rings. Life-threatening dehiscence is now rare; partial dehiscence is still occasionally encountered but typically heals with expectant management only. The most common form of airway complication that remains is anastomotic stenosis, which may result from stricture, excessive granulation tissue, or bronchomalacia. Stenosis typically becomes manifest several weeks following transplantation. Clues to its presence include focal wheezing on the involved side, recurrent bouts of pneumonia or purulent bronchitis, abnormally low spirometric values, and a flow–volume loop demonstrating flattening of the midexpiratory limb. Airway stenosis is now readily correctable in most cases with bronchoscopically placed stents.

INFECTION

Infection rates among lung transplant recipients are several fold higher than among recipients of other solid organs. The greater risk is likely related to the unique exposure of the lung allograft to microorganisms via inhalation and aspiration. Bacterial pathogens account for the majority of infections. Bacterial pneumonia, often due to gram-negative organisms, is most commonly encountered in the immediate postoperative period. Predisposing factors include immunosuppression, blunted cough due to pain and lung denervation, disruption of lymphatic drainage, impaired mucociliary clearance from widespread mucosal ischemic injury, narrowing of the bronchial anastomosis, and passive transfer of organisms with the donor lung. Bacterial infections reemerge as a later complication among recipients who develop chronic rejection. Notably, despite persistent carriage of pathogenic bacteria in the sinuses and proximal airways, recipients with cystic fibrosis are not at greater risk for lower respiratory tract infections than other recipient populations.

CMV is the most common viral pathogen encountered in the post-transplantation period. Active infection can occur by transfer of virus with the lung allograft or blood products, or by reactivation of latent virus remotely acquired by the recipient. Seronegative recipients who acquire primary infection from a seropositive donor are at greatest risk for serious CMV disease, particularly pneumonitis.

CMV infection typically emerges within the first 3 months. Infection can be subclinical, manifested as asymptomatic viremia or shedding of virus in the respiratory tract or urine. Clinical disease can assume a number of forms, including a mononucleosis-like syndrome with fever and malaise, and organ-specific involvement of the lungs, gastrointestinal tract, liver, and central nervous system. Treatment of clinically significant disease with ganciclovir is usually effective, although relapses may occur.

Although rarely lethal, CMV infections contribute substantially to post-transplantation morbidity and have been linked with an increased risk of chronic rejection. In an

attempt to minimize the adverse impact of this infection, many centers have adopted prophylactic strategies. For seronegative recipients, the most effective strategy is matching with seronegative donors and use of screened blood products. However, this strategy is associated with prolonged waiting times since the majority of the donor pool is serologically positive. Antiviral prophylaxis of seronegative recipients of seropositive organs, as well as of seropositive recipients, is an alternative strategy in widespread use. Current data suggest that such an approach delays the onset and may attenuate the severity of infection.

Aspergillus species commonly colonize the airways of lung transplant recipients, but only a minority of patients develop invasive disease. Due to the presence of devitalized cartilage and suture material, the bronchial anastomosis is particularly vulnerable to localized invasion. *Aspergillus* may also cause more diffuse airways infection, characterized by mucosal ulceration and formation of pseudomembranes. Infection restricted to the airway is usually responsive to itraconazole or to inhaled or parenteral amphotericin B, but fatal erosion into the pulmonary artery and widespread fungal dissemination have been reported. In contrast to airway infection, invasive disease of the lung parenchyma and extrapulmonary aspergillosis are associated with high mortality.

REJECTION

Despite the use of potent immunosuppressive agents, allograft rejection remains a pervasive problem. Features of acute and chronic forms of rejection are summarized in [Table 391.5](#) and elaborated on below.

Feature	Acute Rejection	Chronic Rejection
Onset	Initial 3 months	Beyond first year
Risk factors	HLA mismatching	Recurrent or severe acute rejection, cytomegalovirus infection, airway ischemia, HLA mismatching
Histology	Perivascular lymphocytic infiltrates	Bronchiolar submucosal inflammation and fibrosis, luminal obliteration
Signs and symptoms	Malaise, low-grade fever, dyspnea, cough, impaired oxygenation, leukocytosis	Dyspnea, chronic cough, recurrent bouts of purulent bronchitis
Chest radiograph	Alveolar or interstitial opacities, pleural effusions	Clear lung fields (they show hyperinflation)
High-resolution computed tomography	Ground-glass or alveolar opacities	Attenuation of peripheral vascular markings, bronchiectasis, air trapping (on expiratory images)
Pulmonary function testing	Proportional decline in both FEV ₁ and FVC	Disproportionate decline in FEV ₁ , with worsening obstructive pattern
Yield of transbronchial biopsy	High	Low
Response to treatment	Rapid improvement	Refractory; treatment may slow rate of decline

HLA, human leukocyte antigen; FEV₁, forced expiratory volume in 1 second; FVC, forced vital capacity

TABLE 391.5. FEATURES OF ACUTE AND CHRONIC ALLOGRAFT REJECTION

Frequent surveillance of the allograft by transbronchial biopsies has demonstrated that most transplant recipients experience at least one episode of acute rejection in the first several months. Beyond this initial period, the risk of acute rejection declines steadily, reaching a low but not negligible rate by the end of the first year. Episodes of acute rejection may be clinically silent; biopsies from asymptomatic and functionally stable recipients have demonstrated evidence of acute rejection in up to one-third of cases. When present, clinical manifestations are nonspecific and include malaise, low-grade fever, dyspnea, cough, and leukocytosis. Radiographic infiltrates, a decline in arterial oxygenation at rest or with exercise, and an abrupt fall of greater than 10% in spirometric values are important clues to the possible presence of rejection; however, similar findings accompany bouts of infection.

Reliance on clinical criteria alone runs the risk of misdiagnosis and unnecessary augmentation of immunosuppression. In one study, acute rejection was confirmed histologically in only two-thirds of patients in whom it was suspected on clinical grounds. Transbronchial lung biopsy has emerged as the gold standard for diagnosis of acute rejection. The procedure is safe, can be performed in serial fashion over time, and has a sensitivity and specificity in excess of 90% for the diagnosis of acute rejection. To achieve this degree of diagnostic accuracy, at least five pieces of alveolated lung parenchyma, each containing bronchioles and more than 100 alveoli, must be obtained. The hallmark of acute rejection is the presence of perivascular lymphocytic infiltrates, which in more severe cases spill over into the adjacent interstitium and alveolar airspaces. A lymphocytic bronchitis or bronchiolitis may accompany the parenchymal involvement.

Treatment of acute rejection consists of a 3-day pulse of intravenous solumedrol at a daily dose of 15 mg per kilogram and, in some centers, by a transient increase and subsequent taper of maintenance prednisone. In most cases, this results in rapid improvement in symptoms, pulmonary function, and radiographic abnormalities, but follow-up biopsies show persistent histologic evidence of rejection in 30% of mild rejection episodes and 48% of moderate episodes. A variety of modalities have been employed for refractory or recurrent acute rejection, including antilymphocyte antibody preparations, tacrolimus, methotrexate, and photopheresis.

Chronic rejection represents the major impediment to long-term graft function and patient survival following lung transplantation. It is manifested histologically as bronchiolitis obliterans, a fibroproliferative process characterized by submucosal inflammation and fibrosis of the bronchiolar walls ultimately progressing to complete obliteration of the airway lumen. Although presumed to represent an immunologically mediated process, the pathogenesis of bronchiolitis obliterans remains poorly understood. Acute rejection, particularly when recurrent or severe, has been consistently identified as the major risk factor for development of bronchiolitis obliterans. Other proposed risk factors include CMV infection, airway ischemia, and HLA mismatching.

Unlike acute rejection, bronchiolitis obliterans is difficult to diagnose by transbronchial biopsy, with reported sensitivity as low as 17%. For this reason, diagnosis now rests on demonstration of physiologic rather than histologic criteria. The term *bronchiolitis obliterans syndrome* has thus evolved, defined as an otherwise unexplained and sustained decline in FEV₁ of at least 20% below the peak post-transplantation baseline.

Bronchiolitis obliterans syndrome is rarely encountered in the initial year but its prevalence increases steadily beyond that point, involving approximately two-thirds of recipients by the fifth year. Onset of disease is typically insidious and heralded by dyspnea and cough. Recurrent bouts of purulent tracheobronchitis, with recovery of *P. aeruginosa* from sputum cultures, are highly characteristic. Spirometry demonstrates evidence of airflow obstruction, with a disproportionate fall in the FEV₁ and consequent fall in the ratio of FEV₁ to forced vital capacity. The plain chest radiograph is unrevealing, but high-resolution computed tomography of the chest often demonstrates decreased peripheral vascular markings, bronchiectasis, and evidence of air trapping on expiratory images.

Progressive decline in lung function is the rule, although the pace of decline is highly variable and the course may be interrupted by periods of functional stability. A wide range of therapies have been employed, all of which center on augmentation of immunosuppression. Options include high-dose corticosteroids, antilymphocyte antibodies, tacrolimus, inhaled cyclosporine, methotrexate, and total lymphoid irradiation. Current data are insufficient to support the conclusion that treatment impacts favorably on the natural history of bronchiolitis obliterans, and consensus on the optimal therapeutic strategy is lacking. At best, treatment appears to slow the rate of decline rather than to fully arrest or reverse the process. The prognosis is generally poor, with a 40% mortality rate within 2 years of onset. The only definitive treatment is retransplantation, but this strategy remains highly controversial in the context of a scarce donor organ pool.

POST-TRANSPLANTATION LYMPHOPROLIFERATIVE DISORDER

Post-transplantation lymphoproliferative disorder (PTLD) encompasses a group of abnormal B-cell proliferative responses ranging from benign polyclonal hyperplasia to malignant lymphomas. The reported incidence of PTLD in the lung transplant recipient population ranges from 6% to 9%, and most cases occur within the first post-transplantation year. The pathogenesis of PTLD involves Epstein–Barr virus–mediated B-cell proliferation that is permitted to proceed in an uncontained fashion in a host lacking the necessary cellular immune response. Previously unexposed recipients who acquire primary infection are at greatest risk for this complication. In this regard, the incidence of PTLD is 33% to 50% among Epstein–Barr virus–seronegative recipients compared to less than 2% among seropositive recipients. Intrathoracic involvement is most commonly encountered, typically assuming the form of single or multiple pulmonary nodules and/or mediastinal lymphadenopathy. Extrapulmonary sites of involvement include tonsils, intra-abdominal lymph nodes, and gastrointestinal tract as well as widely disseminated disease.

Initial treatment centers on reduction in the magnitude of immunosuppression to permit partial restoration of host cellular immunity. PTLD presenting within the first year is most likely to respond to this strategy. Treatment modalities reserved for refractory cases include chemotherapy, radiation, surgical resection, interferon- α , and anti-B-cell monoclonal antibodies. Antiviral therapy is often concurrently employed but is of unproven efficacy. Mortality related to PTLD or complications of treatment is on the order of 30% for those who develop disease within the first year but rises to 70% for those with later onset of disease.

CHAPTER 392: APPROACH TO THE PATIENT WITH A THYROID NODULE

JAMES A. FAGIN

[Etiologic Factors](#)
[Presentation](#)
[Laboratory Evaluation](#)
[Optimal Management](#)

Thyroid nodules are discrete swellings in the thyroid gland. They are considered as solitary if they are found within an otherwise normal palpable thyroid. Thyroid nodules are present in about 5% of the adult population. Prevalence increases with age, and nodules are more common in women. When prevalence is ascertained by high-resolution ultrasonography, unsuspected thyroid nodules are found in up to 44% of women and 20% of men. Frequency of nodularity is even higher in autopsy studies. By contrast, annual age-adjusted incidence of thyroid cancer in the United States is 2.2 and 5.8 per 100,000 males and females, respectively. The diagnostic challenge is to identify correctly those rare patients with thyroid nodules that are caused by thyroid cancer.

ETIOLOGIC FACTORS

Adenomatous colloid nodules are the most common cause of discrete thyroid enlargement. These hyperplastic lesions are histologic features of multinodular goiters, which can occasionally present with a large dominant nodule that gives the false appearance of being the sole abnormality by palpation. Follicular adenomas are benign neoplasms that are somewhat less prevalent than hyperplastic nodules. Primary thyroid cancers represent fewer than 10% of all clinically apparent nodules. Most of these are papillary thyroid carcinomas. Follicular carcinomas are comparatively uncommon, although their prevalence is higher in iodine-deficient populations. Anaplastic carcinomas are the most malignant form of thyroid cancer and very rare. Medullary thyroid carcinomas are also infrequent and derive from calcitonin-secreting C cells. Occasionally, lymphocytic or subacute thyroiditis can present with regional or nodular thyroid enlargement. Additional causes include thyroid lymphomas, cancers metastasizing to the thyroid, abscesses, and infiltrative/granulomatous diseases.

PRESENTATION

Thyroid nodules are usually asymptomatic and discovered as a visible or palpable neck mass by the physician or patient. Few patients complain of dysphagia, hoarseness, or rapid tumor growth, symptoms that increase the likelihood of cancer. Pain, which is uncommon, is suggestive of subacute thyroiditis or spontaneous bleeding into a preexisting nodule. Risk of cancer is higher in children, male individuals, and older patients. The most significant risk factor for thyroid cancer is a history of radiation exposure, particularly during childhood. Patients receiving external radiation to the head or neck for benign conditions such as thymic or tonsillar enlargement, acne, or tinea capitis are at greater risk for benign nodules as well as thyroid cancer. Although the practice of administering radiation for benign conditions has ceased, the risk persists for several decades after exposure. Also at risk are patients treated with high doses of radiation for Hodgkin's disease, children exposed to internal radiation by radioiodines, such as those living in areas contaminated by fallout from the Chernobyl nuclear accident, and atomic bomb survivors. Radiation exposure is associated specifically with papillary thyroid carcinomas. A family history of medullary thyroid carcinoma, or of multiple endocrine neoplasia type 2 (medullary thyroid carcinomas, pheochromocytomas, and parathyroid adenomas, with or without mucosal neuromas) places patients at a 50% risk of this disease, conferred by inheritance of germ line mutations of the *ret* oncogene. Risk of papillary carcinoma is higher in patients with a family history of adenomatous polyposis coli, Gardner's syndrome, Cowden's disease, or papillary thyroid cancer. The great majority of patients with thyroid nodules, however, have no specific risk factors.

Nodules greater than 1.5 cm can usually be palpated if they are located close to the surface of the gland. Most are of soft or firm consistency. Physical characteristics of the nodule are not usually helpful in differential diagnosis, as most cancers are found within lesions that are clinically indistinguishable from benign tumors. However, presence of a hard nodule, fixation to adjacent structures, vocal cord paralysis, and palpable enlargement of regional lymph nodes are highly indicative of malignancy. Dominant nodules from multinodular goiters can be malignant and should be evaluated in the same manner as solitary nodules. Increasingly, thyroid nodules are discovered incidentally during carotid ultrasonography, neck computed tomography, or magnetic resonance imaging studies. Solitary nodules that are greater than 1 cm in diameter should be evaluated.

LABORATORY EVALUATION

Thyroid function should be routinely assessed in patients with thyroid nodules. If such nodules are thought to be euthyroid based on their clinical presentation, as is most often the case, measurement of thyroid-stimulating hormone (TSH) levels is sufficient. Patients with clinical suspicion of hyperthyroidism or hypothyroidism should also have measurements of serum free T_4 and T_3 . Patients with lymphocytic (Hashimoto's) thyroiditis may present occasionally with regional thyroid enlargement giving the appearance of a discrete thyroid nodule. Determination of antithyroid antibodies is helpful in these cases. Patients confirmed to be thyrotoxic should have a radionuclide scan with iodine 131, technetium Tc 99m pertechnetate, or iodine 123 to determine whether the nodule is "hot" (i.e., incorporates higher levels of the isotope than the surrounding gland). This is caused by autonomously functioning thyroid nodules, which are usually benign. Alternatively, hyperthyroidism may be associated with diffusely increased thyroid uptake, with the nodule appearing as a hypofunctioning ("cold") lesion; this unlikely eventuality is of concern, as thyroid cancers may run an aggressive course in patients with Graves' disease. Because of this, cold nodules in this setting should be evaluated carefully by fine-needle aspiration (FNA) biopsy (see below).

Most patients with thyroid nodules have no abnormalities in thyroid function. Here an FNA biopsy is the initial procedure of choice. This is also the case for thyroid nodules discovered incidentally as a consequence of imaging studies of the neck. Solitary nodules greater than 1 cm should be biopsied, under ultrasonographic guidance if necessary. Cytologic evaluation of the aspirate indicates whether the nodule is benign (i.e., features consistent with colloid nodules, thyroiditis, or benign cysts), suspicious (hypercellular follicular lesions, Hürthle cell changes without lymphocytic infiltration), or malignant. When the smear does not contain at least five or six groups of well-preserved cells, the aspirate is considered unsatisfactory or nondiagnostic. In this event, a repeat aspirate may be diagnostic in about 50% of cases. The false-negative rate of a benign cytologic diagnosis is about 5%, whereas false-positive tests are seen in about 1% of aspirates classified as malignant. Classification of aspirates as indeterminate or suspicious stems from the inability to distinguish benign follicular or Hürthle cell adenomas from their malignant counterparts (i.e., follicular or Hürthle cell carcinomas) based on their cytologic appearance. About 25% of all aspirates fall into this category, and 10% to 15% ultimately prove to be malignant. As mentioned above, likelihood of cancer is considerably diminished in autonomously functioning nodules, which are also follicular neoplasms, and thus give rise to suspicious aspirates. It is therefore prudent to perform radionuclide scans and exclude hyperthyroidism in patients with suspicious or indeterminate cytology. Aspirates from patients with medullary thyroid carcinomas are often not diagnostic, particularly if not followed by immunostaining for calcitonin. The diagnostic accuracy and cost-effectiveness of screening all patients with thyroid nodules for medullary thyroid carcinoma by determining plasma basal calcitonin levels has not been established conclusively, and this test is therefore not performed on a routine basis.

High-resolution ultrasonography is not recommended in the initial evaluation of a thyroid nodule, as it does not help to distinguish benign from malignant tumors. Furthermore, as this technique allows imaging of lesions of 1 to 2 mm, its use in screening could result in inappropriate evaluation of subclinical conditions. Occasionally, ultrasonography-guided FNA biopsy is indicated to assess nodules that are difficult to palpate or embedded deeply within the gland. It is also useful when conventional FNA has failed to provide a diagnostic specimen and to help direct the biopsy needle to the solid component of cystic nodules. In patients with cystic lesions, aspiration decreases the size of nodules and cures many of them. There is a place for ultrasonography in the management of patients with presumed benign nodular disease when palpation is not sufficient to track lesion size during prolonged follow-up, as discussed below.

OPTIMAL MANAGEMENT

About 60% to 70% of patients will prove to have a benign thyroid aspirate, in many cases corresponding to colloid adenomas. These patients are best managed expectantly, i.e., by monitoring changes in nodule size over time. Nodules showing significant growth during the observation period should be rebiopsied. As cells from colloid adenomas are thought to retain responsiveness to TSH, some physicians treat these patients with L -thyroxine to suppress TSH levels below the normal range, and hence reduce the size of the nodule. (*Note:* a suppressive dose of thyroid hormone is one that reduces TSH to levels below the normal range, as opposed

to a *replacement* dose in which TSH levels are maintained within the normal range). The use of suppressive doses of thyroid hormone for benign nodules is controversial. Short-term treatment (about 6 months) with *L*-thyroxine was formerly advocated to help identify those nodules most likely to be malignant based on their failure to decrease in size when TSH levels were low. However, the good predictive power of FNA cytology and the fact that many benign nodules do not shrink with *L*-thyroxine suppressive therapy have largely rendered this practice outmoded. Long-term TSH-suppressive therapy to prevent growth of benign nodules is also of uncertain efficacy. It is unknown as to whether this practice decreases the likelihood that benign tumors will become malignant over time, a rare occurrence in these nodules. Furthermore, supraphysiologic doses of thyroid hormone are associated with osteopenia and cardiac arrhythmias, and should therefore be avoided in postmenopausal women and older patients. In summary, suppressive therapy with thyroid hormone is usually not indicated for benign nodules, which are best followed by clinical observation (with or without ultrasonography) over time. Suppressive therapy should be restricted to selected patients with large nodules, particularly if they cause symptoms (dysphagia, stridor) or are cosmetically disfiguring, and possibly to prevent recurrence of nodules in irradiated patients previously treated with partial thyroidectomy.

Patients with suspicious or indeterminate aspirates should be referred for surgery, as the possibility of malignancy cannot be excluded. Intraoperative histologic evaluation of frozen sections of the nodule may help determine the extent of operation but is often still not sufficient to distinguish benign from malignant follicular neoplasms. In this event, a lobectomy and isthmectomy are appropriate. A completion thyroidectomy is performed at a later date if malignancy is diagnosed on the permanent sections (see Chapter). Another circumstance in which surgery is advisable is for clinically significant nodules in which FNA biopsy has been repeatedly non-diagnostic. Cysts that are greater than 4 cm in size or that recur after drainage may also require surgery.

Nodules from patients with a history of radiation exposure have a higher likelihood of being malignant (about 30%), and therefore merit closer surveillance and a lower threshold for surgical referral. In solitary nodules from irradiated patients, FNA biopsy with multiple sampling of the lesion is appropriate. If the patient has multiple nodules, particularly if many of them are larger than 1 cm, FNA sampling becomes more cumbersome, and these patients should be treated with a near-total thyroidectomy. Treatment with suppressive doses of TSH may prevent recurrence of nodules after partial thyroid removal in these patients.

Patients with malignant aspirates are treated surgically. Although most require a total or near-total thyroidectomy, the type of surgery is dependent on the size of the nodule and the histologic diagnosis. In those in whom medullary thyroid carcinoma is suspected based on FNA, family history, or calcitonin levels, it is important to redouble efforts to make this diagnosis preoperatively, as this cancer requires more extensive surgery.

CHAPTER 393: APPROACH TO MENSTRUAL DISORDERS AND GALACTORRHEA

ROBERT L. BARBIERI

[Primary Amenorrhea](#)
[Secondary Amenorrhea](#)
[Galactorrhea](#)

The menstrual cycle is controlled by the interaction of the hypothalamus [pulsatile secretion of gonadotropin-releasing hormone (GnRH)], pituitary [secretion of luteinizing hormone and follicle-stimulating hormone (FSH)], ovary (follicular growth, ovulation, and corpus luteum formation), and uterus (cyclic growth and shedding of the endometrium). Abnormalities in any of these systems can result in menstrual abnormalities, including primary amenorrhea, secondary amenorrhea, and oligomenorrhea.

PRIMARY AMENORRHEA

Primary amenorrhea is present when a girl's first menses has not occurred by 16 years of age. Girls who reach 14 years of age and have not had breast development should undergo an evaluation similar to that for primary amenorrhea. Primary amenorrhea usually is caused by a genetic or congenital defect and often is associated with disorders of puberty.

In large case series, the most common causes of primary amenorrhea are gonadal dysgenesis resulting from chromosomal abnormalities such as 45, X, 45,X/46,XX, and 46,XY (45%); physiologic delay of puberty (20%); müllerian agenesis (15%); transverse vaginal septum or imperforate hymen (5%); absence of hypothalamic GnRH production, such as in Kallmann's syndrome (5%); anorexia nervosa (2%); and hypopituitarism (2%). Less common causes of primary amenorrhea are found in [Fig. 393.1](#).

FIGURE 393.1. Causes of primary amenorrhea. FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; T₄, thyroxine; TSH, thyroid-stimulating hormone.

EVIDENCE LEVEL: C. Expert Opinion.

Primary amenorrhea is evaluated most efficiently by focusing on the presence or absence of breast development, the presence or absence of the uterus and cervix, and the FSH level. If there is no breast development and the FSH level is elevated, the probable diagnosis is gonadal dysgenesis ([Fig. 393.1](#)). If the uterus is absent, the probable diagnosis is müllerian agenesis. If the FSH level is elevated, a karyotype must be obtained. An elevated FSH level with a 46,XY karyotype indicates a high risk for the development of gonadoblastoma and dysgerminoma, and surgical removal of the gonads is necessary. In many cases of primary amenorrhea, long-term therapy with estrogen and progesterone is required to stimulate the development of secondary sex characteristics and to protect bone mass. Women with gonadal dysgenesis due to 45,X are at high risk for developing thyroid disease and diabetes mellitus.

SECONDARY AMENORRHEA

Secondary amenorrhea is present when a woman who has been menstruating experiences the absence of periods for a time greater than three of her previous cycle intervals, or 6 months.

A common cause of secondary amenorrhea is pregnancy, and this possibility can be eliminated by measuring the serum human chorionic gonadotropin level ([Fig. 393.2](#)). Once pregnancy is excluded, the major causes of secondary amenorrhea are as follows:

FIGURE 393.2. Major causes of secondary amenorrhea. CT, computed tomography; D&C, dilation and curettage; FSH, follicle-stimulating hormone; hCG, human chorionic gonadotropin; R/O, rule out; T₄, thyroxine.

EVIDENCE LEVEL: C. Expert Opinion.

Hypothalamic dysfunction (35%). This category includes problems associated with decreased GnRH pulse frequency and amplitude, such as abnormalities of weight and nutrition (including anorexia nervosa), stress, strenuous exercise, and infiltrative diseases of the hypothalamus (lymphoma, histiocytosis). Hypothyroidism occasionally presents as secondary amenorrhea, probably because of changes in hypothalamic GnRH production. Elite athletes and ballet dancers commonly have anovulation and amenorrhea.

Pituitary disease (17%). The single most common cause of secondary amenorrhea is hyperprolactinemia (13%). Hyperprolactinemia causes amenorrhea by decreasing GnRH production. Empty-sella syndrome, (1.5%), Sheehan's syndrome (1.5%), and Cushing's disease (1%) also can cause amenorrhea.

Ovarian disease (40%). Both ovarian failure (10%) and the polycystic ovary syndrome (PCOS) (30%) can cause amenorrhea. Ovarian failure occurs with the loss of all follicles, which are the source of 95% of the estradiol produced in women. Hypoestrogenic women often have hot flashes. Women with ovarian PCOS often have

insulin resistance and hirsutism and/or acne.

Uterine disease (7%). Asherman's syndrome (intrauterine synechiae), which typically occurs after curettage of the uterus, often presents as amenorrhea.

Other causes. Adrenal hyperplasia, hypothyroidism, and ovarian and adrenal tumors also can cause secondary amenorrhea.

On physical examination, height and weight should be measured and recorded. Women who are more than 10% below their ideal body weight need to be evaluated for anorexia nervosa. The laboratory evaluation of secondary amenorrhea includes measurement of prolactin and FSH levels, and a progestin withdrawal test. The progestin withdrawal test is performed by administering progesterone in oil (100 mg intramuscularly) or medroxyprogesterone acetate (10 mg per day orally for 5 days) and monitoring any uterine bleeding. The absence of uterine bleeding after a progestin challenge suggests that endogenous estrogen levels are particularly low or that Asherman's syndrome is present. The presence of uterine bleeding after an estrogen–progestin withdrawal test indicates that Asherman's syndrome is not present. Some women with amenorrhea and low endogenous estrogen (negative progestin challenge) have a hypothalamic or pituitary tumor.

In women with secondary amenorrhea and hyperprolactinemia caused by a pituitary tumor, the therapeutic goals are to reduce the hyperprolactinemia, preserve pituitary function, and prevent tumor growth. This often can be achieved with bromocriptine therapy. Bromocriptine is an ergot alkaloid that is a dopamine agonist. Administered at a dosage of 2.5 mg orally twice a day, it reduces prolactin levels and decreases tumor size in most patients with prolactinoma. Nausea, vomiting, and orthostatic hypotension are common initial side effects, so that bromocriptine therapy should be started at a low dosage (0.625 mg orally once a day) and titrated upward.

Women with secondary amenorrhea are at risk for developing osteoporosis. Some authorities recommend that all women with secondary amenorrhea be treated with estrogen–progestin hormone replacement. Others suggest that bone density be measured and only those women who have a low bone density measurement receive therapy.

GALACTORRHEA

Galactorrhea is the secretion of breast milk not associated with nursing. Galactorrhea can be caused by a distant pregnancy, oral contraceptive use, hyperprolactinemia, or hypothyroidism. Measurement of the prolactin level and thyroid function is useful. Of all women with galactorrhea, 20% have hyperprolactinemia and a few have hypothyroidism. Women with galactorrhea and regular, ovulatory menses seldom have hyperprolactinemia or hypothyroidism. In these women, a distant pregnancy or oral contraceptive use has sensitized the breast to be stimulated by normal levels of circulating prolactin. In contrast, 80% of women with galactorrhea and secondary amenorrhea have hyperprolactinemia. Irrespective of its cause, galactorrhea usually can be managed with bromocriptine.

CHAPTER 394: APPROACH TO THE PATIENT WITH VIRILIZATION

RICHARD S. LEGRO

[Presentation](#)
[Pathophysiologic Factors](#)
[Laboratory Studies and Diagnostic Tests](#)
[Differential Diagnosis](#)
[Optimal Management](#)

PRESENTATION

Virilization in an adult women is a rare disorder and must be separated from more common and less severe causes of androgen excess in women, such as polycystic ovary syndrome (PCOS). This chapter focuses primarily on virilization in an adult woman, acknowledging that the differential diagnosis is broader for a newborn infant or young child. Virilization includes the common signs of acne and hirsutism but is also accompanied by other peripheral effects such as temporal balding, clitoromegaly, deepening of the voice, breast atrophy, and changes in body contour. Amenorrhea may occur in a premenopausal woman. A rapid presentation of the virilization often leads to a speedy evaluation and diagnosis, whereas the more lingering forms may be overlooked until there is marked masculinization. Virilization is never “idiopathic,” and all cases must be investigated until a cause is discovered ([Table 394.1](#)). Virilization rarely occurs with the common forms of androgen excess that present in postmenarchal women, such as PCOS or nonclassical congenital adrenal hyperplasia (NC-CAH). These disorders rarely produce androgen excess to the degree of virilization.

Cause	Onset	Diagnosis
Ovarian tumor	Rapid, but gradual possible	Pelvic exam, transvaginal ultrasonography, elevated testosterone level
Adrenal tumor	Rapid, but gradual possible	CT or MRI, elevated cortisol or DHEA-S
Hyperthecosis	Gradual, but rapid possible	Ultrasonography, elevated testosterone, insulin, and lipid levels
Hyperprolactinemia	Gradual or rapid	Elevated prolactin levels, CT or MRI of pituitary
Polycystic ovary syndrome	Gradual, perimenarchal onset	Elevated testosterone and/or DHEA-S levels, menstrual irregularity, exclusion of the other causes above

CT, computed tomography; MRI, magnetic resonance imaging; DHEA-S, dehydroepiandrosterone sulfate.

TABLE 394.1. CAUSES OF VIRILIZATION IN AN ADULT WOMAN

Virilization presents with a variety of peripheral effects. Acne and hirsutism are invariably present. A deepening of the voice has been reported in women with androgen-secreting tumors or undergoing exogenous androgen treatment. Increase in the size of the larynx is one factor in the voice change. Clitoromegaly is defined as a clitoral index greater than 35 mm² (the clitoral index is the product of the sagittal and transverse diameters of the glans of the clitoris). In a normal woman these diameters are in the range of 5 mm each. The degree of clitoral enlargement correlates with the degree of androgen excess. Androgens can lead to body composition changes, especially in the upper body, with increased muscle mass and decreased fat mass. This is accompanied by breast atrophy.

PATHOPHYSIOLOGIC FACTORS

The degree of androgen excess that can result in virilization almost always has its source in increased production (or intake) of androgens. However, other factors, such as the potency of the androgen produced [dihydrotestosterone (DHT) > testosterone > androstenedione > dehydroepiandrosterone (DHEA)], the amount of androgen that is free or weakly bound in serum and thus bioavailable [sex hormone-binding globulin (SHBG) preferentially binds more potent androgens], and the peripheral metabolism of androgens (primarily the intracellular production of DHT from prohormones), all figure in the phenotype of virilization.

Both the adrenal glands and ovaries contribute to the circulating androgen pool in women. The adrenal preferentially secretes weak androgens such as DHEA and DHEA-S (the latter referring to the sulfate preparation) (up to 90% of adrenal origin). These hormones, in addition to androstenedione, may serve as prohormones for more potent androgens, such as testosterone or DHT. The ovary is the preferential source of testosterone, and it is estimated that 75% of circulating testosterone originates from the ovary (mainly through peripheral conversion of prohormones by liver, fat, and skin; but also through direct secretion). Androstenedione, largely of ovarian origin, is the only circulating androgen that is higher in premenopausal women than men, yet its androgenic potency is only 10% of that of testosterone. DHT is the most potent androgen, though it circulates in negligible quantities and results primarily from the intracellular 5 α reduction of testosterone.

Androgen excess is most commonly evident in its effects on the pilosebaceous unit. Hirsutism occurs when androgens stimulate the transformation of fine, unpigmented vellus hair to coarse, pigmented, thickened terminal hair. This is thought to be mediated by the intracellular actions of enzymes 17-ketosteroid reductase, which converts androstenedione to testosterone, and 5 α -reductase, which converts testosterone to DHT. Androgen-dependent hair is midline hair: that on the upper lip, chin, and cheeks, intermammary hair; and hair in the escutcheon, inner thighs, and lower back attributable to the intergluteal area. Paradoxically, androgens can exert opposite effects in hair follicles on the scalp, causing conversion of terminal follicles to velus-like follicles and leading to male pattern baldness characterized by frontal and temporal balding. Androgens can also cause increased sebum production and abnormal keratinization in the pilosebaceous unit, contributing to the development of acne.

It is important to note that factors other than androgens may contribute to the development of signs and symptoms of virilization. Hyperinsulinemia, which accompanies many benign forms of virilization, can also stimulate the pilosebaceous unit both directly and indirectly (the latter by acting as a gonadotropin in the ovary to stimulate thecal and stromal androgen production). Both hyperinsulinemia and androgen excess suppress SHBG, leading to a greater pool of bioavailable androgens.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

The purposes of the physical and laboratory evaluations are to rule out adrenal and ovarian tumors, assess the severity of the androgen excess, and evaluate the source of the hyperandrogenism (adrenal vs. ovarian). The history and physical examination are essential to arriving at a diagnosis of virilization. The history should focus on the onset and duration of the various symptoms of virilization, menstrual background, and concomitant medications. During physical examination, the physician should carefully check the patient for balding and body hair distribution. The presence and severity of acne should be noted. Acanthosis nigricans (a velvety, verrucous, brownish skin lesion frequently noted on the nape of the neck, axilla, and under the breasts) is a peripheral skin manifestation of circulating hyperinsulinemia. Coexisting signs of Cushing's syndrome, including moon facies, buffalo hump, abdominal striae, centripetal fat distribution, and hypertension, should be documented. A pelvic examination should be performed on all women with virilization, as 90% of ovarian tumors present with unilateral enlargement. A transvaginal ultrasonographic exam, increasingly office-based, should be sufficient to identify ovarian masses less than 1 cm in diameter, although physiologic follicular and cystic developments throughout the normal menstrual cycle, especially a corpus luteal cyst, can masquerade as more serious pathologic lesions.

Androgen-secreting tumors, primarily of ovarian and secondarily of adrenal origin, are invariably accompanied by elevated circulating androgen levels. However, there is no absolute level that is pathognomonic for a tumor, just as there is no minimum androgen level that excludes a tumor. In the past, testosterone levels greater than 2 ng per milliliter and DHEA-S levels greater than 700 mg per deciliter were regarded as indicative of a tumor of ovarian and adrenal origin, respectively, but these cutoffs display poor sensitivity and specificity. Nonetheless, they are useful to quantify the amount of circulating androgen excess and potential source. Diagnostic tests that involve suppression or stimulation of the ovary or adrenal to identify the source of androgen production are not generally useful. Both functional states of androgen excess and tumors can variably respond or not respond to these dynamic challenges. However, a prolonged course of dexamethasone (1 mg t.i.d.

for 5 days because androgens are suppressed less readily than cortisol) that fails to suppress androgens may potentially identify an adrenal tumor. A fasting insulin level may be useful in suspected cases of stromal hyperthecosis, and a prolactin level can identify prolactinomas that secrete massive amounts of prolactin, which can stimulate ovarian androgen production.

The preferred screening tool for an ovarian tumor is transvaginal ultrasonography. For an adrenal tumor, transabdominal ultrasonography is less sensitive. Computed tomography scan or magnetic resonance imaging can detect adrenal nodules less than 5 mm in diameter, providing a greater resolution than ultrasonography. However, about 2% of the population harbors a clinically insignificant adrenal adenoma (i.e., incidentaloma) such that their localization is not diagnostic for an androgen-secreting adrenal tumor. Functional radiologic techniques, such as selective venous catheterization or scintigraphy with ¹³¹iodomethyl norcholesterol, are rarely used for the initial screening for such tumors.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of androgen excess leading to virilization, especially combined with a sudden onset and rapid progression, will always begin and end with tumors or dysfunctional states, usually of the ovary and less commonly of the adrenal gland. The most common androgen-producing tumor in a premenopausal woman is a Sertoli–Leydig cell tumor. Other common tumors are thecomas and hilus cell tumors. Hilus cell tumors are often small (even less than 1 cm) and theoretically below the range of imaging visualization. Tumors may also present with a more indolent history, such as granulosa cell tumors, 10% of which primarily secrete androgens instead of estrogens. Any large ovarian tumor can produce androgens indirectly by causing hyperplasia of the surrounding normal stroma (benign cystic teratomas, dysgerminomas, epithelial tumors). The vast majority of ovarian androgen-secreting tumors are benign. Adrenal tumors are rare, with an estimated incidence of two cases per one million persons per year, which are equally divided among adenomas and carcinomas. The age of onset in adults peaks in the fifth decade. Virilization can accompany both tumors that primarily produce androgens and tumors that primarily produce cortisol (Cushing's syndrome). A long history of symptoms, as in the case of an ovarian tumor, does not preclude the presence of an adrenocortical neoplasm.

Dysfunctional states of the ovary, primarily hyperthecosis, may also result in virilization. In stromal hyperthecosis, most of the ovarian androgen overproduction results from hyperplasia of the ovarian stroma and not from the accumulation of small follicles, as is the case with PCOS. Most women with stromal hyperthecosis have severe hyperinsulinemia, which may be the stimulus for stromal androgen overproduction. It has been reported in both premenopausal and postmenopausal women, often with coexisting sequelae of the insulin resistance syndrome such as dyslipidemia and glucose intolerance.

The differential diagnosis of virilization in a woman must also consider the use of exogenous androgens, such as anabolic steroids in a body builder or an overdose of androgens in a postmenopausal woman. Virilization that occurs during pregnancy has its own unique differential diagnosis, including benign ovarian sources such as hyperreactio luteinalis (gestational ovarian theca–lutein cysts) or luteomas, and extremely rare fetoplacental sources such as aromatase deficiency, resulting in androgen excess due to the placental inability to convert precursor androgens to estrogens.

OPTIMAL MANAGEMENT

Congenital causes of virilization rarely present in an adult woman, and most causes of virilization in the adult are acquired. Thus, the ideal treatment involves removal of the acquired insult. This may mean stopping or revising exogenous medications. For the vast majority of women, treatment of virilization involves surgical removal of the tumor or gland(s), depending on the cause of the androgen production and the menopausal status of the woman. Almost all ovarian androgen-secreting tumors or hyperfunctioning states can be treated initially with surgery. In patients with inoperable adrenal tumors, chemotherapy may be the primary therapy. Choice of medical or surgical treatment of a prolactinoma with virilization is not clear. Many of the peripheral effects of virilization may require additional treatment, such as electrolysis for the hirsutism or a clitoral reduction for massive clitoromegaly. Changes in the voice are also thought to be permanent.

For those rare cases of virilization associated with common causes of androgen excess such as PCOS or NC-CAH, treatment involves suppression of the hyperfunctioning gland (ovary with the oral contraceptive pill and/or a gonadotropin hormone–releasing hormone agonist, or the adrenal with a glucocorticoid) combined with peripheral antagonism of androgen action through an androgen receptor antagonist such as spironolactone. This treatment may also be utilized in a premenopausal woman with hyperthecosis who desires to preserve ovarian function, though response must be closely monitored. There is no current evidence to suggest that the use of insulin-sensitizing agents can improve signs of virilization in women with marked androgen excess, although they are theoretically appealing.

CHAPTER 395: APPROACH TO THE PATIENT WITH GYNECOMASTIA

GLENN D. BRAUNSTEIN

[Pathophysiologic Factors](#)
[History and Physical Examination](#)
[Laboratory Studies and Diagnostic Tests](#)
[Differential Diagnosis](#)
[Optimal Management](#)

Gynecomastia represents the benign proliferation of breast glandular tissue that begins beneath the nipple–areolar complex and spreads laterally. It is a common condition that is found in approximately two-thirds of pubertal boys and at least one-third of adults.

PATHOPHYSIOLOGIC FACTORS

Estrogen stimulates breast glandular epithelium growth, an effect that is antagonized by androgens. Therefore, gynecomastia results when there is an imbalance between estrogen and androgen action at the breast tissue level. This can occur through increased serum free estrogen concentrations resulting from exogenous estrogen exposure, increased endogenous production through secretion or conversion of androgens to estrogens by the widely distributed aromatase enzyme complex, displacement of estrogens from sex hormone–binding globulin (SHBG), decreased androgen secretion, or abnormalities of the androgen receptor ([Table 395.1](#)). In many instances the gynecomastia is multifactorial, as, for example, with aging. Aging is associated with an enhanced activity of the aromatase enzyme in fat cells, as well as an increase in the proportion of fat to lean body mass. In addition, many men have a slight decrease in their testosterone production rate, which reduces their free testosterone level. Finally, older men may be ingesting medications that can alter androgen production or action.

Mechanism	Specific Causes
Increased Serum Estrogens Exogenous	Topical estrogen creams and lotions Ingestion of estrogens Use of aromatizable androgens Environmental exposure
Increased aromatization in testes, adrenals, or peripheral tissues	Testicular tumors Adrenal tumors Obesity Liver disease Hyperthyroidism Aging Functio laesa or sporadic excessive aromatase activity
Displacement of estrogens from SHBG	Spironolactone Ketoconazole Chronic alcoholism Lung, liver, renal, gastric carcinoma
Decreased testosterone synthesis	Primary hypogonadism Secondary hypogonadism Drug-induced Spironolactone Ketoconazole
Androgen receptor defects	Congenital mutations Drug interference: Cimetidine Cyproterone Flutamide Spironolactone

TABLE 395.1. MECHANISMS AND CAUSES OF GYNECOMASTIA

HISTORY AND PHYSICAL EXAMINATION

Inquiries into medication and recreational drug (e.g., ethanol, marijuana) use, the circumstances surrounding the onset of gynecomastia, and the presence of breast tenderness, which indicates recent onset of the condition, should be made. Symptoms suggestive of renal or hepatic insufficiency, hyperthyroidism, pituitary dysfunction, and hypogonadism should be sought. Examination for these conditions as well as a careful breast examination to confirm the presence of gynecomastia, along with testicular palpation for masses or atrophy should be carried out.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

If the cause of gynecomastia is not readily apparent from the history and physical examination, measurement of serum concentrations of human chorionic gonadotropin (hCG), luteinizing hormone (LH), testosterone, and estradiol can help differentiate among the various causes ([Fig. 395.1](#)).

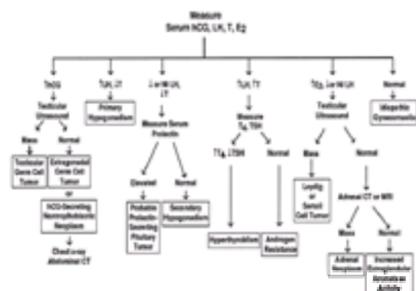

FIGURE 395.1. Evaluation of gynecomastia. hCG, human chorionic gonadotropin; LH, luteinizing hormone; T, testosterone; E₂, estradiol; T₄, thyroxine; TSH, thyroid-stimulating hormone; ↑, increased; ↓, decreased; NI, normal. (From Braunstein GD. Gynecomastia. *N Engl J Med* 1993;328:490–495, with permission.)
EVIDENCE LEVEL: C. Expert Opinion.

An elevated hCG concentration is found with gonadal or extragonadal germ cell tumors or with nontrophoblastic neoplasms, such as lung, liver, or kidney tumors. A suppressed testosterone with elevated LH indicates primary hypogonadism, whereas low levels of both is indicative of a hypothalamic or pituitary disorder. Elevations of both LH and testosterone are found in patients with hyperthyroidism as well as those with androgen resistance, which can be distinguished through measurements of thyroid function tests. Elevations of estradiol may be found with Leydig or Sertoli cell tumors of the testes, feminizing adrenocortical neoplasms, or in situations in which the extraglandular aromatization of androgens is increased ([Table 395.1](#)). If all tests are normal, then the patient is considered to have idiopathic gynecomastia.

DIFFERENTIAL DIAGNOSIS

It is important to differentiate gynecomastia from pseudogynecomastia, which reflects an enlargement of the breast subcutaneous fat. This can be accomplished by having the patient lie on his back with hands behind the head. The examiner places his or her thumb and forefinger on either side of the breast and gradually brings the fingers together. If gynecomastia is present, a ridge of rubbery tissue will be felt spreading radially from the nipple, whereas in pseudogynecomastia, the fingers will not meet any resistance until they touch the nipple. The most important condition to differentiate is breast carcinoma. Breast carcinoma often presents as a unilateral, painless, hard, eccentric mass, which may be associated with dimpling of the skin and axillary adenopathy, rather than the concentric subareolar rubbery tissue that may be tender and is often bilateral in patients with gynecomastia. If uncertainty exists after the examination, mammography or fine-needle aspiration biopsy may be performed.

OPTIMAL MANAGEMENT

Correction of the identified inciting cause of the gynecomastia will lead to a resolution of the breast enlargement if the gynecomastia is of recent onset. However, if the gynecomastia has been present for over a year, much of the hyperplastic glandular component can be replaced by fibrous tissue that will not regress. The indications for specific medical or surgical treatment of the gynecomastia include persistent pain as well as intense emotional discomfort and/or embarrassment. Medical therapies are generally useful only during the early proliferative phase of the condition (when pain and tenderness are prominent). The antiestrogen tamoxifen citrate or aromatase inhibitors, such as testolactone or anastrozole, may be tried for up to 3 months. If they fail to reduce the breast size sufficiently or if the gynecomastia is in the fibrotic stage, the only curative therapy is reduction mammoplasty, which can be accomplished by excision of the glandular tissue through a periareolar incision accompanied by liposuction to remove the subcutaneous fat and contour the breast.

CHAPTER 396: APPROACH TO THE INFERTILE MALE

FRANCES J. HAYES

[Presentation](#)
[Pathophysiologic Factors](#)
[History and Physical Examination](#)
[Laboratory Studies and Diagnostic Tests](#)
[Optimal Management](#)

PRESENTATION

Using the definition of failure to conceive after a year of regular unprotected intercourse, 10% to 15% of couples in the United States are infertile. Of these, a male factor is the sole abnormality in 30% of cases and a contributory factor in an additional 20%. Given this high prevalence of male factor infertility, obtaining a semen analysis is an essential component of the workup of every infertile couple. While male infertility is typically diagnosed in the setting of a couple who fail to conceive, the diagnosis may be made earlier in the subset of infertile men presenting with concomitant symptoms of hypogonadism.

PATHOPHYSIOLOGIC FACTORS

NORMAL SPERMATOGENESIS

Reproductive competence in the male requires the integration of a normal hypothalamic–pituitary–testicular (HPT) axis. Pulsatile secretion of gonadotropin-releasing hormone (GnRH) from the hypothalamus stimulates release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from the pituitary. LH stimulates the testicular Leydig cells to produce testosterone, which is important for virilization and normal sexual function. In addition, high intratesticular levels of testosterone are necessary for spermatogenesis. FSH plays a critical role in the initiation and, to a lesser extent, maintenance of spermatogenesis. The process of spermatogenesis, which occurs in the seminiferous tubules, takes approximately 75 days. Once spermatogenesis is complete, sperm are transported through the epididymis to the ejaculatory duct. During this period of 12 to 21 days, sperm acquire the capacity for sustained motility.

DISORDERS OF SPERMATOGENESIS

The differential diagnosis of male infertility includes hypergonadotropic (primary) versus hypogonadotropic (secondary), congenital versus acquired, and treatable versus untreatable causes.

Primary testicular disorders are the commonest cause of male infertility. These include hormonal abnormalities such as Klinefelter's syndrome (47, XXY); damage to the seminiferous tubules as a consequence of infection, trauma, chemotherapy, or radiation therapy; and structural abnormalities such as a varicocele or congenital bilateral absence of the vas deferens (CBAVD). Hypogonadotropic hypogonadism (HH) may be idiopathic or arise from structural or functional lesions of the hypothalamus or pituitary gland. Congenital GnRH deficiency may be an isolated finding, as in idiopathic hypogonadotropic hypogonadism (IHH), or it may occur in association with anosmia plus or minus a variety of midline defects to which the term Kallmann's syndrome is applied. In a subset of patients, GnRH deficiency is acquired in adult life. Puberty occurs normally in these men with adult-onset IHH. However, postpubertally there is a decrease in libido and fertility in the presence of testes that are of normal or near-normal size.

In the past, many patients with severe oligospermia or azoospermia were labeled as having idiopathic infertility. However, as our understanding of the molecular basis of male infertility increases, the percentage of patients in the idiopathic category has decreased. In fact, careful genetic screening of men with “idiopathic” azoospermia indicates that approximately 15% of these men have microdeletions in the Y chromosome.

HISTORY AND PHYSICAL EXAMINATION

A careful history and physical examination are essential to the workup of the infertile male patient. In the history one should ask specifically about problems with libido, potency, or ejaculation. It is important to determine if there is a history of congenital defects, such as cryptorchidism and micropenis, or of delayed puberty, anosmia, or orchitis. The physician should also inquire about ingestion of drugs or exposure to toxins known to interfere with testosterone production or spermatogenesis. On physical examination, it is important to look for features of hypogonadism (eunuchoid body habitus, i.e., upper/lower body ratio less than 1 with an arm span 6 cm greater than standing height, absence of virilization, gynecomastia). Testicular volume should be estimated with a Prader orchidometer (normal 3 15 mL) and the presence of a varicocele excluded.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

A semen analysis is the single most important diagnostic test and may be all that is required if the history and physical examination are normal ([Fig. 396.1](#)). A normal semen analysis (volume greater than 2 mL, count greater than 20 million per milliliter, motility greater than 50%, morphology greater than 30% normal, *WHO Criteria, 1992*) excludes male factor infertility provided that libido and potency are normal. If an abnormal semen analysis is obtained, an additional sample should be examined after 2 to 3 months. If no sperm are present in the ejaculate (azoospermia), an obstructive cause, such as CBAVD, must be distinguished from a seminiferous tubular defect. If an obstruction is causing azoospermia, seminal fructose, which is produced by seminal vesicles, is low. In azospermic men in whom the diagnosis of CBAVD has been made, screening for the cystic fibrosis gene should be performed as mutations in the *CFTR* gene have been reported in up to 70% of such patients.

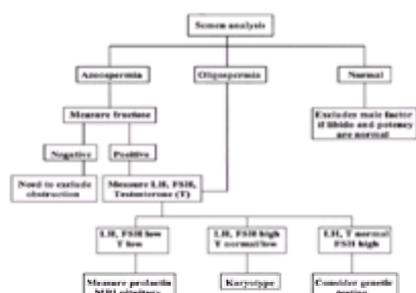

FIGURE 396.1. Approach to the evaluation of an infertile man.
EVIDENCE LEVEL: C. Expert Opinion.

In men with oligo- or azoospermia in whom obstruction has been excluded, an endocrine evaluation, comprising measurement of testosterone, LH, FSH, and prolactin, should be undertaken. If the hormonal pattern is consistent with HH (low testosterone with low or inappropriately normal gonadotropin levels) or if serum prolactin is elevated, magnetic resonance imaging of the hypothalamic–pituitary region is indicated. The commonest hormonal abnormality seen in infertile men is an elevated FSH level in association with normal LH and testosterone levels, reflecting selective seminiferous tubular damage. Serum inhibin B is inversely related to FSH in infertile men, suggesting that it may serve as a useful marker of Sertoli cell function. However, the clinical utility of serum inhibin B measurements in the routine assessment of the infertile male has yet to be definitively established. The role of genetic analysis of the Y chromosome is controversial and presently limited

to specialist centers. Genetic testing is particularly important in couples contemplating assisted reproductive technology so that appropriate genetic counseling can be provided. In men with gynecomastia, small testes, and an elevated FSH level, a karyotype should be obtained to screen for Klinefelter's syndrome.

OPTIMAL MANAGEMENT

Treatment of male infertility is guided by the underlying diagnosis. While HH is a relatively uncommon cause of infertility in men, it is an important diagnosis to make as exogenous gonadotropins or pulsatile GnRH can be used to stimulate spermatogenesis. In contrast, men with normal testosterone levels and severe oligo- or azoospermia require assisted reproductive technology to achieve fertility. For men with primary testicular failure, therapeutic options are limited to donor insemination or adoption.

INDUCTION OF SPERMATOGENESIS

Gonadotropin therapy consists of administration of human chorionic gonadotropin (hCG) in combination with human menopausal urinary gonadotropin (hMG) or recombinant FSH formulations. Therapy with hCG is usually initiated with a dose of 500 to 1,000 IU subcutaneously on alternate days and titrated based on testicular growth and trough testosterone levels. Most patients also require FSH to stimulate spermatogenesis. Because hMG contains both LH and FSH, when administered in combination with hCG, estradiol concentrations may become disproportionately elevated, thus leading to gynecomastia. Gynecomastia can be avoided by reducing the hCG dose prior to the addition of hMG so that serum testosterone levels are maintained at the lower end of the normal range. Alternatively, recombinant FSH may confer an advantage in this clinical setting.

Although not approved by the U.S. Food and Drug Administration for use in hypogonadotropic men, pulsatile GnRH is a highly effective therapy for inducing spermatogenesis. GnRH is administered subcutaneously by a portable mini-infusion pump at a frequency of every 2 hour. Most patients require treatment for 1 to 2 years (depending on pretherapy testicular size) to maximize testicular growth and achieve spermatogenesis. In the authors' experience, pulsatile GnRH is successful in inducing spermatogenesis in the vast majority of hypogonadotropic men, with the exceptions tending to be those with a history of bilateral cryptorchidism, rare patients who develop antibodies to GnRH, or patients with GnRH receptor mutations. The choice of gonadotropin versus GnRH therapy depends on a number of factors. Patients with extensive pituitary damage are unlikely to respond to GnRH and should be treated with gonadotropins. While both are very effective therapeutic modalities, data suggest that testicular growth is greater and the time taken to achieve spermatogenesis shorter in patients treated with GnRH.

ASSISTED REPRODUCTIVE TECHNOLOGY

It is intuited that when sperm counts are low, the chances of sperm-egg interaction in vivo are reduced. To overcome this difficulty, intrauterine insemination (IUI) was developed as a means of bringing sperm closer to the egg. However, the clinical effectiveness of IUI in couples with male factor infertility is not significantly different from that of no treatment, unless IUI is coupled to ovulation induction in the female partner. At least 1 million to 2 million motile sperm are required for IUI to be successful. If pregnancy does not ensue within the first three cycles, more invasive forms of assisted reproduction should be considered.

As a result of exciting advances in the treatment of male infertility in recent years, couples who would previously have been offered donor insemination or adoption are now achieving pregnancy. While male factor infertility was initially considered a contraindication to in vitro fertilization (IVF), IVF is now viewed as an acceptable treatment option for infertile men. However, for men with severe male factor infertility, the main drawback of IVF is that at least 100,000 sperm must be inseminated per oocyte for fertilization to occur. This has led to the development of a number of micromanipulation techniques to assist fertilization, including intracytoplasmic sperm injection (ICSI).

The first pregnancy to result from the direct injection of a single sperm into the cytoplasm of an oocyte using the technique of ICSI occurred in 1992. ICSI is now recommended in the following circumstances: (a) fertilization failure with standard IVF; (b) severe male factor infertility (i.e., sperm count greater than 2 million per milliliter, normal morphology less than 4%, sperm motility less than 5%); and (c) the use of surgically retrieved spermatozoa. Sperm for ICSI can be retrieved from the ejaculate, from epididymal aspiration, or from testicular aspiration/biopsy. The clinical outcome of ICSI to date has been very encouraging, with fertilization rates of 50% to 60% and pregnancy rates of 30% per cycle. The incidence of congenital malformations does not appear to be increased. However, a slight increase in chromosomal aberrations, especially of the sex chromosomes, has been observed. The increase in chromosomal abnormalities underscores the importance of proper genetic counseling of couples contemplating ICSI.

CHAPTER 397: APPROACH TO SEXUAL DYSFUNCTION IN THE FEMALE

ROBERT L. BARBIERI

[Sexual Response Cycle](#)
[Sexual History](#)
[Sexual Pain Disorders](#)
[Decreased Sexual Desire](#)
[Advances in Pharmacologic Treatment](#)
[Sexual Abuse](#)

Sexual function allows individuals to come together to bond, enjoy each other, and reproduce; it is influenced by physical, emotional, and social factors. Fewer than half of all women discuss issues of sexuality with their physicians. Although a comprehensive examination is not complete unless the patient is given the opportunity to discuss this topic, many physicians are too busy and most patients too anxious to initiate such a discussion. By creating a supportive and nonjudgmental atmosphere and by initiating a discussion of sexuality, physicians can determine quickly whether sexual problems requiring further attention are present.

SEXUAL RESPONSE CYCLE

Masters and Johnson first characterized the female sexual response as consisting of four successive phases: excitement, plateau, orgasm, and resolution. Kaplan proposed sexual desire, or libido, as the first phase in the female sexual response cycle. The excitement phase is initiated by psychological (fantasy) and physiologic (kissing) stimuli. During this phase, the woman experiences nipple erection, hyperemia of the clitoris and labia minor, swelling of the labia, an increase in vaginal fluid, expansion of the vaginal cavity, and elevation of the uterus. In the plateau phase, the shaft of the clitoris retracts, vaginal transudation occurs, and the outer third of the vagina contracts. Orgasm typically lasts 5 to 30 seconds and is associated with rhythmic contractions of the vagina, uterus, and pelvic musculature. In the resolution phase, the hyperemia of the genitalia slowly resolves.

SEXUAL HISTORY

For the premenopausal woman, a discussion of sexuality can be approached as part of a discussion of contraceptive practices using the following types of questions: Are you sexually active? Do you need birth control? Are sexual relations enjoyable and comfortable? Are you having pain with sexual relations? Is there any aspect of your sexual life that is not satisfactory? For the menopausal woman, a discussion of sexuality can be initiated as part of the interview pertaining to the effects of hypoestrogenism. This line of questioning leads naturally to questions pertaining to libido (sexual desire), sensation, vaginal dryness, and pain with sexual relations.

SEXUAL PAIN DISORDERS

In premenopausal women, vaginismus, the involuntary contraction of the perineal muscles in the outer third of the vagina, may cause pain with sexual relations. If genital anatomy is normal, vaginismus is best treated by desensitization training; allowing the woman to self-insert vaginal dilators of increasing length and diameter. In postmenopausal women, vaginal dryness resulting from low estrogen concentration can contribute to pain with sexual relations. Estrogen replacement therapy can improve vaginal lubrication and sexual function. In postmenopausal women, estrogen replacement enhances clitoral and vaginal vibration and pressure thresholds, and increases blood flow to the pelvic tissues. For menopausal women with contraindications to systemic estrogen treatment, vaginal rings that release estradiol can often improve vaginal function. Insufficient foreplay and performance anxiety can also result in insufficient vaginal secretions, contributing to pain with sexual relations.

DECREASED SEXUAL DESIRE

During the perimenopause and menopause, some women report a decrease in sexual desire. Low estrogen and testosterone levels may contribute to decreased sexual desire. In one study of sexual desire and function after surgical oophorectomy, androgen plus estrogen treatment was reported to be more effective in enhancing sexual desire than estrogen alone. Oral combinations of conjugated estrogen (estrone sulfate) and androgen (methyl testosterone; Estratest) may be effective in enhancing libido in some menopausal women. Health status, past level of sexual activity, partner availability, and social status are also important determinants of libido in menopausal women.

In both pre- and postmenopausal women, psychoactive agents such as selective serotonin reuptake inhibitors, tranquilizers, and excess quantities of alcohol can impair sexual desire. Conditions such as severe rheumatoid arthritis, diabetes, and HIV disease can have a major impact on sexual functioning in a couple.

ADVANCES IN PHARMACOLOGIC TREATMENT

Sildenafil (Viagra) is a selective type 5 (cGMP-specific) phosphodiesterase inhibitor that increases cGMP levels, resulting in relaxation of clitoral and vaginal smooth muscle, enhancing blood flow into these tissues. Sildenafil is approved for the treatment of erectile dysfunction in men but is not currently approved for use in women. Recent data indicate that central nervous system dopamine may mediate libido and sexual excitement. Apomorphine may prove useful in the treatment of disorders of libido.

SEXUAL ABUSE

Approximately 25% of adult women report a previous history of sexual abuse, including undesired vaginal penetration and other undesired direct contact with the genitals. In some cases, a result of sexual abuse can be sexual dysfunction and chronic pelvic pain syndromes. Childhood sexual abuse is especially likely to result in sexual dysfunction, depression, and chronic pelvic pain.

CHAPTER 398: APPROACH TO SEXUAL DYSFUNCTION IN THE MALE

MAX HIRSHKOWITZ AND GLENN R. CUNNINGHAM

[Evaluation of Erectile Dysfunction](#)
[Nonspecific Treatment with Noninvasive Therapies](#)
[Transurethral and Intracavernosal Injection Treatments](#)
[Surgery](#)
[Summary](#)

Four fundamental processes are involved in male human sexuality: desire, arousal (both attaining and maintaining erections), ejaculation/orgasm, and fertilization. In men, problems with arousal [(erectile dysfunction (ED)] and desire (loss of libido) are common. Among 1,290 noninstitutionalized men between the ages of 40 and 70 years, an estimated 5% to 15% reported severe ED and 17% to 34% reported moderate ED. The age-adjusted probabilities calculated for *complete ED* were 39% in men treated for heart disease, 28% in treated diabetes, and 15% in treated hypertension. Smoking and lower HDL cholesterol also correlated with increased ED.

Until fairly recently, ED and libido were infrequently evaluated or treated by nonspecialists. Evaluation and treatment of sexual dysfunction has become common practice because of increasing emphasis on maximizing quality of life, more precise diagnostics, and improved therapeutics. After the U.S. Food and Drug Administration's approval of sildenafil (Viagra), an orally administered agent for treating ED, widespread media attention produced a flood of patients seeking treatment. Physicians administered the drug as an empirical challenge with little regard for etiology or diagnosis. When it proved effective and well tolerated, it was continued. Thus, we have witnessed a revolutionary change in who seeks treatment, who administers treatment, and the approach to treatment.

EVALUATION OF ERECTILE DYSFUNCTION

Ideally, etiology should direct therapeutic selection. However, ED diagnostic techniques are not readily available to many physicians, are not fully refined, and are expensive. Thus, available noninvasive therapies make it more practical to administer a therapeutic challenge than to perform extensive diagnostic procedures. Nonetheless, evaluation should begin with a careful history and physical examination ([Fig. 398.1](#)). Sexual functioning inventories and psychometric tests can be extremely valuable for delineating ED type, severity, and complication by relationship or psychiatric problems. Appropriate referrals for counseling, behavioral therapy, and/or psychiatric treatment should be made. The patient's medication regimen should be reviewed because iatrogenic ED must be considered. Furthermore, ED as a medication side effect tends to foster noncompliance with needed medications. Drugs adversely affecting erectile function include antiandrogens (cimetidine, cyproterone acetate, estrogens, finasteride, ketoconazole, progestins, spironolactone), anticholinergics (atropine, butyrophenones, disopyramide, ganglionic blocking agents), antidepressants (monoamine oxidase inhibitors, tricyclic antidepressants, selective serotonin reuptake inhibitors), antihypertensives (a-methyldopa, reserpine, clonidine, propranolol, thiazides, prazosin, phenoxybenzamine, phentolamine), antipsychotics (phenothiazines, thioridazine), central nervous system depressants (barbiturates, benzodiazepines, carbamazepine, methadone, morphine, phenytoin, primidone), and substances of abuse (amphetamines, cocaine, heroin, ethanol, tobacco).

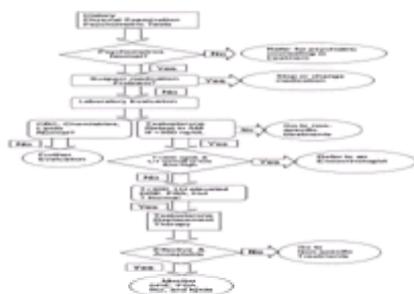

FIGURE 398.1. Evaluation and treatment of erectile dysfunction.

Laboratory tests should be ordered to exclude a systemic disease or testosterone deficiency. Placebo-controlled trials repeatedly demonstrate that testosterone replacement therapy improves libido and erectile function in men with hypogonadism. However, comorbid diseases may limit testosterone's effectiveness in improving ED, particularly in men over 50. Normalizing hyperprolactinemia with dopamine agonists or surgically removing a prolactinoma may increase serum testosterone level and restore potency. Dopaminergic erectogenic properties likely derive from D₂ receptors and oxytocin neuronal action. Apomorphine has been shown to produce erections in a small sample of men with ED. Larger clinical trials are under way; however, at present its therapeutic role is not defined.

NONSPECIFIC TREATMENT WITH NONINVASIVE THERAPIES

Topically applied preparations represent another approach and formulations of nitroglycerin, prostaglandins E₂ and E₁, papaverine, stearyl vasoactive intestinal peptide, and minoxidil are being evaluated. They show promise; however, these agents tend to have systemic effects when applied in quantities sufficient to affect erections.

Other approaches to nonspecific treatment are outlined in [Fig. 398.2](#). A general purpose, orally administered agent to treat ED has long been sought, and in 1998 sildenafil was approved for use. Smooth-muscle relaxation in cavernosal bodies is triggered by sexual stimuli. This leads to nitric oxide (NO) release from nonadrenergic, noncholinergic nerves; NO innervates the cavernosal smooth muscle. Sildenafil is a selective inhibitor of cGMP-specific phosphodiesterase type 5. It appears to potentiate erections induced by physiologic mechanisms as opposed to directly stimulating corporal smooth-muscle relaxation.

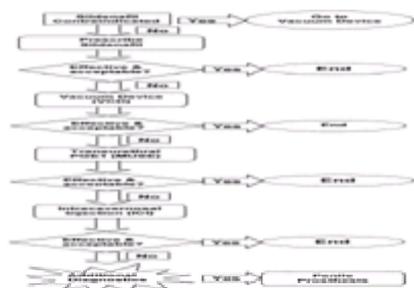

FIGURE 398.2. Nonspecific treatments for erectile dysfunction.

Sildenafil reportedly improved erectile function in men with presumed organic, psychogenic, or mixed causes. Outcome data were self-reported assessments. The study did not measure erections physiologically. Dose escalation increased the chance of headaches, flushing, dyspepsia, rhinitis, and visual disturbances; however,

priapism was not a problem. The Food and Drug Administration issued an advisory warning against using both sildenafil and nitrates after several deaths were attributed to sildenafil. Additionally, sildenafil should be used very cautiously in men with significant cardiac disease.

If sildenafil is either ineffective or contraindicated, an external vacuum constriction device (VCD) can be tried. This device is a cylinder-like chamber in which a vacuum is created around the penis with a suction pump. The negative pressure induces blood flow into the corpora cavernosa, thereby producing an erection. Erection is maintained by placing a constricting band at the penile base to restrict outflow. VCDs have been used with success by many patients with ED, especially men with venous leaks and neurologic disorders (traumatic and nontraumatic). Complications include mild numbness in the penis, mild cyanosis, painless ecchymoses, petechiae, and blocked ejaculation. Some men and spouses complain of a cool penis.

TRANSURETHRAL AND INTRACAVERNOSAL INJECTION TREATMENTS

Aprostadiil (prostaglandin E₁, PGE₁) can be administered with the Medicated Urethral System for Erection (MUSE). Tested in 1,511 men, MUSE's efficacy and safety were demonstrated in a double-blind, placebo-controlled clinical trial. Trial doses were administered in the clinic, and responders were randomly assigned to either their effective dose or placebo for 3 months of in-home use. Two-thirds of the men had an intercourse-sufficient erection in the clinic. Seventy percent of the responders reported successful intercourse at home. Side effects included penile pain (11%) and hypotension (3.3%).

Intracavernosal injections (ICIs) of vasodilators usually produce erections in patients with neurogenic, vasculogenic, and psychogenic ED. Consistent erectile responses are obtained with PGE₁, administered alone or in combination with papaverine and phentolamine. The maximum dose for monotherapy is considered to be 20 µg. Compared to papaverine and/or nitroprusside, PGE₁ onset is slower and action–duration longer. Furthermore, better self-rating of erection was found with PGE₁ than with nitroprusside (a nitric oxide donor). Side effects (including plaque formation and priapism) reportedly appeared less often with PGE₁ than with papaverine; however, PGE₁ costs more. PGE₁ can produce penile pain. Should priapism occur, medical treatment usually is effective.

SURGERY

Surgery is considered for men with ED who do not respond to less invasive treatments. Patients with neurologic causes, genital abnormalities, or severe vascular disease who cannot be treated medically may be candidates for penile prosthesis. In experienced hands, implantation of either a semirigid or an inflatable penile prosthesis achieves satisfactory results in 74% to 95% of patients. Complications include infection and perforation of the penile skin by the prosthesis; however, such problems are rare. Inflatable prostheses fail mechanically more often than semirigid rods, but inflatable prostheses are more acceptable to patients. Other surgical approaches include attempts to correct venous leaks and to revascularize the penis. Both of these approaches have limited success.

SUMMARY

A clinical hypothesis should be formed about underlying cause based on the history, physical examination, and psychometric testing. Patients with mood disturbance, performance anxiety, obvious relationship problems, and/or current alcohol or drug abuse should be referred for psychiatric treatment or counseling. Medication-induced ED should be considered. Systemic disease and testosterone deficiency should be excluded by laboratory tests. After this, a pharmacologic challenge with sildenafil can be performed, if not contraindicated. Other noninvasive therapies also may be tried (VCDs). If noninvasive therapies fail, a minimally invasive approach (transurethral PGE₁) is appropriate. Side effects or ineffectiveness would justify even more invasive procedures. ICI could be tried in the clinical setting, and the doses should be titrated. Additional diagnostics could be performed before surgical intervention is undertaken.

Treatment of ED is becoming a commonplace aspect of medical practice. Once the exclusive domain of the specialist, new drugs, devices, and procedures that provide relief are increasingly being used by primary care and internal medicine physicians. The field of male sexual disorders is rapidly transforming, and patients are benefiting from the expanded treatment options.

CHAPTER 399: APPROACH TO HYPERGLYCEMIA IN THE PATIENT WITH DIABETES MELLITUS

JAY S. SKYLER

[Therapy of Type I Diabetes](#)
[Therapy of Type II Diabetes](#)
[Therapy of Acute Decompensated Diabetes](#)

This chapter addresses the therapeutic approach to hyperglycemia in patients with diabetes. The discussion is divided into three sections: therapy of hyperglycemia in type I diabetes, therapy of hyperglycemia in type II diabetes, and therapy of acute decompensated diabetes (diabetic ketoacidosis and hyperosmolar hyperglycemic nonketotic coma). The pathophysiologic characteristics of these conditions are discussed in [Chapter 411](#), as is the treatment of chronic diabetic complications.

THERAPY OF TYPE I DIABETES

Patients with type I diabetes do not produce insulin and thus depend on exogenous insulin for survival. The diabetic state is recognized and characterized by virtue of the hyperglycemia that ensues as a consequence of insulin deficiency. Physiologic insulin secretion includes both continuous basal insulin secretion and substrate-related incremental insulin secretion after meal consumption (see [Fig. 411.2](#) in Chapter 411). Basal insulin secretion modulates hepatic glucose production and metabolic homeostasis in the postabsorptive period. Thus, basal insulinemia restrains hepatic glucose production and keeps it in equilibrium with basal glucose utilization by the brain and other tissues that are obligate glucose consumers. After meals, substrate-related incremental insulin secretion stimulates glucose utilization and storage, while inhibiting hepatic glucose output.

Insulin is essential for the physiologic use of all substrates and therefore is the primary regulator of energy metabolism. Thus, underlying the management of type I diabetes is the necessity to balance energy availability (food intake) with energy expenditure (activity) and insulin dosage. From this framework, three components of therapy emerge: the nutritional plan, exercise, and insulin dosage. Successful treatment of diabetes, by definition, involves balancing these three components and carefully monitoring that balance (self-monitoring of blood glucose by the patient). The attainment of an equilibrium of food intake, activity, and insulin assumes that neither physical nor emotional stress alters this balance by stress-induced secretion of glucose counterregulatory hormones (catecholamines, glucagon, cortisol, growth hormone). Because the patient must be engaged in maintaining this equilibrium on a daily basis, two additional critical principles emerge: education of patients is essential to successful therapy, and the treatment program must be sufficiently flexible and dynamic to allow for highly varied and changing lifestyles without sacrificing careful metabolic control.

THERAPEUTIC OBJECTIVES IN TYPE I DIABETES

[Table 399.1](#) lists three levels of treatment for type I diabetes, as developed by the American Diabetes Association (ADA), along with the characteristics of metabolic control in each of these categories. Given the demonstration by the Diabetes Control and Complications Trial that intensive therapy markedly lessens the risks of the chronic complications of diabetes, the goal for most patients should be the achievement of the intensive level of control. Specific glycemic targets for this level are listed in [Table 399.2](#). Blood glucose targets must be individualized for each patient, however, and must be explicitly defined to be achieved. For otherwise healthy, young patients who readily recognize hypoglycemic symptoms and who spontaneously recover from hypoglycemia, targets may be similar to those listed in [Table 399.2](#). Targets need to be lowered during pregnancy and raised in patients who have difficulty perceiving hypoglycemic symptoms, who do not spontaneously recover from hypoglycemia, or in whom hypoglycemia might be particularly dangerous (e.g., patients with angina pectoris or transient ischemic attacks). In motivated patients, realistic targets are achievable 70% to 80% of the time.

Minimal (unacceptable under all normal circumstances)
HbA_{1c} 11–13% or GHB 13–15%
Many SMBG values >300 mg/dL (>16.7 mmol/L)
Intermittent ketonuria
Mean blood glucose level >300 mg/dL (>16.7 mmol/L)
Average (improvement should be attempted if the patient's clinical and personal situations permit)
HbA_{1c} 8–9% or GHB 10–11%
Premeal SMBG 160–200 mg/dL (8.9–11.1 mmol/L)
Rare ketonuria
Mean blood glucose level 160–240 mg/dL (8.9–13.3 mmol/L)
Intensive (desired, if possible to achieve without significant serious side effects)
HbA_{1c} 6–7% or GHB 7–9%
Before SMBG 80–120 mg/dL (4.4–6.7 mmol/L)
Bedtime SMBG 100–140 mg/dL (5.6–7.8 mmol/L)
Essentially no ketonuria
Mean blood glucose level 120–160 mg/dL (6.7–8.9 mmol/L)

HbA_{1c}, the major fraction of glycosylated hemoglobin; SMBG, self-monitored blood glucose.

TABLE 399.1. LEVELS OF TREATMENT FOR TYPE I DIABETIC PATIENTS: BIOCHEMICAL AND CLINICAL CHARACTERISTICS

Time	Ideal ^a	Acceptable ^a
Fasting/preprandial	70–105 mg/dL (3.9–5.8 mmol/L)	70–130 mg/dL (3.9–7.2 mmol/L)
Postprandial (1 hr)	100–160 mg/dL (5.6–8.9 mmol/L)	100–180 mg/dL (5.6–10.0 mmol/L)
Postprandial (2 hr)	80–120 mg/dL (4.4–6.7 mmol/L)	80–150 mg/dL (4.4–8.3 mmol/L)
Bedtime	100–140 mg/dL (5.6–7.8 mmol/L)	100–160 mg/dL (5.6–8.9 mmol/L)
2:00–4:00 a.m.	70–105 mg/dL (3.9–5.8 mmol/L)	70–130 mg/dL (3.9–7.2 mmol/L)

^a Ideal values approximate those seen in nondiabetic individuals; they are included for illustrative purposes. Acceptable values are attainable in a reasonable number of patients without provoking undue hypoglycemia; they are provided to appropriate patients.
EVIDENCE LEVEL: C, Expert Opinion.

TABLE 399.2. REPRESENTATIVE TARGET LEVELS FOR SELF-MONITORING OF BLOOD GLUCOSE LEVELS SUITABLE FOR A YOUNG, OTHERWISE HEALTHY PATIENT WITH TYPE I DIABETES IN A PROGRAM OF INTENSIVE THERAPY

TREATMENTS FOR TYPE I DIABETES

As noted, the management of type I diabetes entails balancing the three components of therapy: the nutritional plan, exercise, and insulin dosage.

Nutritional Plan

There should be careful balance of food intake, activity, and insulin dosage. A meal plan based on the person's usual food intake should be determined and used as a basis for integrating insulin therapy into the usual eating and exercise patterns. To accomplish this, patients (and their families) need to learn a system that incorporates the calorie and nutrient content of foods (carbohydrate content or exchanges). They also should learn general principles of the influence of various foods and of activity on glycemia and the balancing of these factors to achieve glycemic control.

In the past, it was common to recommend an insulin program and dosage, a particular pattern of food intake, and perhaps an exercise or activity prescription. The pattern of food intake almost invariably included three meals (breakfast, lunch, and supper) and one or more (often three) snacks. The dietary prescription usually

included a specific calorie intake, proportions of nutrients (carbohydrate, fat, and protein distribution), and specified distribution of calories into meals. It was recommended that patients eat at consistent times synchronized with the time-action profile of the insulin preparation used. Unfortunately, such dietary prescriptions often were at odds with the previous habits of patients or families. Many patients prefer to eat at different hours some days, to skip meals either routinely or occasionally, or to vary portion sizes or meal composition. This created conflict between dietary prescriptions and a patient's desires, frequently leading to frustration or abandonment of the dietary prescription.

Contemporary dietary practices are considerably more flexible. Intensified insulin therapy allows flexibility in when and what patients eat. With intensified therapy, insulin regimens are integrated with lifestyle and doses calculated for the amount of food usually eaten. Patients monitor blood glucose levels and adjust insulin for variations in blood glucose and for deviations from usual eating and exercise habits.

Diabetic patients should follow sound general nutritional practices. In particular, this means avoiding excess intake of saturated fats and cholesterol, which influence serum lipids, which, in turn, also may be elevated if there is suboptimal diabetic control. It also means limiting salt consumption, which can aggravate the risk of blood pressure elevation and alter vascular reactivity.

Dietary protein should contribute approximately 10% to 20% of the total caloric content of the diet, leaving 80% to 90% of the calories to be distributed between dietary fat and carbohydrate. For people who have normal lipid levels and maintain a reasonable weight—and for normal growth and development in children and adolescents—the appropriate recommendations are those of the Dietary Guidelines for Americans (that 30% or less of the calories come from total fat). Less than 10% of calories should be derived from saturated fats and up to 10% calories from polyunsaturated fats, leaving 60% to 70% of total calories from monounsaturated fats and carbohydrates. The distribution of calories from fat and carbohydrate can vary and is individualized based on the nutrition assessment and treatment goals. Dietary cholesterol should be limited to 300 mg or less daily. Sucrose and sucrose-containing foods, when used, must be substituted for other carbohydrates and not simply added to the meal plan.

In making such substitutions, the nutrient content of concentrated sweets and sucrose-containing foods, as well as the presence of other nutrients frequently ingested with sucrose, such as fat, must be considered. Saccharin, aspartame, sucralose, and acesulfame-K may be used as non-nutritive sweeteners. There should be a tendency to avoid foods that have a high glycemic index (those that cause rapid rises in plasma glucose), while also favoring foods relatively high in fiber. There is no need to limit disproportionately the intake of complex carbohydrates or foods that have a low glycemic index. If the patient is not overweight (most patients with type I diabetes are not), there is no need to limit calorie consumption arbitrarily.

Exercise

Many variables, including fitness, duration and intensity of exercise, and time of exercise in relationship to insulin administration and meals, affect the metabolic response to exercise. The energy expended in the patient's usual daily routine determines the calorie content of the diet and influences the insulin dose and regimen. Regular physical activity is factored into this balance. On the other hand, for sporadic physical activity that is a departure from the daily routine, patients must take action to avert hypoglycemia. Patients might want to take in extra food to provide energy for increased activity, initially perhaps 10 to 15 g of carbohydrates every 30 to 45 minutes during the activity. Blood glucose is monitored before, during, and after exercise to determine the effectiveness of the extra carbohydrate. Insulin dose reductions may be used in addition to or instead of extra carbohydrate. All patients should have quick-acting, rapidly absorbed carbohydrate available during activity in case of hypoglycemia. Patients should realize that moderately intensive exercise may deplete glycogen stores, resulting in a sustained food requirement to replace the glycogen. As a consequence, hypoglycemia may develop well after exercise (e.g., 12 hours after jogging). For this reason, patients should be cautious when planning vigorous physical activity in the evening hours; nocturnal hypoglycemia may ensue.

INSULIN IN TYPE I DIABETES

Patients with type I diabetes lack both basal and prandial insulin secretion. Contemporary flexible insulin programs have multiple components that attempt to mimic these two types of endogenous physiologic insulin secretion by providing components that give prandial insulin coinciding with each meal and separate components that provide basal insulinemia overnight and between meals. All insulin treatment programs at best approximate normal physiology, because they are contingent on the time-action profiles of available insulin preparations ([Table 399.3](#)).

Insulin Preparation	Onset of Action (hours)	Peak Action (hours)	Duration of Action (hours)
Rapid onset			
Lispro	5-15	1-2	3-5
Aspart	5-15	1-2	3-5
Short acting			
Regular	5-1	2-4	4-6
Intermediate acting			
NPH	1-4	8-10	12-20
Lente	2-4	8-12	12-20
Long acting			
Ultralente	2-5	10-16	18-24
Gargis	2-4	None	20-26
Combinations			
70/30—70% NPH, 30% regular	5-1	Dual	12-20
50/50—50% NPH, 50% regular	5-1	Dual	12-20

This table summarizes the typical time course of action of various insulin preparations. It is based on doses of 0.1–0.2 units/kg in the abdomen for human insulin. These values vary among individuals, depending on the site and depth of injection, skin temperature, and level of exercise.

TABLE 399.3. TIME COURSE OF ACTION OF INSULIN PREPARATIONS

Prandial Insulin Therapy

Prandial incremental insulin secretion is best duplicated by giving preprandial rapid-onset insulin before each meal, by syringe, pen, or infusion pump. Each preprandial insulin dose is adjusted individually to provide insulinemia appropriate to the size of the meal. The use of preprandial insulin doses permits total flexibility in meal timing. The timing of meals need not be fixed, and meals may be omitted along with the accompanying preprandial insulin dose.

Regular human insulin administered subcutaneously is relatively rapid in its onset of action, but not immediate. Thus, if preprandial regular insulin is used, it is best to administer it at least 20 to 30 minutes before eating a given meal, in an attempt to have prandial insulinemia parallel meal-related glycemic excursions. With the very rapid-onset human insulin analogs, insulin lispro and insulin aspart, this waiting period is not needed. As a consequence, insulin lispro and insulin aspart are becoming the standard prandial insulins.

Basal Insulin Therapy

Basal insulinemia is given either as intermediate-acting human insulin (NPH or lente) at bedtime and in a small morning dose ([Fig. 399.1A](#)) or, occasionally, just as a bedtime dose ([Fig. 399.1B](#)); one ([Fig. 399.2A](#)) or two ([Fig. 399.2B](#)) daily injections of long-acting ultralente human insulin can also be administered, which in most patients is relatively peakless after steady state has been attained.

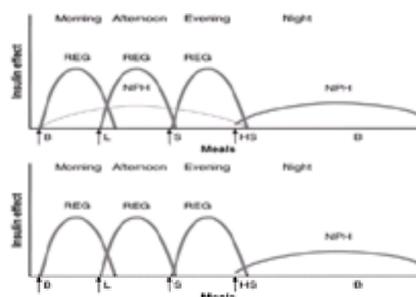

FIGURE 399.1. Schematic representation of the idealized insulin effect provided by a multiple-dose regimen of preprandial injections of regular (REG) insulin before meals and a basal regimen consisting of two daily injections of intermediate-acting insulin (NPH) (**A**) or basal intermediate-acting insulin (NPH) just at bedtime (**B**). B, breakfast; L, lunch; S, supper; HS, bedtime snack. Arrows indicate time of insulin injection, 30 minutes before meals.

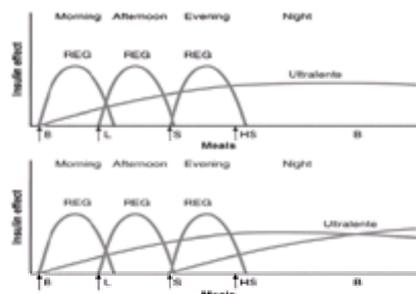

FIGURE 399.2. Schematic representation of the idealized insulin effect provided by a multiple-dose regimen of preprandial injections of regular (REG) insulin before meals and basal long-acting ultralente insulin either once daily (**A**) or twice daily (**B**). B, breakfast; L, lunch; S, supper; HS, bedtime snack. Arrows indicate time of insulin injection, 30 minutes before meals.

The intermediate-acting human insulins NPH (neutral protamine Hagedorn—also known as isophane insulin suspension) and lente have an onset of action about 2 hours after injection and produce peak insulin levels after 8 to 10 hours. Bedtime intermediate-acting insulin provides overnight basal insulinemia with peak serum insulin levels before breakfast, a time of relative insulin resistance known as the “dawn phenomenon.” Bedtime administration of intermediate-acting insulin also eliminates nocturnal peaks of insulin action, thus lessening the risk of nocturnal hypoglycemia. A small morning dose of intermediate-acting insulin provides daytime basal insulinemia.

Human ultralente insulin has a broad peak about 12 to 16 hours after injection, with sustained action up to 24 hours and sometimes beyond. In most patients, the peak of human ultralente insulin is sufficiently blunted at steady state to permit use of this preparation as a “peakless” basal insulin. As a consequence of waning insulin effect at about 24 hours, there may be a rise in fasting glucose if human ultralente insulin is administered in a single morning dose. Thus, it probably is best to divide ultralente insulin into two doses, or give a single dose in the evening. A program consisting of multiple-dose preprandial insulin, together with bedtime intermediate insulin (and a small morning dose), has become increasingly popular because it offers flexibility in meal size and timing. Moreover, it is straightforward and easy to understand and implement, because each meal and each time period of the day has a well-defined insulin component, providing primary insulin action. In addition, the introduction of insulin pens has stimulated its popularity in many countries, such that it is the most widely used insulin regimen in several countries in Europe.

Continuous Subcutaneous Insulin Infusion

The most precise way to mimic normal insulin secretion in clinical practice is to use an insulin pump in a program of continuous subcutaneous insulin infusion ([Fig. 399.3](#)). The pump delivers microliter amounts of insulin on a continual basis, thus replicating basal insulin secretion. With many pumps, the basal rate can be programmed to vary at times of diurnal variation in insulin sensitivity, if these variations result in disruption of glycemic control. Thus, the basal infusion rate may be decreased overnight to avert nocturnal hypoglycemia or increased to counteract the dawn phenomenon that often results in hyperglycemia on awakening. The pump is activated before meals to provide increments of insulin as meal boluses or “boosts,” allowing total flexibility in meal timing. If a meal is skipped, the insulin bolus is omitted. If a meal is larger or smaller than usual, a larger or smaller insulin bolus is selected. With increased physical activity, patients may either suspend insulin delivery or use the quick-release option of disconnecting the pump from its indwelling catheter, thus lowering the risk of exercise-related hypoglycemia.

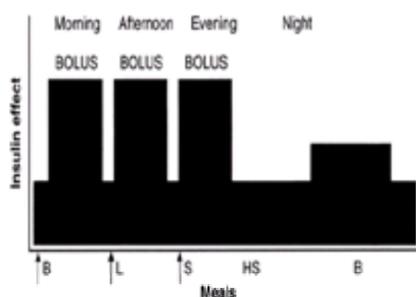

FIGURE 399.3. Schematic representation of idealized insulin effect provided by continuous subcutaneous insulin infusion. B, breakfast; L, lunch; S, supper; HS, bedtime snack.

Other Insulin Programs

Separately considering prandial and basal insulin needs permits flexibility in eating and activity. Such an approach requires motivated, educated patients who carefully monitor blood glucose several (four or more) times daily. In the absence of motivation, education, or frequent blood glucose monitoring, an alternative (and clearly not optimal) approach is to maintain day-to-day consistency both of activity and of timing and quantity of food intake and thus permit prescription of a relatively constant insulin dose. This approach allows the patient to use either twice-daily administration of mixtures of regular insulin and intermediate-acting insulin (NPH or lente)—the so-called split-and-mixed insulin regimen ([Fig. 399.4A](#)), or morning administration of a mixture of regular insulin and intermediate-acting insulin with regular insulin before supper and intermediate-acting insulin at bedtime ([Fig. 399.4B](#)), a method used to minimize nocturnal hypoglycemia and to counteract the dawn phenomenon. In general, it is not possible to control glycemia in type I diabetes adequately using one or two injections of intermediate-acting insulin alone. The exception may be early in the course of the disease, when some endogenous insulin secretion remains.

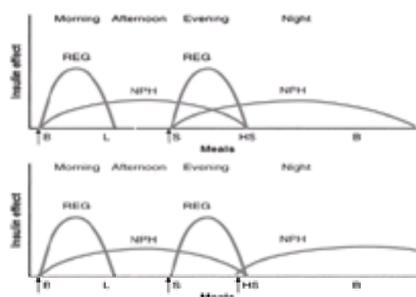

FIGURE 399.4. (A) Schematic representation of the idealized insulin effect provided by an insulin regimen consisting of two daily injections of regular (REG) insulin and intermediate-acting insulin (NPH). (B) A similar program, with the evening insulin dose divided into an injection of regular insulin before supper and a bedtime injection of intermediate-acting insulin. B, breakfast; L, lunch; S, supper; HS, bedtime snack. Arrows indicate time of insulin injection, 30 minutes before meals.

Initial Insulin Doses and Distribution

The insulin dosage required for meticulous glycemic control in typical patients with type I diabetes who are within 20% of their ideal body weight, in the absence of intercurrent infections or other periods of instability, approximates 0.5 to 1.0 U per kilogram per day. During the “honeymoon” period of relative remission early in the course of disease, insulin requirements are lower. In the context of intercurrent illness, the dosage may increase markedly. Dosage needs rise during the adolescent growth spurt, and some adolescents have a sustained increased dose requirement. About 40% to 50% of the total daily insulin dose is used to provide basal insulinemia. The remainder is divided among the meals empirically, proportionate to the relative carbohydrate content of the meals, or by initially giving (adults) approximately 1.0 to 1.2 U of insulin for every 10 g of carbohydrate consumed.

Alteration of Insulin Doses

Patients are provided with an action plan to alter therapy to achieve individually defined blood glucose targets. Actions are guided by self-monitored blood glucose determinations and daily records. Specific action depends on answers to several questions the patients ask at the time of insulin administration before meals: What is my blood glucose level now? What do I plan to eat now (usual meal, large meal, or small meal and the amount of carbohydrate)? What do I plan to do after eating (usual activity, increased level of activity, decreased level of activity)? What has happened under these circumstances previously? The answers dictate the treatment response. The actions include changes in food intake (altering the size or content of food), activity, insulin dosage, and timing of injections in relation to meals. The plan also should call for separate measures in response to a *pattern* of glycemia occurring over several days, assuming the patient has a relatively stable pattern of meals and activities, has no intercurrent illness, and is free from unusual stress.

ASSESSMENT AND MONITORING OF TYPE I DIABETES

Glycosylated hemoglobin determination (Hb A_{1c} or Hb A₁) is carried out quarterly to monitor long-term glycemic control. The value obtained from a random plasma glucose test is used to compare with that obtained simultaneously by the patient using his or her own monitoring system. A lipid profile should be determined for patients older than 2 years, after diagnosis of diabetes and when glucose control has been stabilized. If values fall within accepted risk levels, the assessment should be repeated every 2 years for adults or every 5 years for children. Treatment should be instituted if there are abnormalities, and patients should be followed appropriately.

Patient self-monitoring of blood glucose levels must be done on a daily basis, four times per day most days (before meals and at bedtime), with additional samples obtained in the middle of the night (2:00 to 4:00 a.m.) once every 1 to 2 weeks and any time that overnight insulin dosage is to be altered. Additional samples are obtained any time hypoglycemia is suspected. Periodically, postprandial samples should be taken as well, particularly if there is a disparity between preprandial results and Hb A_{1c} determinations. The patient should keep a careful diary of daily blood glucose measurements, insulin doses, hypoglycemic episodes, and departures from daily routine (unusually large meals, increased physical activity, intercurrent illness). The patient's record is the focus of discussion at follow-up visits. Patient-determined blood glucose values are part of treatment, not assessment (but should be compared with the glycosylated hemoglobin value). In addition, the patient's compliance and responsibility for diabetes management should be assessed on a regular basis.

EDUCATION AND SUPPORT

To implement the management plan, considerable education of the patient is necessary. Moreover, the patient needs continued access to and interaction with a specialized diabetes management team, if successful control is to be achieved. Thus, the control of type I diabetes with a contemporary flexible insulin program mandates management by an expert multidisciplinary diabetes team. Successful participation in a demanding treatment program requires a committed, motivated patient. The team must take extra effort to help maintain motivation. This is often the most difficult component of treatment. Patients and families with new-onset type I diabetes need psychological support to adjust to having diabetes. Additional support is required to aid in the management program. To this end, ongoing psychological support, such as regular diabetes support group meetings, may be desirable for all patients with type I diabetes.

SPECIAL CONSIDERATIONS CONCERNING PREGNANCY

To lower the risk of fetal malformations and maternal and fetal complications, pregnant women and women planning pregnancy need to have excellent control of blood glucose levels. Because of the need for prepregnancy planning and excellent glucose control, pregnancy in women with diabetes should be planned in advance. Therefore, women not attempting to conceive should use effective methods of contraception.

Glycemic targets during pregnancy are more stringent than otherwise because of the profound potential adverse impact of even modest hyperglycemia on the fetus (Table 399.4). Treatment should include more frequent self-monitoring of blood glucose values, extra snacks to avert hypoglycemia, and the expectation of a progressive increase in insulin requirement during the course of gestation, as a consequence of insulin resistance induced by placental hormones.

Time	Glucose
Fasting	60–90 mg/dL (3.3–5.0 mmol/L)
Preprandial	60–105 mg/dL (3.3–5.8 mmol/L)
Postprandial (1 hr)	70–140 mg/dL (3.9–7.8 mmol/L)
Postprandial (2 hr)	60–120 mg/dL (3.3–6.7 mmol/L)
Bedtime	60–120 mg/dL (3.3–6.7 mmol/L)
2:00–4:00 a.m.	60–100 mg/dL (3.3–5.5 mmol/L)

TABLE 399.4. REPRESENTATIVE TARGET LEVELS FOR SELF-MONITORING OF BLOOD GLUCOSE LEVELS SUITABLE FOR A PREGNANT WOMAN WITH TYPE I DIABETES

THERAPY OF TYPE II DIABETES

For clinical purposes, the severity of type II diabetes can be related to the degree of hyperglycemia on a stable diet and activity program. This clinical subclassification has four categories: mild, moderate, severe, and very severe (Table 399.5). Because basal (fasting) glycemia is relatively constant from day to day on a stable diet and activity program, the fasting plasma glucose (FPG) is the principal determinant. Also used is the postprandial glucose response to a meal. Although type II diabetes is characterized by a prolonged period of postprandial hyperglycemia (glucose intolerance), such patients typically have intact endogenous insulin response to meals such that postprandial glycemia is restored to basal levels (± 20 to 25 mg per deciliter) within 4 to 5 hours of meal consumption. When this stabilization does not occur, patients are considered to have very severe type II diabetes. Otherwise, they are subclassified on the basis of FPG.

Category	Fasting (Basal) Plasma Glucose ^a	Postprandial Glucose Response to Meals ^b
Mild	<140 mg/dL (<7.8 mmol/L)	Restored to basal
Moderate	140–250 mg/dL (7.8–13.9 mmol/L)	Restored to basal
Severe	>250 mg/dL (>13.9 mmol/L)	Restored to basal
Very severe	>250–300 mg/dL (>13.9–16.7 mmol/L)	NOT restored to basal

^a On a stable diet and activity program.
^b Within 4–5 hours, within 20–25 mg/dL.

TABLE 399.5. SUBCLASSIFICATION OF TYPE II DIABETES

In this subclassification, *mild* describes the diabetes of patients with an FPG less than 140 mg per deciliter. These patients sometimes can be treated with medical nutritional therapy (MNT) and an activity prescription without pharmacologic intervention. When this regimen proves inadequate, they may benefit by the addition of pharmacologic agents. *Moderate* type II diabetes refers to the condition of patients with an FPG in the range of 140 to 250 mg per deciliter. In addition to MNT and an activity program, they usually require pharmacologic intervention. *Severe* type II diabetes describes the disease in patients with an FPG greater than 250 mg per deciliter, with restoration of glycemia to basal levels within 4 to 5 hours of meal consumption. Initial glycemic control can be attained most readily with insulin therapy that provides around-the-clock insulinization. Long-term glycemic control then can be maintained either with oral pharmacologic agents or with insulin.

Patients with a nonintact endogenous insulin response to meals, such that postprandial glycemia is not restored to basal levels within 5 hours of meal consumption have *very severe* type II diabetes. The FPG usually is quite elevated as well (above the 250 to 300 mg per deciliter range), but it may not be. There is such profound insulin deficiency that these patients initially may be difficult to distinguish from patients with type I diabetes, though in general they do not manifest ketosis. Initially they are best treated like type I patients. In all four subcategories of type II diabetes, it should be recognized that with adequate treatment there can be improvement both in islet B-cell function and in peripheral insulin action at target cells. As a consequence, there may be sufficient improvement in glucose homeostasis for a patient to be reclassified to a less severe subcategory, with glycemic control maintained by a treatment program typical for that category.

THERAPEUTIC OBJECTIVES IN TYPE II DIABETES

The Diabetes Control and Complications Trial (DCCT) and the United Kingdom Prospective Diabetes Study (UKPDS) have shown that meticulous glycemic control is important in both type I and type II diabetes. Results from the DCCT and UKPDS serve as the basis for recommendations of glycemic targets in diabetes management. Table 399.6 lists the biochemical indexes of glycemic control for type II diabetes suggested by the ADA. The recommended treatment goals are fasting and preprandial glucose levels below 120 mg per deciliter, with a glycosylated hemoglobin (Hb A_{1c} or Hb A_{1c}) level normal or near normal. Furthermore, it is desirable to minimize excessive postprandial hyperglycemia and obviate glycosuria. Ideally, patients should strive for normal fasting and preprandial levels (less than 110 mg per deciliter) and normal glycosylated hemoglobin (Hb A_{1c} or Hb A_{1c}). Various therapies should be used progressively until the glycemic treatment goals are attained. Such goal-based therapy is the basis for contemporary management of type II diabetes.

Index	Ideal	Goal	Not Acceptable
Fasting/preprandial plasma glucose	<110 mg/dL (<6.1 mmol/L)	<120 mg/dL (<7.8 mmol/L)	<80 or >140 mg/dL (<4.4 or >7.8 mmol/L)
Postprandial (2 hr) plasma glucose	<140 mg/dL (<7.8 mmol/L)	<180 mg/dL (<10.0 mmol/L)	>200 mg/dL (>11.1 mmol/L)
Bedtime plasma glucose	<140 mg/dL (<7.8 mmol/L)	100–140 mg/dL (5.6–8.9 mmol/L)	<80 or >160 mg/dL (<4.4 or >8.9 mmol/L)
Hb A _{1c} (%) ^a	<6.0%	<7.0%	>8.0%
Ghb (%) ^b	<7.0%	<8.0%	>15%

Hb A_{1c}, the major fraction of glycosylated hemoglobin.

^a Referenced to a nondiabetic range of 4–6%.

^b Referenced to a nondiabetic range of 4.5–7%.

EVIDENCE LEVEL: C, Expert Opinion.

TABLE 399.6. INDEXES OF GLYCEMIC CONTROL IN TYPE II DIABETES

In addition to glycemic goals, attention must be paid to other variables, particularly those related to atherosclerotic risk, which is substantial (Table 399.7). Thus, lipids and blood pressure need careful control, and smoking cessation should be promoted. A final objective is to attain and maintain weight as close as possible to ideal body weight. Normalizing weight in obese patients with type II diabetes is as crucial as controlling glycemia, because success with the former often leads to success with the latter.

- Aglycosuria
- Freedom from symptoms
- Normalize plasma total cholesterol
- Normalize plasma LDL cholesterol
- Normalize plasma triglycerides
- Normalize blood pressure
- Smoking cessation
- Body weight stable and as close to normal as possible

LDL, low-density lipoprotein.

TABLE 399.7. OTHER THERAPEUTIC GOALS IN TYPE II DIABETES

TREATMENTS FOR TYPE II DIABETES

MNT and the promotion of physical activity are the cornerstones of management of type II diabetes. Pharmacologic therapy is required for most patients.

Medical Nutritional Therapy

MNT is integral to total diabetes care and management. Although adherence to nutrition and meal-planning principles is one of the most challenging aspects of diabetes care, MNT is an essential component of successful diabetes management. The emphasis of MNT in type II diabetes should be placed on achieving glucose, lipid, and blood pressure goals. In obese patients with type II diabetes, a major nutritional principle is promotion of weight reduction by restriction of total calorie intake. Unfortunately, most patients are unable to adhere to a calorie-restricted diet to attain an ideal body weight. Even mild to moderate weight loss (10 to 20 pounds [5 to 10 kg]) has been shown to improve short-term glycemic control, even if desirable body weight is not achieved. It also has the potential to increase long-term metabolic control.

Weight loss is best attempted through a moderate decrease in caloric intake and an increase in caloric expenditure. Moderate caloric restriction (250 to 500 calories less than the average daily intake) usually is recommended, though very-low-calorie diets may be needed to achieve weight loss. If so, this diet should be monitored carefully. Although weight loss is desirable, and some people are able to lose weight and maintain the loss, several additional MNT strategies can be implemented to improve metabolic control.

In type II diabetes patients who are not obese and in those who have either completed weight reduction or who are unable to lose additional weight, different MNT principles apply. There are five such principles: a balanced nutrient intake; emphasis on appropriate alterations for achieving lipid and blood pressure goals; adequate spacing between meals (4 to 5 hours apart); consideration for additional consumption of dietary fiber; and avoidance of excessive intake of rapidly absorbed, simple sugars (sucrose, glucose, maltose), confining their use to substitution for other carbohydrates and not simply as additions to the meal plan. Although these principles are seemingly straightforward, each is the subject of controversy.

The nutrient proportions recommended by the ADA and American Dietetic Association emphasize the need to correct lipid abnormalities and lessen the risk of accelerated atherosclerosis, which remains the major cause of death in type II diabetes. These recommended proportions are listed in [Table 399.8](#). The current ADA recommendations do not curtail the use of rapidly absorbed sugars, provided these are substituted for other carbohydrates. Many experts disagree with such liberalization, unless there is careful measurement of glycemic excursions by the patient, to ensure that there is no deterioration of glucose control. The basis for the concern is that in type II diabetes endogenous insulin secretion is delayed, and consumption of rapidly absorbed simple sugars may result in rapid incremental increases in plasma glucose. The need for adequate spacing between meals is perhaps the most neglected nutritional principle in the management of type II diabetes. Because the period of postprandial hyperglycemia is prolonged in patients with type II diabetes, necessitating 4 to 5 hours before glucose levels are restored to preprandial (basal) levels, it is important to space meals at a like interval. Initial meal planning should thus include a 5-hour interval between food consumption, unless there is documentation that glycemia is restored to basal levels in a shorter interval for any given patient.

Nutrient	Content
Proteins	10–20% of calories
Total fats	≤30% of calories
Saturated fats	≤10% of calories
	<7% with elevated LDL
Polysaturated fats	≤10% of calories
Carbohydrates and monounsaturated fats	60–70% of calories
Cholesterol	<300 mg/day
Fiber	20–35 g/day
Sodium	<3,000 mg/day
Alcohol	<2 alcoholic beverages daily

LDL, low-density lipoprotein.

EVIDENCE LEVEL: C. Expert Opinion.

TABLE 399.8. RECOMMENDED NUTRIENT INTAKE FOR AMERICANS

Coexisting conditions may require alteration in nutrient content. Particular attention needs to be paid to dyslipidemia, which may mandate even greater restriction of saturated fats (to less than 7% of calories) and cholesterol (to less than 200 mg per day) or use of monounsaturated fats. The presence of renal disease may require reduction of protein intake to less than 0.8 g per kilogram ideal body weight per day, approximately 10% of total calories. The presence of hypertension may result in the reduction of sodium intake.

Exercise

Exercise in patients with type II diabetes has several potential benefits. Moderate exercise has been shown to improve insulin sensitivity and facilitate insulin action, thus improving glucose tolerance even in the absence of weight loss. Moreover, increased physical activity has the benefit of intensifying energy expenditure in a relatively sedentary population, thus augmenting the effects of calorie restriction to promote weight loss when used in combination with a proper diet program. In addition, exercise may lower the risk of macrovascular disease by improving cardiovascular conditioning, facilitating control of hypertension, and improving dyslipidemia. In the latter regard, exercise may increase levels of high-density lipoprotein (HDL) cholesterol and also lower levels of triglycerides and low-density lipoprotein (LDL) cholesterol. The greatest beneficial effects are seen with regular (at least three times per week), moderate, sustained exercise. Regular exercise also can improve psychological well-being.

It must be recognized, however, that most patients with type II diabetes are older, usually are obese, and often have significant coexisting medical conditions, all of which makes initiation of an exercise program more complicated. Nevertheless, all patients with type II diabetes should be encouraged to increase physical activity to a level that is tolerable to them. For some patients, it may be acceptable only to expand familiar daily activities, such as walking or climbing stairs. Any program of increased physical activity taken up by these patients should start slowly and build up gradually. If a serious exercise program is contemplated, it should be preceded by an evaluation specifically designed to uncover previously undiagnosed hypertension, neuropathy, retinopathy, and nephropathy. If neuropathy or peripheral vascular disease is present, the activity program should be designed to avoid lower extremity injury and the feet should be carefully inspected after conclusion of each activity period. Evaluation should include an exercise-stress electrocardiogram in all individuals older than 35 years of age to detect silent ischemic heart disease. Patients should self-monitor their glycemic response to exercise.

Pharmacologic Agents

There are now five classes of oral antidiabetic drugs. Those available in the United States are listed in [Table 399.9](#).

Generic Name	Brand Name	Dosage Range (mg/day)	Duration of Action (hr)	Dosing Frequency (per day)	Excitotoxic
Sulfonylureas					
Tolazamide	Orinase	100–200	6–12	2–3 times	None
Chlorpropamide	Diabinese	50–250	30	Once	None
Tolazamide	Tolazur	100–200	12–24	Twice	None
Acetohexamide	Diapine	250–500	12–24	Twice	None
Gliclazide	Glucotrol XL	25–60	12–24	Twice	None (50% 24hr)
Glibenclamide	Glucotrol XL	5–20	24	Once	None (50% 24hr)
Gliburide	Diabeta	1.25–25	16–24	Twice	None (50% 24hr, 50% 24hr)
Gliburide	Glucotrol	5–15	12–24	Twice	None (50% 24hr, 50% 24hr)
Insulin					
Glargine	Lantus	1–2	24	Once	None (50% 24hr)
Biguanides					
Metformin	Glucophage	1,500–2,550	5–12	2–4 times	None
Thiazolidinediones					
Glimepiride	Amaryl	1–2	24	Once	None
Glipizide	Glucotrol	5–20	12–24	Twice	None (50% 24hr, 50% 24hr)
Glipizide	Glucotrol XL	5–20	24	Once	None (50% 24hr, 50% 24hr)
α-Glucosidase Inhibitors					
Acarbose	Acetose	100–300	6	2–4 times	—
Miglitol	Glucobay	15–60	6	2–4 times	—

TABLE 399.9. CHARACTERISTICS OF ORAL ANTIDIABETIC AGENTS AVAILABLE IN THE UNITED STATES

Insulin Secretagogues

Insulin secretagogues act to stimulate insulin secretion and improve B-cell function, thus correcting one of the two fundamental defects that characterize type II diabetes. There are two classes of insulin secretagogues available at present—the sulfonylureas and the meglitinides. The sulfonylureas include older, first-generation drugs (tolbutamide, chlorpropamide, acetohexamide, and tolazamide) and newer, second-generation drugs (glyburide, glipizide, and glimepiride). There are two drugs in the meglitinide class, though they are structurally different both from meglitinide and from each other: repaglinide is a benzoic acid derivative, while nateglinide is a phenylalanine derivative.

The primary mechanism of action of insulin secretagogues is binding to the SUR subunit of an adenosine triphosphate (ATP)–dependent potassium (K) ion channel (K-ATP channel) on the membrane of the pancreatic islet B cell. This results in closure of the K-ATP channel, causing membrane depolarization and influx of calcium. Calcium entry leads to migration of insulin secretory granules down microtubules to the B cell, thus improving B-cell function and facilitating insulin secretion. Insulin secretion occurs primarily in response to plasma glucose, though with longer-acting sulfonylureas there may be spontaneous insulin secretion. Although insulin is secreted in response to glycemic excursions with meals, there is modulation of hepatic glucose production as well, since insulin is secreted into the hepatic portal circulation. Secretagogues are ineffective in the absence of concomitant adherence to diet, and their effects are enhanced by promotion of physical activity. Secretagogues are efficacious only in patients with some retention of endogenous insulin secretion and thus have no role in the management of type I diabetes.

Sulfonylureas

Sulfonylureas were first introduced in the 1950s and have long played an important role in the management of type II diabetes. In fact, as of the early 1990s, sulfonylureas were the only class of oral antidiabetic medication available in the United States. As a consequence of their long usage, convenient dosing, rapidity of response, and low price, they still command a large share of the market of antidiabetic medications. Sulfonylureas are indicated for patients with mild or moderate type II diabetes who have not experienced correction of fasting hyperglycemia with MNT and physical activity; they are used in combination with any other class of antidiabetic medication when adequate glycemic control has not been attained with one medication.

When initiating sulfonylurea therapy, it is desirable to use the second-generation drugs. In contrast to the first-generation drugs, which are prescribed only rarely, the second-generation drugs have fewer overall side effects and less potential for interaction with other drugs. The newest sulfonylurea formulations—glipizide-GITS and glimepiride—have resulted in long-acting sulfonylureas that can be taken once daily to achieve both effective control of fasting glycemia and improvement of meal-related insulin secretion. The traditional formulations of second-generation drugs—glyburide and glipizide—must be taken two to four times daily; less adequately control fasting glycemia; and increase the risk for hypoglycemia due to large, sustained postprandial peaks of drug. In fact, satisfactory glycemic control can be achieved with glipizide-GITS using a lower total daily dose than with the traditional formulation. The sulfonylureas available in the United States are listed in [Table 399.9](#), along with other oral antidiabetic drugs.

After an initial response, effectiveness of therapy may not be sustained. Most of the time this decline stems from progression of the disease process rather than loss of pharmacologic effect. As a consequence, the sulfonylurea should not be discontinued when another drug is added. Other potential explanations for loss of glycemic control are lack of dietary adherence and deterioration in control due to intercurrent illness. In view of the possibility of secondary failure, plasma glucose should be monitored frequently to regulate dosage and to verify that any beneficial effects are sustained.

Advantages of sulfonylureas include improvement in a primary pathophysiologic impairment, that of insulin secretion; a physiologic route of insulin delivery (from the pancreas into the hepatic portal circulation); a high initial response rate (80% to 90% of subjects showing a response of at least a 30 mg per deciliter decrement in plasma glucose); a rapid response time (improvement in glycemia within 24 to 48 hours); and no intolerance to initiation. The effect on glycemia is quite good, with an Hb A_{1c} decrease of about 1.5% to 2% when used in monotherapy. Disadvantages of sulfonylureas include the risk of hypoglycemia (which in some instances may be prolonged or severe), weight gain, drug interactions (especially with first-generation compounds), and hyponatremia with chlorpropamide. The major side effects are weight gain and hypoglycemia.

Meglitinides

This relatively new class of drugs, the non-sulfonylurea insulin secretagogues, were first introduced in the late 1990s. They also bind to the SUR subunit of the K-ATP channel, though apparently at different sites than the sulfonylureas. Meglitinide was the first such agent studied in the laboratory, and the class has been given that designation. As noted, however, the two drugs in the class have different chemical structures from meglitinide and also differ from each other. Repaglinide is a benzoic acid derivative, and nateglinide is a phenylalanine derivative. Both are ultrashort in duration of action, stimulating insulin to coincide with meals. Therefore, these agents need to be taken together with any meal consumed. This regimen offers flexibility in dosing and allows meals to be skipped easily (omitting the medication as well), which some patients may find advantageous. The effect is primarily on postprandial glucose, though repaglinide (but not nateglinide) also lowers the fasting glucose.

Advantages of meglitinides include improvement in a primary pathophysiologic impairment, that of insulin secretion; a physiologic route of insulin delivery (from the pancreas into the hepatic portal circulation); a high initial response rate; a rapid response time; flexible dosing in relationship to meals; no intolerance to initiation; and the fact that they can be used in the context of renal insufficiency. Disadvantages of meglitinides include the risk of hypoglycemia, weight gain, and unknown long-term side effects of these new agents.

Insulin Sensitizers

Insulin sensitizers improve insulin action at target cells, thus correcting one of the two fundamental defects that characterize type II diabetes. There are two classes of insulin sensitizers available at present—the biguanides and the thiazolidinediones. The only biguanide available in the United States is metformin. There are three available drugs in the thiazolidinediones class, though many others are in development. The available thiazolidinediones are troglitazone, rosiglitazone, and pioglitazone.

Biguanides

Biguanides have had a long history; they were shown to lower glucose in the nineteenth century and were introduced clinically in the 1950s. One biguanide, phenformin, was sold in the United States until 1977, when it was withdrawn by the Food and Drug Administration because of its propensity to lead to lactic acidosis. Another biguanide, metformin, which had been available throughout the world, except in the United States, for nearly four decades, was finally released in the United States in 1995. The molecular mechanism of action of metformin is complex and poorly understood. The drug appears to affect glucose metabolism directly. Thus, it lowers blood glucose levels by decreasing hepatic glucose output, increasing glucose uptake, and enhancing peripheral glucose utilization. Metformin is an “antihyperglycemic” agent that does not cause hypoglycemia.

Metformin often is used as initial monotherapy in type II diabetes, particularly in obese patients, because, unlike secretagogues, it is not associated with weight gain upon improvement in glycemia; in fact, modest weight loss may ensue. It is particularly effective in combination with secretagogues, since biguanides and secretagogues have complementary mechanisms of action. Indeed, most patients require this combination to achieve glycemic targets. On the other hand, in the context of inadequate glycemic regulation, switching from a secretagogue to metformin, or vice versa, does not result in improvement of glycemic control. For this reason, several formulations combining metformin with a secretagogue are under development. The earliest available data suggest that these combination drugs are highly effective in lowering glucose levels.

In treating patients, it should be appreciated that because of the need for slow-dose titration (to minimize the gastrointestinal side effects of nausea, abdominal discomfort, and, less frequently, diarrhea that arise with initiation of therapy), the full effectiveness of metformin may not be seen for 4 to 6 weeks. It also is important to ensure that patients receive adequate doses of metformin. One dose-response study showed that maximum glucose lowering was achieved with a dose of 1,000

mg twice daily, which is substantially higher than that prescribed by most physicians.

Advantages of metformin include improvement in a primary pathophysiologic impairment, that of insulin resistance; a high initial response rate (80% to 90% of subjects show a response); a long record (40 years) of relative safety; absence of weight gain (even modest weight loss); and beneficial effects on plasma lipids. Disadvantages of metformin include gastrointestinal side effects on initiation of metformin, which forces administration of gradually rising dose increments, and the risk of lactic acidosis in patients with elevated serum creatinine, hepatic disease, congestive heart failure, or cardiovascular compromise. After radiographic procedures that use contrast dyes, metformin should be withheld until it is ensured that acute renal insufficiency has not been induced by the contrast media. Unlike phenformin, metformin rarely is associated with lactic acidosis if attention is paid to proper selection of patients.

Thiazolidinediones

Thiazolidinediones (TZDs), also known as glitazones, are a relatively new class of oral agents for the treatment of diabetes, first introduced in the late 1990s. In the United States, troglitazone became available in 1997 and rosiglitazone and pioglitazone in 1999, with several other TZDs in various stages of development. These agents act by binding to nuclear receptors called peroxisome proliferator-activated receptors (PPARs), specifically to the PPAR γ subtype (PPAR γ). This results in the expression of a number of gene-encoding proteins that enhance cellular insulin action on glucose and lipid metabolism. As a consequence, there is improvement in insulin sensitivity, particularly resulting in increased peripheral (muscle and adipose) glucose uptake and utilization, with a modest effect on the liver to inhibit glucose production. The TZDs have been shown to improve insulin action in type II diabetes, in impaired glucose tolerance, and in obese people with normal glucose tolerance.

TZDs are most effective in combination with insulin in type II diabetes. This combination can achieve both lowering of insulin dose and improvement in glycemic control. In fact, some patients previously refractory to glucose lowering in spite of large doses of insulin may experience control of their diabetes on this regimen. TZDs are also effective in combination with secretagogues, metformin, or both (so-called triple therapy). Unfortunately, in monotherapy the response rate varies, and there is no easy way to anticipate who will be a responder. Rosiglitazone and pioglitazone appear to have a higher response rate than troglitazone, but troglitazone is no longer labeled as approved for monotherapy.

Advantages of TZDs include improvement in a primary pathophysiologic impairment, that of insulin resistance; a unique mechanism of action that allows it to be combined with any other class of glucose-lowering agent; once-daily dosing; lowering of serum triglycerides and increase in HDL cholesterol; and the fact that some agents may be used in the context of renal insufficiency. The biggest disadvantage is that troglitazone has been associated with idiosyncratic liver disease, which in some cases has led to acute hepatic necrosis, resulting either in death or the need for liver transplantation. As a consequence, the product label notes the recommendation that liver enzyme levels be measured at the start of therapy and monthly thereafter. Nonetheless, in spite of monitoring, some cases of severe liver dysfunction have been missed. Although this is a rare problem, it is unpredictable. Fortunately, however, the clinical trial experience with rosiglitazone and pioglitazone suggests that these agents may not carry this risk of liver disease. It is hoped that this finding will be confirmed in the clinical arena. Other disadvantages of TZDs include the fact that there is a delayed onset of action (up to 3 weeks) and a prolonged time before the full effect becomes evident (up to 8 to 12 weeks); weight gain; a relatively high lack-of-response rate in monotherapy; increased levels of LDL cholesterol; and unknown long-term side effects (stemming from the fact that this is a relatively new class of drugs).

α -Glucosidase Inhibitors

The α -glucosidase inhibitors compete with carbohydrates for binding to the α -glucosidase enzymes (sucrase, maltase, isomaltase, amylase, glucoamylase) in the intestinal brush border. This results in slowing of digestion of complex carbohydrates, oligosaccharides, and disaccharides, with consequent retardation of gastrointestinal glucose absorption and reduction in postprandial glycemic excursions. There is a consequent modest improvement in Hb A_{1c}, which, on average, is about 0.5% to 1%. Although these inhibitors occasionally are used alone, their primary role is in combination with other agents when glycemic targets are not met. There are several α -glucosidase inhibitors. In the United States, acarbose became available in 1996 and miglitol in 1999; voglibose is in clinical trials. Carbohydrates are retained in the gastrointestinal tract. As a consequence, there frequently are gastrointestinal side effects, including a high rate of flatulence, which often is severe; nausea; abdominal discomfort; borborygmi; and diarrhea. These effects can be minimized, to some extent, by slow-dose titration to therapeutic levels.

Advantages of α -glucosidase inhibitors include a good safety profile, lack of weight gain with improved glycemic control, and a unique mechanism of action that allows these drugs to be combined with any other class of glucose-lowering agent. Disadvantages of α -glucosidase inhibitors include the need for a high-carbohydrate diet for efficacy, since these are competitive enzyme inhibitors; flatulence and other gastrointestinal side effects; a limited impact on FPG; and the necessity for caution in the treatment of hypoglycemia. Because the enzymes are inhibited, hypoglycemia cannot be treated with sucrose, maltose, or starch, since glucose is not readily available for absorption. Lactose (milk) may be used to treat hypoglycemia, however, because lactase is a α -glucosidase. Monosaccharides (glucose or fructose) may be used to correct hypoglycemia.

Weight Loss Agents

Effective control of weight leads to improved glucose control as well. Therefore, agents that expedite weight loss may be helpful in facilitating glycemic control. There are two weight-loss agents available in the United States—sibutramine, an inhibitor of serotonin and norepinephrine reuptake that limits food intake, and orlistat, an inhibitor of gastrointestinal lipases that blocks systemic absorption of dietary fat. Both have been used in patients with type II diabetes with modest success. One disadvantage is that sibutramine is associated with blood pressure elevation. Another is that because of retained fat in the gastrointestinal tract, orlistat often causes fat loss in stools, with resulting greasy bowel movements.

Other Pharmacologic Approaches

A number of therapeutic agents are under development. These agents include compounds that overcome insulin resistance, enhance insulin secretion, retard glucose absorption, increase thermogenesis (facilitating weight loss), inhibit gluconeogenesis, and suppress fatty acid oxidation. All have potential glucose-lowering effects.

INSULIN IN TYPE II DIABETES

The primary pathophysiologic defects in type II diabetes are impairment in B-cell function and resistance to insulin action. Although it has been argued that insulin is not an effective therapy in type II diabetes because insulin deficiency per se is not the primary defect, it is possible with insulin therapy to overcome insulin resistance and to ensure insulin availability in the face of islet B-cell dysfunction. Moreover, given the aggravation of the pathophysiologic defects with glucose toxicity, insulin therapy can be used effectively to overcome glucose toxicity and restore the potential effectiveness of other therapies, making maintenance of the improved metabolic state easier. Such a “feed-forward” system would explain the clinical aphorism that it is *much easier to maintain glucose control than it is to attain glucose control*.

Temporary Insulin Therapy

One important use of insulin is as temporary initial therapy to attain glycemic control in patients with severe type II diabetes, to overcome glucose toxicity, and to re-regulate decompensated patients. Indeed, type II diabetes may be considered a disease of periodic decompensation with the need for re-regulation, usually with insulin therapy. For this reason, all patients with type II diabetes should learn insulin administration techniques and be prepared to initiate insulin therapy in the face of expected periodic decompensation, which occurs spontaneously and particularly with intercurrent illness or stress.

Combination Insulin Therapy

Over the past several decades, the use of combinations of insulin and oral antidiabetic agents has grown in popularity. One popular program has combined oral medication with the use of bedtime intermediate-acting insulin to control fasting hyperglycemia. All of the classes of oral medication have been used successfully with insulin. In particular, the combination of metformin with bedtime intermediate-acting insulin is effective in improving glycemic control and does so without hypoglycemia or weight gain. By restoring responsiveness to insulin, the TZDs are quite successful in improving glycemic control in patients on large doses of insulin.

Ongoing Insulin Therapy

If insulin therapy is used for patients with moderate type II diabetes (FPG 140 to 250 mg per deciliter), it is often sufficient to use basal insulin therapy to correct fasting hyperglycemia, with endogenous insulin secretion being adequate to control meal-related, postprandial glucose excursions. Basal insulin therapy may be provided as a bedtime dose of intermediate-acting insulin (NPH or lente), as long-acting ultralente insulin to supplement basal insulin secretion, or as a continuous insulin infusion. Doses required usually are in the range of 0.3 to 0.6 U per kilogram per day. When intermediate-acting insulin is administered at bedtime, its peak effect 8 to 10 hours later coincides with the period before breakfast, thus controlling basal (fasting) glycemia.

For patients with severe type II diabetes (FPG more than 250 mg per deciliter), clinical experience has shown that around-the-clock administration of insulin is necessary. Thus, in contrast to patients with moderate type II diabetes, bedtime intermediate-acting insulin cannot be used (though twice-daily intermediate-acting insulin may be used). Most patients with severe type II diabetes require a more intensive insulin program (with addition of regular insulin) to attain glucose control. Necessary doses are usually in the range of 0.5 to 1.2 U per kilogram per day. Large doses, even in excess of 1.5 U per kilogram per day, may be needed, at least initially, to overcome prevailing insulin resistance. Such high-dose therapy may be necessary only to attain control, with subsequent control maintained on lower doses—on a basal insulin program or with oral hypoglycemic agents. Often, insulin therapy is continued at doses in the range of 0.3 to 1.0 U per kilogram per day. The use of premixed insulin preparations (70/30, which contains 70% NPH and 30% regular insulin) may facilitate implementation of such programs. Another option is to attain glycemic control through the use of continuous insulin infusion, with subsequent maintenance of control as outlined previously. Patients with very severe type II diabetes are severely insulin deficient and need to be treated like patients with type I diabetes.

In all categories of patients with type II diabetes, there is improvement of the pathophysiologic defects as glycemic control is attained and maintained. This facilitates ease of control and may permit patients initially treated with insulin to be maintained on oral hypoglycemic therapy or even a diet and activity program alone. The insulin dose can be adjusted to lower and lower amounts; when the dosage reaches less than 0.3 to 0.4 U per day, maintenance on oral antidiabetic agents can be considered. For most patients, type II diabetes can be controlled with insulin, if adequate doses are given and if the patient follows an appropriate MNT and exercise program. The latter factors facilitate the action of insulin. Failure to follow a proper diet may counter the effects of insulin and lead to a vicious cycle of progressively increasing insulin doses, yet failure to control glycemia. In patients already on insulin therapy who are experiencing inadequate glycemic control, it is often desirable to add an insulin sensitizer—either metformin or a TZD—in an effort to improve insulin action and gain better glycemic control.

ASSESSMENT AND MONITORING OF TYPE II DIABETES

Office measurement of glycosylated hemoglobin (Hb A_{1c} or Hb A₁) and FPG should be carried out quarterly to judge glycemic control in patients with type II diabetes. The level obtained from a laboratory plasma glucose measurement may be useful for comparison with the value obtained simultaneously by the patient using his or her own monitoring system. A lipid profile (total cholesterol, fasting triglycerides, high-density lipoprotein cholesterol, and low-density lipoprotein cholesterol) should be assessed annually. If treatment is instituted for dyslipidemia, the appropriate laboratory measurement should be repeated as needed to monitor therapy. If all values are within acceptable limits, the clinician may consider obtaining this lipid profile less frequently. The patient should monitor fasting blood glucose levels on a daily basis. In addition, insulin-treated patients should take at least one additional daily reading—either before meals or at bedtime. Once every 1 to 2 weeks, patients should take a profile, including fasting, preprandial, and bedtime measurements.

THERAPY OF ACUTE DECOMPENSATED DIABETES

THERAPY OF DIABETIC KETOACIDOSIS

The first priority of treatment of diabetic ketoacidosis (DKA) is to restore intravascular volume to normalize tissue perfusion and aid in the delivery of insulin to target organs. Treatment is aimed at restoration of body water and electrolytes. There must be provision of adequate insulin to correct the defects in carbohydrate, fat, and protein metabolism. Other priorities are the treatment of infection and circulatory collapse, if present. Treatment must be energetic yet not so vigorous as to result in hypoglycemia, hypokalemia, or cerebral edema, all of which are potentially disastrous complications of therapy.

Patients with DKA and mild degrees of acidemia who are able to tolerate increased oral fluids can be treated at home, with supplemental regular insulin before meals in addition to their usual daily regimen. With moderate to severe ketoacidosis, volume depletion, or vomiting, the patient requires hospitalization. Fluid and electrolyte replacement is critical and should be vigorously pursued. Average fluid losses are 10% of body weight. Electrolyte losses, notably of sodium and chloride but also of potassium and phosphate, need to be corrected as well. Close, careful clinical and biochemical monitoring of the patient is a mandatory component of therapy. A prospective flow sheet should be used.

Isotonic solutions are the fluids of choice; hypotonic solutions run the risk of rapid reduction of plasma osmolality, with large fluid shifts precipitating cerebral edema and hypovolemia. Appropriate solutions are either 0.9% saline or, alternatively, one ampule (50 mEq) of sodium bicarbonate (plus appropriate potassium supplements) added to each liter of 0.45% saline. The latter solution has several advantages. First, its osmolality is close to physiologic but hypotonic relative to plasma, thus minimizing fluid shifts. Second, it provides sodium at a higher rate than chloride, thus minimizing the likelihood of the development of hyperchloremic acidosis with treatment. Last, when given slowly over an hour or more, bicarbonate therapy does not cause any of the adverse consequences sometimes associated with a bolus dose. In adult patients with DKA, fluid is given at a rate of 1 to 2 L over the first hour and 1 L per hour for the next 3 to 4 hours, then decreased and maintained according to intake and output measurements and clinical assessment of the patient's state of hydration, supplemented by central venous pressure readings (if available). When the plasma glucose level falls to 250 to 300 mg per deciliter, glucose is included in the intravenous fluids to prevent hypoglycemia and to permit intravenous insulin infusion to be continued until acidosis is resolved. The goal is to restore the normal metabolic state gradually, without creating complications due to treatment.

Serum potassium levels do not reflect total body levels accurately. Potassium deficiency puts patients at risk for cardiac arrhythmias or arrest, particularly if potassium levels decline further with correction of acidosis and hyperglycemia. Therefore, unless the patient has anuria, potassium supplementation is initiated immediately in the course of treatment, at a rate of 10 to 40 mEq per hour in adult patients, depending on initial and subsequent repeated potassium determinations, the degree of acidosis, and the development of electrocardiographic changes. The goal is to aim for a serum potassium of 4 to 5 mEq per liter, as follows:

- If the serum K⁺ is less than 3 mEq per liter, potassium is infused at 40 mEq per hour.
- If the serum K⁺ is 3 to 4 mEq per liter, potassium is infused at 30 mEq per hour.
- If the serum K⁺ is 4 to 5 mEq per liter, potassium is infused at 20 mEq per hour.
- If the serum K⁺ is 5 to 6 mEq per liter, potassium is infused at 10 mEq per hour.
- If the serum K⁺ is greater than 6 mEq per liter or there are hyperkalemic T-wave changes on the electrocardiogram, potassium infusion is withheld.

Although deficient total body levels of phosphate invariably exist in DKA, serum phosphate levels do not accurately reflect them. Phosphate deficiency is associated with low 2,3-diphosphoglycerate levels, rhabdomyolysis, and respiratory muscle weakness, particularly if phosphate levels decline further with treatment of acidosis and correction of fluid depletion and hyperglycemia. Nevertheless, the issue of phosphate supplementation is the subject of controversy. The major concern is the potential of inducing hyperphosphatemia and resultant hypocalcemia. Therefore, phosphate should be withheld during the initial few hours of treatment of DKA, to avoid aggravation of preexisting hypocalcemia. Afterward, phosphate supplementation can be initiated using half potassium phosphate and half potassium chloride.

The use of bicarbonate in the treatment of DKA also is debated. There are good arguments on both sides of the issue. On the one hand, there are severe potential adverse effects of acidosis, including depressed cardiac and respiratory function, arrhythmias, and hypotension. On the other hand, overzealous bolus bicarbonate use aggravates hypokalemia, may lead to metabolic alkalosis, can result in paradoxical induction of cerebral spinal fluid acidosis (due to disparities in the rates by which HCO₃⁻ and carbon dioxide cross the blood-brain barrier), and may contribute to the development of cerebral edema. Early bolus administration of bicarbonate also can prolong ketonemia. Therefore, universally accepted guidelines for bolus bicarbonate administration are difficult to formulate. Its use probably should be restricted to cases of very severe acidemia (pH less than 7.0) or less severe acidemia (pH 7.0 to 7.1) with severe underlying medical problems (myocardial infarction, cardiac arrhythmias, sepsis).

Insulin administration is vital to treatment and is initiated immediately, unless there is evidence of severe hypovolemia or hypokalemia. Low doses of insulin are as effective as high doses for treating hyperglycemia and ketoacidosis; they help avoid the development of hypoglycemia and hypokalemia, which may occur with high doses. An initial priming dose of 0.1 U of regular insulin per kilogram body weight as an intravenous bolus is followed by a continuous infusion of regular insulin at a rate of 0.1 U per kilogram per hour. This infusion may be adjusted approximately every 2 hours according to glycemic levels, which should fall at a rate of 50 to 100 mg per deciliter per hour. The infusion is continued until the plasma glucose level falls to 200 to 300 mg per deciliter, after which it may be cut back to 0.05 U per

kilogram per hour, with the infusion maintained for at least 6 hours after acidosis has resolved.

THERAPY OF HYPEROSMOLAR HYPERGLYCEMIC NONKETOTIC COMA

The first priority of therapy is to restore intravascular volume. Fluid replacement also lowers plasma glucose levels by hemodilution and by improvement in renal blood flow and glucose excretion. Fluid replacement considerations are similar to those in the management of DKA, but fluid typically is replaced at slower rates because of the fragility of these usually elderly patients, who often have compromised cardiovascular or renal systems. The actual rate of fluid replacement is individualized, based on clinical assessment of the patient's status. The initial rate of fluid replacement generally is restricted to 1 L per hour until peripheral perfusion is normalized. Hypotonic fluids then are given at a rate approximately equal to twice urine output. The goal is gradual restoration of a normal metabolic state. In patients with hyperosmolar hyperglycemic nonketotic coma, who are profoundly volume depleted and often hypotensive, insulin therapy is withheld until the volume status is normalized, because the movement of glucose and water from the extracellular to the intracellular fluid compartment may precipitate shock. Low doses of insulin are used.

CHAPTER 400: APPROACH TO THE PATIENT WITH HYPOGLYCEMIA

F. JOHN SERVICE

[Definition](#)
[Symptoms](#)
[Classification](#)
[Evaluation](#)

DEFINITION

Hypoglycemia is a clinical syndrome arising from diverse causes, in which low levels of plasma glucose eventually lead to neuroglycopenia.

SYMPTOMS

Symptoms of hypoglycemia may begin at plasma glucose levels of approximately 60 mg per deciliter and impairment of brain function at approximately 50 mg per deciliter. The rate of plasma glucose decline does not influence the occurrence of symptoms. Hypoglycemic symptoms have been classified into two major groups: autonomic and neuroglycopenic. Symptoms of hypoglycemia differ among patients but are usually consistent from episode to episode for each patient. Autonomic symptoms (sweating, trembling, anxiety, nausea, palpitation, hunger, tingling) do not always precede neuroglycopenic symptoms (confusion, abnormal behavior, visual disturbance, seizure). In many patients, neuroglycopenic symptoms are the only ones experienced. None of the previously listed symptoms is specific to hypoglycemia; the presence of one or several may be due to other causes.

CLASSIFICATION

The long-established classification of hypoglycemia as fasting is no longer useful because segregation by timing does not result in different nosologic entities. A more useful approach is a classification based on clinical characteristics ([Table 400.1](#)). Persons who appear healthy are likely to have different hypoglycemic disorders from those experienced by persons who are ill. Hospitalized patients are at additional risk for hypoglycemia, often from iatrogenic factors. Hypoglycemia may stem from accidental drug ingestion in healthy persons, the mistaken dispensing of a sulfonylurea, or the idiosyncratic actions of some of the drugs used in the treatment of seriously ill patients. The occurrence of symptoms in a patient with an illness known to be associated with hypoglycemia requires little, if any, investigation, only recognition of the association of the disease with the risk for hypoglycemia. Asymptomatic patients may have artifactual hypoglycemia due to leukemia or severe hemolysis or may have adapted to lifelong hypoglycemia caused by glycogen storage disease.

TABLE 400.1. CLINICAL CLASSIFICATION OF HYPOGLYCEMIC DISORDERS

EVALUATION

A healthy-appearing patient with no coexisting disease who has a history of neuroglycopenic spells requires an approach quite different from that taken for a hospitalized patient with acute hypoglycemia.

THE HEALTHY-APPEARING PATIENT

Plasma Glucose Levels

Because symptoms of hypoglycemia are nonspecific, it is necessary to verify a low plasma glucose level at the time that spontaneous symptoms arise and to establish that symptoms are relieved through correction of the low glucose level ("Whipple's triad"). A normal plasma glucose level, reliably obtained when spontaneous symptoms are present, eliminates the possibility of a hypoglycemic disorder; no further evaluation is required. Glucose measurements made by the patient with a reflectance meter while experiencing spontaneous symptoms are likely to provide false information. Often, the measurement of the plasma glucose level is not feasible when spontaneous symptoms occur during the activities of ordinary life. Under such circumstances, a judgment by the physician about whether to proceed with further evaluation depends on a detailed history. A history of neuroglycopenic symptoms or a confirmed low (less than 50 mg per deciliter) plasma glucose level warrants further testing.

The Prolonged (72 Hour) Fast

The prolonged (72 hour) fast is the classic diagnostic test for hypoglycemia. It should be conducted following standardized procedures. A suggested protocol is shown in [Table 400.2](#). For patients who have neither symptoms nor signs of hypoglycemia and who do not show signs of severely depressed plasma glucose concentrations (less than 40 mg per deciliter), the fast should be terminated at 72 hours. Fasting, however, should be terminated before 72 hours should a patient have both symptoms of hypoglycemia and a plasma glucose level in the hypoglycemic range or, in the case of a patient previously shown to satisfy Whipple's triad, a plasma glucose level less than 55 mg per deciliter. The decision to end the fast may not be easy for the house officer to make. Because of possible delays in the availability of the results of plasma glucose testing, the bedside reflectance meter may have to serve as a guide to glucose levels. Careful examination and testing for subtle signs or symptoms of hypoglycemia should be carried out repeatedly when the patient's plasma glucose level is near or in the hypoglycemic range.

1. Date the onset of the fast as of the last ingestion of calories. Discontinue all nonessential medications.
2. Allow the patient to drink calorie-free and caffeine-free beverages.
3. Ensure that the patient is active during waking hours.
4. Measure plasma glucose, insulin, and C-peptide levels and, if an assay is available, proinsulin in the same specimen; repeat measurements every 6 hours until the plasma glucose is <60 mg/dL, when the interval should be reduced to every 1-2 hours.
5. End the fast when the plasma glucose is <45 mg/dL and the patient has symptoms and/or signs of hypoglycemia or <55 mg/dL when Whipple's triad is not the goal.
6. At the end of the fast, measure plasma glucose, insulin, C-peptide, proinsulin, β -hydroxybutyrate, and sulfonylurea levels in the same specimen; then inject 1 mg of glucagon IV and measure plasma glucose after 10, 20, and 30 minutes. Then feed the patient.
7. When a deficiency is suspected, measure plasma cortisol, growth hormone, or glucagon at the beginning and end of the fast.

TABLE 400.2. PROTOCOL FOR PROLONGED SUPERVISED FASTS

Criteria for hyperinsulinemic hypoglycemia are the following: a plasma insulin level ≥ 6 μU per milliliter (radioimmunoassay) or ≥ 3 μU per milliliter (ICMA), a C-peptide value ≥ 200 pmol per milliliter (ICMA), a proinsulin level ≥ 5 pmol per milliliter (ICMA), a b-hydroxybutyrate level ≥ 2.7 mmol per liter, an increment of plasma glucose in response to 1 mg glucagon i.v. ≥ 25 mg per deciliter, and absence from the plasma of first- and second-generation sulfonylureas. These criteria apply whether hypoglycemia develops in the fasting state or after meals, that is, 2 to 4 hours pc.

Ratios of glucose to insulin are useless for identification of relative hyperinsulinemia. Not infrequently, it becomes apparent that a patient undergoing a history and physical examination after fasting overnight is frankly hypoglycemic at that time or has a plasma glucose close to the hypoglycemic range. In the former instance, all the measurements recommended for the end of the prolonged supervised fast should be made at that time in the outpatient setting. In the latter instance, the fast protocol should be initiated in the outpatient setting. Often, Whipple's triad can be verified (i.e., completion of the fast) before the end of the business day; if not, the patient is admitted to the hospital to complete the fast.

C-Peptide Suppression Test

The C-peptide suppression test may be used as a screening test. Interpretation of the C-peptide suppression test requires normative data appropriately adjusted for the patient's body mass index and age.

Insulin Antibodies

The presence of insulin antibodies, once considered to be firm evidence of factitious hypoglycemia due to self-administered insulin, (when animal insulin was the only type commercially available), at present (in the era of human insulin use) is diagnostic of insulin autoimmune hypoglycemia, especially if titers are high.

Localization Studies

Once a diagnosis of endogenous hyperinsulinemic hypoglycemia has been made, an attempt should be made to localize the tumor. Success with various procedures—transabdominal ultrasonography, endoscopic ultrasonography, triple-phase computed tomography, angiography, octreoscan—varies with local skill and experience. Transhepatic portal venous sampling has been abandoned in most tertiary centers. The selective arterial calcium stimulation test not only regionalizes the lesion but also is a useful dynamic test to identify hyperfunctioning islet cell tissue.

Clinical Features

Insulinoma may develop at any age; it is more common in women and has an estimated incidence of one case per 250,000 patient-years. Multiple endocrine neoplasia type 1 syndrome (MEN1), multiplicity, and malignancy occur in less than 10% of cases. The tumor recurrence rate is less than 10% without MEN1 and 20% with MEN1. Long-term survival in the context of benign insulinoma is normal. Treatment is surgical removal.

Factitious hypoglycemia, whether from sulfonylurea or insulin use, is probably more common than reported. It may result from self-injury or may play a part in suicide, homicide, or child abuse. Perpetrators are more frequently women in a health-related occupation or those who have diabetes. Treatment is discontinuation of the drug. Insulin autoimmune hypoglycemia is extraordinarily rare, reported mostly but not exclusively in Asians of all ages without gender preference. Often, there is a history of antecedent autoimmune disease or use of drugs containing sulfhydryl. Insulin antibody titers are high. Often spontaneous remission occurs. There is no known effective treatment. Noninsulin pancreatogenous hypoglycemia syndrome is a newly described entity of neuroglycopenia occurring postprandially primarily in men who have negative results on 72-hour fast, negative results on radiologic localization studies, positive outcomes on calcium stimulation tests, amelioration of symptoms by gradient-guided partial pancreatectomy, and presence of islet hyperplasia and nesidioblastosis in resected pancreata.

THE ILL-APPEARING PATIENT

In persons with coexisting disease, it may be sufficient to recognize the underlying disease and its association with hypoglycemia and to take action to minimize recurrences of hypoglycemia. Confirmation of the suspected source of hypoglycemia may be sought, for example, low insulin and C-peptide levels in ethanol hypoglycemia, elevated insulin-like growth factor II levels in non-B-cell tumor hypoglycemia, low levels of cortisol in adrenal insufficiency, and blunted plasma glucose responses to intravenous glucagon in hypoglycemias due to abnormal liver function (glycogen storage disease, sepsis, and congestive heart failure).

Hospitalized patients are often severely ill with multisystem disease. They are at risk for iatrogenic forms of hypoglycemia (insulin added to total parenteral nutrition) as well as for any type of hypoglycemia that may be produced by the underlying disease. In determining the cause of hypoglycemia in a hospitalized seriously ill patient, diligent examination of the record may be more profitable than examination of the patient.

CONCLUSION

The diagnosis of a hypoglycemic disorder requires a high level of suspicion, careful assessment of the patient for the presence of mediating drugs or a predisposing illness, and, where indicated, methodical evaluation of the basis of well-defined diagnostic criteria. The diagnostic burden is heaviest for healthy-appearing persons with episodes of confirmed neuroglycopenia. The insulin mediation of hypoglycemia are a plasma insulin level ≥ 6 μU per milliliter (radioimmunoassay), a C-peptide value ≥ 200 pmol per liter (ICMA), a proinsulin level ≥ 5 pmol per liter (ICMA), a b-hydroxybutyrate value ≥ 2.7 mmol per liter, and generous (≥ 25 mg per deciliter) response of plasma glucose to i.v. glucagon administered when the patient is hypoglycemic. Sulfonylurea should be sought in the plasma of any hypoglycemic patient, especially by an assay that can detect the second-generation of these drugs.

CHAPTER 401: APPROACH TO THE PATIENT WITH FLUSHING

JEROME M. FELDMAN

[Pathophysiology](#)
[Physiologic Flushing](#)
[Ethanol Ingestion](#)
[Neoplastic Diseases](#)
[Diagnostic Tests](#)

Flushing, or blushing, is a transient reddening of the skin resulting from vasodilation. Although it occurs most commonly in the face and neck, the chest, abdomen, arms, and legs can be affected. Facial flushing often is accompanied by increased facial perspiration and a subjective feeling of facial warmth. The flushing can last for minutes, hours, or even days. The cause of flushing in most patients is not serious. In a few patients, however, it is the first sign of a neoplasm. Not all patients with a red face have flushing; patients with lupus erythematosus, seborrhea, or drug-induced photosensitivity reactions may have red faces without flushing.

PATHOPHYSIOLOGY

In some individuals, vasodilation of the superficial capillary loops of the skin is caused by altered sympathetic tone from the central nervous system. In others, it results from a circulating neurohumor released by a normal or pathologic condition. The neurohumors that have been suggested to play a role in flushing include histamine, serotonin, bradykinin, substance P, prostaglandins, and endorphins.

PHYSIOLOGIC FLUSHING

In response to embarrassment or nervousness, healthy individuals may flush. In an attempt to dissipate heat, they also may flush after drinking a hot beverage or during a febrile illness. Individuals who flush can be divided into three types: psychologically sensitive, physiologically sensitive, and anatomically predisposed. At the time of spontaneous menopause, 40% to 50% of women experience flushing. This type of flushing also is common after surgical removal of the ovaries and after damage to or surgical removal of the testes. Although the mechanism of the vasomotor instability that develops after the loss of gonadal function is not completely understood, flushing usually responds dramatically to the replacement of estrogen in women and testosterone in men.

ETHANOL INGESTION

The ingestion of ethanol can provoke flushing in normal individuals, particularly those of Asian ancestry. Medications such as nicotinic acid, b-adrenergic antagonists, calcium channel antagonists, and nitroglycerin can produce spontaneous flushing. Other groups of medications sensitize patients to ethanol-induced flushing. These include antimicrobial agents, such as cephalosporins, chloramphenicol, griseofulvin, quinacrine, furazolidone, and metronidazole; drugs used to treat chronic alcohol abuse, such as disulfiram and calcium carbamide; the calcium channel blockers, such as verapamil and nifedipine; and sildenafil, a medication for erectile dysfunction. Medications that interfere with gonadal function, such as leuprolide, flutamide, danazol, tamoxifen, and clomiphene citrate, also provoke flushing.

NEOPLASTIC DISEASES

Patients with islet cell tumors that secrete vasoactive intestinal polypeptide, gastrin, or insulin occasionally have attacks of facial flushing. Although most patients with pheochromocytoma have facial pallor, a few patients with these catecholamine-secreting tumors experience flushing. Patients with medullary carcinoma or even lymphoma sometimes have facial flushing after ethanol ingestion. Some patients with systemic mastocytosis have attacks of facial flushing. The neoplastic condition most often associated with episodes of flushing is carcinoid tumor and the carcinoid syndrome. Carcinoid tumors have been reported to originate in virtually every organ in the body. The two most common sites are the ileum and the bronchus. In some patients who ultimately prove to have carcinoid syndrome, episodes of facial flushing precede the diagnosis by 15 years. If a patient describes flushing attacks within 10 minutes of ingesting ethanol, the rapidity of onset is suggestive of carcinoid syndrome.

The character of flushing attacks in carcinoid syndrome varies. One type lasts a few minutes and leaves no residual redness. Another type lasts only a few minutes but results in residual telangiectasia. A third type lasts for hours to days and causes lacrimation and furrowing and edema of the brow, and a fourth type produces a bright red, but patchy flush. The first two types of flushing can be caused by a carcinoid tumor arising from any anatomic site, the third type can originate in the bronchus, and the fourth type can originate in the stomach.

DIAGNOSTIC TESTS

The most serious diseases to be ruled out in a patient with flushing are systemic mastocytosis and carcinoid syndrome. Systemic mastocytosis can be excluded by measuring histamine in plasma and urine or by measuring methylhistamine or imidazole acetic acid in urine. Punch biopsy of the skin with stains for mast cells also is helpful. Carcinoid syndrome can be dismissed by measuring serotonin in platelets, serum, or urine or by measuring 5-hydroxyindoleacetic acid, the principal metabolite of serotonin, in urine.

irradiation to the head and neck region.

Clinical Features and Prognosis

The widespread use of multiphasic screening has had a significant effect on the modern clinical features of primary hyperparathyroidism. Whereas patients with this disorder traditionally had symptoms of kidney (nephrolithiasis) or bone disease or protean symptoms referable to prolonged hypercalcemia, today they often have no symptoms whatsoever. Eighty percent of patients with primary hyperparathyroidism have no complaints at the time of diagnosis, and it is common for mild, asymptomatic hypercalcemia to persist for years with little progression. In some patients, however, symptoms attributable to the disease develop insidiously.

Nephrolithiasis causes renal colic, hematuria, and passage of stones or gravel. Although the incidence of this complication has declined over the years, it still occurs in 15% to 20% of the population at risk. The incidence of hypercalciuria has remained constant (35% to 40%), however, and urinary calcium excretion is no higher in patients with primary hyperparathyroidism who have renal stones than in those who do not. Rarely, affected patients also have nephrocalcinosis, radiographic features of diffuse renal calcification, and a diminished glomerular filtration rate.

Bone symptoms, when present, include pain and tenderness, usually over areas of increased bone turnover, such as the tibial periosteum; recurrent back pain stemming from vertebral compression fractures or progressive kyphosis; and abnormal fractures at the sites of bone cysts. This complication is rare (less than 2%), however, and subperiosteal resorption, salt-and-pepper changes in the skull, bone cysts, and brown tumors are so unusual that skeletal radiographs no longer are taken routinely in the diagnostic evaluation of patients with primary hyperparathyroidism.

Nonspecific symptoms or those related to hypercalcemia can include muscle weakness, depression, memory impairment, personality changes, pruritus, anorexia, constipation, polyuria, and polydipsia. Occasionally, intercurrent illness, dehydration, or immobilization triggers an episode of acute hypercalcemia. Serum calcium in these cases can climb rapidly to levels of 15 to 20 mg per deciliter. In addition, an inordinate concurrence has been found between primary hyperparathyroidism and other disease states, such as peptic ulcer, chondrocalcinosis, pancreatitis, and hypertension. It remains difficult to associate these complications directly with the hyperparathyroid state itself. With severe or prolonged hypercalcemia, corneal calcification (band keratopathy), anemia, weight loss, mental obtuseness, or coma and death can occur.

Although many biochemical tests have been advocated for the identification of parathyroid-related disorders, none are as discriminating as PTH immunoassays. More than 90% of patients with primary hyperparathyroidism found at surgery have elevated intact PTH levels. Assays for intact PTH involve the immunoradiometric technique, which uses two different antibodies against two different regions of the 84-amino-acid peptide. Immunoradiometric assays have substantial sensitivity and can detect levels of intact PTH within the normal range. These assays are helpful in distinguishing primary hyperparathyroidism from virtually all other causes of hypercalcemia. The only exceptions are hypercalcemia resulting from thiazide diuretic and lithium use and familial hypocalciuric hypercalcemia. Hypercalcemic patients taking lithium or thiazides should be retested when drugs are discontinued, if possible, since both drugs can alter serum calcium and PTH secretion. In young, asymptomatic individuals who have mild hypercalcemia, a marginally elevated PTH determination may be due to familial hypocalciuric hypercalcemia rather than hyperparathyroidism (see later discussion).

The medical treatment of hyperparathyroidism is largely dependent on the serum calcium concentration. If hypercalcemia is severe and symptomatic, the calcium level must be lowered rapidly (see Medical Management of Hypercalcemia). In the absence of marked hypercalcemia, primary hyperparathyroidism presents a dilemma in management because most patients have no symptoms. Surgical resection of parathyroid tissue is the treatment of choice, but it is unclear whether it should be used for asymptomatic patients. Indications for parathyroidectomy are a history of renal stones, progressive bone disease, symptoms attributable to hypercalcemia, or a serum calcium level greater than 11.5 mg per deciliter. In less severe cases, the potential for increased bone loss, mental impairment, or hypercalcemic crisis with advancing age must be weighed against the risk of surgery. Evidence suggests that many asymptomatic patients with primary hyperparathyroidism do not experience progressive increases in serum calcium levels or reductions in bone mass. Nevertheless, serum calcium levels greater than 12 mg per deciliter; hypercalciuria; bone mineral density at cortical sites more than two standard deviations below age- and sex-matched control values; or specific complications, such as nephrolithiasis or bone disease, develop in at least 50% of asymptomatic patients and are clear indications for surgery. Because many asymptomatic patients eventually become surgical candidates, early surgical intervention may be most appropriate.

Unfortunately, we still lack an effective and safe therapeutic agent for the medical treatment of primary hyperparathyroidism. While oral phosphate will lower the serum calcium concentration in affected patients, the development of ectopic calcification in soft tissues, stemming from an increased calcium-phosphate product, and further elevation of the serum PTH levels have limited extensive use of this therapy. Estrogen has been advocated for postmenopausal women, but the known antagonism of this agent on PTH-mediated bone resorption has limited effects on the serum calcium concentration. More recently, bisphosphonates have been considered as a therapeutic intervention. Unexpectedly, studies of etidronate have proved this drug ineffective in the treatment of hypercalcemia, whereas investigations of dichloromethylene bisphosphonate show that this agent does not have sustained effects on the serum calcium concentration. Whether alendronate will prove efficacious in the management of primary hyperparathyroidism remains unknown. Finally, a new class of drugs, termed calcimimetics, is under study to determine whether altering the function of the extracellular calcium-sensing receptor might reduce PTH levels in primary hyperparathyroidism. Pilot studies have given credence to this approach, and larger clinical studies are under way to determine the usefulness of this management strategy.

Between 5% and 10% of patients who undergo cervical exploration for primary hyperparathyroidism have persistent or recurrent hyperparathyroidism requiring re-operation. Recent studies indicate, however, that the incidence of surgical failure may be lessened markedly through the use of intraoperative PTH immunoassay as a determinant of satisfactory resolution of the disease state. This procedure is cost-effective and accurate and may minimize the morbidity of surgical intervention in revision procedures. Indeed, given the increased risk of morbidity in re-operative parathyroid exploration and the higher probability of ectopic gland location after failed parathyroid exploration, preoperative localization of parathyroid tissue usually is warranted when an initial attempt at parathyroidectomy has been unsuccessful. Technetium-sestamibi localization studies are the most efficacious way to pinpoint cervical and mediastinal ectopic glands.

After successful surgery, transient mild hypocalcemia occasionally occurs but rarely requires treatment. In patients with extensive bone disease, however, severe and persistent hypocalcemia can arise as the result of "bone hunger." Acute treatment with calcium infusions and long-term management with oral calcium and vitamin D may be necessary. If normal parathyroid tissue remains, patients generally tolerate cessation of therapy.

Familial Hypocalciuric Hypercalcemia

Familial hypocalciuric hypercalcemia is a benign disorder with an autosomal dominant pattern of inheritance. It has a high rate of penetrance and is characterized by hypercalcemia and relative hypocalciuria. In the vast majority of patients the disease is caused by mutations in a gene on the long arm of chromosome 3 encoding a calcium-sensing receptor. Hypercalcemia often manifests during childhood, but patients usually remain asymptomatic throughout life. The PTH concentration usually is elevated slightly, though normal levels have been reported. Not surprisingly, subtotal parathyroidectomy does not resolve hypercalcemia.

The mildly elevated serum calcium level of familial hypocalciuric hypercalcemia results from enhanced renal tubular reabsorption of calcium. The defect in the calcium-sensing receptor, located in the parathyroid glands and kidneys, leads to exaggerated renal reabsorption of filtered calcium (and magnesium) and failure of the resultant hypercalcemia to suppress PTH secretion fully. As a consequence, the parathyroid glands invariably display pathologic changes suggestive of chief cell hyperplasia.

The finding of hypercalcemia in relatively young patients, with only a slight elevation of the serum PTH level and a family history of unsuccessful neck exploration for presumed parathyroid disease, should raise suspicion regarding the presence of this disorder. Hypermagnesemia and urinary calcium/creatinine ratios of less than 0.01:1 strongly support the diagnosis, as does documentation of hypercalcemia in first-degree relatives. In affected families, specific genetic diagnosis is possible by screening for mutations in the calcium-sensing receptor gene. Because nephrolithiasis, bone disease, and other complications of primary hyperparathyroidism or hypercalcemia do not occur often, conservative treatment is indicated. In general, these patients should not undergo neck exploration because subtotal parathyroidectomy fails to resolve hypercalcemia. Instead, once the diagnosis is made, continued observation for unexpected complications and avoidance of aggressive intervention are appropriate therapeutic strategies. In the rare situation where an adult has a complication, such as relapsing pancreatitis or a serum calcium level consistently greater than 14 mg per deciliter, total parathyroidectomy is recommended.

NON-PARATHYROID-RELATED HYPERCALCEMIA

Malignancy-associated Hypercalcemia

Many malignant diseases are complicated by the development of hypercalcemia. This complication results from osteolytic metastases (local osteolytic hypercalcemia), most often associated with solid tumors, such as carcinoma of the breast, kidney, lung, or thyroid; from hematologic malignant disorders with skeletal infiltration, such as multiple myeloma; or from humoral hypercalcemia, in which a humoral agent that causes hypercalcemia is produced and secreted by tumors not of parathyroid origin, such as squamous cell carcinomas (head and neck, esophagus, lung, cervix, vulva, skin), renal or bladder carcinomas, and ovarian malignancies.

Etiology

The mechanisms of action responsible for hypercalcemia associated with malignancy are heterogeneous, but the final common pathway leading to hypercalcemia in most cases is osteoclastic bone resorption. The agency underlying osteoclast-mediated acceleration of bone turnover in local osteolytic hypercalcemia remains uncertain. Most investigators agree that the osteolytic metastases probably produce paracrine or local cell-to-cell chemical messengers that activate or increase the production of osteoclasts. Several lymphokines, including tumor necrosis factor α (cachectin), tumor necrosis factor β (lymphotoxin), and interleukin-1, have been identified as potential osteoclast-activating factors involved in hypercalcemia associated with lymphoma and multiple myeloma. The production of these factors appears to be mediated by the local production of prostaglandin E_2 . Less commonly, hypercalcemia caused by osteolytic metastases can result, in part, from direct bone resorption by tumor cells.

In humoral hypercalcemia of malignancy, extensive evidence supports the role of a tumor-derived humoral agent in osteoclast activation, bone resorption, and consequent hypercalcemia. Most notably, affected patients have little or no evidence of skeletal tumor involvement, and resection of the primary tumor, when possible, leads to resolution of the hypercalcemia. Identification of the presumptive humoral factor has been impaired by the apparent heterogeneity of the syndrome. Nevertheless, several substances have been identified as mediators of humoral hypercalcemia. Although these substances include ectopically produced PTH, which was once considered to be the primary mediator of the syndrome, investigators have documented the production of authentic PTH by a source other than parathyroid tumor in a few patients. Instead, observations suggest that two classes of proteins mediate hypercalcemia in most patients with this paraneoplastic syndrome: PTH-related protein (PTHrP) and tumor-derived growth factors.

PTHrP has been identified in tumors of patients who have the humoral hypercalcemia of malignancy syndrome and displays biologic activity remarkably similar to that of PTH. This protein is larger than PTH, however. Even though it manifests partial homology, it does not react with antibodies directed at PTH and is derived from a gene distinct from that which encodes PTH. Moreover, antisera to PTHrP reverse many of the biochemical manifestations of the syndrome in vitro and in vivo, whereas those to PTH usually do not. Nevertheless, PTHrP and PTH bind with equivalent affinities to a common receptor, accounting for the very similar ranges of biologic activities of these hormones. Studies indicate that PTHrP is almost ubiquitous in normal tissues. It appears that PTHrP may play roles different from those initially identified, including differentiation of the skin and skin appendages, lactation, placental calcium transport, fetal calcium regulation, smooth-muscle function, and bone and chondrocyte development. PTHrP probably is a multipurpose autocrine–paracrine factor that is produced in excess amounts by the malignant transformation of normal squamous epithelial cells.

Tumor-derived growth factors (a and b classes) also have been identified in tumors of patients with humoral hypercalcemia of malignancy. These agents cause hypercalcemia when injected in vivo and are powerful stimulants of osteoclastic bone resorption. Moreover, they impair osteoblast function and probably decrease the bone formation rate, a common complication observed in the humoral hypercalcemia of malignancy syndrome. These agents can be extracted from virtually all tumors, however, including those that produce PTHrP, and their role in the paraneoplastic syndrome is uncertain. Nevertheless, it is probable that the tumor-derived growth factors and the PTHrPs act synergistically to produce the full spectrum of the malignancy-associated hypercalcemic syndrome.

Less often, the humoral hypercalcemia syndrome results from the elaboration of lymphotoxin, a multifunctional cytokine that is produced under normal circumstances by activated T lymphocytes. Convincing evidence suggests that this factor plays an important role in the bone destruction and hypercalcemia that occur in multiple myeloma. Established cultures of human myeloma cells produce this factor, and a major portion of bone-resorbing activity generated by these cells in vitro is accounted for by lymphotoxin. Lymphotoxin is not the only cytokine that has been implicated in myeloma, however. Several studies suggest that interleukin-1 and interleukin-6 have roles in bone destruction. Further investigations are necessary to indict these factors. Even though essentially all patients with myeloma experience extensive bone destruction, less than 40% become hypercalcemic. The explanation for this disparity rests with the observation that increased bone resorption likely leads to hypercalcemia only in the context of impaired glomerular filtration, a common abnormality in multiple myeloma.

In a small subset of patients with humoral hypercalcemia of malignancy, the elevated serum calcium concentration does not result from increased bone resorption but from enhanced production of calcitriol and consequent intestinal hyperabsorption of calcium. This mechanism has been described in some patients with T-cell lymphoma, B-cell lymphoma, Hodgkin's disease, and other types of lymphoproliferative disorders in which the neoplastic cells are the source of the active vitamin D metabolite. In most patients with lymphoma and hypercalcemia, increased calcitriol production is not a factor.

Incidence and Epidemiology

Studies indicate that hypercalcemia complicates various malignant disorders in 5% to 10% of hospitalized patients, and the incidence of humoral hypercalcemia of malignancy is equal to or greater than that of local osteolytic hypercalcemia, depending on the series of patients examined. Regardless of syndrome type, an elevated serum calcium concentration is a marker of advanced cancer in affected patients. Consequently, uncontrolled hypercalcemia contributes directly to death in only 25% of cases. Most patients die of progressive cancer or its complications, with only slightly elevated serum calcium values before death.

Clinical Features and Prognosis

Hypercalcemia of malignancy in general has clinical features similar to those of hyperparathyroidism per se but modified by symptoms referable to the underlying cancer. The complications of long-term primary hyperparathyroidism (nephrolithiasis and subperiosteal resorption of bone) rarely are encountered in these patients. This probably relates to the relatively short course of the malignant disease. Polyuria, polydipsia, dehydration, renal compromise, constipation, and varying degrees of neurologic dysfunction ranging from lethargy to coma are common symptoms, and patients with skeletal metastases often have significant bone pain or abnormal fractures. Although the relationship between tumor size and the presence of hypercalcemia is unclear, small occult tumors rarely cause malignancy-associated hypercalcemia. In contrast, osteolytic lesions can be the initial signs of malignancy in multiple myeloma or lymphoma.

In some patients with cancer, the onset of hypercalcemia seems to be unrelated to the malignancy. In these cases, the elevated serum calcium level may be provoked by recent immobilization, the use of thiazide drugs, prerenal or renal azotemia leading to inadequate renal calcium clearance, coincident hypophosphatemia, gastrointestinal fluid loss, or the administration of calcium as part of a hyperalimentation regimen. Such patients do not have the hypercalcemia of malignancy syndrome, and the serum calcium concentration normalizes with correction of the ancillary event. In less than 5% of patients, coincident primary hyperparathyroidism is the cause of hypercalcemia.

Abnormal or suppressed levels of immunoreactive PTH in conjunction with elevated urinary cyclic adenosine monophosphate (cAMP) excretion favors the presence of malignancy-associated hypercalcemia. The level of PTH observed is largely dependent upon the assay employed. Using a two-site immunoradiometric assay for PTH (1-84), several groups have found virtually universal suppression of PTH levels to values below normal. In contrast, levels that approach (within 25%) only the lower limits of the reference range are obtained with midregion-specific immunoassays. Conversely, immunoreactive PTHrP values are elevated in the majority of patients with malignancy-associated hypercalcemia. In this regard, immunoradiometric assays measuring large N-terminal species of PTHrP discriminate affected patients most effectively. Nonetheless, not all patients with hypercalcemia caused by malignancy will have elevated levels of PTHrP. Approximately 20% of patients, generally those with decreased urinary cAMP excretion (and likely osteolytic hypercalcemia), will have normal or suppressed values. Discrimination of malignancy-associated hypercalcemia is also limited by increased levels of C-terminal PTHrP in renal insufficiency, elevated N-terminal levels associated with nonmalignant pheochromocytomas, and increased PTHrP in a few patients with mammary hypertrophy or lymphedema.

Despite the suppressed PTH concentration, the hypercalcemia of malignancy syndrome bears a strong clinical resemblance to the hyperparathyroid state. In this regard, patients with both clinical disorders manifest reduced renal tubular reabsorption of phosphorus and consequent phosphaturia, a lower serum phosphorus concentration, elevated urinary cAMP levels, and increased markers of bone resorption. Several clinical features distinguish hypercalcemia of malignancy from primary hyperparathyroidism. While osteoblastic bone formation is amplified and coupled to the increased bone resorption rate in patients with hyperparathyroidism, in patients with malignancy and hypercalcemia, osteoblastic bone formation is diminished. In addition, patients with hypercalcemia of malignancy often have

low-normal to frankly low calcitriol levels, in contrast to patients with primary hyperparathyroidism, who have high-normal or elevated calcitriol levels. However, this discrepancy is not invariable. Studies suggest that in the absence of bone metastases, patients with malignancy-associated hypercalcemia may show an elevated serum calcitriol level. A significant correlation between serum PTHrP and calcitriol concentrations in patients without bone metastases supports this possibility. These findings suggest that in metastatic disease, locally produced factors can override the effects of PTHrP on vitamin D metabolism.

In general, hypercalcemia in patients with cancer has grave prognostic significance. Many studies indicate that the median survival term of such patients varies from 1 to 6 months. In most cases, the shortened life span is not related to uncontrolled hypercalcemia. The elevated serum calcium level is a marker of advanced cancer, and death results from the progress of this disease or its complications. Treatment of hypercalcemia has little effect on the patient's survival, but it does ameliorate polyuria, polydipsia, central nervous system abnormalities, nausea, vomiting, and constipation and often allows patients to be cared for at home during the terminal phases of their illnesses. Standard therapies for hypercalcemia are applicable in these cases, but patients with malignancy-associated hypercalcemia who have high circulating levels of PTHrP respond less well to treatment with such agents as bisphosphonates than do those who have normal levels of PTHrP. Concomitant elevation of calcitriol concentrations further compromises therapy.

MEDICAL MANAGEMENT OF HYPERCALCEMIA

Short-term Treatment

The short-term treatment of life-threatening hypercalcemia often is successful, resulting in a 2 to 7.5 mg per deciliter decline of the serum calcium value within 24 to 48 hours. The necessity for such therapy is signaled by the occurrence of anorexia, nausea, mental status changes, hypertension, or deterioration of renal function in association with a serum calcium level greater than 13.5 mg per deciliter. An understanding of the pathogenesis of such profound hypercalcemia can guide appropriate intervention. For example, the high serum calcium concentration observed in vitamin D intoxication results in part from excessive gastrointestinal calcium absorption. In such cases, dietary restriction of calcium intake may be beneficial. Alternatively, when hypercalcemia results from excessive osteolytic destruction stemming from metastatic tumor or prolonged immobilization, drug-induced blockade of bone resorption may be preferable.

Regardless of its pathogenesis, the clinical picture of a hypercalcemic crisis often includes superimposed dehydration, which reduces renal calcium excretion. The initial therapy for this disorder should be restoration of hydration. This normalizes the glomerular filtration rate and increases renal tubular sodium and calcium clearance, resulting in a 100- to 300-mg increment per day of urinary calcium excretion. After the volume deficit has been restored, calciuresis can be enhanced further with a saline diuresis induced by the administration of large volumes of isotonic saline (up to 6 L per day) plus intravenous furosemide (in doses up to 100 mg every 2 hours). Urine volume and sodium and potassium concentrations must be monitored throughout this aggressive treatment and maintained to preserve euvolemia and prevent hyponatremia and hypokalemia. Pulmonary edema can be precipitated, and appropriate measures must be taken to prevent this effect.

Alternative or adjunctive forms of therapy have emerged for the life-threatening hypercalcemic state. Bisphosphonates have become some of the principal agents used in the treatment of severe hypercalcemia. These drugs are osteoclast inhibitors and effectively block the mobilization of calcium from bone, influencing an important pathophysiologic mechanism of action underlying hypercalcemia. Four bisphosphonates are available: etidronate, pamidronate, alendronate, and clodronate. Of these four, pamidronate is the preferred agent for the urgent treatment of acute hypercalcemia, because of its potency, efficacy, and formal Food and Drug Administration approval as a single intravenous therapy. The effective dose of pamidronate is between 30 and 90 mg administered as a single intravenous infusion over 24 hours. The 90-mg dose is recommended only for the most severe hypercalcemic states. For most patients, 30 to 60 mg is adequate and minimizes the hypocalcemia that can arise when the highest dose is used. Treatment with this drug leads to normalization of the serum calcium level in 70% to 100% of patients. Adverse effects, which develop in up to one-third of treated patients, include transient fever, a small decline in the serum phosphorus level, and myalgia. Administering the drug over a prolonged period (no less than 2 hours) prevents potential nephrotoxicity.

Other pharmacologic interventions for hypercalcemia include glucocorticoids, calcitonin, and indomethacin. These agents are of particular value in the treatment of acutely elevated serum calcium levels resulting from specific causes. Glucocorticoids enhance urinary calcium excretion, decrease gastrointestinal calcium absorption, and diminish renal 25(OH)D-1 α -hydroxylase activity. Consequently, they are effective in combating hypercalcemia resulting from vitamin D intoxication (by blocking end-organ effects) and granulomatous diseases (by impairing extrarenal calcitriol production). In general, the hypercalcemic action of glucocorticoids manifests over several days, and the usual dosage is 40 to 100 mg of prednisone (or its equivalent) given in four divided doses per day. In contrast, calcitonin diminishes the skeletal resorption of calcium and phosphorus within minutes of administration and is particularly suited for the treatment of hypercalcemia caused by rapid bone turnover.

The most impressive results are seen in patients with vitamin D intoxication, thyrotoxicosis, or immobilization hypercalcemia, disease states that are characterized by a high rate of bone mobilization. Nevertheless, many patients with malignancy-associated hypercalcemia resulting from osteolysis do not respond to treatment. Calcitonin is administered parenterally at doses of 25 to 50 U every 6 to 8 hours. In patients who receive continuous therapy for 1 to 5 days, escape from drug action often occurs via an unknown mechanism of action. Because the humoral factor that causes hypercalcemia in some patients with malignancy is a prostaglandin, indomethacin can be useful in combating hypercalcemia in selected cases. Responsive patients manifest a decline in the serum calcium concentration in response to the administration of 25 mg orally every 6 hours.

Plicamycin (mithramycin) at one time was a first-line drug for the treatment of hypercalcemia, particularly the form caused by bone dissolution and refractory to adequate hydration. A dose of 2.5 g per kilogram is administered intravenously and often results in the restoration of normocalcemia. One or two doses per week usually are sufficient, with treatment withheld until hypercalcemia recurs. If there is no response during the first 24 to 48 hours after initial treatment, the 2.5 g per kilogram dose can be given daily until the serum calcium level begins to fall. Because toxicity to plicamycin can be striking, careful monitoring is necessary when repeated doses are administered. Major side effects include thrombocytopenia, hepatocellular necrosis, and decreased clotting factors. Hypocalcemia, hypophosphatemia, and hypokalemia also can develop, as can nausea, vomiting, and stomatitis. Other concerns include nephrotoxicity. Because of these adverse effects and the emergence of other effective therapies, this drug is reserved for particularly difficult and unusual situations.

In life-threatening emergencies, when other medicines have failed, oral (2,000 mg per day) or intravenous (1,500 mg over 6 to 8 hours) phosphorus may be advantageous. This treatment can be dramatically effective, causing a decrement in the serum calcium level ranging from 4 to 7 mg per deciliter. Phosphorus should be used only in extreme emergencies, however, because overdose can result in fatal hypocalcemia. The serum calcium concentration must be monitored frequently during treatment. Phosphate does not remove calcium from the body. Instead, colloidal calcium-phosphate precipitation results in a redistribution of the total body calcium and inevitable soft-tissue calcification. Alternatively, treatment of life-threatening hypercalcemic emergencies can include peritoneal or hemodialysis. This therapy generally is reserved for the severely hypercalcemic patient who has not responded adequately to various drug-related interventions. Use of a low- or zero calcium dialysate frequently will lower the serum calcium level rapidly in those patients who are refractory to other measures (or who have renal insufficiency).

Long-term Treatment

In general, long-term outpatient therapy for hypercalcemia is ineffective. Mild hypercalcemia can be treated with modest success using hydration with or without furosemide or ethacrynic acid, moderate-dose oral phosphate (maintaining normophosphatemia), estrogens, or indomethacin. More potent remedies (mithramycin, glucocorticoids, and high-dose phosphate) have significant long-term toxicity or side effects. Long-term treatment is directed more appropriately at management of the underlying disease. This approach is best when hyperparathyroidism, thyrotoxicosis, or other disorders that respond to surgical or pharmacologic intervention are the cause of hypercalcemia.

Elevated serum calcium concentrations resulting from intractable diseases (e.g., malignancy) often do not respond to such treatment. In these cases, long-term combination therapy with calcitonin and low-dose glucocorticoids may be beneficial. Calcitonin (salmon or human) is administered by subcutaneous injection at a dose of 25 to 50 U every 6 to 8 hours on an alternate-week schedule. Prednisone is given concurrently, without interruption, at a dosage of 10 mg per day. This program permits long-term delivery of calcitonin without the rapid development of refractoriness to the drug. Although the serum calcium value may remain elevated after the initiation of therapy, an adequate therapeutic response usually occurs, precluding recurrent episodes of life-threatening hypercalcemia. Bisphosphonates are another option in the long-term treatment of hypercalcemia. The availability of these drugs in oral formulations and experience in their use will define the future role of this therapeutic approach.

HYPOCALCEMIA

Although numerous mechanisms of action are involved in the genesis of hypercalcemia and homeostatic compensatory responses are easily overwhelmed, adequate

parathyroid function and end-organ responsiveness to PTH normally ensure the maintenance of ionized calcium concentrations within normal limits when hypocalcemic challenges are encountered. A defect in bioactive PTH secretion or a primary or acquired (e.g., vitamin D deficiency, hypomagnesemia) resistance to the action of the hormone, however, can result in chronic hypocalcemia.

The most common hypocalcemic disorders seen in clinical practice are hypoparathyroidism and vitamin D–related diseases, including chronic renal failure. Other causes of hypocalcemia include pseudohypoparathyroidism (PHP), magnesium deficiency, drug-induced hypocalcemia, malignancy, neonatal hypocalcemia, and acute pancreatitis (Table 402.2 and Table 402.3). False hypocalcemia (normal levels of ionized calcium with low levels of albumin-bound and total serum calcium) is common among chronically ill, hospitalized patients. True hypocalcemia (decreased levels of ionized calcium, which may produce symptoms of neuromuscular excitability) is less common but more important. Because the evaluation of a patient with hypocalcemia always involves determination of the specific causative disease entity, this section focuses on the major diseases in which hypocalcemia plays an important role, including idiopathic and surgical hypoparathyroidism and PHP. Other disorders associated with hypocalcemia are reviewed in the chapters devoted to malignant disease of the prostate (Chapter 207 and Chapter 223) and breast (Chapter 205 and Chapter 220), acute pancreatitis (Chapter 117), and vitamin D abnormalities (Chapter 412).

131 treatment of hyperthyroidism has increased and thyroid operations have diminished. In contrast, the incidence of the disorder in the general community has remained unchanged.

Clinical Features and Prognosis

The onset of symptoms in idiopathic hypoparathyroidism typically is insidious, with a slow increase in the number of episodes related to the neuromuscular and neurologic systems. Patients experience paresthesia (particularly in the oral area), muscle spasm, carpopedal spasm, facial grimacing, and, in extreme cases, laryngeal spasm and convulsion. Common central nervous system manifestations include irritability, depression, impaired memory, and psychosis. Often, the symptoms are precipitated or intensified by physical or emotional stress-induced hyperventilation and consequent alkalosis. With long-standing hypocalcemia, patients variably manifest increased intracranial pressure, often in association with papilledema, subcapsular cataracts, and calcification of the basal ganglia. In addition, the skin and hair become dry, and the teeth may be hypoplastic or have ridges stemming from enamel hypoplasia.

Hypocalcemia also can lead to the exacerbation of psoriasis. Cardiovascular manifestations of a decreased serum calcium level include arrhythmias, bradycardia, hypotension, and impaired cardiac contractility. Hypotension is unresponsive to the use of fluids and pressors until calcium is administered. Similarly, impaired cardiac contractility responds poorly to inotropic agents unless hypocalcemia is corrected. On physical examination, Chvostek's or Trousseau's signs can be used to confirm latent tetany. A false-positive Chvostek's sign is present in about 10% of the normal population.

Serum calcium concentrations in affected individuals vary from about 5.5 mg per deciliter to low-normal levels, depending on the degree of PTH deficiency. Serum phosphorus concentrations usually rise to values as high as 7.5 mg per deciliter. Two-site immunoradiometric and immunochemiluminometric assays for intact PTH are now sensitive enough that low or undetectable values are obtained routinely. In contrast, older PTH radioimmunoassays that measure midregion or C-terminal peptides of PTH sometimes yield inappropriately low results for the prevailing serum calcium concentration but often falsely elevated levels that do not distinguish between idiopathic hypoparathyroidism and nonparathyroid causes of hypocalcemia. Serum calcitriol levels are low, and bone remodeling is markedly impaired. When the diagnosis is suspected but unproved, PTH provocation of urinary cAMP excretion (an increase of four to ten times) can be used to confirm normal end-organ responsiveness.

Treatment with vitamin D (50,000 to 100,000 U per day) or calcitriol (0.5 to 1.5 µg per day) with calcium supplements (1 to 2 g per day) effectively restores serum calcium levels to normal in most patients and lowers serum phosphorus levels. Although vitamin D is the least expensive form of therapy, it has the longest duration of action and can result in prolonged toxicity. Thus, calcitriol is the contemporary treatment of choice. Therapy in the absence of PTH effects on the renal tubule often results in hypercalciuria, however, and the potential for renal toxicity exists when serum calcium levels are maintained within the normal range. Therefore, a therapeutic balance must be found between minimizing episodes of hypocalcemia with their attendant symptoms and stimulating hypercalciuria with the consequent risks of nephrolithiasis and nephrocalcinosis. Chlorthalidone often is added to the treatment regimen and is effective in lowering urinary calcium concentrations. Careful monitoring of renal function is essential. Occasionally, the disease is refractory to treatment, and serum calcium levels remain well below the normal range. In some cases, a coincident magnesium deficiency underlies such refractoriness. Treatment with intravenous magnesium sulfate or oral magnesium citrate may restore responsiveness. Close monitoring of the urine and serum calcium is essential in the treated patient until stable laboratory values are reached, generally in 1 to 3 months. Thereafter, follow-up at 3- to 6-month intervals usually is adequate.

PSEUDOHYPOPARATHYROIDISM

PHP refers to a heterogeneous group of disorders characterized by end-organ unresponsiveness to PTH. In its prototypic form, the disease is a hereditary syndrome of short stature, mental retardation, distinctive skeletal abnormalities, hypocalcemia, and hyperphosphatemia, which are present despite excessive secretion of PTH. These manifestations are found in different combinations in various forms of the disorder, reflecting both biochemical and genetic heterogeneity.

PHP can be subdivided into several syndromes according to a classification scheme based on signs of ineffective PTH action (low calcium, high phosphorus levels), blunted urinary cAMP and phosphate response to exogenous PTH, the presence or absence of Albright's hereditary osteodystrophy, and assays of the Gs subunits and enzyme activity of the adenylate cyclase moiety (Table 402.4). Using these criteria, there are five well-characterized forms of the disease: PHP type I, subdivided into a, b and c categories; PHP type II; and pseudo-PHP. Patients with PHP type I have a diminished nephrogenous cAMP response to PTH. In the Ia variant of the disease, this defect stems from a decreased amount of the stimulatory G proteins (Gsa) and occurs in association with the constellation of somatic abnormalities referred to as Albright's hereditary osteodystrophy. These patients also exhibit resistance to a variety of other hormones, such as thyroid-stimulating hormone and gonadotropins, the effects of which are mediated through the G proteins. Unexpectedly, a subgroup of these patients, with the phenotype of Albright's hereditary osteodystrophy and a deficiency of Gsa, have no evidence of hormone resistance and a normal nephrogenous cAMP response to PTH. This disease subtype, referred to as pseudo-PHP, exists in the same kindreds as does PHP Ia, and mutations in the gene encoding Gsa have been described in affected patients. Studies indicate that genomic imprinting may explain the alternative phenotypes that result from identical Gsa mutations. Male transmission of the gene results in pseudo-PHP, whereas female transmission results in PHP type Ia.

	Serum		PTH-Responsive Cyclic AMP		PTH-Responsive Urine Phosphate	GS Deficiency	Generalized Hormone Resistance	AHO
	Ca	P	Urine	Fibroblasts				
PHP Ia	↓	↑	↓	↓	↓	Yes	Yes	Yes
PHP Ib	↓	↑	↓	OK	↓	No	No	No
PHP Ic	↓	↑	↓	↓	↓	No	Yes	Yes
PHP II	↓	↑	↓	?	↓	No	No	No
Pseudo-PHP	↓	↑	↓	↓	↓	Yes	No	Yes

AHO, Albright's hereditary osteodystrophy; AMP, adenosine monophosphate; Ca, calcium; P, phosphate; PTH, parathyroid hormone; PHP, pseudohypoparathyroidism; PTH, parathyroid hormone; PTH, parathyroid hormone.

TABLE 402.4. CLASSIFICATION OF PSEUDOHYPOPARATHYROIDISM

Patients with PHP type Ib lack Albright's hereditary osteodystrophy and manifest hormone resistance that is limited to the PTH target organs. Normal Gsa activity in some tissues has been documented in patients with this disease variant. Hence, speculation has focused on the possibility that the defect underlying this disorder may involve abnormal regulation of PTH receptor messenger RNA expression. Nonetheless, a genome-wide search in four PHP type Ib kindreds has established linkage to a small telomeric region on chromosome 20q, which contains the stimulatory G protein gene. Moreover, the genetic defect is imprinted paternally, as is the genetic defect underlying PHP type Ia and pseudo-PHP.

Thus, it appears possible that the PTH-resistant hypocalcemia found in patients with PHP type Ib is caused by a tissue- or cell-specific defect in Gs gene expression. Since Gs transcripts are derived from only one parental allele—at least in some tissues or cells—mutations in a promoter or enhancer of the Gs gene could explain the kidney-specific resistance toward PTH and the resulting hypocalcemia in patients with PHP type Ib. In PHP type Ic, there is resistance to several hormones in the absence of a defect in Gsa, for reasons that are unclear. Patients with PHP type II have a normal nephrogenous cAMP response to PTH and normal Gsa activity, but a subnormal phosphaturic response to PTH. There is no clear genetic basis for this disorder. Several investigators postulate that a defect exists between the generation of cAMP in the renal tubular cell and the effect of this increase in cAMP on phosphate reabsorption.

Clinical Features and Prognosis

Most of the symptoms of PHP reflect enhanced neuromuscular excitability, a consequence of a reduced serum calcium concentration. Symptoms appear, on average, at about 8 years of age but usually persist for 9 to 12 years before the correct diagnosis is made. Many patients remain essentially asymptomatic for many years, and the diagnosis is not established until late in life. In patients with PHP types Ia and Ic, signs and symptoms of associated endocrine abnormalities can be initial features of the disease. The spectrum of these abnormalities is wide, but it can include mild hypothyroidism and primary amenorrhea or oligomenorrhea.

On physical examination, patients have evidence of tetany or developmental defects referable to Albright's hereditary osteodystrophy. Most notably, the physiognomic changes, primarily in patients with type Ia disease, include short stature, obesity, and brachydactyly (unilateral or bilateral, involving the hands or feet). Posterior subcapsular cataracts can develop in patients with long-standing hypocalcemia, resulting in poor vision. Basal ganglion calcification occurs in nearly half of all patients and occasionally is associated with extrapyramidal movement disorders. Although hypocalcemia is characteristic, normocalcemia can be present, particularly in children. Hypocalcemia can lead to emotional derangements varying from depression to schizophrenia. Cognitive defects often are observed.

Laboratory test abnormalities in most patients include hypocalcemia, hyperphosphatemia, an elevated PTH concentration, and a defective urinary cAMP response to PTH. Urinary hydroxyproline excretion is universally high, consistent with PTH-mediated bone resorption. Although bone cells are presumed to be unresponsive to PTH, evidence has been inferential. Studies of bone density in the radius show that patients with PHP have reduced bone mass. Moreover, bone biopsy evidence of increased resorption or decreased mineralization is common, and a few patients have severe osteitis fibrosis cystica. The hypocalcemia in PHP may not result solely from intrinsic resistance but from a deficiency of calcitriol as well, which can compromise the bone homeostatic mechanisms.

The treatment of PHP is similar to that of hypoparathyroidism, except that the dosages of vitamin D and calcium required usually are lower. Lesser amounts of medication are needed because vitamin D or its metabolites restores bone responsiveness to PTH in part in many patients. The decreased serum calcitriol concentrations in patients with PHP and the role of this metabolite in maintaining bone homeostasis indicate that improved therapy might be achieved by using physiologic replacement doses of this active metabolite.

MEDICAL MANAGEMENT OF HYPOCALCEMIA

Short-term Treatment

The objectives of emergency therapy for hypocalcemia with tetany are to relieve symptoms and prevent laryngeal obstruction. These complications are unlikely if the serum calcium concentration is maintained at more than 7 mg per deciliter. In adults, 10 to 20 mL of 10% calcium gluconate is given by intravenous push at a rate of at least 10 mL per minute. In patients receiving digitalis, caution is essential and electrocardiographic control advisable. If a patient can take oral medications, 100 mg of calcium should be given every 2 hours, increasing the dose to 500 mg if necessary. Repeated intravenous administration of calcium, if it is essential, should be accomplished by the continuous infusion of 10 mL of a 10% solution added to 500 mL of intravenous fluids over 6 hours. After acute hypocalcemia has been controlled, persistent decrements of the serum calcium concentration are managed appropriately through long-term therapy for the underlying disease.

Long-term Treatment

The long-term treatment of hypocalcemia depends largely on the specific cause of the disorder. In diseases marked by a deficiency of vitamin D, treatment requires provision of this substance in amounts sufficient to overcome the inadequate vitamin stores. When the underlying disease involves abnormal metabolism of the parent vitamin or resistance to the active metabolite, the use of vitamin D metabolites in physiologic or pharmacologic amounts often is required. In states of parathyroid deficiency or resistance, maintenance of a normal serum calcium level can be achieved by the administration of vitamin D (or its metabolites) and calcium supplements.

CHAPTER 403: DISORDERS OF THE HYPOTHALAMUS AND ANTERIOR PITUITARY

JOHN C. MARSHALL AND ARIEL L. BARKAN

Anatomy
Disorders of the Hypothalamus and Anterior Pituitary

Pituitary hormone secretion is controlled by the central nervous system (CNS). The neurons involved in the final regulatory pathways are located in the ventral hypothalamus (Fig. 403.1). Hypothalamic regulation of pituitary function occurs by two distinct pathways. The first is a neuroendocrine system. Amine-secreting and peptide-secreting neurons release their products from axon terminals in the median eminence into capillaries of the hypothalamic-hypophyseal-portal system. The peptides travel to the anterior lobe of the pituitary and stimulate or inhibit pituitary hormone secretion by interacting with specific receptors on pituitary cells. Most hypothalamic peptides stimulate pituitary hormone synthesis and secretion, but somatostatin and dopamine exert inhibitory actions. Thus, medications that interfere with the synthesis of monoamines or peptides and lesions that destroy the median eminence or pituitary stalk result in reduced secretion of luteinizing hormone (LH), follicle-stimulating hormone (FSH), thyroid-stimulating hormone (thyrotropin, TSH), adrenocorticotropic hormone (corticotropin, ACTH), and growth hormone (GH), but secretion of prolactin, which is inhibited by dopamine, is increased.

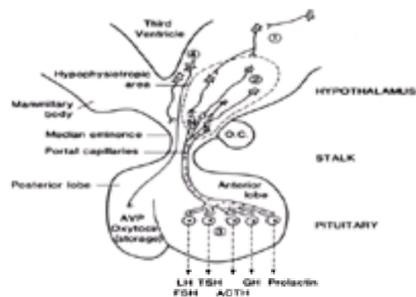

FIGURE 403.1. Hypothalamic-pituitary connections: (1) Intermediary neurons secrete neurotransmitters. (2) Hypophysiotropic neurons located in the hypophysiotropic area secrete releasing and inhibiting hormones. (3) Anterior pituitary cells. (4) neurons in the paraventricular and supraoptic nuclei secrete AVP and oxytocin. *ACTH*, adrenocorticotropic hormone; *AVP*, arginine vasopressin; *GH*, growth hormone; *FSH*, follicle-stimulating hormone; *LH*, luteinizing hormone; *O.C.*, optic chiasm; *TSH*, thyroid-stimulating hormone.

The second pathway, a neurosecretory system, is involved in osmoregulation and control of the onset of labor and subsequent nursing. Large neurons of the magnocellular system are located in the supraoptic nuclei of the anterior hypothalamus and in the paraventricular nuclei (adjacent to the third ventricle). Some axons from these neurons terminate in the median eminence, but others pass down the pituitary stalk and terminate on modified neural (glial) cells in the posterior pituitary. These cells store arginine vasopressin and oxytocin. Because their function is storage only, removal of the posterior pituitary does not cause diabetes insipidus as long as the neuronal perikarya and the median eminence remain intact. Regulation of arginine vasopressin secretion is discussed elsewhere in this text (see [Chapter 404](#)).

ANATOMY**HYPOTHALAMUS AND PITUITARY STALK**

The hypothalamus extends from the optic chiasm anteriorly to the mammillary bodies posteriorly. The hypothalamic sulcus of the third ventricle separates the thalamus above. Inferiorly, the hypothalamus forms a tubular structure, the tuber cinereum, which contains the infundibular recess of the third ventricle. The median eminence (infundibulum) continues down to form the pituitary stalk. The portal capillaries form from a capillary plexus in the median eminence, become the veins of the pituitary stalk (six to eight in all), and form a second capillary plexus interspersed among the cells of the anterior pituitary. Thus, most of the blood supply to the anterior pituitary (about 1 mL per gram per minute) originates from the superior hypophyseal arteries and has passed through the median eminence before reaching the pituitary. The blood-brain barrier is relatively permeable in the median eminence, allowing circulating hormones to gain access to the axon terminals, which respond by modifying release of hypothalamic regulatory hormones.

The cell bodies of hypothalamic secretory neurons are not in discrete nuclei but are distributed throughout the hypophysiotropic area of the hypothalamus. Gonadotropin-releasing hormone (GnRH) neurons are located in the arcuate nucleus and in the anterior hypothalamus, corticotropin-releasing hormone (CRH) neurons in the paraventricular area, somatostatin neurons in the anterior hypothalamus, growth hormone-releasing hormone (GH-RH) neurons in the ventromedial arcuate nuclei, and thyrotropin-releasing hormones (TRH) neurons in the anterior hypothalamus. The hypothalamic secretory neurons are influenced by neural input from other areas of the brain, but function often is maintained after hypothalamic deafferentation, indicating that the neurons are relatively autonomous.

PITUITARY GLAND

The human pituitary consists of three parts: an anterior lobe (adenohypophysis), an intermediate lobe (poorly developed in humans except during fetal life), and a posterior lobe (the neurohypophysis). The gland weighs 0.5 to 1 g; measures 15 mm across, 6 mm deep, and 10 mm long; and lies within the sella turcica ("Turkish saddle"), a depression in the sphenoid bone. The roof of the sella turcica is formed by dura mater, the diaphragma sellae, through which the pituitary stalk passes. The posterior wall of the sella is formed by the bony dorsum sellae, but the lateral walls are fibrous and include the medial wall of the cavernous sinus. The proximity of the optic chiasm above and the presence of cranial nerves III, IV, V, and VI in the cavernous sinus are important. Pituitary tumors may impinge on these nerves and manifest clinically as visual field defects or cranial nerve palsies.

The anterior and posterior lobes of the pituitary are functionally independent and have distinct embryologic origins. The anterior lobe is formed from an upward extension of ectoderm from the primitive oral cavity (Rathke's pouch). The posterior lobe arises as a downgrowth of the diencephalon and fuses with Rathke's pouch. The cystic center of Rathke's pouch usually is obliterated, but small cystic structures may persist, typically in the superior part of the pituitary. Tumors arising from these cystic remnants form craniopharyngiomas, which may be intrasellar or suprasellar in position. Remnants of Rathke's pouch often are present in or below the sphenoid bone, forming a pharyngeal pituitary that can be the site of tumor formation in rare instances.

Pituitary cells were originally classified as acidophils, basophils, or chromophobes based on the staining properties of the cytoplasmic granules; this system is now outmoded. Five distinct pituitary cell types have been identified in the anterior pituitary by electron microscopy and immunocytochemistry. The various cell types are scattered throughout the anterior pituitary, though some areas of the gland contain a predominance of one cell type. The characteristics and location of the pituitary cell types, together with their secretory products, are shown in [Table 403.1](#).

Cell Type	Original Classification	Percentage of Cells	Secretion	Secreted Hormone	Location and Other Features
Hypophyseal	Neuroglial	3-7	Neurosecretory	TRH	Anterior part of the intermediate lobe of the pituitary gland
Secretory	Chromophilic in human	2-7	Neurosecretory	TRH, PRL, GH, and others	Dispersed throughout the gland and after exposure to secretagogues, some cells may secrete only TRH, TRH-related peptides, and others
Chromophilic	Chromophilic in human	18-20	Large (200-400 m ²) or intermediate size cells	ACTH, PMS, and others	One group is in the intermediate lobe. Other cells are in the anterior part of the pituitary. These cells increase in number after and degenerate during pregnancy and normal aging, suggesting that they are the site of active secretion
Secretory	Neuroglial or chromophilic	45-50	Small (200-300 m ²)	Growth hormone	Lateral part of gland
Lactotrophic	Neuroglial or chromophilic	18-20	Large, varying in size (800-1,200 m ²)	Prolactin	Dispersed through the gland, most in lateral part. Increased in pregnancy to 50-70% of cells and in some degree with estrogen therapy
Other		10-15	Other	Not identified as hormones	Not known by present techniques. May represent undifferentiated cells or other secretory hormones

TABLE 403.1. CHARACTERISTICS OF CELL TYPES IN THE ANTERIOR PITUITARY

HYPOTHALAMIC HORMONES

Regulation of Hypophysiotropic Hormone Secretion

Secretion of hormones by the hypophysiotropic neurons is regulated by neurotransmitters from intermediary neurons and by the negative or positive feedback effects of target gland hormones (Fig. 403.1 and Fig. 403.2). The feedback actions of target gland hormones are usually negative and may be exerted directly on the hypophysiotropic neurons or through modification of the secretion of neurotransmitters, including catecholamines, indoleamines, and other neuropeptides. In humans, the exact pathways are uncertain, and, in particular, the role of other neuropeptides is unclear. Many peptides have been shown to be distributed widely in the hypothalamus and throughout the CNS, and some have been shown to function as neurotransmitters. Neuropeptides that have been identified in the CNS include TRH, somatostatin, enkephalins, endorphins and dynorphin, neuropeptide PYY, substance P, calcitonin, and angiotensin. Peptides originally identified in the gastrointestinal tract are also present in the CNS, including insulin, glucagon, pancreatic polypeptide, gastrin, cholecystokinin, vasoactive intestinal peptide, secretin, and motilin. The function of these peptides and their role as neurotransmitters are unclear, but their presence in the CNS has led to the hypothesis of a *brain-gut axis* that may be involved in regulation of nutritional and metabolic function.

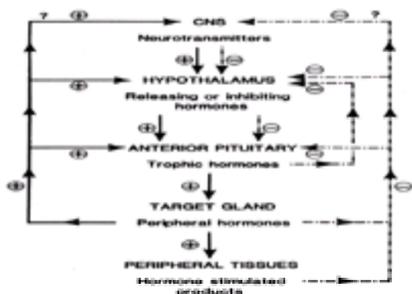

FIGURE 403.2. Feedback regulation of hypothalamic and anterior pituitary function. Stimulatory (+) feedback pathways are shown as solid lines; inhibitory (-) pathways, as dashed lines. Question marks indicate presumed pathways.

Catecholamines (dopamine, norepinephrine, epinephrine) are all derived from tyrosine. Tyrosine hydroxylase converts tyrosine to L-dihydroxyphenylalanine (L-dopa), which is decarboxylated to dopamine. Dopamine is stored in the secretory granules of dopaminergic neurons but is converted to norepinephrine by dopamine-β-hydroxylase in noradrenergic neurons. Adrenergic neurons contain phenylethanolamine N-methyltransferase, which converts norepinephrine to epinephrine. Catecholamines are released into the synaptic cleft and act on postsynaptic receptors. After dissociation from postsynaptic receptors, catecholamines can be taken up by the presynaptic neuron (reuptake) or can be degraded by the enzymes monoamine oxidase and catechol-O-methyltransferase. The actions of catecholamines are enhanced by drugs that inhibit the reuptake process (tricyclic antidepressants, cocaine) or by monoamine oxidase inhibitors (pargyline).

Indoleamines (serotonin, melatonin) are formed by hydroxylation and decarboxylation of tryptophan, and the rate of serotonin synthesis depends on the serum levels of tryptophan. Serotonin is a precursor for melatonin synthesis in the pineal and also functions as a neurotransmitter; its storage, release, and reuptake processes are similar to those of catecholamines. Cyproheptadine and methysergide are serotonin antagonists, and lysergic acid diethylamide acts as an agonist; serotonin effects are potentiated by monoamine oxidase inhibitors and some tricyclic drugs. Endogenous opioid peptides (endorphins, enkephalins, and dynorphin) are present in the hypothalamus and exert predominantly inhibitory effects, mainly on GnRH secretion. Endorphins appear to be the principle product of proopiomelanocortin metabolism in the brain, and dynorphin is secreted by the magnocellular neurons that secrete arginine vasopressin.

There are other neurotransmitters. Histamine acts through two types of receptors: H₁, blocked by such antihistamines as diphenhydramine, and H₂, blocked by cimetidine and ranitidine. Acetylcholine also acts through two receptor types, muscarinic and nicotinic, with muscarinic effects being blocked by atropine. Gamma-aminobutyric acid (GABA) is formed from L-glutamate and appears to function as an inhibitory neurotransmitter, though it may have a stimulatory role in GH regulation.

Hypophysiotropic Hormones

TRH was the first hypothalamic hormone to be isolated and characterized and has subsequently been shown to be widely distributed throughout the CNS and the gut. TRH release is stimulated by norepinephrine and dopamine and is inhibited by serotonin. TRH causes release of TSH and prolactin, though the physiologic importance of its action on prolactin secretion is uncertain. TRH-stimulated secretion of TSH is inhibited by somatostatin, by thyroxine and triiodothyronine, and by dopamine and high levels of glucocorticoids. TRH is used in the clinical assessment of pituitary function and in the evaluation of thyrotoxicosis. In acromegalic patients, TRH induces secretion of GH.

GnRH stimulates the synthesis and release of LH and FSH (Fig. 403.3). GnRH is secreted in a series of pulses, and regulation of secretion is discussed in detail later. GnRH is available for clinical assessment of pituitary gonadotrope responsiveness, but its value is limited. Because GnRH is required to stimulate LH synthesis, the absence of LH release with GnRH stimulation may result from deficient endogenous GnRH secretion or from absence of functional gonadotropes.

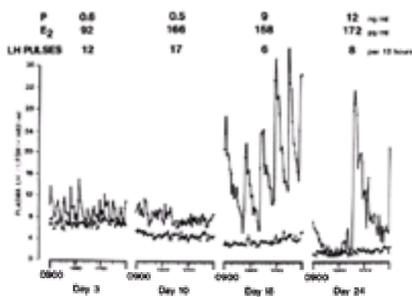

FIGURE 403.3. Patterns of pulsatile luteinizing hormone (LH; O) and follicle stimulating hormone (FSH; -) secretion and ovarian steroid concentrations during the early and late follicular (days 3 and 10) and luteal phases (days 18 and 24) of an ovulatory menstrual cycle. The first day of menstrual bleeding is designated day 1 of the cycle, and ovulation occurred on day 14. LH and FSH were measured in samples drawn every 10 minutes. P, progesterone, E₂, estradiol. (Marshall JC, Kelch RP, Saunderson SE, et al. Pulsatile GnRH—studies of puberty and the menstrual cycle. In: Labrie F, ed. *Endocrinology. International Congress Series 655*. Amsterdam:Elsevier BV, 1984:25.)

CRH is the major regulator of ACTH release and is secreted in pulses that occur more frequently during sleep and produce the nocturnal increase in ACTH and cortisol secretion. Secretion of CRH is influenced by numerous neurotransmitters. Acetylcholine stimulates CRH release and is involved in the so-called stress-induced increase in CRH secretion. Serotonin also stimulates CRH secretion, but GABA, norepinephrine, enkephalin, and melatonin are inhibitory, and melatonin may be involved in reducing CRH secretion during periods of daylight. CRH stimulation of ACTH secretion is enhanced by vasopressin and is blocked by somatostatin and elevated levels of glucocorticoids. CRH can be used in the assessment of excess cortisol secretion. ACTH responses to CRH are enhanced in Cushing's disease despite the elevated levels of plasma cortisol, but they are reduced or absent in Cushing's syndrome stemming from adrenal tumors or ectopic ACTH secretion.

GH-RH was originally isolated from a GH-RH-secreting pancreatic tumor in a patient with acromegaly. Somatotrope hyperplasia was present in the pituitary gland, which was the clue to the presence of an ectopic GH-RH-secreting tumor. Subsequently, GH-RH has been identified in the hypothalamus and is also present in the pancreas. GH-RH shows structural homology to a family of hormones that includes glucagon, secretin, vasoactive intestinal peptide, and gastric inhibitory peptide. Hypothalamic GH-RH secretion is stimulated by dopamine, norepinephrine, epinephrine, GABA, acetylcholine, and serotonin. GH-RH stimulates GH secretion, and this action is blocked by somatostatin. The regulation of GH release involves a complex interplay between GH-RH and somatostatin; however, GH-RH appears to play the predominant role, because GH levels fall after pituitary stalk section. GH-RH has been used in clinical testing of pituitary function and has been shown to be effective in stimulating growth in GH-RH-deficient children.

Somatostatin originally was isolated from the hypothalamus, but it is now known to be widely distributed throughout the CNS and to function as a neurotransmitter in the cerebral cortex and spinal cord. Somatostatin also is present in the gut and in the D cells of the pancreatic islets; it regulates secretion of insulin and glucagon. Stimulation of hypothalamic somatostatin release is complex and not well understood. Norepinephrine, epinephrine, dopamine, GABA, and acetylcholine all have been found to increase somatostatin secretion. Hypothalamic somatostatin blocks the actions of GH-RH and blunts TRH-induced TSH release. The latter effect may be responsible for the TSH deficiency that can develop during GH therapy of GH-deficient children (GH stimulates somatostatin release). Somatostatin, and particularly long-acting analogues of somatostatin (octreotide), have been used successfully in the treatment of acromegaly and TSH-secreting pituitary tumors.

A family of small peptides and of their non-peptidyl analogues, collectively called GH secretagogues (GHS), have been shown to stimulate GH secretion. A specific receptor for GHS has been found in the hypothalamus and the pituitary. The GHS receptor and its intracellular second messenger system leading to GH release are distinct from GH-RH, which strongly supports the existence of a still unidentified endogenous hypothalamic peptide that serves as a "third regulator" of GH secretion. Dopamine is the predominant regulator of prolactin secretion, but evidence suggests that a prolactin-releasing hormone, not yet identified, is present in the hypothalamus. The role of these compounds in regulating prolactin secretion is discussed later.

The actions of hypophysiotropic hormones are modified by circulating levels of the respective target gland hormones, cortisol, somatomedin C, thyroxine, androgens, and estrogens. These hormones can modify hypophysiotropic hormone modulation of the number of hypophysiotropic hormone receptors on specific pituitary cells. They also exert effects at postreceptor sites, including regulation of transcription, though the exact mechanisms of action remain to be identified.

ANTERIOR PITUITARY HORMONES

The hormones produced by the anterior pituitary can be grouped into three types: glycoproteins (TSH, LH, FSH), proopiomelanocortin-derived peptides, and somatomammotropins (GH and prolactin). The structural characteristics of the hormones and their main actions are shown in [Table 403.2](#).

Hormone	Molecular Weight (kD)	Structure	Stimulatory Action
Glycoproteins			
TSH	28,200	47 amino acids (glycosylated), α and β	Thyroid hormone secretion
LH*	23,800	The α subunit is identical, and the β subunit confers biologic specificity	Sexual steroid secretion
FSH	23,800		Ovarian follicle development and testicular spermatogenesis
PMOC-derived hormones			
MSH	5,800	Peptide hormone	Adrenocortical hormone secretion
ACTH	4,500	Midportion of PMOC	
α-MSH	3,800	N-terminal amino acid of ACTH	Appetite
β-MSH	3,800	C-terminal amino acid of ACTH	Uterus
β-endorphin	3,100	C-terminal portion of PMOC	Uterus
β-lipotropin	4,600	C-terminal amino acid of β-lipotropin	Uterus
Somatomammotropins			
GH†	22,000	Single-chain protein with disulfide bridges	Somatomedin C production and direct metabolic effects
Prolactin	23,000		Lactation

*Ovarian gonadotropin has action on both α and β subunits.
 †Prolactin (Prl) (formerly mamatotrophic hormone) has a structure (80% homology) similar to that of GH.
 ACTH, adrenocorticotrophic hormone; α-MSH, α-melanocyte stimulating hormone; β-MSH, β-melanocyte stimulating hormone; MSH, melanocyte stimulating hormone; PMOC, proopiomelanocortin; TSH, thyroid stimulating hormone.

TABLE 403.2. ANTERIOR PITUITARY HORMONES AND THEIR ACTIONS

DISORDERS OF THE HYPOTHALAMUS AND ANTERIOR PITUITARY

Disorders of the hypothalamus and pituitary may take the form of endocrine or neurologic dysfunction. Hyposecretion or hypersecretion of one or more pituitary hormones can occur, and neurologic manifestations are caused by pressure effects from tumors or reflect abnormal autonomic function. The clinical endocrine manifestations of hypothalamic and pituitary disorders are similar, and it may be difficult to differentiate hypothalamic and pituitary causes of abnormal hormone secretion.

HYPOTHALAMIC DISORDERS

The hypothalamus regulates both endocrine and autonomic function. Small lesions may cause symptoms if they affect a specific hypothalamic nucleus, but lesions are often large and bilateral before clinical evidence becomes apparent. Hypothalamic tumors are commonly slow growing and usually cause endocrine abnormalities, eating disturbances, or cognitive dysfunction. Patients with rapidly expanding lesions often experience autonomic dysfunction or coma. Diseases that may show initial symptoms of hypothalamic disorders are shown in [Table 403.3](#).

Disorder	Pathogenesis	Clinical Manifestations
Hypothalamic		
Craniopharyngioma	Neoplastic	Endocrine dysfunction (hypopituitarism), visual impairment, increased intracranial pressure
Hamman-Rich syndrome	Idiopathic	Endocrine dysfunction (hypopituitarism), growth retardation
Prader-Willi syndrome	Genetic	Endocrine dysfunction (hypopituitarism), obesity, mental retardation
Kallmann syndrome	Genetic	Endocrine dysfunction (hypogonadotropic hypogonadism), anosmia
Pituitary		
Pituitary adenoma	Neoplastic	Endocrine dysfunction (hypopituitarism), visual impairment, increased intracranial pressure
Pituitary macroadenoma	Neoplastic	Endocrine dysfunction (hypopituitarism), visual impairment, increased intracranial pressure
Pituitary microadenoma	Neoplastic	Endocrine dysfunction (hypopituitarism)
Pituitary carcinoma	Neoplastic	Endocrine dysfunction (hypopituitarism), increased intracranial pressure
Pituitary metastasis	Neoplastic	Endocrine dysfunction (hypopituitarism), increased intracranial pressure
Pituitary infarction	Vascular	Endocrine dysfunction (hypopituitarism)
Pituitary apoplexy	Vascular	Endocrine dysfunction (hypopituitarism), visual impairment, increased intracranial pressure
Pituitary stalk transection	Traumatic	Endocrine dysfunction (hypopituitarism)
Pituitary stalk interruption syndrome	Developmental	Endocrine dysfunction (hypopituitarism)
Pituitary stalk thickening	Developmental	Endocrine dysfunction (hypopituitarism)
Pituitary stalk thinning	Developmental	Endocrine dysfunction (hypopituitarism)
Pituitary stalk cyst	Developmental	Endocrine dysfunction (hypopituitarism)
Pituitary stalk calcification	Developmental	Endocrine dysfunction (hypopituitarism)
Pituitary stalk ossification	Developmental	Endocrine dysfunction (hypopituitarism)
Pituitary stalk fibrosis	Developmental	Endocrine dysfunction (hypopituitarism)
Pituitary stalk gliosis	Developmental	Endocrine dysfunction (hypopituitarism)
Pituitary stalk inflammation	Infectious	Endocrine dysfunction (hypopituitarism)
Pituitary stalk tumor	Neoplastic	Endocrine dysfunction (hypopituitarism)
Pituitary stalk metastasis	Neoplastic	Endocrine dysfunction (hypopituitarism)

TABLE 403.3. DISEASES THAT MAY HAVE INITIAL SIGNS OF ABNORMAL HYPOTHALAMIC FUNCTION

Clinical Findings

Hypothalamic disorders may be neurologic, endocrine, or a mixture of the two. In some instances, endocrine failure may result in symptoms similar to neurologic dysfunction. If temperature regulation is abnormal, hypothyroidism and cortisol deficiency should be excluded before attributing the symptoms to neurologic causes.

Neurologic Findings

Eating Behavior

Lesions of the ventromedial nuclei lead to loss of satiety, hyperphagia, and progressive obesity. Hypothalamic lesions are a rare cause of obesity, but unidentified abnormalities of satiety regulation may be present in some obese patients. The lateral hypothalamus monitors hunger, and bilateral lesions result in anorexia. In men with apparent anorexia nervosa, a hypothalamic lesion should be sought actively.

Temperature Regulation

The hypothalamus monitors and increases core temperature. Prostaglandin E is involved in raising the set point, which results in increased heat production (shivering) and reduced heat loss (vasoconstriction). Hypothalamic diseases also may alter temperature regulation in cycles lasting days to weeks. Hyperthermia with paroxysms of fever, shaking, chills, and sweating may be interspersed with periods of normal temperature regulation. Hypothermia occasionally is reported and may be associated with sweating and flushing. More often, sustained hypothermia reflects hypothyroidism, which may also be of hypothalamic origin.

Thirst

Hypothalamic osmoreceptors monitor serum osmolality and regulate water excretion through secretion of antidiuretic hormone (ADH). The syndrome of inappropriate ADH secretion may develop in association with hypothalamic lesions, meningitis, or subarachnoid hemorrhage. Hypothalamic lesions also may inhibit ADH release, and if perception of thirst is lost, it may lead to hypernatremia and dehydration. Now and then, primary polydipsia may occur, which is difficult to distinguish from diabetes insipidus.

Memory, Behavior, and Sleep

In Wernicke's encephalopathy, hemorrhage into the mammillary bodies and hypothalamus may occur and is associated with short-term memory loss. Ventromedial lesions can lead to expressions of rage, whereas lateral lesions typically result in apathy. Dementia may be a symptom of bilateral lesions. Sleep patterns also can be disturbed; agitation and insomnia are features of anterior hypothalamic lesions, and marked somnolence or coma occur with posterior lesions.

Autonomic Nervous System Functions

Diencephalic epilepsy is a rare condition characterized by episodes of increased autonomic activity. Anterior hypothalamic lesions usually affect parasympathetic outflow, whereas posterior lesions result in sympathetic manifestations.

Endocrine Findings

Endocrine manifestations of hypothalamic disease reflect altered secretion of hypothalamic hormones. Usually, secretion is reduced. Because most hypothalamic hormones stimulate pituitary secretion, the typical clinical picture is hypopituitarism. A hypothalamic origin of deficiencies of TSH, GH, ACTH, and gonadotropin can be differentiated from pituitary causes by the injection of hypophysiotropic hormones. Normal increases in plasma TSH after injection of TRH, in GH after injection of GH-RH, in ACTH after injection of CRH, and in LH and FSH after repeated injections of GnRH indicate a hypothalamic origin.

Pituitary Hypofunction

Deficiency of hypophysiotropic hormones usually is reported in children as *idiopathic hypopituitarism* and commonly involves several hypothalamic hormones. Hypothalamic lesions can produce single or several hormone deficiencies. Isolated deficiencies of TRH, CRH, and, most often, GnRH or GH-RH also may be seen in the absence of demonstrable hypothalamic disease.

On occasion, hypophysiotropic hormone deficiency may be functional and reversible. In emotional deprivation syndromes (psychosocial dwarfism), spontaneous GH secretion may be impaired, and GH responses to provocative stimuli are subnormal. After several days in a better home environment, GH secretion is restored, and linear growth resumes. This finding probably reflects restoration of normal neurotransmitter regulation of GH-RH secretion. Similarly, GnRH deficiency may develop after severe weight loss (to less than 70% of ideal body weight) from any cause and is reversible after weight gain. Amenorrhea seen in female athletes results from reduced GnRH secretion, which may be provoked by excess hypothalamic opioid activity and consequent suppression of GnRH pulse frequency. Reduced GnRH pulse frequency is the cause of amenorrhea in the context of hyperprolactinemia. GnRH secretion returns to normal after suppression of prolactin by bromocriptine or removal of a prolactinoma.

Pituitary Hyperfunction

Less commonly, hypothalamic diseases may appear in the form of pituitary hypersecretion. Idiopathic hyperprolactinemia is a disorder in which serum prolactin is elevated (usually to more than 100 ng per milliliter) in the absence of established pituitary or hypothalamic disease. Irregular ovulation and amenorrhea are noted, and the disorder is rare in women older than 40 years of age. The abnormality presumably reflects reduced dopamine secretion, and in many cases the disorder appears to be self-limiting. Serum prolactin levels do not rise, and in half the patients they tend to fall over 5 to 10 years of follow-up.

Precocious puberty may be the initial feature of hypothalamic disease in children. In girls, anatomic lesions usually are not found, but in boys a tumor should always be sought. The presence of hypothalamic tumors may initiate the early onset of normal mechanisms of pubertal maturation. Other tumors have been shown to contain GnRH or human chorionic gonadotropin (hCG). GnRH stimulates pituitary LH and FSH secretion, whereas hCG acts on the gonad to increase steroid synthesis.

Acromegaly or gigantism also may result from hypothalamic tumors; some tumors have been shown to secrete GH-RH, with consequent GH release. Cerebral gigantism is a syndrome in children characterized by rapid growth, accelerated bone age, clumsiness, and sometimes mental retardation. Enlarged cerebral ventricles may be seen on computed tomographic (CT) scan, but hypothalamic tumors are not found. Hormone data are limited, but GH secretion appears to be normal and the mechanisms of rapid growth are unknown.

Polycystic ovarian disease may result from increased GnRH pulse frequency, leading to enhanced LH secretion with consequent development of ovarian cysts and excess ovarian androgen secretion. This would explain the hirsutism, amenorrhea, and elevated serum LH levels usually found in this syndrome, but definite evidence of abnormal GnRH regulation is lacking.

Hypothalamic Tumors

Hypothalamic tumors usually are located in the midline beneath the third ventricle. The most common tumors are craniopharyngiomas and their variants (epidermoid cysts and ependymomas), followed by gliomas and germinomas. The tumors may lead to any of the neurologic or endocrine manifestations described previously, but

the common symptoms are visual abnormalities, raised intracranial pressure, diabetes insipidus, hypogonadism, or delayed puberty and growth retardation.

Craniopharyngiomas

Craniopharyngiomas arise from remnants of Rathke's pouch and hence are of ectodermal origin. Most tumors are suprasellar and have features of a hypothalamic disorder, though others are partly intrasellar and partly suprasellar. Craniopharyngiomas may appear in childhood, but more than half the patients are older than 20 years of age at diagnosis. The tumors are benign and usually cystic. They contain a thick, cholesterol-rich fluid, and half are calcified.

In children, the usual manifestations are headache, vomiting, and papilledema due to increased intracranial pressure or hydrocephalus. Visual field defects are often present; less common findings are short stature, delayed puberty, and diabetes insipidus. In adults, visual abnormalities and field defects are present in 80% to 90% of cases. Papilledema is less typical, but headaches, hypogonadism, and mental or behavioral changes occur in 20% to 40% of patients. The serum prolactin level is elevated (less than 150 ng per milliliter) in about half the patients; diabetes insipidus, weight gain, and panhypopituitarism occur less frequently (10% to 20%). The presence of curvilinear suprasellar calcification on skull roentgenography or CT scan suggests a craniopharyngioma, but other hypothalamic tumors may calcify. Treatment of craniopharyngiomas is difficult. If feasible, total removal of the lesion is preferred and is often associated with long remissions. Complete removal usually is not possible, however; in that case, drainage of the cyst fluid or partial removal is carried out, followed by postoperative radiation therapy to reduce the rate of tumor regrowth. For predominantly cystic craniopharyngiomas, stereotactic intracavitary instillation of phosphorus-32 appears to be effective.

Germinomas

Germinomas (atypical teratomas, pinealomas, ectopic pinealomas) are often adjacent to the lower part of the third ventricle and usually infiltrate the hypothalamus. The tumors may metastasize through the cerebrospinal fluid (CSF) to the meninges and form distal deposits. Diabetes insipidus is a common initial feature, as is precocious puberty in boys. The mechanisms of sexual precocity are unclear. Some tumors infiltrate the hypothalamus and remove the normal prepubertal inhibition of GnRH secretion. Human chorionic gonadotropin has been found in other tumors, and plasma levels of hCG may be elevated. The management of these tumors is difficult—surgical removal usually is not possible. Tumors containing mainly germinal elements are radiosensitive, but those with a predominantly teratomatous component may be resistant.

Hamartomas and Gangliocytomas

Hamartomas typically are located in the posterior hypothalamus, are capsulated, and contain disorganized neuronal and glial tissue. The neurons may incorporate neurosecretory granules. GnRH often is secreted by the tumor, and increased LH and FSH release may cause precocious puberty. Treatment is directed toward inhibiting pubertal maturation, preventing premature epiphyseal fusion, and restoring growth potential. Long-acting GnRH agonists, which desensitize gonadotrope responses to GnRH, have been shown to be effective in arresting pubertal maturation and slowing accelerated bone maturation. Some hypothalamic hamartomas have been shown to contain GH-RH and to result in GH hypersecretion and acromegaly. A similar tumor, the gangliocytoma, has been found within the pituitary and may contain GH-RH or CRH. These tumors are rare causes of acromegaly or Cushing's disease.

Granulomatous Diseases

Histiocytosis X

Histiocytosis X is a histiocytic/eosinophilic granulomatous disorder that manifests as different clinical types. Hand-Schuüller-Christian disease is the type commonly associated with hypothalamic deposits and usually is accompanied by diabetes insipidus (50%), defects in bone, and exophthalmos. GH deficiency, hypogonadism, and panhypopituitarism also may develop; they are usually permanent and require replacement hormonal therapy. Diagnosis rests on biopsy findings, and treatment consists of glucocorticoids or chemotherapy.

Sarcoidosis

Hypothalamic or suprasellar deposits are uncommon in sarcoidosis. When they arise, they typically manifest as a thickening of the stalk, which enhances on the MRI after gadolinium contrast administration. CNS involvement is suggested by the presence of diabetes insipidus, an elevated serum prolactin level (less than 150 ng per milliliter), or galactorrhea or by varying degrees of hypopituitarism. Endocrine dysfunction rarely improves with glucocorticoid therapy for sarcoidosis.

Radiation Therapy

Hypothalamic and pituitary abnormalities may appear several years after radiation therapy for nasopharyngeal or intracranial tumors. The effects of radiation are rarely evident until 1 to 3 years after treatment and may arise 10 or more years later. Hypopituitarism often develops after radiation therapy in children; GH and LH-FSH deficiencies are the most common side effects. Radiation may involve both the hypothalamus and the pituitary, but studies using releasing hormones suggest that the major lesion is one of hypothalamic dysfunction.

Trauma

Head injuries that result in coma may be associated with hypothalamic-pituitary failure. Gonadotropin and TSH deficiencies have been described, presumably as a result of defective releasing hormone secretion; these effects may improve with time. If the pituitary stalk has been severed, anterior pituitary hormone deficiency is usually permanent, and diabetes insipidus is also present. Stalk damage often is seen in the context of basal skull fractures.

Syndromes Associated with Hypothalamic Dysfunction

Laurence-Moon-Biedl and Prader-Willi Syndromes

Laurence-Moon-Biedl and Prader-Willi syndromes are familial disorders associated with characteristic facies, mental retardation, and hypotonia. The Laurence-Moon-Biedl syndrome is characterized by retinitis pigmentosa, polydactyly, and congenital heart defects. Abnormalities of hypothalamic function include hyperphagia, resulting in severe obesity, disordered diurnal rhythms, temperature dysregulation, and hypogonadism. The latter is caused by reduced GnRH secretion, but other hypophysiotropic hormones are usually intact.

Anorexia Nervosa

Anorexia nervosa is a disorder of unknown origin that typically takes the form of anorexia, severe weight loss, and amenorrhea (see [Chapter 37](#)). Several aspects of hypothalamic-pituitary function are abnormal. Amenorrhea results from reduced GnRH secretion, which reverts to the low-amplitude, slow-frequency pattern seen in prepubertal girls. If weight is regained, GnRH secretion returns to the adult pattern by rising first during sleep and later during the day, a progression identical to that seen in normal pubertal maturation.

Approach to the Patient with Suspected Hypothalamic Dysfunction

The initial features of hypothalamic dysfunction vary widely (for example, with the age of the patient) and may be endocrine or neurologic in nature. In adults, the presence of diabetes insipidus, alone or in association with hypopituitarism, is suggestive of hypothalamic disease. Pituitary hormone secretion should be assessed; a head CT or magnetic resonance imaging (MRI) test is needed to exclude a pituitary or hypothalamic mass lesion. If individual hormone deficiencies are found, the diagnosis of hypothalamic failure can be confirmed by normal pituitary responses to releasing hormones. Treatment is directed to replacing deficient hormones, particularly cortisol and thyroxine and, if appropriate, by surgical removal of a tumor.

PITUITARY TUMORS

Pituitary tumors represent 10% to 15% of intracranial tumors diagnosed during life. They may be more common, however, because small adenomas have been

reported in up to 30% of autopsy series. In most cases, the cause is unknown, though some hormone-secreting tumors may stem from enhanced stimulation by hypophysiotropic hormones. Studies have indicated that most, if not all, pituitary tumors are monoclonal (they appear to arise from a single cell). A single-cell somatic mutation, rather than diffuse hypothalamic stimulation, is likely to be the initiating event in pituitary tumorigenesis. Pituitary tumors are almost always benign in histologic manifestations and usually expand slowly over a period of years. On occasion, tumors may be aggressive and invade surrounding structures, but true pituitary carcinomas are rare.

Tumors are classified based on immunocytochemical staining for pituitary hormones, which characterizes the cell type, identifies the tumor product, and allows correlation with serum hormone levels. With this system, 15% to 20% of pituitary adenomas are apparently nonfunctioning. Classification by size is based on radiologic findings. Stage I tumors are microadenomas (less than 1 cm) without sella expansion, stage II tumors are macroadenomas (more than 1 cm) and may extend above the sella, stage III tumors are macroadenomas with enlargement and invasion of the sella floor or with suprasellar extension, and stage IV tumors are macroadenomas with extensive invasion or destruction of the sella turcica.

Clinical Findings

Patients with pituitary adenomas may have initial endocrine symptoms or neurologic features due to pressure effects; alternatively, the lesion may be found incidentally on skull roentgenography or CT scan. In the past, tumors were large at diagnosis, and patients usually first experienced neurologic symptoms. Improvements in hormone assays have led to earlier diagnosis, and fewer than 20% of patients now have visual field defects as a first symptom.

Endocrine Findings

Endocrine features may be those of hypopituitarism, hypersecretion of one or more hormones, or a mixture of hypofunction and hyperfunction. Patients with nonfunctioning tumors usually have initial symptoms of hypopituitarism. Hypogonadism may reflect destruction of pituitary gonadotropes but more often results from suppression of GnRH secretion by an elevated prolactin level. The most common functioning pituitary tumors are prolactinomas, followed by GH- and ACTH-secreting tumors. TSH- and gonadotropin-secreting tumors are rare. Tumors may secrete more than one hormone; immunocytochemical studies have shown that 10% to 20% of tumors fall into this category. GH and prolactin commonly are co-secreted, and GH-TSH and ACTH-prolactin secretion also has been described.

Functioning tumors produce symptoms early. ACTH-secreting tumors in both sexes and prolactinomas in women typically are diagnosed as microadenomas. In men, the early symptoms of hypogonadism are impotence and loss of libido. These symptoms often are not investigated; as a consequence, prolactinomas and nonfunctioning tumors often are large at the time of diagnosis. Symptoms of acromegaly also are not recognized early in men, and GH-secreting tumors are frequently large at diagnosis. Pituitary tumors may develop as part of the multiple endocrine neoplasia type 1 syndrome (see [Chapter 415](#)). Generally, GH-secreting or prolactin-secreting tumors are found, but nonfunctioning tumors also may be associated with parathyroid and pancreatic tumors.

Neurologic Findings

Headache is the most common symptom of pituitary tumor and is usually present in patients with large tumors. The headache is often generalized, tends to be of a dull character, and frequently is not relieved by analgesics. It is believed to result from pressure on the diaphragma sellae, and sudden cessation of headache may signal rupture of the diaphragma.

Visual field defects develop in patients with large tumors with suprasellar extensions—they are the initial symptom in 20% of cases. The classic defect is a bitemporal hemianopsia, but field defects vary and often are asymmetric. In 80% of patients, the optic chiasm lies 0.5 to 1 cm above the diaphragma sellae, but it may be prefixed (anterior to the tuberculum sellae) or postfixed (overlying the dorsum sellae) in the other 20%. Visual field defects depend on the relative positions of the optic chiasm and the tumor, and they range in character from small, unioocular scotomata to varying degrees of field loss in both eyes. Consequently, clinical testing of peripheral fields is not adequate, and formal assessment by Goldman perimetry should be undertaken.

Oculomotor nerve palsies occur if the tumor extends laterally into the cavernous sinus. Palsies typically are unilateral, and diplopia due to third cranial nerve involvement is most common. Fourth and fifth cranial nerve palsies may be seen alone or together. Diminished sensation or pain in the face indicates involvement of the fifth cranial nerve. Pituitary adenomas rarely cause papilledema, which, when present, suggests a craniopharyngioma. Suprasellar extension of pituitary tumors may be large (3 to 5 cm), and patients have initial symptoms of hypothalamic dysfunction. Rarely, tumors extend over or through the dorsum sella, compress the brain stem, and manifest as long tract signs. Occasionally, compression of the temporal lobe produces seizures, and erosion down into the sphenoid sinus may appear in the form of CSF rhinorrhea or nasopharyngeal bleeding.

Pituitary Apoplexy

Infarction may occur after hemorrhage into a tumor and is more common in large tumors and after radiation therapy. The clinical manifestations vary, ranging from the acute onset of severe headache that resolves spontaneously over a few days to progression to coma and circulatory collapse. Mild forms of the syndrome are probably more common than is recognized. Patients with large tumors often have a history of acute headache, fever, and mild meningismus. Frequently, the history shows that the patient visited an emergency department and that spinal tap confirmed the presence of a few white or red blood cells or xanthochromia. In these circumstances, a diagnosis of viral encephalitis often is made, and symptoms resolve spontaneously over the next few days.

Severe forms of pituitary apoplexy are life-threatening situations. Onset is dramatic, with severe headache, vomiting, and progressive loss of consciousness. Meningismus is marked, and there may be third, fourth, and sixth cranial nerve paresis with periorbital hemorrhage, suggesting cavernous sinus thrombosis. CSF examination shows several hundred white and red blood cells, which may suggest subarachnoid hemorrhage. Angiography may be required to exclude a leaking aneurysm, but the presence of an enlarged sella on roentgenography strongly suggests the diagnosis. Acute hypopituitarism with hypotension requires immediate replacement of fluids and hydrocortisone. Deficiency of thyroid and gonadal function may develop over days to weeks.

Acute surgical decompression by the transsphenoidal route is indicated in the context of acute neurologic pressure symptoms. Studies have suggested, however, that this treatment may not be necessary in all cases, and recovery has been reported after supportive therapy with intravenous fluids and hydrocortisone. If visual symptoms are pronounced, however, decompression reduces pressure on the optic or oculomotor nerves.

After recovery of pituitary apoplexy, pituitary function may be normal or partially or completely deficient. Formal assessment of pituitary function should be carried out. Infarction of a functioning pituitary tumor may result in diminution of pituitary hypersecretion, but true normalization of secretion or “spontaneous cure” of pituitary tumors is exceedingly rare.

Diagnosis

Evaluation of pituitary tumors consists of assessment of pituitary function, assessment of tumor anatomy by radiologic procedures, and differentiation of pituitary tumors from extrasellar or parasellar lesions or the empty sella syndrome. Endocrine tests should be conducted before therapy, because the results influence subsequent treatment. In hormone-secreting tumors (particularly prolactinomas), medical therapy may be the optimal approach. Basal hormone studies always should be obtained before treatment, and appropriate replacement therapy should be given before surgery. If progressive visual loss or other neurologic symptoms necessitate immediate surgery, preoperative hydrocortisone in stress doses should be administered.

Radiologic Assessment of the Pituitary

Plain roentgenograms of the skull identify an enlarged sella and show bony erosions due to a large tumor ([Fig. 403.4](#)). Irregularities of the sella floor, particularly the presence of a double floor, may suggest the presence of an intrasellar tumor. CT scanning or MRI is needed to verify intrasellar lesions and to define the extent of any suprasellar extension. CT scans with contrast enhancement usually show homogeneous enhancement of the pituitary, but areas of low density are seen in 20% of normal subjects, which can cause problems in the diagnosis of microadenomas. In coronal views, microadenomas typically appear as hypodense areas within the pituitary, though small lesions (less than 3 mm) are difficult to detect ([Fig. 403.5](#)). Macroadenomas generally manifest as an enhancing intrasellar mass, though the center may be hypodense or the sella partially empty, suggesting previous infarction. MRI offers better delineation of the tumor and the surrounding soft tissues, such as the optic chiasm and the cavernous sinus content (internal carotid artery and cranial nerves) ([Fig. 403.6](#)). This is facilitated by gadolinium enhancement. MRI does not provide direct information about surrounding bone structures, however. In some instances, homogeneous enhancement of suprasellar or parasellar areas may be

difficult to differentiate from aneurysms, and angiography is required to establish the diagnosis.

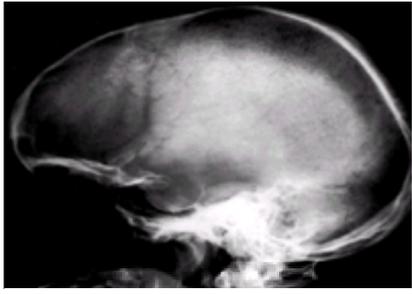

FIGURE 403.4. Lateral skull roentgenogram in a 57-year-old man who presented with bitemporal hemianopia and hypogonadism due to a nonfunctioning pituitary tumor. The sella is enlarged, a double floor is present, and the dorsum sellae has been eroded by the tumor. (Courtesy of T.O. Gabrielsen, M.D.)

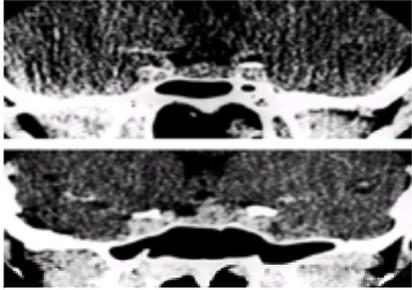

FIGURE 403.5. Computed tomography scans showing pituitary tumors. Both scans were taken in the coronal plane after contrast injection in patients with acromegaly. In the upper panel, the tumor was small and intrasellar and is seen as an upward bulging on the upper surface of the center of the pituitary. The lower panel shows a large tumor with a suprasellar extension on the right side and in the midline. The nonenhancing area on the left side of the fossa is cerebrospinal fluid in a partially empty sella.

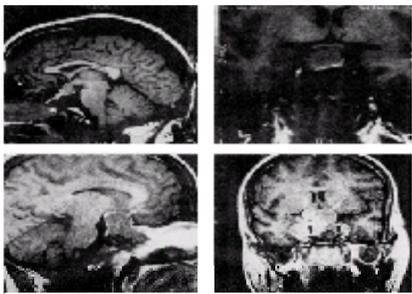

FIGURE 403.6. Magnetic resonance imaging scans in two patients with acromegaly. The upper panel shows coronal and sagittal images of a generous macroadenoma (*thick white arrow*) that reaches the optic chiasm (*black arrow*) and borders on the right internal carotid artery (*thin white arrow*). The lower panel shows coronal and sagittal images of a giant tumor. Optic chiasm is not discernible, and both cavernous sinus are invaded. Internal carotid arteries (*black arrows*) are firmly embedded within the tumor.

Secondary Pituitary Enlargement

Failure of a target gland (thyroid, adrenals, gonads) results in loss of negative feedback and resultant hyperplasia of the corresponding pituitary cells. Occasionally, this leads to significant pituitary enlargement, which may compromise other pituitary function in rare cases. The finding of an enlarged sella, together with evidence of target gland hypofunction, may lead to erroneous diagnosis of a true pituitary tumor. This is especially pertinent in the context of primary hypothyroidism, in which the serum prolactin level may be elevated. The finding of an elevated trophic hormone level provides the clue to the true nature of the process; appropriate replacement therapy is followed by the shrinkage of the hyperplastic pituitary and restoration of pituitary function.

Empty Sella Syndrome

The usual clinical picture in empty sella syndrome is the finding of an enlarged sella turcica on roentgenography. It is important to consider this syndrome in the differential diagnosis of pituitary tumors. In the primary empty sella syndrome, the sella is symmetrically enlarged and partially filled with CSF. The pituitary gland is flattened to a crescent of tissue in the lower posterior part of the sella. The origin of the syndrome is unknown; it may be associated with previous raised intracranial pressure. In most instances, the abnormality is believed to result from a defect in the diaphragma sellae, which allows CSF pressure to herniate the arachnoid down into the sella turcica, resulting in ballooning of the bony sella. The primary empty sella syndrome should be distinguished from a partially empty sella resulting from infarction of the pituitary tumor. The latter condition is suggested by an irregularly enlarged sella and by a double floor or erosions of the surrounding bone.

The primary empty sella syndrome usually develops in women, and headaches may be the initial feature. Most patients are obese and multiparous, and one-third have hypertension. CSF rhinorrhea occurs from time to time, and a minority of patients have a history of pseudotumor cerebri. Pituitary function is typically normal, but sometimes mild hyperprolactinemia may be present, perhaps because of stretching of the pituitary stalk. Dynamic testing may show impairment of TSH and GH reserve, which may reflect concomitant obesity. The diagnosis is established by CT scan or MRI and the presence of normal endocrine function. No therapy is required in most cases, though CSF rhinorrhea needs surgical correction.

Optimal Management

Treatment of pituitary tumors is aimed at limiting hormonal oversecretion, preventing progressive loss of pituitary function, and halting progression of tumor size. Medical therapy is often successful in hyperprolactinemia and in some patients with acromegaly. In other hormone-secreting tumors and in nonfunctioning tumors, medical therapy is ineffective, and treatment consists of pituitary surgery or radiation therapy. The optimal mode of therapy is the subject of controversy and often depends on experience in different centers. In considering treatment, the benefits and risks of therapy should be weighed against the present and future risks of the pituitary tumor. In Cushing's disease and acromegaly, it is important to prevent the progression of the metabolic effects of hormonal hypersecretion, and more aggressive approaches are appropriate. In nonfunctioning tumors without neurologic manifestations, expansion of the tumor takes place slowly. In an elderly patient, replacement of the hormone deficiency may be the most efficacious approach. In general, good results are obtained with microadenomas, but it is rarely possible to

cure large tumors by surgery.

Surgery

Except for patients with large suprasellar extensions, pituitary surgery is carried out by the transsphenoidal route. This approach is safe, with a mortality rate of less than 0.5%; morbidity due to such complications as CSF rhinorrhea is also low (less than 2%). The transsphenoidal approach allows visualization of the sella contents, and microadenomas often can be removed selectively without impairment of other pituitary function. Glucocorticoids always should be administered during the perioperative period, even if preoperative testing does not show ACTH deficiency. Hydrocortisone, 100 mg, should be administered intravenously immediately before surgery, followed by 50 mg intramuscularly every 6 hours during the subsequent 2 or 3 days. A replacement hydrocortisone dose (usually 25 mg per day) typically is administered on discharge and continued before formal assessment of pituitary function 2 to 3 months later. Polyuria due to diabetes insipidus commonly is seen during the first 2 to 3 postoperative days and may require treatment with oral or intranasal desmopressin. Diabetes insipidus usually is transient and results from mild trauma to the pituitary stalk. If polyuria persists beyond 7 to 10 days after surgery, it suggests the presence of permanent stalk damage.

The results of surgery for microadenomas that secrete prolactin, GH, and ACTH are good; normalization of hypersecretion has been reported in 70% to 80% of cases. Results are not as good for macroadenomas. Excess secretion is abolished in less than 50% of patients, and a high proportion (10% to 20%) experience postoperative hypopituitarism. The efficacy of pituitary surgery is highly operator-dependent. Several studies have shown that in the hands of an experienced pituitary neurosurgeon (more than 200 to 500 previous operations), elimination of hormone hypersecretion is three to four times more common, and the complication rate is three to four times lower, than after intervention by a general neurosurgeon with only limited pituitary experience. Surgery is rarely successful in curing the mass effects of large tumors, and symptoms recur in 70% to 80% of patients. This rate can be lowered to 10% to 20% if postoperative radiation therapy is given.

Radiation Therapy

Radiation therapy often is used as an adjunct to surgical therapy of macroadenomas, but it also can be used as primary treatment. A major disadvantage is that the effects of radiation are delayed and suppression of pituitary hypersecretion may not be evident until 3 to 5 years after treatment. In addition, a growing body of evidence suggests that hypopituitarism, in part as a result of effects on the hypothalamus, is common after radiation therapy; as many as 50% of patients may experience it. Conventional radiation is given using a rotational technique, and 20 to 25 treatments over 4 to 6 weeks are required to deliver the total dose of 45 to 50 Gy. Heavy-particle therapy with proton beams or α -particles also can be used; this treatment has the advantage of delivering a higher radiation dose (up to 140 Gy) to the pituitary. This treatment allows somewhat improved results in limiting hypersecretion, but the full effects are still not manifest until several years after treatment, and the incidence of hypopituitarism may be higher than after conventional radiation therapy. This type of radiation therapy is contraindicated if significant suprasellar expansion is present, because it may lead to optic nerve damage. Stereotactic radiosurgery utilizing γ -knife is rapidly becoming more widespread owing to the commercial availability of the equipment. Nevertheless, direct comparison of its efficacy versus conventional radiotherapy is still largely unavailable.

HYPOPITUITARISM

Hypopituitarism results from impaired secretion of one or more pituitary hormones. It may be caused by primary pituitary disease or abnormal hypothalamic hormone secretion. Patients with pituitary and hypothalamic diseases have clinical features similar to endocrine manifestations. Radiologic investigation and pituitary responses to hypothalamic hormones are useful in localizing the site of the lesion, but it is not always possible to distinguish between hypothalamic and pituitary disorders. Hypothalamic and pituitary causes of hypopituitarism are listed in [Table 403.3](#) and [Table 403.4](#), respectively.

Tumors
Pituitary adenoma
Craniopharyngioma
Metastatic carcinoma
Primary pituitary carcinoma
Ependyoma
Pituitary infarction
Pituitary apoplexy (pituitary tumor)
Postpartum pituitary necrosis (Sheehan's syndrome)
Diabetes mellitus
Shock
Sickle cell anemia (crisis)
Infections (meningitis, epidemic hemorrhagic fever)
Cavernous sinus thrombosis
Vasculitis (temporal arteritis, Takayasu's arteritis)
Trauma (stalk section or sella fracture)
Infiltrative diseases
Sarcoidosis
Tuberculosis
Lymphoma
Lymphoma
Lymphoma
Hemochromatosis
Autoimmune hypophysitis
Miscellaneous
Hypophysectomy
Radiation necrosis
Carotid artery aneurysm
Pituitary abscess
Congenital anomalies (hypoplasia, aplasia)

TABLE 403.4. PITUITARY LESIONS CAUSING HYPOPITUITARISM

In patients with functioning pituitary tumors, hypersecretion of one hormone may coexist with reduced function of other pituitary cells. Hypopituitarism may be permanent (pituitary necrosis or hypophysectomy) or reversible (function may be restored after removal of a pituitary tumor). As a rule, GH and gonadotropin secretion is lost early, followed by failure of TSH, ACTH, and prolactin later in the course of the disease. In practice, however, any permutation of hormonal deficiencies may be seen, and the effects of individual hormone failure should be considered separately.

Clinical Findings

Patients with hypopituitarism typically are well nourished, and the skin is often pale and waxy with increased wrinkling around the eyes and mouth. General apathy and mental slowing often occur and may not be recognized because of the insidious nature of their onset. Mild anemia is common and usually is normochromic and normocytic, probably reflecting deficiency of thyroid and gonadal hormones. Hypoglycemia is rare in adults, but it may develop in diabetic patients who require insulin, because GH and ACTH deficiency leads to increased sensitivity to insulin.

Growth Hormone Deficiency

In adults, GH deficiency is the most frequently encountered component of hypopituitarism stemming from pituitary tumors, surgery, and irradiation. In the past, GH deficiency in the adult patient was believed to be devoid of any appreciable clinical significance. Studies using recombinant GH preparations, however, have suggested that daily administration of GH to hypopituitary patients increases lean body mass, decreases body fat content, and strengthens bone density. Many additional studies have to be done to validate GH use in various clinical situations. Until that time, there is no justification for using GH for the treatment of obesity, for the purpose of bodybuilding, or for other unproven indications.

In children, isolated GH deficiency likely is caused by isolated GH-RH deficiency. This is often a familial disease, and autosomal recessive (type I), autosomal dominant (type II), and X-linked recessive (type III) modes of transmission have been documented. No abnormalities in GH or GH-RH genes have been detected. A special form of GH deficiency (type IA) has been reported in Switzerland; these children appear to lack a gene for GH. Administration of exogenous human GH in these patients leads to a rapid rise in the titer of GH-blocking antibodies and attenuation or cessation of clinical responses to exogenous GH, because GH is regarded by the immune system as a completely foreign substance.

Other causes of congenital GH deficiency include defective GH-RH receptor and mutations in the transcription factors pit-1 and prop-1. In the latter cases, GH deficiency may coexist with partial or complete prolactin and TSH deficiencies. GH deficiency also may be seen in patients with several hormonal deficits stemming from hypothalamic or pituitary tumors, pituitary hypoplasia (or aplasia), or the so-called midline brain syndrome. In this congenital condition, hormonal abnormalities are associated with hypoplasia of the optic nerves, absent septum pellucidum, cleft palate, and a single central incisor. Increasingly, cranial irradiation for malignant diseases is being seen as a cause of clinically apparent GH deficiency because of the longer survival of affected children.

The hallmark of GH deficiency in childhood is short stature with progressive downward deviation from the predicted growth curve. Classically, these children are short and appear to be somewhat fat. The genitalia may be small, and the presence of micropenis at birth always should alert the clinician to the possibility of combined GH and gonadotropin deficiency. Bone age typically is delayed. Severe hypoglycemia may be a feature of GH deficiency in children, especially when ACTH also is

missing.

Gonadotropin Deficiency

The clinical picture of gonadotropin deficiency depends on the age at onset of the disease. Failure of LH and FSH secretion before puberty results in absent or incomplete sexual maturation. In men, the testes are small (less than 2 cm), as is the penis, and scrotal rugosity, facial and pubic hair, and the laryngeal notch are absent. Women have primary amenorrhea, and the breasts and uterus are underdeveloped. Body proportions are eunuchoid, with long extremities (arm span exceeds height by more than 5 cm) due to failure of epiphyseal closure. Isolated gonadotropin deficiency of prepubertal onset may be associated with anosmia (Kallmann's syndrome, olfactory-genital dysplasia). The disorder is more common in boys and is caused by GnRH deficiency, which may be complete or partial. Other congenital abnormalities, such as color blindness and midline facial defects, also may be present. GnRH deficiency also is seen in the absence of other defects. In individual members of an affected family, GnRH deficiency and anosmia may be present together or as isolated abnormalities. The disease apparently results from the embryologic failure of GnRH cells to migrate from the olfactory placode into the brain during fetal life. Mutations in the *KAL* gene, normally coding for a neural cell adhesion molecule, which normally "guides" the embryologic migration of GnRH and olfactory neurons, have been documented in these patients.

Postpubertal gonadotropin deficiency in men takes the form of impotence, infrequent need to shave, infertility, and general weakness. Examination shows a normal penis, testicular atrophy initially manifest as soft testes, sparse pubic hair, atrophic skin, and poor muscle development. Fine radial wrinkling of the skin around the mouth is evident, and gynecomastia may be present. Women have amenorrhea and decreased vaginal lubrication and may have atrophic breasts and uterine involution. Osteoporosis is common in both sexes.

Thyroid-Stimulating Hormone Deficiency

Cold intolerance, fatigue, somnolence, dry skin, constipation, bradycardia, and mental impairment are common in both primary and secondary hypothyroidism. The symptoms are usually less severe in TSH deficiency, and a goiter does not develop.

Adrenocorticotropic Hormone Deficiency

Isolated ACTH deficiency leads to diminished cortisol secretion. Aldosterone secretion typically is intact, because the renin-angiotensin system continues to function normally. Patients with ACTH deficiency do not experience severe volume depletion, hyperkalemia, and hyponatremia. In contrast to Addison's disease, the skin is pale and does not tan, because melanocyte-stimulating hormone also is deficient. ACTH deficiency usually appears as weakness, fatigue, and orthostatic hypotension. Patients often describe the clinical course of minor illnesses, such as a common cold, as unusually severe and exhausting. Surgery or intercurrent illness increase cortisol demand and may precipitate nausea, vomiting, abdominal pain, and vascular collapse.

Prolactin Deficiency

Failure to lactate is the only known consequence of prolactin deficiency in women and is the usual clinical feature of postpartum pituitary necrosis (Sheehan's syndrome). In men, prolactin deficiency is of no known physiologic or clinical consequence. Isolated prolactin deficiency has been reported rarely, but it may be more common, owing to the lack of clinical manifestations.

Disease Syndromes

Pituitary tumors are the most common cause of hypopituitarism. Postpartum pituitary necrosis (Sheehan's syndrome) has become a rare cause of hypopituitarism because of improved obstetric care. In nonindustrialized countries, however, it remains a common cause of pituitary failure when delivery is associated with severe hemorrhage and shock. Pituitary hypertrophy during pregnancy makes the gland especially vulnerable to reduced blood flow, and spasm of the superior hypophyseal artery results in anterior pituitary necrosis. Occasionally, necrosis is complete, and if ACTH deficiency is not treated immediately, the postpartum mortality rate is high. More often, necrosis is partial and takes the form of failure of lactation and amenorrhea. Pituitary fibrosis leads to progressive loss of pituitary function during subsequent months, and a partial or completely empty sella becomes evident on CT scan. Endocrine testing usually shows panhypopituitarism, though partial or selective loss of anterior pituitary secretion may occur. Clinical ADH deficiency is rare. Pituitary necrosis can develop in any patient with profound shock, but it is most common in diabetics, because of microangiopathy and macroangiopathy. Pregnancy and ketoacidosis are important predisposing factors. Rarely, necrosis can develop in patients with infectious diseases, sickle cell anemia, or arteritis or after trauma to the pituitary stalk.

Infiltrative Diseases

The pituitary may be affected by the same diseases that produce infiltrative lesions in the hypothalamus ([Table 403.3](#)). Autoimmune hypophysitis typically occurs during the third trimester of pregnancy or in the first few months postpartum. The cause is unknown, but it is believed to result from the autoimmune destruction of pituitary cells. Histologic examination shows diffuse lymphocytic infiltration of the anterior pituitary. Another form of autoimmune hypophysitis is associated with other autoimmune endocrine diseases, such as Addison's disease, Hashimoto's thyroiditis, pernicious anemia, hypoparathyroidism, or gonadal failure. In some cases, circulating antibodies directed against prolactin-secreting cells have been found.

Miscellaneous Causes

Radiation therapy of the head is often followed by hypopituitarism that may not become evident for months to years after treatment. Deficiencies of GH in children and gonadotropins in adults are the most common manifestations. Carotid artery aneurysms may simulate a pituitary tumor on CT scan but seldom cause pituitary compression. Congenital pituitary anomalies are rare and usually are recognized in childhood during the workup to assess growth retardation.

Diagnosis

The clinical suggestion of hypopituitarism should be substantiated by endocrine testing. The presence of low pituitary and corresponding target gland hormone levels establishes the diagnosis. Differentiation of pituitary from hypothalamic failure and assessment of the degree of the pituitary impairment require appropriate stimulation tests (see [Chapter 417](#)).

Approach to the Patient With Suggested Hypopituitarism

The clinical history in a patient believed to have hypopituitarism is of paramount importance. A history of pituitary surgery, head radiation or trauma, a traumatic delivery, or existing systemic diseases may provide valuable clues. Several questions should be addressed:

Is the patient truly hypopituitary? Growth failure in a child may result from causes other than GH deficiency, and short stature is most often constitutional. Similarly, delayed sexual maturation may be provoked by gonadotropin deficiency or primary gonadal failure, but more often it is of constitutional origin or the result of systemic illness. In adults, organic causes of hypopituitarism are more likely, and symptoms and signs of hormonal failure should not be attributed to functional causes. Basal assessment of thyroid, gonadal, and adrenal function always should be performed, and low or borderline values must be followed by assessment of pituitary hormone secretion.

What is the origin of hypopituitarism? History and examination may provide important clues to the source of pituitary failure. Concomitant diseases, such as blood dyscrasias, hemochromatosis, or granulomatous diseases, in a patient with hypopituitarism suggest a common origin. Absent sexual maturation indicates a prepubertal onset of hypogonadism, and the presence of anosmia strongly suggests Kallmann's syndrome. Visual field defects or ophthalmoplegia indicate a mass lesion. CT scans or MRI always should be performed in the context of hypopituitarism, to exclude mass lesions.

Should dynamic tests of pituitary function be performed? If hypopituitarism is caused by a lesion that requires surgery, preoperative dynamic tests of pituitary function are unnecessary, because they may not reflect the postoperative situation. Before surgery, all patients should be viewed as having ACTH deficiency and treated with stress doses of glucocorticoids during the perioperative period. Dynamic assessment of pituitary function should be performed 2 to 3 months after surgery, and appropriate hormonal replacement must be given. If surgery is not indicated, assessment of pituitary reserve should be carried out via a combined pituitary function

test (see [Chapter 417](#)). Diminished ACTH or TSH reserve is an indication for replacement therapy with glucocorticoids or thyroxine, even when the basal plasma cortisol or thyroxine levels are apparently normal. In patients with potentially progressive diseases (radiation damage, infiltrative diseases, vasculitis), residual pituitary function should be assessed on a semiannual basis with basal tests. Dynamic tests should be undertaken if a decline in basal function is observed.

Optimal Management

Treatment of hypopituitarism should be directed toward the underlying cause and to replacement of hormonal deficiencies. The first objective is usually possible only with mass lesions, such as pituitary tumors. Pituitary function may improve after surgery, but more often it remains deficient or deteriorates further. Replacement therapy should take into account the patient's age, sex, and desire for fertility.

Adrenocorticotrophic Hormone Deficiency

Maintenance therapy consists of hydrocortisone, 25 mg per day, generally administered in split doses: 10 to 15 mg in the morning, 10 mg with lunch, and 5 mg with dinner. If the patient experiences insomnia and restlessness in the late evening, the evening dose may be omitted or given earlier. Prednisone, 7.5 mg per day, can be used as an alternative; mineralocorticoid replacement usually is not required. If an intercurrent disease develops, especially one associated with fever, the daily dose of hydrocortisone should be doubled until recovery is complete. Nausea, vomiting, or diarrhea may require parenteral therapy. Acute surgery or severe illness should be covered by stress doses of parenteral hydrocortisone, 200 mg per day. As the patient's condition improves, the dose should be tapered to replacement levels over 3 to 7 days. All patients with ACTH deficiency should wear an identification necklace or bracelet.

Thyroid-Stimulating Hormone Deficiency

Thyroid hormone replacement consists of 0.1 to 0.2 mg per day of L-thyroxine; the individual dosage is determined on the basis of serum thyroxine levels, since TSH is not a reliable marker in hypothalamic or pituitary disease. Desiccated thyroid or triiodothyronine should not be used. In elderly individuals (older than 70 years) or in patients with coronary artery disease or dysrhythmias, the initial dose should be lower, 0.025 mg per day, and gradually increased by 0.025 mg each week to full replacement dosage. In otherwise healthy individuals and in those with recent-onset hypothyroidism (postpituitary surgery), full replacement doses can be started immediately. Thyroid replacement increases cortisol degradation and basal metabolism and may precipitate adrenal insufficiency in patients with diminished ACTH reserve. If the ACTH or cortisol reserve is impaired, hydrocortisone must be administered before thyroxine replacement.

Gonadotropin Deficiency

If fertility is not desired, gonadal steroid replacement therapy is given. Women should be treated with 17 α -estradiol in the form of skin patches (Estraderm) or taken orally (Estrace), 1 to 2 mg per day, which allows monitoring of plasma estradiol (80 to 100 pg per milliliter). Estrogens are administered on a cyclical basis for the first 3 weeks of each month; medroxyprogesterone acetate (Provera), 5 to 10 mg per day, is added during the third week. This regimen induces regular withdrawal bleeding during the week off therapy and avoids the risk of endometrial cancer. Cyclical therapy is not required in women who have had a hysterectomy. Men should be treated with long-acting testosterone preparations (testosterone enanthate or cypionate), 200 to 300 mg administered intramuscularly every 2 to 3 weeks. Transdermal testosterone delivery systems are available, but the theoretical advantage of constant plasma hormone levels often is outweighed by lower efficacy (due to only low-normal hormone levels), high cost, and skin irritation. Oral testosterone preparations are weak androgens and are rarely effective. At adequate dosage they may cause cholestatic jaundice or hepatitis. In men older than 50 years, testosterone may produce prostatic hyperplasia, and the prostate should be examined at regular intervals.

In pituitary failure, fertility can be achieved only by using exogenous gonadotropins. Human chorionic gonadotropin exerts LH-like actions, whereas human menopausal gonadotropin is a mixture of LH and FSH. In men, hCG, 2,000 IU, should be administered intramuscularly three times a week for at least 4 months, followed by the addition of human menopausal gonadotropin, 75 IU administered intramuscularly three times a week. Therapy generally is required for more than a year to induce adequate spermatogenesis, and the best results occur when gonadotropin deficiency develops after puberty. In prepubertal women, sexual maturation and uterine growth should be induced by estrogen treatment for 4 to 6 months. Cyclical estrogen and progesterone therapy is then given for 3 to 4 months, to induce menses before gonadotropin therapy. Human menopausal gonadotropin, 75 to 150 IU per day, is administered for up to 2 weeks, and follicular maturation is monitored by estradiol assays and ovarian ultrasonography. Ovulation then is induced by intramuscular injection of hCG (2,000 IU). Recombinant FSH is replacing hCG as a drug of choice. Care should be taken to avoid ovarian hyperstimulation. This therapy should be reserved for use in medical centers where rapid estradiol assays and ovarian ultrasonography are available.

In GnRH deficiency, sexual maturation and fertility can be induced in both sexes by pulsatile GnRH therapy. Pituitary responsiveness to exogenous GnRH should be determined before long-term treatment. GnRH pulses are given every 60 to 120 minutes by portable pump, either intravenously at a dose of 25 to 50 ng per kilogram or subcutaneously at a dose of 50 to 100 ng per kilogram. Ovulatory cycles can be induced rapidly in women, but restoration of spermatogenesis in men requires a year or more of therapy.

Growth Hormone

No area of clinical endocrinology is as controversial as diagnosis and treatment of GH deficiency. First, the definition of a "short" child should take into account racial and familial backgrounds. Stature correction for parental height may be helpful when appropriate tables are consulted. Because idiopathic GH deficiency is often a genetic disease, however, cursory consideration of parental height may be misleading. Growth velocity (centimeters per year) may be influenced by gonadal status, and delayed puberty often is associated with slow statural growth.

Second, it may be difficult to define "abnormal" GH secretion, because of the pulsatile nature of hormone secretion. Several samples should be taken, and stimulation tests should be used. A normal GH rise to hypoglycemia or any other pharmacologic test, however, does not necessarily mean that a child can have endogenous GH pulses of normal frequency and amplitude. A diagnosis of so-called GH neurosecretory dysfunction is suggested for short children with normal provocative GH test results but an abnormal spontaneous secretory pattern. Plasma insulin-like growth factor I (IGF-I) appears to be lower in short children than tall children, but the within-group variability is significant, and overlaps are common. Even when the biochemical diagnosis was based on the most sophisticated tests with seemingly unquestionable results, 30% to 70% of these children exhibited perfectly normal GH secretion when retested several years later. In this group, GH deficiency might have been functional and transient, akin to gonadotropin deficiency in delayed puberty.

Third, introduction of high-resolution CT scans and MRI showed that more than 90% of children with "idiopathic" GH deficiency have some radiologic evidence of abnormality, most often pituitary hypoplasia. The meaning of these findings is uncertain. Fourth, the question of who should be treated with exogenous GH is still subject to debate. Although it is agreed that an otherwise healthy short child with low growth velocity, delayed bone age, absent GH rises to provocative stimuli, and low IGF-I should be given GH injections, there is no consensus on the use of GH in a much larger group of children with equivocal clinical and biochemical findings. Moreover, in these children the response to GH substitution is less dramatic. In children whose GH deficiency is caused by surgery or radiation for intracranial neoplasm, the benefits of GH replacement should be weighed carefully against the theoretical possibility of induction of tumor-promoting growth factors. The cost of GH replacement is in excess of \$10,000 per year, and the long-term consequences of unnecessary GH therapy are still unknown. A decision to start GH replacement in a child should never be taken lightly and is best accomplished in a pediatric endocrine center specializing in this problem.

GH replacement has been approved for use in GH-deficient adults. Whereas it improves body composition (decrease in fat mass and increase in lean body mass) and bone density, there is still no evidence of tangible benefits, such as a decline in the incidence of cardiovascular events or bone fractures. The purported improvement in the quality of life must be viewed with caution, since many studies were done in an unblinded fashion, the psychometric evaluations were imprecise, and the quality of life in some studies of GH-deficient adults either was normal or, when impaired, was attributed not to GH deficiency itself but rather to previous interventions, such as surgery and, more often, cranial irradiation.

The differential diagnosis of isolated GH deficiency should include chronic diseases, especially those associated with poor nutritional status (cardiopulmonary diseases, celiac disease, inflammatory bowel disease), hypothyroidism, poorly controlled diabetes, Cushing's syndrome, delayed puberty, psychosocial deprivation, and Laron's dwarfism. In the latter condition, GH receptors are missing or defective, and the resultant peripheral GH insensitivity manifests as high GH and low IGF-I levels. High-resolution CT scan or MRI should be carried out, to exclude cranial neoplasm. Assessment of GH secretion should include lists of the dynamic responses of GH to provocative stimuli. Only recombinant human GH is available in the United States for therapeutic purposes, and it is likely to supplant the pituitary-derived preparations worldwide. Optimally, GH should be administered intramuscularly once a day, at a dose between 0.02 and 0.04 mg per kilogram. Treatment should start

as early as possible, to capitalize on the maximal growth potential, and continue until epiphyseal fusion is documented. Maximal growth velocity happens during the first year of therapy (*catch-up growth*). Development of GH-RH and its analogues opens a new avenue for treatment of children with GH-RH deficiency.

PITUITARY HYPERFUNCTION

Hyperprolactinemia

Hyperprolactinemia, the elevation of the serum prolactin level to more than 20 ng per milliliter in men or nonpregnant women who are not nursing, is the most common form of pituitary hyperfunction. Disorders causing hyperprolactinemia are shown in [Table 403.5](#). Prolactin secretion normally is inhibited by dopamine. Therefore, any disorder or medication that interferes with the synthesis or secretion of dopamine, reduces the amount of dopamine reaching the pituitary, or blocks dopamine binding to its receptor results in hyperprolactinemia. Occasionally, elevated prolactin levels are evident in severe primary hypothyroidism and are believed to result from increased TRH secretion. Hypothalamic or stalk disorders produce modest elevations of prolactin (less than 150 ng per milliliter). Similar elevations of prolactin occur in renal failure, because of reduced prolactin metabolism and diminished pituitary sensitivity to dopamine. Now and then, the combination of renal failure and such medications as phenothiazines or methyldopa increases prolactin levels to higher than 150 ng per milliliter. Elevation of serum prolactin above 200 ng per milliliter almost always is caused by a prolactinoma. The differentiation of idiopathic hyperprolactinemia from a prolactinoma, however, rests on the ability to find evidence of a pituitary tumor on CT scanning or MRI.

Physiologic
Pregnancy
Breast feeding (first 6 weeks)
Stress
Stimulate stimulation
Stress
Medications
Dopamine receptor antagonists
- Domperidone
- Metoclopramide
- Methylphenidate
- Methylphenidate
- Methylphenidate
Inhibitors of dopamine synthesis or storage
- Methyldopa
- Methylphenidate
Pituitary tumors
Prolactinomas
Gonadotropin-releasing hormone-secreting tumors (30%)
Nonfunctioning tumors with suprasellar extension and stalk compression
Hypothalamic/pituitary stalk abnormalities
- Craniopharyngiomas, Rathke's cleft cysts
- Craniopharyngiomas and other suprasellar tumors
- Stalk section
- Empty sella syndrome
- Pituitary stalk transection
Other causes
- Primary hypothyroidism
- Chronic renal failure
- Chest wall lesions (post-surgery or herpes zoster)

TABLE 403.5. CAUSES OF HYPERPROLACTINEMIA

Hyperprolactinemia is more common in women and is the underlying abnormality in 20% to 25% of women with amenorrhea. Prolactin is elevated in 25% of women with amenorrhea after discontinuing oral contraceptives, but there is no evidence that the estrogen component of the pill is a causative factor. In men, the incidence of hyperprolactinemia is not well documented, though in some series prolactin levels have been elevated in up to 10% of impotent men and 60% to 70% of those harboring prolactinomas. In both sexes, an elevated prolactin level results in reduced GnRH secretion, and the initial symptoms are those of hypogonadism. In most cases, hypogonadism associated with hyperprolactinemia is reversible after suppression of prolactin secretion.

Clinical Findings

In women, hyperprolactinemia causes oligomenorrhea or amenorrhea, infertility, and galactorrhea. Amenorrhea usually is present if serum prolactin levels exceed 100 ng per milliliter. Galactorrhea, the production of milk in nonpostpartum women, is evident in only 30% to 40% of hyperprolactinemic women, because both an elevated prolactin level and normal or near-normal ovarian steroid levels are needed for sustained milk production. Hyperprolactinemia should be suspected in all amenorrheic women. If amenorrhea and galactorrhea are both present, an elevated prolactin level is found in 80% of patients and a prolactinoma can be confirmed in half these women. Galactorrhea in the presence of normal menses often is not associated with an elevated prolactin value. The mechanisms of action are unclear, but they may relate to the fact that prolactin levels are not elevated after the first 6 weeks of breast-feeding, yet milk production is maintained. A transient elevation of prolactin may initiate milk secretion, which continues, perhaps maintained by nipple stimulation, even though the prolactin level has returned to normal. Diminished gonadotropin secretion leads to anovulation and estrogen deficiency, which takes the form of reduced vaginal lubrication and dyspareunia—or osteoporosis, if it is of prolonged duration. Hirsutism is sometimes present and may reflect a combination of estrogen deficiency and, possibly, increased androgen production.

In men, prolactin excess results in impotence, diminished libido, infertility, and hypogonadism. Hyperprolactinemia should be considered in all impotent men, especially if the serum testosterone is low or low-normal. Impotence in men often is not investigated early. Consequently, hyperprolactinemia may be missed, and prolactinomas are commonly large at the time of diagnosis. The serum testosterone value is typically low, but impotence and reduced libido sometimes have been reported in men with hyperprolactinemia and normal testosterone levels.

Differential Diagnosis

Investigation of hyperprolactinemia should identify the underlying cause if possible and establish whether a prolactinoma is present. An outline of the investigation of an elevated prolactin level is given in [Chapter 417](#). Minor elevations of prolactin (less than 30 ng per milliliter) may be related to stress or to samples being drawn in the early morning, before the sleep-associated rise in prolactin has declined. A careful drug history should be taken, hypothyroidism and renal failure should be excluded, and a pregnancy test should be carried out in amenorrheic women. Serum prolactin values of less than 150 ng per milliliter may be caused by medications, by nonfunctioning pituitary tumors, or by a small prolactinoma, and careful attention should be paid to the possible presence of hypothalamic disease. Prolactin values more than 200 ng per milliliter are virtually diagnostic of a prolactinoma. The degree of hyperprolactinemia reflects the size of the tumor, and levels may reach 20,000 ng per milliliter in patients with large macroadenomas.

Tests using TRH or metoclopramide to stimulate prolactin or dopamine agonists to suppress prolactin are not helpful in distinguishing prolactinomas from other causes of hyperprolactinemia. The presence of a prolactinoma is confirmed by a CT scan or MRI, and in most women the tumor is a microadenoma (less than 1 cm in size). If the scan result is negative and no other cause for the elevated prolactin value is found, the patient is said to have idiopathic hyperprolactinemia. Small tumors cannot be excluded by MRI, however, and follow-up, with measurement of prolactin at 6-month intervals, and an annual scan are recommended. Microadenomas do not compromise other aspects of pituitary function, and formal testing of pituitary reserve is not needed. Macroadenomas may cause hypopituitarism, and pituitary function should be assessed by a combined pituitary function test. If a macroadenoma is present on scanning and the serum prolactin value is less than 150 ng per milliliter, the tumor is unlikely to be a prolactinoma, and a nonfunctioning pituitary tumor with suprasellar extension should be suspected.

Optimal Management

Considerable change has occurred in the management of hyperprolactinemia, which reflects the availability of dopamine agonists and recognition of the fact that most microadenomas do not progress to form macroadenomas. In addition, though surgery results in an initial remission in 80% to 90% of microadenomas, follow-up has shown that up to 50% of patients have a recurrence of hyperprolactinemia within 5 to 6 years. Surgery may be required for large tumors—to reduce tumor mass and relieve pressure symptoms—but rarely results in normalization of serum prolactin levels. The management of hyperprolactinemia may involve observation only; drug therapy; or a combination of dopamine agonist, surgery, and radiation therapy. The approach used should reflect the patient's age and sex, their desire for fertility, and the need to preserve pituitary function and avoid the consequences of tumor growth.

If a woman with idiopathic hyperprolactinemia or a microadenoma experiences regular menses and fertility is not desired, a case can be made for observation. Series have suggested that many microadenomas do not enlarge over 5 to 8 years. With idiopathic elevation of prolactin to the range of 30 to 60 ng per milliliter, prolactin levels have been shown to decline in 50% of women over 3 to 5 years and occasionally fall to normal. If fertility is desired and the CT scan result is negative or shows a microadenoma, then dopamine agonist therapy should be given. Bromocriptine suppresses serum prolactin values to normal in 95% of women, menses resume within 6 to 8 weeks in 90%, and galactorrhea is reduced or abolished in 80%. The usual dose required is 2.5 mg three times daily, but a total dose of 5 mg per day or less is effective in some women.

Side effects include nausea, anorexia, fatigue, nasal congestion, and postural hypotension. These side effects usually can be prevented by starting therapy at a low dose of 1.25 mg administered at bedtime and increasing by 1.25-mg increments every 2 or 3 days, to a total dose of 2.5 mg three times daily taken with meals. Occasionally, the side effects of bromocriptine persist and prevent the use of doses needed to suppress prolactin to normal levels. In such patients, an alternative is to use pergolide mesylate, 25 to 50 µg per day. Pergolide is a dopamine agonist that has been shown to be effective in clinical research studies. A newer dopamine agonist, cabergoline, is effective as a once- or twice-weekly dose (0.25 to 1 mg each) and has a lower incidence of reported side effects.

The patient should avoid pregnancy until at least one spontaneous menstrual period has occurred, to allow more accurate dating of conception. Bromocriptine or cabergoline have not been shown to have adverse effects on the fetus. The drug is usually stopped when menses are overdue, however, and not restarted if the patient is pregnant. Microadenomas may enlarge during pregnancy but rarely cause symptoms. In 15% to 20% of women with larger tumors, however, headaches and visual field defects occur, and visual fields should be carefully checked during the first trimester. Minor field defects generally do not progress, and specific therapy often is not required. Progression of visual field defects is found occasionally and usually responds to reinitiation of dopamine agonist during the remainder of the pregnancy.

In amenorrheic women who do not desire fertility, treatment of microadenomas is more controversial. Suppression of prolactin secretion is needed to restore ovarian function and to prevent the possible development of osteoporosis. Dopamine agonists restore gonadal function and prevent tumor growth for as long as the medication is taken, but prolactin levels typically rebound to previous values when the drug is discontinued. These drugs are effective in suppressing prolactin, but they are expensive and rarely curative. For these reasons, some centers prefer to remove the microadenoma, even though the disorder may recur after an apparently successful operation. Surgery also may be indicated for patients who are intolerant of drugs. Treatment is required for all patients with macroadenomas and may consist of dopamine agonists, surgery, radiation therapy, or a combination of all three. Bromocriptine is effective in suppressing prolactin in 95% of macroadenomas, and tumor size usually decreases by up to 50%.

Suprasellar extensions are reduced in size and visual fields usually become normal within a few days to weeks, though doses up to 20 mg per day may be needed to produce these effects. In moderate-sized macroadenomas, dopamine agonists are a reasonable choice for initial therapy. In women, menses typically resume. In men, testosterone levels increase within 3 months as a rule but may not rise to normal until after 9 months of treatment. Dopamine agonists are not curative, however, and tumors expand rapidly with recurrence of field defects if the drug is discontinued. Surgery may be needed for patients who do not respond or who are intolerant of dopamine agonists. Radiation is reserved for patients with unusually aggressive lesions or for those whose tumors continue to grow despite surgery and/or dopamine agonists.

Acromegaly

Acromegaly is a chronic debilitating disorder caused by hypersecretion of GH and secondary overproduction of IGF-I, which was formerly called somatomedin C. The clinical manifestations are overgrowth of bone and soft tissues, metabolic abnormalities, and mass effects of the GH-secreting pituitary tumor. The annual incidence of acromegaly is three new cases per million, and the overall prevalence is 40 cases per million. Acromegaly occurs with equal frequency in both sexes, and most patients are diagnosed in the third or fourth decade of life. A careful history usually shows a 5- to 10-year lag between the onset of symptoms and diagnosis. During this interval, pituitary tumors enlarge, and at diagnosis 70% to 80% are macroadenomas. The pathologic processes causing acromegaly are listed in [Table 403.6](#).

Process	Percentage
Pituitary GH-producing adenoma	>99
Pituitary GH-producing carcinoma	
Adenoma of the ectopic pharyngeal pituitary	<1
Ectopic GH-producing tumor	
Hypothalamic or pituitary GHRH-producing gangliocytoma	
Ectopic GHRH-producing tumor	
Autonomous production of insulin-like growth factor I (not yet described)	

GH: growth hormone, GHRH: growth-hormone-releasing hormone.

TABLE 403.6. PATHOLOGIC PROCESSES CAUSING ACROMEGALY

Pituitary GH-secreting tumors account for virtually all cases of acromegaly. Most are benign adenomas, though they often exhibit rather aggressive behavior, with infiltration of peripituitary tissues. GH-producing adenomas account for 25% to 30% of pituitary tumors and exhibit substantial clinicopathologic heterogeneity, with 20% to 25% producing prolactin, ACTH, or TSH in addition to GH. GH-producing pituitary adenomas may develop in a remnant of Rathke's pouch, but ectopic GH secretion by bronchial or pancreatic islet cell carcinomas is rare. Ectopic GH-RH secretion resulting in somatotrope hyperplasia has been described in pancreatic islet cell carcinomas, carcinoid tumors, and pheochromocytomas. Plasma GH-RH levels are higher than 300 pg per milliliter (normal, less than 50) and usually exceed 1 ng per milliliter. Hypothalamic or pituitary gangliocytomas also may produce GH-RH. In these patients, pituitary adenoma rather than hyperplasia is usually present, which may reflect the longer duration of GH-RH stimulation. GH-independent overproduction of IGF-I has not yet been clearly documented. The pathogenesis of GH-producing pituitary tumors is uncertain. In theory, they may arise de novo as an autonomous pituitary tumor or result from chronic hypothalamic overstimulation of pituitary somatotropes by increased GH-RH or deficient somatostatin secretion. Evidence supports both possibilities, and a clear consensus is not available.

Clinical Findings

The clinical picture of GH excess depends on the age at onset. Before puberty, GH excess results in accelerated linear growth and pituitary gigantism. Because patients often become hypogonadal as a result of tumor-induced hypopituitarism, the epiphyses remain open, and somatic growth may persist after the expected age of puberty. After puberty, GH excess results in acromegaly (large extremities). The somatic changes result from increased production of IGF-I, but some metabolic changes may be caused by a direct action of GH. The clinical features of GH excess are shown in [Fig. 403.7](#).

FIGURE 403.7. Appearance and progression of acromegalic features in a young man. Mild coarsening of facial features is noticeable at age 16 years, but at that time it could have easily been attributed to pubertal changes. The patient became unmistakably acromegalic at age 19 years, and the disease progressed relentlessly until 40 years of age, when the diagnosis was made by a *blina* physician who shook the patient's hand. At that time, plasma growth hormone was in excess of 200 ng/mL, and invasive pituitary macroadenoma was found. Coarse facial features, frontal bossing, overdevelopment of lower jaw, and prominent frontal and nasolabial furrows are apparent.

A history of changes in shoe, glove, or ring sizes and coarsening of facial features is characteristic of acromegaly. A large nose, thick lips, accentuated nasolabial and frontal furrows, and frontal bossing are usually obvious. Comparison of earlier photographs is of great help in establishing the approximate age at onset of the disease. Most patients notice oily skin and malodorous perspiration, and the degree of sweating is an index of disease activity. Skin tags, hypertrichosis, and increased pigmentation with acanthosis nigricans are common. Prognathism and malocclusion lead to difficulties in chewing and frequent changes of dentures. Voice changes result from hypertrophy of the larynx, edema of the vocal cords, and enlarged sinuses. Almost all patients experience severe snoring, and sleep apnea is very common. Arthralgias are typical, and arthropathy is caused by overgrowth of the cartilage plates and joint deformities. There is often visceral hypertrophy, and the salivary glands and thyroid are enlarged. Cardiac hypertrophy is common, in part because of hypertension, and frequently is associated with dysrhythmias and congestive heart failure. Acroparesthesias frequently are caused by nerve entrapment, and the carpal tunnel syndrome is present in most patients.

About 80% of patients with acromegaly are insulin resistant, and overt diabetes mellitus is present in 15%, usually those with a family history of diabetes. Hyperphosphatemia, hyperphosphaturia, and hypercalciuria are frequently present, but hypercalcemia suggests the coexistence of hyperparathyroidism. Hyperlipidemia results from inhibition of plasma lipoprotein lipase and hepatic triglyceride lipase. Hypopituitarism is typical with large tumors. A low serum testosterone level in men may reflect the inhibitory action of GH on synthesis of testosterone-binding globulin rather than hypogonadism; they can be differentiated by measurement of the binding protein or bioavailable testosterone. Hyperprolactinemia may be caused by stalk compression or by concomitant secretion of prolactin from a mixed pituitary tumor. Acromegaly is associated with an increased frequency of colonic polyps. The disease may be part of the multiple endocrine neoplasia type 1 syndrome, but familial acromegaly, not associated with other neoplasia, has been described.

Laboratory Findings

The diagnostic criteria of acromegaly have been redefined as a result of the introduction of sensitive GH assays. In normal individuals, most plasma GH values are within the 0.05 to 0.5 ng per milliliter range; they are always above 1 ng per milliliter in untreated patients, however, and most often are frankly elevated, reaching values as high as 500 ng per milliliter. Owing to the normally occurring GH pulsatility, random GH values up to 20 to 30 ng per milliliter are nondiagnostic. The presence of an elevated IGF-I level confirms GH hypersecretion. The hallmark of acromegaly is the nonsuppression of plasma GH below 1 ng per milliliter in a sensitive GH assay after an oral glucose load. TRH stimulates GH secretion in 60% to 80% of patients with acromegaly, and this test is helpful when plasma GH is relatively low. GnRH has a similar effect in 20% to 30% of patients. In contrast to healthy subjects, L-dopa or bromocriptine suppress plasma GH in half the patients, and both are helpful in assessing whether bromocriptine may be of value for medical treatment. Plasma GH-RH should be measured in patients with lung or abdominal tumors. This is the only way to diagnose ectopic GH-RH secretion, because dynamic GH responses are indistinguishable from those in pituitary tumors. A pituitary CT scan or MRI is required to assess tumor size, and the degree of extrasellar expansion. Chest radiography or abdominal CT scan should be considered if lung or gastrointestinal malignancy is suspected.

Differential Diagnosis

The clinical features of acromegaly are characteristic and are rarely confused with other diseases. On occasion, pachydermoperiostosis (skin hypertrophy and large hands) can mimic some features of acromegaly, but GH secretion is normal. Plasma GH levels may be elevated in other diseases, such as renal failure, cirrhosis, uncontrolled diabetes, and malnutrition. In these conditions, the clinical features of acromegaly are not present and the IGF-I value is either normal or low.

Natural History, Prognosis, and Optimal Management

Acromegaly is a slowly progressive disease, and appreciable changes in the patient's status occur over years. Therefore, aggressive therapy may not be required in elderly patients with mild disease. The mortality rate for patients with acromegaly, however, is two to three times that of the general population and is mainly the result of cardiovascular and respiratory diseases. Lowering GH secretion below 2.5 ng per milliliter has been associated statistically with the normalization of mortality rates. Pituitary apoplexy occurs in 30% of untreated patients, but this rarely results in complete tumor necrosis, and the GH level remains elevated. Treatment always should be considered in young patients with acromegaly.

Normalization of GH secretion results in reduced somatic growth and reversal of metabolic abnormalities. Shrinkage of soft tissues takes place rapidly (even within 24 to 48 hours after surgery), and skin changes and hyperhidrosis improve markedly over time. Transsphenoidal surgery is the treatment of choice in most patients. The results depend on tumor size, and intrasellar lesions can be removed successfully in 60% to 80% of patients. Long-term follow-up (up to 8 years) has shown that recurrence is unusual when normal basal GH and IGF-I levels and normal GH responses to provocative stimuli are present after surgery. Pituitary irradiation is reserved for patients with elevated GH and IGF-I levels after surgery or for those in whom surgery is contraindicated. In patients who respond to therapy, GH declines by 50% over the first 1 to 2 years and by 10% to 20% per year for the next 5 to 7 years. Patients with GH levels in excess of 50 ng per milliliter are unlikely to respond to radiation therapy. Despite plasma GH suppression below 0.5 to 1 ng per milliliter, many patients retain high IGF-I levels. Normalization of IGF-I is seen in less than 5% of patients after a 5- to 10-year interval after external radiation. Whether stereotactic radiosurgery is more effective in this regard remains unknown.

Bromocriptine is effective in suppressing the plasma GH level to the near-normal range in 20% of patients with acromegaly; however, normalization of IGF-I levels occurs in less than 10% of patients. The drug is administered four times a day. A total dose of up to 40 mg per day may be required and is used if surgery is unsuccessful or while waiting for the full effects of radiation to occur. In the latter instance, therapy should be stopped temporarily every 1 to 2 years to assess residual GH secretion. Pergolide and cabergoline have been used with similar success. The long-acting somatostatin analogue octreotide has been shown to be effective in normalizing GH secretion in 50% to 70% of patients with acromegaly. Shrinkage of pituitary GH-producing tumors has been noted regularly using 50 to 250 g by subcutaneous injection two to four times a day. Octreotide is also effective in suppressing plasma GH in ectopic GH-RH secretion, and pituitary hyperplasia is diminished. Side effects include nausea, abdominal discomfort, diarrhea, steatorrhea, and formation of gallstones. Newer preparations include slow-release octreotide (Sandostatin LAR, available in the United States) and lanreotide (available in Europe). The former is given as an intramuscular injection of 10 to 30 mg once a month. Since these preparations also shrink the tumors and/or halt their progression, they often obviate the need for radiotherapy.

Cushing's Disease

Cushing's disease is bilateral adrenal hyperplasia caused by an ACTH-secreting pituitary tumor; it is one cause of Cushing's syndrome. The presentation, diagnosis, and management of Cushing's disease are discussed in [Chapter 407](#).

Thyroid-stimulating Hormone Hypersecretion

Rarely, hyperthyroidism results from pituitary TSH hypersecretion due to a TSH-secreting tumor or to selective pituitary resistance to thyroid hormone. In both disorders, the patient has hyperthyroidism and a goiter. Plasma thyroid hormone levels are elevated, and thyroid scan shows diffusely increased radioiodine uptake. Many patients initially are diagnosed as having Graves' disease and treated accordingly. Hyperthyroidism and goiter may recur, however, because of continuing stimulation by the elevated TSH. The absence of ophthalmopathy in a hyperthyroid patient with a diffuse goiter suggests TSH hypersecretion, and the serum TSH should be measured.

TSH-secreting pituitary tumors are usually large and do not respond to TRH with an increase in TSH. Pituitary surgery with subsequent radiation is not always effective. The somatostatin analogue octreotide has been shown to be effective in suppressing TSH and restoring euthyroidism. Selective pituitary resistance to thyroid hormone is often familial. A pituitary tumor is not found on CT scan, and TRH elicits normal or augmented TSH release in the context of hyperthyroidism. Several therapies have been tried, including triiodothyronine, inactive triiodothyronine analogues, bromocriptine, and propylthiouracil, but they are only partially effective.

GONADOTROPIN HYPERSECRETION

Gonadotropin-secreting pituitary tumors are being recognized with increasing frequency. Most tumors are large and take the form of field defects in middle-aged men. Most tumors secrete free α subunit or FSH; LH secretion is either normal or low and is reflected by a normal or low plasma testosterone level. Rarely, hypersecretion of intact LH is accompanied by high testosterone concentrations. Surgery is required to salvage vision, usually followed by irradiation. Bromocriptine may suppress hormonal secretion and slightly reduce tumor size.

CHAPTER 404: DISORDERS OF POSTERIOR PITUITARY FUNCTION

ALAN G. ROBINSON

[Synthesis and Anatomy](#)
[Vasopressin](#)
[Diabetes Insipidus—Hyposecretion of Vasopressin](#)
[Syndrome of Inappropriate Secretion of Antidiuretic Hormone—Hypersecretion of Vasopressin](#)

SYNTHESIS AND ANATOMY

The hormones of the posterior pituitary, oxytocin and vasopressin, are synthesized in individual oxytocin cells and vasopressin cells of the paired supraoptic nuclei and paraventricular nuclei in the hypothalamus. The paraventricular nuclei are located in a middle position just lateral to the walls of the third ventricle. The supraoptic nuclei are located bilaterally above the lateral extremes of the optic chiasm. In these nuclei are large neurons (magnocellular) in which the hormones are synthesized. Axons extend from the paraventricular nuclei anterolaterally and inferiorly, passing around and through the supraoptic nucleus. Then, with the axons of the magnocellular neurons of the supraoptic nuclei, they pass medially to the midline, where they join the tracks from the opposite side and extend together as the supraopticohypophyseal track down the pituitary stalk to axon storage terminals in the posterior pituitary. Hormones are stored in the axon terminals until stimulated exocytosis releases the hormones into the systemic circulation.

For vasopressin, in addition to the pathways to the posterior pituitary, there are additional axons that extend from the paraventricular nuclei to the median eminence to terminate on the initial capillary plexus of the hypothalamic pituitary portal system. Vasopressin is secreted into the capillaries, which drain via the long portal veins to the second capillary system in the anterior pituitary. Vasopressin secreted by this pathway acts on pituitary corticotrophs to stimulate release of adrenocorticotrophic hormone (ACTH). For both hormones there are ill-defined pathways that terminate in the wall of the third ventricle and secrete into the cerebrospinal fluid. There is no known function for the hormones in cerebrospinal fluid.

In the magnocellular neurons, the hormone vasopressin or oxytocin (1,100 dalton) is synthesized as part of a precursor molecule including a 10,000-dalton neurophysin that is specific for oxytocin or vasopressin. For vasopressin, but not oxytocin, there is a third component of the precursor molecule, a 12,000-dalton glycopeptide. After synthesis, the precursor is packaged into neurosecretory granules, and in the granules the precursor is enzymatically cleaved into the hormone, the neurophysin, and (for vasopressin) the glycopeptide. In the granules, the neurophysins form complexes with the hormone, which stabilizes the hormone during axon transport and storage.

At the time of release, the entire contents of the neurosecretory granule are liberated by exocytosis into the perivascular space, and each component of the neurosecretory granule can be detected in the bloodstream. Although the neurophysins (or glycopeptide) might serve in the plasma as surrogate markers for the hormone, they have not been found to have any physiologic function after release from the neuron. The gross anatomy of this system is localized entirely in the pituitary fossa and the basal hypothalamus. The osmoreceptor that is described later herein is located just anterior to the third ventricle in this same anatomic region. The discrete location of the osmoreceptor and the sites of synthesis and secretion of vasopressin have important implications for pathophysiology, as explained later.

VASOPRESSIN

OSMOTIC REGULATION

Sensation of thirst and secretion of vasopressin are the main mechanisms whereby the body controls water balance and osmolality. Although the range of serum osmolality, 275 to 295 mOsm per kilogram, is relatively broad for the normal human population, for each individual, osmolality is tightly regulated around that individual's normal value. When water is lost in excess of solute, there is an increase in plasma osmolality. As little as a 1% increase in osmolality will cause secretion of vasopressin, which stimulates renal conservation of water. Increased osmolality also induces thirst, to replace the water deficit. Thirst is less well studied in humans and is generally thought to have a somewhat higher threshold for stimulation of water intake. In fact, because of social custom, most people drink adequate fluid during the day without experiencing severe thirst. Some studies in animals indicate that thirst is regulated tightly, similarly to secretion of vasopressin. It may be that thirst in humans is more tightly regulated physiologically but is overridden by social custom. Nonetheless, water intake is an important and necessary component to replete loss of water. The action of vasopressin on the kidney only conserves that water which is present in the body, while repletion of water loss requires water intake.

The role of vasopressin in the relationship between plasma osmolality and urine output is illustrated in [Fig. 404.1](#). There is a direct linear and sensitive relationship between plasma osmolality and levels of plasma vasopressin, and there is a similar linear and sensitive relationship between plasma vasopressin and urine osmolality. These relationships ([Fig. 404.1](#)) illustrate why there is a sensitive and linear relationship between plasma osmolality and urine osmolality. Thus, measure of urine osmolality often can serve as an internal "bioassay" for the level of plasma vasopressin. In pathologic situations, there may be wider than normal excursions of plasma osmolality—as in abnormal states of water retention at the low end of the osmolality scale or abnormal states of dehydration at the high end of the osmolality scale.

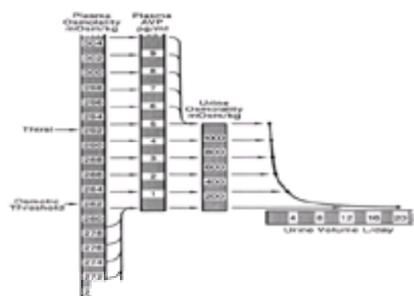

FIGURE 404.1. Idealized schematic of normal physiologic relationships, showing the direct relationship between plasma osmolality and plasma vasopressin. At low levels of osmolality, however, there may be no subsequent lowering of vasopressin because it is completely suppressed. There is also a direct relationship between plasma vasopressin and urine osmolality, except that once maximum concentration of the urine is obtained, further elevations of plasma vasopressin will not produce a higher urine osmolality. Urine volume is plotted as a horizontal scale to emphasize the geometric relationship of urine volume to urine osmolality. Urine volume is relatively well maintained until urine osmolality is compromised severely by an extremely low level of vasopressin in plasma. At the far left the osmotic threshold is illustrated as a floor for plasma osmolality below which the plasma osmolality will not normally fall because of excretion of a high volume of dilute urine. Thirst is illustrated as a physiologic ceiling for plasma osmolality, because above this level thirst will be sensed and water imbibed to avoid further elevation of plasma osmolality. (From Robinson AG. Disorders of antidiuretic hormone secretion. *Clin Endocr Metab* 1985;14:55.)

At plasma osmolality below the threshold for release of vasopressin, vasopressin is absent, and there is maximum dilution of the urine and excretion of the abnormal water content. Alternatively, markedly elevated levels of osmolality will produce superphysiologic levels of vasopressin in plasma. These abnormally high levels of vasopressin will not, however, produce a urine osmolality above the normal physiologic ceiling. This is because the maximum concentration of the urine is determined by the osmolality of the inner medulla of the kidney (see later description of vasopressin action on renal tubules). The relationship of urine volume to urine osmolality and, hence, the relationship of urine volume to plasma vasopressin and plasma osmolality are distinctly different. Urine volume is illustrated as a horizontal bar in [Fig.](#)

Urine volume is related to urine osmolality logarithmically. Thus, urine volume will change very little as plasma vasopressin levels decline from a level producing maximum urine concentration until very low levels of plasma vasopressin are reached. For example, in the idealized schema a reduction of plasma vasopressin from 5 pg per milliliter to 2 pg per milliliter results in a marked decrease in urine osmolality but only a modest increase in urine volume. Nevertheless, when plasma vasopressin is completely suppressed and urine osmolality becomes maximally dilute, there is a dramatic exponential increase in urine volume to approximately 18 L per day (which represents the quantity of fluid delivered to the collecting duct). In summary, normally osmolality is regulated within a small range, and this is accomplished by a small range of levels of plasma vasopressin. Urine osmolality has a wider range, but there is not a dramatic change in urine volume until plasma vasopressin levels are extremely low.

RENAL RESPONSE TO VASOPRESSIN

See [Chapter 9](#) for a description of the normal physiology of glomerular filtration of fluid and regulation of fluid and electrolyte absorption in the renal tubules. At the end of the physiologic processes of filtration and reabsorption in the descending and ascending loops of Henley, approximately 18 L of dilute fluid enters the collecting duct, which passes back through the inner medulla of the kidney. Acting on specific vasopressin receptors in the collecting duct, V_2 receptors, vasopressin causes water to move from the lumina of the duct across the ductal epithelium and into the concentrated inner medulla. This reabsorption conserves water and concentrates the urine. The vasopressin-stimulated movement of water is facilitated by aquaporin 2 water channels. When V_2 receptors are activated by the binding of vasopressin, cyclic AMP levels inside the cell rise; cAMP activates protein kinase A and, subsequently, phosphorylation of aquaporin 2. Aquaporin 2 water channels then move from the cytoplasm to the apical membrane of the collecting duct. This allows transport of water from the collecting duct into the cytoplasm. The water then exits from the basolateral surface through aquaporin 3 and aquaporin 4 water channels. Aquaporin 3 and 4 are constitutively synthesized, whereas the synthesis of aquaporin 2 is controlled by vasopressin (as is the shuttle movement in and out of the membrane). When the action of vasopressin dissipates, the aquaporin 2 channels move out of the membrane back to the cytoplasm.

VOLUME REGULATION

While the body regulates volume primarily through retention and excretion of sodium, there is also regulation of secretion of vasopressin in response to volume. The volume receptors are located in the chest, with low-pressure volume receptors in the atrium and pulmonary vessels and pressure receptors in the aorta. Signals from these receptors are carried via the ninth and tenth cranial nerves to the brain stem, through the medulla, and through synapses to terminate on the perikarya of the magnocellular neurons in the hypothalamus. The primary action of volume receptors is to inhibit secretion of vasopressin. When pressure falls or volume declines, the amount of inhibition is decreased, and vasopressin is released. The released vasopressin acts to restore pressure and/or volume. The effector mechanism for volume-regulated release of vasopressin is the V_1 receptors in blood vessels. Acting on V_1 receptors, vasopressin produces increased intracellular calcium and contraction of vascular smooth-muscle cells to raise pressure. Increased pressure will close the loop by raising pressure in the chest and restoring the inhibition of release of vasopressin. The vasopressin that is released in response to hypovolemia also will stimulate V_2 receptors in the kidney to provoke water retention, as described earlier. The water retention will help restore volume. Not described here is the retention of sodium to maintain and restore extracellular fluid volume through mechanisms of action that are discussed in [Chapter 9](#).

INTERACTION OF REGULATION OF OSMOLALITY AND REGULATION OF VOLUME

In most physiologic situations there is concurrence between increased osmolality and decreased volume (or pressure), which produces additive effects to enhance release of vasopressin. Similarly, expanded volume and hypo-osmolality would lessen the secretion of vasopressin and cause water excretion. These mechanisms of action are usually complimentary, but in some conditions either system can augment pathologic conditions. For example, in excessive loss of salt by the kidney or gut or through sweat, there may be hyponatremia, yet vasopressin levels will be high because of the diminished volume. With excess secretion of vasopressin, water retention causes dilutional hyponatremia. Hyponatremia may be worsened, however, by sodium excretion in response to the volume expansion produced by water retention.

ANTERIOR PITUITARY FUNCTION

As mentioned previously, in addition to the secretion of vasopressin from the posterior pituitary, there are axons predominantly of the paraventricular nuclei that terminate on the portal capillary vessels in the hypothalamus. Vasopressin released at this site traverses the long portal capillaries to the anterior pituitary, where V_{1a} receptors are present on pituitary corticotrope cells. Acting on the V_{1a} receptor, vasopressin stimulates release of ACTH. The importance of vasopressin in regulating ACTH varies among animal species. While response of the V_{1a} receptors can be verified in humans using experimental manipulations, the physiologic function of this action of vasopressin in humans has not been determined.

DIABETES INSIPIDUS—HYPOSECRETION OF VASOPRESSIN

Diabetes insipidus is the excretion of an excess volume of dilute insipid (tasteless) urine. Hypotonic polyuria can be induced by the absence of vasopressin (hypothalamic diabetes insipidus), lack of renal response to vasopressin (nephrogenic diabetes insipidus), or physiologic suppression of vasopressin in response to excessive ingestion of water (primary polydipsia). The pathophysiologic condition that produces polyuria and polydipsia in each of the three is easily distinguished. In the case of hypothalamic diabetes insipidus, there is a lack of vasopressin, which causes excretion of dilute urine, subsequent concentration of plasma with increased osmolality, and stimulation of thirst to induce polydipsia. In nephrogenic diabetes insipidus, vasopressin action on the kidney is ineffective, which produces excretion of a large volume of dilute urine with subsequent elevation of plasma osmolality and stimulation of thirst. In primary polydipsia, there is abnormal thirst and excessive ingestion of water, which causes dilution of plasma osmolality, physiologic suppression of release of vasopressin, and excretion of a large volume of dilute urine.

CLINICAL FEATURES

The initial clinical symptoms of diabetes insipidus are polyuria and polydipsia. Polyuria should be differentiated from urinary frequency by documenting that there is a large volume of urine excretion. Usually, patients will not complain of polyuria until the urine volume exceeds 4 L per day. If patients are able to drink sufficient water to maintain a normal plasma osmolality, other than the polyuria there are few, if any, symptoms, owing to lack of vasopressin. With sufficient fluid intake, the serum electrolytes and routine laboratory study results are not abnormal. Indeed, diabetes insipidus may be thought of primarily as a disease of inconvenience due to polyuria. In addition to excessive thirst, patients with hypothalamic diabetes insipidus prefer cold liquids, owing to temperature-sensitive receptors in the oropharynx. Patients frequently will go to unusual lengths to carry water and to be close to sources of water during the day. Polyuria and polydipsia is continuous throughout the day and night.

In patients who have primary polydipsia with a psychological or psychiatric basis, thirst and secondary polyuria may decline during times of diminished stress or at night. The increased urine volume caused by absent vasopressin does not exceed 18 to 20 L per day, which is the maximum urine volume delivered to the distal diluting segment. Patients with diabetes insipidus often are chronically mildly dehydrated, with a subsequent modest decrease in urine volume (to 6 to 12 L per day) by vasopressin-independent mechanisms of action. When urine volumes exceed 18 L per day, the possibility of a primary disorder of thirst should be considered. In cases of partial diabetes insipidus, formal testing with dehydration may verify the patient's ability to produce isotonic or hypertonic urine osmolality, even though the patient drinks sufficient water so that the urine osmolality never reaches this maximum and there is a corresponding large urine volume.

In these cases, there is no normal relationship of plasma osmolality to plasma vasopressin, as shown in [Fig. 404.1](#). Instead, there is a shift upward in the level of plasma osmolality required to stimulate a given level of vasopressin release. For example, a plasma osmolality level above 295 may be required to stimulate maximum AVP release. If there is no shift in the threshold for thirst, the patient will sense thirst at a plasma osmolality that is not sufficient to stimulate release of vasopressin and will drink sufficient fluid to assuage thirst. Thus, thirst will maintain a plasma osmolality that is below that necessary to stimulate release of vasopressin. There will then be an excessive volume of dilute urine, similar to the situation with patients who have more complete diabetes insipidus.

As a group, patients with complete diabetes insipidus may have a slightly greater than normal serum sodium level; there may be a slightly lower serum sodium level in patients with primary polydipsia. For an individual patient, however, the concentration of sodium is frequently within the normal range. Loss of posterior pituitary function may be associated with loss of anterior pituitary function, and, therefore, endocrine deficits related to the anterior pituitary should be sought, and anterior pituitary testing should be undertaken as indicated. In patients with a large pituitary tumor and a history of diabetes insipidus, it should be noted that both adrenal

insufficiency and severe myxedema can impair the ability to excrete free water and mask manifestations of diabetes insipidus. Replacement with thyroid hormone, but especially adrenal steroids, can result in sudden massive excretion of dilute urine and abrupt manifestation of diabetes insipidus in a patient who previously had no polyuria. In patients with diabetes insipidus and an associated disruption of the hypothalamic portal vascular system leading to the anterior pituitary, there may be increased levels of prolactin because of diminished hypothalamic inhibition of prolactin. Symptoms related to a tumor or other disease in the hypothalamus or symptoms related to systemic disease that also involves the hypothalamus may appear as manifestations of the pathologic process. With adequate water intake, the course may be benign, but in any situation in which a patient with diabetes insipidus is unable to take in sufficient fluid, marked and severe dehydration can develop, leading to vascular collapse, coma, and death.

DIAGNOSIS

The diagnosis of diabetes insipidus is established when it is determined that a patient is unable to concentrate the urine in response to normal physiologic input. As mentioned earlier, physiologic input is from osmoreceptors and baroreceptors (volume receptors). If the patient is dehydrated when he or she is first seen, with an elevated plasma osmolality and dilute urine unexplained by osmotic diuresis, the diagnosis of diabetes insipidus is made. Measuring the plasma vasopressin and determining the response to an administered vasopressin agonist (desmopressin) will distinguish nephrogenic from hypothalamic diabetes insipidus. In hypothalamic diabetes insipidus, the plasma vasopressin level is absent or low, and there is a prompt response to administered vasopressin, whereas in nephrogenic diabetes insipidus, the plasma vasopressin level is elevated, and there is little or no response to administered vasopressin.

Most patients are conscious when first seen, and on ad lib fluids with an intact thirst mechanism these patients will drink a sufficient amount to maintain a normal plasma osmolality and dilute urine. In this case, it is necessary to carry out a test to stimulate secretion of vasopressin. The best described and easiest test to administer is the dehydration test outlined in [Chapter 137](#). The test is done under controlled conditions with no fluid intake while observing urine osmolality. Patients are dehydrated to a weight loss of 2% of body weight and a constant urine osmolality. At this state of dehydration the plasma vasopressin level is obtained, and the patient is given 2 µg of desmopressin intravenously. Normal patients concentrate urine with dehydration and have less than a 5% increase in urine osmolality in response to the administered desmopressin.

Patients with complete hypothalamic diabetes insipidus have little increase in urine osmolality with dehydration and then experience a greater than 50% increase in urine osmolality in response to administered desmopressin. Patients with nephrogenic diabetes insipidus show little concentration of the urine with dehydration but may have some response to the pharmacologic dose of desmopressin. Nephrogenic diabetes insipidus is distinguished by the elevated level of plasma vasopressin. There has been some debate as to whether the standard dehydration test distinguishes partial hypothalamic diabetes insipidus from primary polydipsia. If patients with partial diabetes insipidus are severely dehydrated, they may secrete sufficient vasopressin to reach their own maximum urine concentration and not respond to desmopressin. On the other hand, patients with primary polydipsia may reach a plateau in urine osmolality before there is maximum secretion of vasopressin and, hence, may respond to administered desmopressin. These conditions can be distinguished by a reliable and sensitive assay of vasopressin in plasma but may not be adequately differentiated by the vasopressin levels available from commercial laboratories. Any patient started on desmopressin therapy who experiences hyponatremia should be assessed for an abnormality of thirst; attention should be given to the potential diagnosis of primary polydipsia rather than partial diabetes insipidus.

ETIOLOGY

In rare cases, hypothalamic diabetes insipidus is a congenital disorder that develops in children with a family history of the disease. In other situations a specific cause is first sought by an evaluation of hypothalamic anatomy. Because of the discrete location of synthesis described earlier, hypothalamic diabetes insipidus always involves the area of the hypothalamus above the sella and around the base of the third ventricle. Pathologic lesions in the hypothalamus are not usually subtle. As noted, V_2 receptors in the kidney are extremely sensitive to plasma levels of vasopressin, and even low levels of vasopressin maintain urine volume in a normal range. Thus, more than 90% of the vasopressin cells must be lost before symptomatic diabetes insipidus occurs. Lesions in the hypothalamus must be sufficiently large to destroy the paired paraventricular and supraoptic nuclei on both sides of the hypothalamus or must be located in a discrete position just above the diaphragma sellae, where there is convergence of the axons from the paired right and left nuclei into the supraopticohypophyseal track, which courses through the infundibular stalk to the posterior pituitary.

Magnetic resonance imaging of the hypothalamus is the best initial test of anatomy. Primary tumors in this area include dysgerminoma (ectopic pinealoma), craniopharyngioma, and pituitary tumors (but only with suprasellar extension). Infiltrative lesions of the hypothalamus, such as sarcoidosis, histiocytosis X, or tuberculosis, may be found, usually with accompanying peripheral manifestations of the disease. Metastatic lesions to the hypothalamic area stemming from carcinoma elsewhere, especially of the lung and breast, may cause diabetes insipidus. On T1-weighted magnetic resonance images, the normal posterior pituitary shows a high-intensity (white) signal. This high-intensity signal is due to stored hormone content and is present in most (but not all) normal subjects and absent in most (but not all) patients with diabetes insipidus. Widening of the posterior pituitary stalk has been reported in inflammatory diseases of the neurohypophysis and may be seen in the context of recent-onset diabetes insipidus for which no other source is found (idiopathic). A thickened stalk with absence of the posterior pituitary bright spot should prompt a thorough body search for the infiltrative systemic diseases described previously. Most often, diabetes insipidus is provoked by pituitary surgery or a readily identified tumor, or else it is idiopathic diabetes insipidus. If no suprasellar mass is identified and no systemic disease is found in the course of 4 years of follow-up, the patient probably has idiopathic diabetes insipidus.

Nephrogenic diabetes insipidus is most often due to pharmacologic agents ([Table 404.1](#)), such as lithium, demeclocycline, or cisplatin, or electrolyte disturbances, such as hypercalcemia or hypokalemia. With the exception of lithium, which may produce permanent defects, diabetes insipidus usually abates when the offending agent is withdrawn. Inability to concentrate the urine maximally also may be caused by a variety of structural lesions in the kidney, including sickle cell disease and inflammatory disorders, as described in [Chapter 152](#). Hereditary nephrogenic diabetes insipidus due to abnormalities of the V_2 receptor or abnormalities of the aquaporin gene also have been described. Patients with inherited nephrogenic diabetes insipidus usually show signs of profound dehydration, fever, and vomiting in childhood. Severe hypernatremia with hypotonic polyuria and absent response to desmopressin confirm the diagnosis.

Level of Action	Enhance Vasopressin	Inhibit Vasopressin
Hypothalamus (secretion)	Nicotine Vinorelbine Chlorpropamide Phenothiazine Clofibrate Morphine Carbamazepine Amitriptyline	Ethanol Vinblastin Narcotic antagonists Phenytoin
Kidney (action)	Oxytocin dDAVP Chlorpropamide Prostaglandin inhibitors Cyclophosphamide	Lithium Demeclocycline Tolazamide Darvon Acetohexamide Cisplatin Hypokalemia Hypercalcemia

TABLE 404.1. DRUGS THAT AFFECT VASOPRESSIN RELEASE OR ACTION

SPECIAL CONSIDERATIONS

Triphasic Diabetes Insipidus

In trauma-induced diabetes insipidus or diabetes insipidus developing after surgery of the hypothalamic area, there is the possibility of a “triphasic” pattern. In the first phase, the patient experiences diabetes insipidus due to axon shock and lack of function of the damaged neurohypophyseal neurons. This lasts a few hours to several days and is followed by the second antidiuretic phase, which stems from uncontrolled release of vasopressin from the disconnected posterior pituitary or from the remaining severed neurons. Excess fluid intake during the second phase does not suppress the vasopressin and leads to hyponatremia. Antidiuresis lasts 2 to 14 days and is followed by the third phase, when the store of hormone is depleted and there is return of diabetes insipidus.

Essential Hypernatremia

Some patients with diabetes insipidus have normal synthesis of vasopressin but inadequate secretion, because they lack the osmoreceptor input to the neurohypophysis. Volume receptors are intact. These cases are described as “essential hypernatremia.” In response to increased osmolality (serum sodium), the patient does not secrete vasopressin to concentrate the urine and similarly does not develop thirst to stimulate drinking. Therefore, dehydration with hypernatremia ensues. When dehydration becomes sufficient to stimulate volume receptors, vasopressin is secreted, and the urine is concentrated. The patients may not have a large urine volume at first, but only a high serum sodium with modest dehydration. Administration of fluids to replace the volume deficit turns off the release of vasopressin stimulated by the volume receptor and causes excretion of dilute urine owing to absence of the vasopressin response to osmolality. These patients require replacement with desmopressin and often a prescribed intake of fluid, which is taken regardless of the absence of thirst.

Diabetes Insipidus in Pregnancy

The normal serum sodium level in pregnancy is as low as 136 mEq per liter; thus, pregnant patients with symptoms of diabetes insipidus and a serum sodium level in the normal range may, in fact, have severe dehydration. The diagnosis of diabetes insipidus in pregnancy is complicated by a cystine aminopeptidase in the plasma of pregnant women. This enzyme, oxytocinase, also destroys vasopressin in plasma, which speeds the clearance of vasopressin but also may produce artifactually elevated measures of vasopressin by radioimmunoassay. The shortened half-life of vasopressin during pregnancy may cause partial hypothalamic diabetes insipidus or mild, asymptomatic nephrogenic diabetes insipidus to become overtly symptomatic, with excessive polyuria and polydipsia.

TREATMENT

Water diuresis is the primary manifestation of diabetes insipidus, and drinking water in sufficient quantity will correct the metabolic abnormalities. Pharmacologic therapies are designed to limit the amount of necessary water intake to a tolerable level and to decrease polyuria to an acceptably low volume and frequency. Desmopressin is the treatment of choice for diabetes insipidus. This analogue acts predominantly on the antidiuretic V_2 receptors of the kidney, with little action on the V_1 pressor receptors. Desmopressin is available in tablets of 0.1 and 0.2 mg for oral administration, a metered spray bottle that delivers 10 μ g per spray, or a dropper bottle with a rhinal catheter that can deliver doses of 5 to 20 μ g. Most new patients will want to try the tablets first.

When beginning therapy it is desirable to determine the duration of action of the chosen dose in each patient, because there is considerable individual variation. This can be done by having the patient record the time and volume of each voided urine after an administered dose. A decline in urine volume is usually noted 30 to 60 minutes after the dose and reaches a maximum in 1 to 2 hours. The return of polyuria is rapid and is readily determined by the increased excretion of a large volume of urine. Therapy is initiated with a low dose, 0.05 mg (half a tablet) orally, one spray intranasally, or 50 μ L (5 μ g) intranasally via rhinal catheter. The dose is increased to achieve a convenient schedule of two (most common with intranasally administered medication) or three (most common with orally administered medication) doses per day. Raising the dose above 0.2 mg for an oral dose or 20 μ g for an intranasal dose usually does not result in significant prolongation of the effect.

If the patient never becomes polyuric on a fixed dose, it may be advantageous, at least once a week, for the patient to delay an administered dose of desmopressin to ensure that he or she does not become water intoxicated. Recurrent episodes of hyponatremia may indicate abnormal thirst and should prompt reevaluation of the patient. Desmopressin is also available as a solution of 4 μ g/mL to be given parenterally. The usual dose is 0.5 to 2 μ g and may be given during surgical procedures or if a patient develops an allergy to other routes of administration. Desmopressin is the preferred agent in pregnancy because dDAVP is not destroyed by the cystine aminopeptidase.

Orally administered pharmacologic agents ([Table 404.1](#)) are effective in some patients with diabetes insipidus, especially those with partial hypothalamic diabetes insipidus. Chlorpropamide in a dose of 100 to 500 mg per day enhances the renal action of vasopressin and often reduces urine volume to an acceptable level. Carbamazepine and chlorthalidone cause release of vasopressin from the pituitary. Thiazide diuretics and amiloride lessen urine volume as the result of volume contraction. Prostaglandin inhibitors enhance the action of vasopressin by suppressing the normal action of prostaglandin E to suppress the action of vasopressin on the kidney. The diuretics (especially potassium-sparing amiloride) and prostaglandin inhibitors are useful in nephrogenic diabetes insipidus. For each of these pharmacologic agents, the “antidiuretic” action is not the primary therapeutic action of the drug and potential side effects and toxicity should be noted. Complicated cases of diabetes insipidus, for example, with anterior pituitary deficits, in children, with associated electrolyte imbalance, or during pregnancy should be evaluated in consultation with an endocrinologist or other physician familiar with the disorder.

PROGNOSIS

The prognosis of diabetes insipidus per se is excellent. If the disease is not treated, patients may experience problems with bladder enlargement and dilatation of the ureters and renal pelvis; when treatment is adequate, however, the disorder does not predispose to other disease or influence longevity. The ultimate prognosis may depend more on the pathologic condition that caused the diabetes insipidus. The long-term prognosis of diabetes insipidus due to trauma or surgery varies. Some patients eventually regain sufficient function (usually within 1 year) and are able to come off replacement therapy. For this reason, such patients should be periodically withdrawn from vasopressin replacement to determine whether there has been return of function.

SYNDROME OF INAPPROPRIATE SECRETION OF ANTIDIURETIC HORMONE—HYPERSECRETION OF VASOPRESSIN

The diagnosis of inappropriate secretion of antidiuretic hormone, vasopressin (SIADH), is considered in the differential diagnosis of hyponatremia. The differential diagnosis of hyponatremia is discussed in detail in [Chapter 144](#). With the exceedingly rare exception of someone drinking more than 20 L of water per day, causes of hyponatremia are associated with impaired renal diluting ability and a urine osmolality that is greater than the maximum urine dilution, that is, greater than 100 mOsm per kilogram. Thus, urine osmolality is uniformly elevated and is not useful in the differential diagnosis. Instead, the first consideration in the differential diagnosis of hyponatremia is the extracellular fluid volume, and the second is urinary sodium.

If the extracellular fluid volume is diminished and the urinary sodium level is low, less than 10 mEq per liter, the patient has had extra renal loss of sodium, for example, from sweat or gastrointestinal losses, and is showing a normal physiologic accommodation by retaining sodium via the kidney. If the patient has decreased extracellular fluid volume but inappropriately high urinary sodium values, more than 20 mEq per liter, the problem is renal loss of sodium due to an intrinsic renal defect caused by diuretics, osmotic diuresis, or renal disease or due to an inappropriate signal to the kidney caused by decreased aldosterone (as in Addison's disease). If the extracellular fluid volume is high but the urinary sodium is low, the cause is usually an edematous disorder such as occurs in congestive heart failure, cirrhosis, or nephrotic syndrome. If the extracellular volume is normal but the urine sodium is inappropriately high, the diagnosis is SIADH. In SIADH the pathophysiologic condition is related to expanded extracellular fluid volume, but the extracellular fluid volume may be normal at the time the patient is seen. Similarly, urinary sodium loss is a part of the pathophysiologic picture, but urinary sodium may be in balance with intake at the time the patient is examined. Nonetheless, the urinary sodium level is inappropriately elevated for the degree of hyponatremia. In SIADH, in addition to the low levels of serum sodium, decreased blood urea nitrogen and low uric acid levels may be noted as a consequence of volume expansion and natriuresis.

PATHOPHYSIOLOGY

The pathophysiologic picture of hyponatremia in SIADH is initially that of water retention, volume expansion, and dilution of serum sodium. In response to volume expansion, the body undergoes physiologic reactions in an attempt to bring the extracellular fluid volume back to normal. These physiologic responses to provoke excretion of sodium include an increased glomerular filtration rate, suppression of aldosterone, and initiation of natriuretic factors, most notably, atrial natriuretic peptide. When the excretion of sodium and water by the kidney brings the extracellular fluid volume back to normal, the stimulus to natriuresis ceases, and the patient may be in sodium balance at this new lower level of serum sodium. Ingestion of salt (and water) reproduces the cycle of extracellular fluid volume expansion and natriuresis, to maintain the serum sodium at the new low level. Further ingestion of water reproduces the expansion and dilution of sodium and prompts sodium loss, to further diminish serum sodium. Note, however, that the excretion of sodium produces correction only in the extracellular fluid volume.

All cellular spaces participate in volume expansion produced by water retention, and intracellular fluid volume remains expanded after sodium excretion. Subsequently, the body attempts to return the intracellular fluid volume to normal by excreting potassium, the major intracellular electrolyte, and other intracellular osmoles, such as creatinine, glutamate, glutamine, taurine, myoinositol, and glycerophosphorycholine. While the correction of extracellular fluid volume in response to volume expansion is immediate, it takes about 48 hours to see a correction of the intracellular fluid volume expansion. It should be noted that when the intracellular

organic osmoles are lost, there is a decline in the ability of the intracellular fluid compartments to buffer volume in response to a rise in extracellular fluid osmolality. This has important therapeutic implications, as discussed later.

ETIOLOGY

The three major causes of excess secretion of vasopressin to produce SIADH are ectopic secretion by a tumor, a pharmacologic agent that affects vasopressin release or action, and secretion from the normal store of vasopressin in the neurohypophysis. A variety of tumors can cause ectopic production of vasopressin and should be considered in the case of any patient with hyponatremia and malignancy. Among the most common tumors are carcinoma of the lung, thymus, duodenum, and pancreas. Drugs that affect the release or action of vasopressin are illustrated in [Table 404.1](#).

Secretion of vasopressin by the neurohypophysis may be caused by pressure or irritation of the magnocellular neurons. Essentially any pathogenetic mechanism in the hypothalamic area that, in some cases, causes diabetes insipidus may provoke excess secretion of vasopressin, in other situations, if the neurons are "irritated" rather than destroyed. Similarly, head trauma, subarachnoid hemorrhage, stroke, encephalitis, meningitis, and other central nervous system disorders can produce excess secretion of vasopressin in this manner. A more common cause of excess secretion of vasopressin by the neurohypophysis is, however, interruption of the normal inhibitory input of the volume receptor system. As noted previously, both low-pressure volume receptors and high-pressure receptors are located in the chest. These receptors usually inhibit the release of vasopressin, and when their input to the central nervous system is interrupted, there is excess secretion of vasopressin. Thus, numerous pulmonary diseases, including granulomatous diseases, acute and chronic infections, infiltrative diseases and positive pressure ventilation (by decreasing venous return), can cause SIADH.

The so-called syndrome of inappropriate secretion of antidiuretic hormone develops only if sufficient fluid is ingested to initiate volume expansion and the pathogenetic sequence described previously that leads to clinical hyponatremia. All of the clinical features of the disorder are related to hyponatremia and range from no symptoms in mild long-standing cases to weakness, lethargy, anorexia, vomiting, convulsions, and coma in more severe cases. Usually the symptoms are more severe if there is a rapid decline in the serum sodium level. One form of SIADH that is frequently asymptomatic is the reset osmostat. Patients with this condition have chronic hyponatremia and often some history of excess water ingestion. With dehydration they concentrate urine, and with a water load they dilute urine—but both occur at a lower than normal level of serum sodium. These patients do not require specific therapy. The cause of hyponatremia in myxedema and glucocorticoid insufficiency may be confused with SIADH, and these conditions must be excluded in the differential diagnosis.

TREATMENT

Just as administration of water is the primary form of therapy for diabetes insipidus, so water restriction is the primary therapy for SIADH. This treatment must be accompanied by some repletion of the depleted body sodium. Typically, sodium repletion is accomplished by dietary salt intake, but occasionally supplementation is necessary. The amount of fluid to be restricted varies from patient to patient and depends on the level of vasopressin. This is all that is required in most cases of chronic and asymptomatic hyponatremia. Treatment of extremely low serum sodium levels, that is, less than 120 mEq per liter, especially when accompanied by neurologic symptoms and signs, may require more aggressive therapy. The rapidity of therapeutic correction depends upon the chronic nature of hyponatremia.

Where it is known that hyponatremia has occurred over several hours, for example, during fluid administration for a surgical procedure, cerebral edema may be present, and it may be lifesaving to bring the sodium level rapidly back to the low 120s, with careful monitoring of central nervous system signs and symptoms. In the context of chronic profound hyponatremia, studies have indicated that abrupt correction may produce an osmotic demyelination syndrome that is characterized by gradual neurologic deterioration several days after alleviation of hyponatremia. There is fluctuating consciousness, convulsions, hypoventilation, and hypotension. Eventually, pseudobulbar palsy with swallowing dysfunction, inability to speak, and quadraparesis may develop. Recovery varies. Osmotic demyelination probably occurs only in situations in which hyponatremia has been present for longer than 48 hours and the neurons have accommodated chronic hyponatremia by extruding potassium and intracellular organic osmoles.

Extrusion of intracellular osmoles allows the neurons that were expanded by extracellular osmolality to shrink back to normal size but also removes any buffering capacity for the neurons to respond to increased extracellular fluid osmolality that may be caused by aggressively treating the low serum sodium. Overly rapid correction (increase) of extracellular osmolality causes osmotic loss of intracellular fluid and shrinkage of central nervous system cells and, by unknown mechanisms, may produce osmotic myelinolysis. The recommendation for patients with chronic hyponatremia is to correct at a rate no more than 0.5 mEq per hour, not to exceed 12 mEq over 24 hours. One might start with an initial correction of 5% to 10% of the measured sodium, to remedy residual cerebral edema. Because of the rigidity of the skull, the brain can enlarge a maximum of 10%—this is the maximum brain expansion. A slower rate of correction is continued after this minimal rapid increase in serum sodium.

Although fluid restriction is the most physiologic treatment, chronic cases may require additional therapy. One might consider demeclocycline at doses of 600 to 1,200 mg per day. This treatment provokes nephrogenic diabetes insipidus by inhibiting the action of vasopressin at the kidney. A maximum clinical response is not noted until approximately 4 days after adjusting the dosage. The serum sodium level should be followed, to determine that patients do not become hypernatremic. It should be noted that the drug may worsen liver disease.

CHAPTER 405: DISORDERS OF THE PINEAL GLAND

WARNER BURCH

[Anatomy](#)
[Physiology](#)
[Clinical Significance](#)
[Evaluation for Pineal Disease](#)

ANATOMY

The pineal gland, a pine cone–shaped structure that measures 4 × 8 mm and weighs 100 to 180 mg in adults, is attached to the posterior roof of the third ventricle. It rests in a groove between the superior colliculi and lies very close to the opening of the cerebral aqueduct connecting the third and fourth ventricles. Thus, any pineal enlargement may paralyze upward conjugate gaze by pressure on the superior colliculi (Parinaud's syndrome) or impair the flow of cerebrospinal fluid (CSF), leading to obstructive hydrocephalus.

The pineal consists of lobules of parenchymal cells (pinealocytes) that are separated by nonparenchymal connective tissue septa (mostly astrocytes). The pineal gland has no direct neural attachment to the brain. Its innervation comes from sympathetic postganglionic fibers of the superior cervical ganglia. Historically, the pineal was thought to be a vestigial third eye because in anamniotic animals (fish, amphibia) it contains cells similar to the neuroepithelial cells of the retina that respond directly to light. In mammals, the direct photic response is lost and a complex neural pathway is established through the autonomic nervous system.

PHYSIOLOGY

The major secretory product of the pinealocytes is melatonin (*N*-acetyl-5-methoxytryptamine). Other pineal hormones include the biogenic amines (norepinephrine, serotonin, histamine, and other indoleamines) and peptides (thyrotropin-releasing hormone, luteinizing hormone–releasing hormone, somatostatin, and vasotocin). Serotonin is converted to melatonin by two rate-limiting enzymes that are unique to the pineal.

Lighting conditions regulate melatonin synthesis. Darkness leads to increased sympathetic outflow, causing adrenergic discharge to the pineal, which stimulates melatonin synthesis. Maximal pineal melatonin production occurs during the dark phase of the photoperiod regardless of whether the animal is nocturnally or diurnally active. Light is inhibitory to melatonin secretion. Ablating the superior cervical ganglion or ingesting propranolol causes decreased melatonin levels. Melatonin is secreted primarily into the blood in adult humans, with the highest levels at night reaching 500 to 700 pg per milliliter, compared with daylight values of 50 to 300 pg per milliliter. Much lower levels of melatonin are found in the CSF. Melatonin is metabolized by the liver to 6-hydroxymelatonin, which is excreted in the urine. Unfortunately, plasma or urine melatonin levels have not proved helpful in diagnosing or treating pineal tumors. Although pineal physiology has been extensively studied in vertebrates (particularly rat and hamster), the pineal's role in human physiology remains largely unknown.

CLINICAL SIGNIFICANCE

The clinical relevance of the pineal relates to tumor formation and to calcification of the pineal gland. No symptoms or signs can be attributed to changes in melatonin secretion.

PINEAL TUMORS

Pineal tumors represent less than 1% of intracranial tumors. Tumors of the pineal region fall into three categories: 20% are parenchymal tumors of the pinealocyte (pineocytoma or pineoblastoma, depending on degree of differentiation); 25% are nonparenchymal tumors of glial origin (astrocytoma, glioblastoma, or ependymoma); and 55% are germ cell tumors (germinoma or teratoma). These latter tumors develop from primordial or embryonic rests of germ cells, similar to germinomas of the testes (seminoma), ovary, or anterior mediastinum. Often, germinomas arise from the floor of the third ventricle and appear histologically similar to germinomas derived from the pineal; hence the term “ectopic pinealoma.” Intracranial germinomas frequently spread locally, infiltrate the hypothalamus, and metastasize to the spinal cord. Teratomas contain evidence of two or more germ lines and often include chorionic tissue that secretes human chorionic gonadotropin (hCG). Pineal tumors may present at any age, but most are found in the second decade of life and more often in males than females (3:1).

Patients with pineal tumors present with neurologic or endocrine manifestations; neurologic symptoms and signs are more common. Increased intracranial pressure causing headache, nausea, vomiting, and altered mental status occurs in nearly 85% of patients with tumors in the pineal region. About half of pineal tumors press against the quadrigeminal plate, leading to Parinaud's syndrome, which consists of paresis of upward gaze, pupillary areflexia to light, paralysis of convergence, and wide-based gait. Endocrine manifestations due to hypothalamic involvement (pressure or invasion) lead to precocious or delayed puberty or anterior pituitary insufficiency. Some pineal tumors are teratomas that secrete abundant quantities of hCG; hCG stimulates testosterone production in males but not estrogen secretion in females, leading to precocious puberty in boys. Precocious puberty is not a common finding in pineal disease (one series of 65 pineal tumors reported no precocious puberty, and another reported that only 10% of 177 patients had precocious puberty). Hypogonadism due to infiltration of tumor in the hypothalamus leads to delayed pubescence, but it has been postulated that pineal tumors secrete an antigonadotropic hormone that may also cause hypogonadism. Diabetes insipidus, visual impairment, and anterior pituitary insufficiency associated with polyphagia and obesity are common in the ectopic pinealoma.

For years, the treatment of tumors in the pineal region consisted of ventricular shunting to relieve the hydrocephalus and radiation therapy without a tissue diagnosis. Germinomas, the most common pineal tumor, are very radiosensitive (in contrast to most tumors of the third ventricle), so that pineal tumors carried a better prognosis than most forms of brain cancer, with 5-year survivals ranging from 60% to 80% and with 10-year survivals of 60%. Surgery was generally avoided because this area was relatively inaccessible. With the advent of better preoperative localization techniques [computed tomography (CT) and magnetic resonance imaging (MRI)] and intraoperative use of the microscope, many neurosurgeons recommend surgical exploration, which may permit total resection of benign encapsulated tumors, provide histologic identification of nonresectable tumors, and identify whether the tumor has spread locally or seeded throughout the CSF. This information permits optimization of the adjunctive therapy (radiation or chemotherapy). Germinomas frequently seed the meninges; thus, whole-brain and spinal irradiation must be considered. Seeding of germinoma cells to the peritoneum from ventriculoperitoneal shunts is not uncommon. Chemotherapy with bleomycin, vinblastine, and cisplatin has been advocated for metastatic germinoma. Ectopic pinealomas in the chiasmal region usually are explored because these procedures are relatively safe, provide tissue diagnosis, and offer the possibility of removing or debulking tumors that are not as radiosensitive as germinomas.

PINEAL CALCIFICATION

Calcium deposits increase with age such that calcification of the pineal gland is evident often in the second decade of life. Pineal calcification serves as a midline marker on routine skull radiographs. Deposition of calcium within the pineal does not interfere with pineal function.

EVALUATION FOR PINEAL DISEASE

The workup of the patient begins with a high index of suspicion for an intracranial process. Signs and symptoms of increased intracranial pressure (headache, vomiting, somnolence, gait disturbance, papilledema), visual impairment, diabetes insipidus, precocious puberty in boys, and delayed puberty point to possible tumors of the third ventricle. Parinaud's syndrome localizes the process to the pineal region. Routine skull radiographs are seldom helpful, although suprasellar calcification is often seen in craniopharyngiomas. Enhanced CT or MRI scans yield important clues as to presence and localization of tumor. Radiographic criteria to differentiate between benign and malignant tumors have not been substantiated. The differential diagnosis of third ventricular tumors is diverse. A significant number are benign, encapsulated, and potentially resectable; these include simple non-neoplastic cysts, ependymal cysts, colloid cysts, dermoids, teratomas, craniopharyngiomas, meningiomas, and certain ependymomas. A large group of gliomas found in this area usually are not resectable. Levels of b-hCG should be determined in serum and in CSF obtained at ventricular shunting. Plasma levels of b-hCG correlate with tumor growth and regression. Unfortunately, most germ cell tumors do not secrete b-hCG.

CHAPTER 406: DISORDERS OF THE THYROID GLAND

LEONARD WARTOFSKY

[Thyroid Hormone Production, Transport, and Action](#)
[Diseases of the Thyroid](#)
[Malignant Tumors of the Thyroid](#)

THYROID HORMONE PRODUCTION, TRANSPORT, AND ACTION

ANATOMY

The thyroid gland consists of two lobes and a connecting isthmus, and lies just anterior to and below the larynx. The glandular tissue is arranged in acini, or follicles, composed of cuboidal epithelium surrounded by a capillary network. Within the lumen of the follicles is a proteinaceous substance—colloid—in which the protein, thyroglobulin, is stored. Other parafollicular or C cells are also present and are the source of calcitonin; their malignant transformation may give rise to medullary thyroid cancer. Thyroglobulin is a 660,000-d glycoprotein that constitutes approximately 75% of the protein content of the thyroid.

THYROID HORMONE BIOSYNTHESIS AND SECRETION

The normal function of the thyroid gland is directed to the secretion of thyroxine (T_4) and triiodothyronine (T_3), the active thyroid hormones that influence diverse metabolic processes. Synthesis of T_4 and T_3 depends on entry into the thyroid of adequate quantities of iodine, on iodine metabolism within the gland, and on thyroglobulin synthesis in which iodination and synthesis of T_4 and T_3 occurs. Iodine enters the thyroid as inorganic iodide, usually derived from dietary sources ([Fig. 406.1](#)). Dietary iodide is rapidly absorbed and distributed into extracellular fluid from which it is trapped by the thyroid or excreted by the kidneys as a function of glomerular filtration rate. In the United States, a dietary iodine intake of 200 to 300 μg per day is generally sufficient to sustain a plasma iodide concentration of approximately 40 nmol per liter (0.5 per deciliter). The thyroid also concentrates other monovalent anions, such as pertechnetate, which is available as the radioactive isotope sodium technetium Tc 99m pertechnetate. Unlike iodide, little pertechnetate is organically bound; hence, its duration of stay in the thyroid is short. This property, together with its short physical half-life, makes pertechnetate a valuable radionuclide for imaging the thyroid by scintillation scanning.

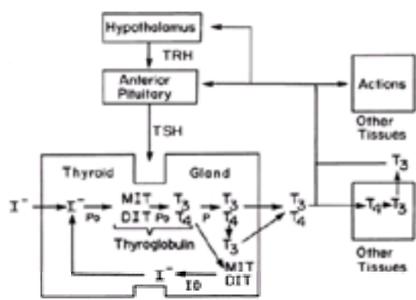

FIGURE 406.1. Iodine enters the thyroid as inorganic iodide, usually derived from dietary sources. Dietary iodide is rapidly absorbed and distributed into extracellular fluid from which it is trapped by the thyroid or excreted by the kidneys as a function of glomerular filtration rate.

Synthesis and secretion of T_4 and T_3 can be divided into four phases, each under the control of thyroid-stimulating hormone (TSH). The first involves active transport of iodide into the thyroid cell, a process mediated by the Na^+/I^- symporter, a protein in the plasma membrane of thyroid cells. Iodide is actively transported such that the thyroid maintains an iodide concentration gradient (thyroid/plasma) of 25 or greater. The second phase of hormone biosynthesis involves the oxidation of iodide mediated by thyroidal peroxidase, with the oxidized iodide serving to iodinate tyrosine residues within thyroglobulin to form the hormone precursors moniodotyrosine (MIT) and diiodotyrosine (DIT). MIT and DIT undergo oxidative condensation or coupling as the third phase of hormone synthesis, again via mediation by peroxidase, to yield the iodothyronines T_4 and T_3 . Phase 4 consists of hormonal secretion of T_4 and T_3 into the blood and involves pinocytosis of follicular colloid at the apical end of the cells into colloid droplets that merge with cellular lysosomes to form phagolysosomes, within which thyroglobulin is hydrolyzed by proteases. Thyroidal secretion is the sole source of circulating T_4 whereas only about 20% of circulating T_3 is produced in the thyroid, with the remainder being generated in extraglandular tissues by deiodination of the 5'-iodine.

The foregoing steps in hormone synthesis may be inhibited by a variety of agents, which may be called goitrogens, and which may include inorganic anions such as perchlorate and thiocyanate, or the thiourea antithyroid agents propylthiouracil or mercaptoimidazole, which are commonly employed in the treatment of hyperthyroidism. Iodine itself, when given in large doses, blocks the organic binding and coupling reactions, a phenomenon known as the Wolff–Chaikoff effect that is normally transient. Iodine in large doses is capable of inhibiting proteolysis of thyroglobulin and hormone release, an effect responsible for the ameliorative action of iodides in hyperthyroidism. Excess iodide also may induce either hypothyroidism or thyrotoxicosis in susceptible individuals, as discussed below.

Approximately 80 to 100 μg of T_4 is produced daily. T_4 is metabolized via deiodination to either T_3 or reverse T_3 (see below). The total extrathyroidal pool of T_4 (in serum and tissues) approximates 600 to 800 μg and is metabolized at a rate of 10% daily. The total extrathyroidal pool of T_3 is 50 to 60 μg and is metabolized at a rate of 75% per day to lesser iodinated compounds (T_2 , T_1 , thyronine).

TRANSPORT AND CELLULAR BINDING OF THYROID HORMONES

Serum Hormone Transport

T_4 and T_3 circulate in the blood almost entirely but reversibly bound to plasma proteins, with only 0.03% of T_4 and 0.3% of T_3 in the free or unbound state. The relatively weaker binding of T_3 accounts for its more rapid onset of action. The binding affinity of T_4 is greatest to thyroxine-binding globulin (TBG), which constitutes the primary determinant of normal hormone binding. Binding affinity is less to T_4 -binding prealbumin (transthyretin, TTR), and least to albumin, and binding affinity is greater for T_4 than for T_3 ([Fig. 406.2](#)). Only free or unbound T_4 or T_3 is available to tissues, and as a consequence, metabolic state correlates more closely with the concentration of plasma free hormone than with total hormone. Homeostatic regulation of thyroid function by the hypothalamic–pituitary axis, and in part by peripheral rates of hormonal deiodination in peripheral tissues, is directed to maintenance of a normal concentration of free hormone. Eighty percent of circulating T_4 is bound to TBG, 15% to TTR, and 5% to albumin. In the case of T_3 , 90% is bound to TBG, 5% to TTR, and 5% to albumin.

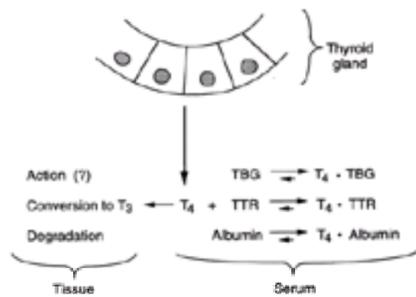

FIGURE 406.2. T_4 and T_3 circulate in the blood almost entirely but reversibly bound to plasma proteins. Relatively weaker binding of T_3 accounts for its more rapid onset of action. Binding affinity of T_4 is greatest to thyroxine-binding globulin (TBG), which constitutes the primary determinant of normal hormone binding. Binding affinity is less to T_4 -binding prealbumin, and least to albumin, and binding affinity is greater for T_4 than for T_3 .

Because nearly all T_4 and T_3 is protein-bound, any change in the capacity or affinity of TBG or TTR will result in changes in measured total T_4 or T_3 . Alterations in the interaction between T_4/T_3 and the binding proteins are of two general types. In one case, there is an intrinsically normal pituitary–thyroid axis with intact thyroid-stimulating hormone (TSH) regulation of thyroid hormone production and secretion. When an increase in the TBG concentration occurs, there is a shift of free hormone to the increased binding sites, thereby lowering the concentration of free hormone and reducing the quantity of hormone available to tissues. Ultimately, a new equilibrium is established, with an increased total hormone concentration but a smaller proportion of hormone that is free, resulting in restoration of the absolute concentration of free hormone (product of total hormone and free fraction) to normal, as well as the metabolic state. With a reduction in TBG concentration, the opposite occurs. Various conditions associated with increases or decreases in the concentration of TBG are listed in [Table 406.1](#). The serum TBG concentration is approximately 20 mg per liter and can bind approximately 200 μg of T_4 . Serum TTR concentration is some tenfold higher, averaging 250 mg per liter and binding up to 2,000 μg of T_4 .

Decreased TBG	Increased TBG
On genetic basis	Newborn
High-dose glucocorticoids	Estrogens
Androgens	Pregnancy
Nephrotic syndrome	Tamoxifen
Acromegaly	Perphenazine
Cirrhosis	Acute hepatitis
Severe systemic illness	Chronic active hepatitis
Asparaginase	Biliary cirrhosis
	Acute intermittent porphyria
	On genetic basis

TBG, thyroxine-binding globulin.

TABLE 406.1. CONDITIONS INVOLVING INCREASED OR DECREASED SERUM THYROXINE DUE TO ALTERATIONS IN THYROID HORMONE BINDING

A second type of altered binding interaction occurs when there is a primary increase or decrease in the concentration of thyroid hormones in the blood, as in thyrotoxicosis or hypothyroidism. In such cases, there are only minor changes in the concentration of TBG, but there can be major alterations in the concentrations of both total and free hormones. The abnormal secretion of thyroid hormone precludes homeostatic restoration of free-hormone levels or the metabolic state back to normal.

Thyroid Hormone Metabolism

T_4 and T_3 bound to TBG or TTR dissociate readily and the free hormone diffuses into cells where sequential removal of a single iodine atom (5'-monodeiodination) yields T_3 . There are two 5'-deiodinases. Most T_4 -to- T_3 conversion is effected by the type I isoenzyme in liver and kidney and the thyroid itself. The type II enzyme is localized in the pituitary, central nervous system, placenta, and brown fat. The type I enzyme is inactive during systemic illness and during normal fetal life, leading to low levels of serum T_3 . Generation of T_3 from T_4 in brain and pituitary is continued in hypothyroidism due to an increase in activity of type II enzyme activity. Approximately 30% of all T_4 is converted to T_3 and the T_3 generated accounts for approximately 80% of total T_3 production. The remaining 20% is secreted directly from the thyroid gland. Since T_3 has approximately three times the metabolic potency of T_4 , virtually all the metabolic action of T_4 can be attributed to T_3 .

An additional 40% of T_4 is disposed of by monodeiodination at the 5-position of its inner ring to yield reverse T_3 (rT_3). There is very little rT_3 produced by the thyroid, and rT_3 has negligible metabolic potency. As a consequence, 5'-deiodination has been termed the activating pathway of T_4 metabolism, and 5-deiodination at the inner ring as the inactivating pathway, and the relative rates of 5- and 5'-monodeiodination of T_4 determine the metabolic state by governing the availability of active hormone.

REGULATION OF THYROID FUNCTION

TSH and the TSH Receptor

Thyroid function is regulated by TSH, a 28-kd glycoprotein secreted by basophilic (thyrotropic) cells in the anterior pituitary. TSH consists of an a subunit common to other glycoprotein hormones and a unique b subunit. TSH controls thyroid function by binding to TSH receptors on the basolateral membrane of thyroid follicular cells. The TSH receptor is an 85-kd glycoprotein member of the guanyl nucleotide (G) protein–coupled receptor family and is organized into an extracellular and intracellular domains. TSH-R binding leads to activation of adenylate cyclase and phospholipase C pathways of intracellular signaling that regulate thyroid function and growth. Effects of TSH stimulation include thyroid hypertrophy, hyperplasia, and goitrogenesis mediated by protein synthesis; acceleration of most aspects of intermediary metabolism (glucose and fatty acid utilization) in the thyroid; enhanced synthesis of nucleic acids and proteins, including synthesis and proteolysis of thyroglobulin; enhanced activity of 5'-deiodinase; increased oxygen consumption by follicular cells; and stimulation of the biosynthesis and secretion of thyroid hormones. Somatic mutations and clonal expansion of the gene for the TSH receptor have been shown to account for development of some types of toxic follicular adenomas presumably due to chronic stimulation of the cyclic adenosine monophosphate (cAMP) cascade.

TSH and TRH

TSH secretion is regulated by two opposing influences at the level of the thyrotropic cell. TSH stimulation is mediated by thyrotropin-releasing hormone (TRH), a tripeptide (pyroglutamyl-histidyl-prolineamide) that is produced from the hypothalamus in the median eminence and paraventricular and arcuate nuclei. TRH reaches the pituitary via the hypophyseal portal blood system and binds to specific high-affinity receptors on the plasma membrane of the thyrotropic cell and via activation of the adenylate cyclase system; in addition, increased calcium flux stimulates the secretion and synthesis of TSH. Along with stimulating release of stored TSH, TRH enhances the synthesis of TSH via transcription and translation of the b-subunit gene. Negative regulation of TSH is mediated by the thyroid hormones, which both antagonize TRH action and directly inhibit the TSH secretory mechanism. Thyroid hormone homeostatic control of TSH secretion is exerted by negative feedback at the level of the thyrotropic cell, with the threshold for feedback inhibition set by TRH. Thyroid hormone inhibition is unopposed and more effective in the absence of TRH due to hypothalamic disease. Experimentally, thyroid hormones both inhibit production of TRH messenger RNA (mRNA) and TRH prohormone and reduce the number of TRH receptors on the thyrotropic cell, thus impairing the cell's responsiveness to TRH. The major negative-feedback action of the thyroid hormones is at

the pituitary level, mediated by binding of the hormones to thyroxine in the nucleus of the thyrotropic cell, resulting in reduced expression of the genes for the α and β subunits of TSH. The principal arbiter of thyroid hormone action in the pituitary is T_3 , both that generated in the pituitary from T_4 and that derived from plasma.

Thyroid Hormone Action

Thyroid hormone bound to its transport proteins dissociates very readily, and the free fractions of T_4 and T_3 enter the cell primarily by diffusion and, to a lesser extent, by active transport. Some T_3 that is derived from intracellular T_4 via type II T_4 -5'-deiodinase activity will diffuse back into the circulation, but most will bind to the nuclear receptors mediating hormone action. Thyroid hormone influences growth and maturation of tissues, cell respiration and total energy expenditure, and the turnover of essentially all substrates, vitamins, and hormones, including the thyroid hormones themselves. Some actions of these hormones on cell metabolism may be mediated at the level of the mitochondrion to influence oxidative metabolism or at the level of the plasma membrane and endoplasmic reticulum to influence the synthesis and activity of Ca^{2+} ATPase and Na^+,K^+ adenosine triphosphatase, as well as several lipogenic and mitochondrial enzymes. Increased activity of these enzymes leads to increased cellular sodium transport, mitochondrial oxidative metabolism, and glucose utilization, accounting for the thermogenic action of T_3 .

THYROID HORMONE RESISTANCE

Generalized thyroid hormone resistance (GTHR) is a rare autosomal recessive syndrome characterized by reduced responsiveness to elevated levels of thyroid hormone. The resistance to thyroid hormone action is due to mutations of the T_3 nuclear receptor with varied phenotypes due to a heterogeneous series of mutations of the Trb. The mutation results in a reduced affinity of the receptor for T_3 and consequently to reduced hormone action. Reduced T_3 effectiveness is compensated for by increases in thyroidal hormone production, and the syndrome is marked by elevated circulating levels of free T_4 and free T_3 , appropriately normal or elevated (nonsuppressed) serum TSH, and intact TSH responsiveness to TRH. Kindreds have been described whose members express variable patterns of resistance, and the responsiveness of target tissues may vary within an individual. The clinical features suggestive of hypothyroidism include short stature, attention deficits with mental deficiency or learning disability, deafness, and goiter. Other features suggestive of hyperthyroidism include hyperactivity, weakness, and tachycardia. While GTHR patients are either euthyroid or hypothyroid, the differential diagnosis includes isolated pituitary resistance to thyroid hormone and a TSH-secreting pituitary tumor, disorders usually associated with hyperthyroidism. The presence of increased serum TSH suggests the need for treatment with supplemental thyroid hormone, and the dosage requirement may be titrated against several parameters of tissue responses to thyroid hormone.

DISEASES OF THE THYROID

HYPOTHYROIDISM

Thyroid hormone deficiency from any cause results in hypothyroidism. The thyroid deficiency may either be due to a primary defect in the thyroid gland or be secondary to TSH deficiency resulting from pituitary or hypothalamic disease. Cretinism refers to hypothyroidism dating from birth, which is usually accompanied by intellectual impairment and developmental abnormalities. Although the term *myxedema* is often used synonymously with hypothyroidism, it originally connoted a more severe hypothyroidism in which patients had a tendency to generalized edema with characteristically puffy facies and a doughy, almost peau d'orange induration of the skin due to infiltration of the skin with hydrophilic mucopolysaccharides.

Causes of Hypothyroidism

Of all cases of hypothyroidism, 95% are due to primary disease of the thyroid gland leading to inadequate production of the thyroid hormones, with the remainder being due to hypothalamic-pituitary disease. The various specific causes of hypothyroidism are listed in [Table 406.2](#). In the United States, the most common cause of primary thyroid deficiencies is autoimmunity due to lymphocytic (Hashimoto's) thyroiditis in which cytotoxic antibodies are directed against thyroid follicular cells, leading to thyroid atrophy and fibrosis. Another variant of autoimmune hypothyroidism is due to TSH receptor antibodies which are of a blocking type. Probably next in frequency are those patients with Graves' disease who have undergone ablative therapy by either radioiodine or thyroidectomy. Both Hashimoto's disease and Graves' disease are primary autoimmune disorders of the thyroid that often coexist with diabetes mellitus and other diseases in which circulating autoantibodies are found, such as Sjögren's syndrome, pernicious anemia, systemic lupus erythematosus, rheumatoid arthritis, primary biliary cirrhosis, and chronic hepatitis. Rarely, hypothyroidism may also be a manifestation of a polyglandular endocrine deficiency state in which various autoantibodies cause impaired function of the thyroid, adrenal, parathyroid, and gonads.

Primary (thyroidal) hypothyroidism
 Chronic autoimmune thyroiditis*
 ^{131}I or external-beam radiation therapy
 Postoperative hypothyroidism
 Transient hypothyroidism
 Infiltrative diseases*
 Thyroid dysgenesis
 Defective thyroid hormone biosynthesis:
 Congenital defects*
 Iodide deficiency*
 Antithyroid agents*
 Iodine excess*
 Secondary (central, hypothalamic) hypothyroidism
 Thyroid-stimulating hormone deficiency
 Thyrotropin-releasing hormone deficiency
 Generalized resistance to thyroid hormone*

* Goiter often present.

EVIDENCE LEVEL: C. Expert Opinion.

TABLE 406.2. CAUSES OF HYPOTHYROIDISM

A number of hereditary defects in the various steps of thyroid hormone biosynthesis can occur at birth and constitute the entity of sporadic goitrous cretinism, and incomplete forms of the same disorders may account for cases of milder hypothyroidism presenting later in adult life. Certain drugs may also induce defects in hormone biosynthesis, such as aminosalicic acid and lithium. Lithium may cause both goiter and hypothyroidism, and patients with underlying Hashimoto's disease may be particularly susceptible. Endemic iodine deficiency as a cause of goiter, hypothyroidism, or cretinism is discussed elsewhere (see section "[Goiter](#)"). As described below (see section "[Thyroiditis](#)"), there typically is a self-limited or transient interval of hypothyroidism that occurs as part of the natural course of de Quervain's (subacute) thyroiditis as well as in lymphocytic "painless" thyroiditis and lymphocytic "postpartum" thyroiditis. Patients who have taken long-term thyroxine therapy in doses sufficient to fully suppress TSH (e.g., for goiter suppression) but who have underlying functional thyroid glands will pass through a period of transient hypothyroidism when the exogenous thyroxine might be discontinued. This interval may last for weeks to as long as a month and represents the time required for recovery first of the pituitary (TSH synthesis and release) and then of the thyroid to trap iodide and synthesize thyroid hormone.

Other than in cases of thyroidal atrophy and fibrosis or congenital athyreosis, the failure to synthesize adequate amounts of thyroid hormone for physiologic needs will lead to goiter mediated by increased secretion of TSH. If thyroid hormone production is sufficient, euthyroidism may ensue, but at the cost of chronic mild TSH elevation maintaining the goiter (see section "[Goiter](#)"). However, both goiter and hypothyroidism will occur when the thyroid gland cannot provide an adequate response. In the United States, the most common cause of goitrous hypothyroidism is Hashimoto's thyroiditis, early in its course prior to its evolution into an atrophic gland. Some of the goiter is actually due to lymphocytic infiltrates rather than thyroid follicular tissue, and the disorder is usually diagnosed on the basis of serologic tests for thyroid autoantibodies. Euthyroid patients with Hashimoto's disease may be uniquely sensitive to exposure to exogenous iodine excess and develop iodine-induced hypothyroidism. Other patients may also develop iodine-induced hypothyroidism, presumably on the basis of incomplete defects in the ability of their thyroid to organically bind iodide and to escape from the Wolff-Chaikoff effect (see section "Physiology," above). Another category of euthyroid patients who are susceptible to iodine-induced hypothyroidism comprises patients with Graves' disease who have been treated by partial thyroidectomy or radioiodine, as well as normal fetuses in utero. The latter may be unusually susceptible to large doses of iodine that may be given during pregnancy and can develop both hypothyroidism and goiter, sometimes large enough to result in neonatal asphyxiation.

Hypothyroidism may be on a secondary (pituitary) or tertiary (hypothalamic) basis, in which case circulating levels of total and free T_4 will be reduced but TSH concentrations will not be increased. In these patients, the thyroid gland is intrinsically normal, as can be demonstrated by increases in serum T_4 or radioiodine uptake that follow injection of recombinant human TSH. A pituitary basis for hypothyroidism may be due to pituitary tumor, postpartum pituitary necrosis (Sheehan's

syndrome), or autoimmune hypophysitis. More rarely, hypothyroidism is due to hypothalamic TRH deficiency such as may be caused by a craniopharyngioma, or granulomatous infiltration seen with sarcoidosis or tuberculosis.

Clinical Presentation

Signs and symptoms of hypothyroidism will vary greatly depending on the severity and duration of the thyroid deficiency, the age of the patient, and the possible coincidence of other systemic illness. Neonatal screening programs have disclosed that hypothyroidism is present in approximately 1 of every 5,000 neonates; it may be manifested as persistent physiologic jaundice, a hoarse cry, constipation, somnolence, and feeding problems. Early diagnosis and treatment is mandatory to achieve normal intellectual development, and consequently all neonates are routinely screened for hypothyroidism with measurements of serum T_4 and/or TSH. The manifestations of hypothyroidism in older children depend on the age at which the deficiency began, and the presence of any residual problems may depend on the promptness with which replacement thyroxine therapy was instituted. Cretinism may be detected at birth but usually becomes manifest several months after birth, depending on the extent of thyroid failure. As the child gets older, a delay in reaching the normal milestones of development becomes evident, and more of the classic physical characteristics of the cretin appear. These include short stature; coarse features with a protruding tongue; a broad, flat nose and widely set eyes; sparse hair and dry skin; delayed dentition; a protuberant abdomen often with an umbilical hernia; and impaired mental development. Sexual precocity has been described, whereas retardation of linear growth and delayed puberty may be seen in the older child. Intellectual deficiency and poor performance at school may first call attention to the potential diagnosis. X-ray examinations may reveal retarded bone age, epiphyseal dysgenesis, and delayed union of the epiphyses.

In adults, early symptoms of hypothyroidism (Table 406.3) are often nonspecific and insidious in onset, and may include fatigue, lethargy, constipation, cold intolerance, muscle stiffness and cramping, carpal tunnel syndrome, and menorrhagia. In the very elderly, the symptoms may be erroneously attributed to the aging process or to other common disorders of the elderly, such as Parkinson's disease, depression, or Alzheimer's disease. Along with apathy, there is slowing in mental agility and motor activity, reduced memory, and weight gain in spite of a reduced appetite. The skin and hair become dry, and the hair becomes thinner as it falls out. Hearing becomes impaired, and edema of the vocal cords may account for deepening of the voice. Somnolence is common, and enlargement of the tongue contributes to a tendency to obstructive sleep apnea. With little functional thyroid reserve, the severity of hypothyroidism progresses to a clinical picture of florid myxedema. At this stage, patients appear pallid, depressed, and hypokinetic, with a hoarse voice, a dull and expressionless facies, sparse hair, and a large tongue. The skin is both cool to touch and dry, rough, or scaly; there is facial and periorbital puffiness, often accompanied by generalized edema. Fluid may collect in various body compartments, and pleural effusion, pericardial effusion, or ascites is not uncommon. Goiter may or may not be present depending on the cause of the hypothyroidism. With so-called primary myxedema due to burned-out Hashimoto's disease, the gland is atrophic and usually not palpable. On physical examination or chest x-ray, the cardiac silhouette will appear enlarged, which may be due to either chamber dilatation or pericardial effusion. A small cardiac silhouette should bring adrenal insufficiency to mind, either on a pituitary basis or due to coincident primary adrenal insufficiency (Schmidt's syndrome). Constipation is common due to slowed gastrointestinal motility, and adynamic ileus may cause megacolon or intestinal obstruction. A psychiatric syndrome ("myxedema madness") has been described, and neurologic findings include a delayed or "hung-up" relaxation phase of deep tendon reflexes, muscle weakness, and ataxia.

Symptoms
Weakness and fatigue
Lethargy
Decreased mental activity
Decreased physical activity
Dry skin
Decrease perspiration
Cold intolerance
Weight gain
Constipation
Paresthesia
Myalgia
Muscle and joint stiffness
Signs
Slow movements
Hoarse voice
Dry, cool skin
Periorbital edema
Edema of hands and feet
Goiter
Bradycardia
Slow relaxation of tendon reflexes
EVIDENCE LEVEL: C, Expert Opinion.

TABLE 406.3. SYMPTOMS AND SIGNS OF HYPOTHYROIDISM

Laboratory Diagnosis

The single most important diagnostic test is measurement of the serum TSH, which is increased in patients with primary thyroid disease of any kind, and is in the low-normal to undetectable range in patients with pituitary or hypothalamic disease. Serum total and free T_4 will be decreased in all forms of hypothyroidism. Measurement of serum total T_3 is less useful and will be within the normal range in the majority of patients with hypothyroidism. This may be due to a relatively augmented rate of conversion of available circulating T_4 to T_3 in peripheral tissues, or to a relative preponderance of T_3 over T_4 secretion from the thyroid as a response to elevated serum levels of TSH. Free T_3 concentration may be low. Thyroid autoantibodies will be detectable in the majority of patients with underlying Hashimoto's disease as the basis for their hypothyroidism. Although the radioiodine uptake may be normal to elevated in the latter patients, it is usually decreased when there is another cause of thyroprivic hypothyroidism and may be of limited diagnostic utility because of the low value for the lower limit of the normal range.

Other nonthyroid laboratory tests may provide further clues to the presence of hypothyroidism. Serum triglycerides, along with total and low-density lipoprotein (LDL) cholesterol level, are usually elevated in hypothyroidism, although not necessarily in hypothyroidism of pituitary origin. Serum levels of carotene may be elevated, thus contributing to the yellow complexion of these patients. Serum levels of creatine phosphokinase (CPK), aspartate transaminase, and lactate dehydrogenase (LDH) will be increased. Anemia may be present on the basis of impaired iron utilization, which can be corrected by thyroxine administration. In patients with Hashimoto's disease, there may be coincident pernicious anemia in about 10% of patients. Electrocardiographic changes include bradycardia, low-amplitude QRS complexes, and flattened or inverted T waves—findings that may be most pronounced in the presence of a pericardial effusion. Cardiac contractility is reduced, as can be assessed by systolic time intervals demonstrating a prolonged pre-ejection period and an increased ratio of the pre-ejection period to the left ventricular ejection time.

"Subclinical" (Mild) Hypothyroidism

As with many disorders, patients with hypothyroidism may present earlier or later in the course of their disease. In its earliest, mild form, hypothyroidism has been called "subclinical" because the symptoms may be so mild as to be overlooked. Moreover, routine thyroid function tests, such as total and free T_4 or T_3 , will still be within the normal range, albeit probably lower than when the patients were truly euthyroid. The diagnosis of subclinical disease rests on the finding of a slight elevation in TSH concentration, and the TSH response to TRH may be augmented. With a normal range for TSH of 0.3 to 4.0 milliunits per liter, patients may have TSH levels between 4 and 10 milliunits per liter with adequate remaining thyroid reserve to maintain T_4 measurably normal. Often, the mild TSH elevation is ignored because of the normal T_4 and T_3 levels, and follow-up of such patients indicates that approximately half will progress to overt hypothyroidism within 5 to 7 years. Subclinical hypothyroidism is most often seen in patients with Hashimoto's disease or those with Graves' disease who have been treated with iodine 131 or surgery, and can be viewed as a stage in the evolution to overt hypothyroidism. Because many studies have shown mild abnormalities in lipoproteins with elevations in total and LDL cholesterol and other atherogenic moieties, such as apolipoproteins (a) and (b), early initiation of thyroxine replacement in low dosage has been recommended. Therapy may eliminate the progression from mild to overt disease, ameliorate symptoms, and possibly reduce cardiovascular risks of ongoing atherogenesis.

Treatment

The overwhelming majority of patients with hypothyroidism are treated with a single daily dose of synthetic levothyroxine. Only once-daily therapy is required because of the long (6 to 7 days) half-life of thyroxine. Other thyroid hormone preparations are available, including desiccated thyroid extract, USP, a T_3 preparation, and a mixture of thyroxine and T_3 (liotrix). While once in popular use, the thyroid extract preparation is no longer recommended because of its content of T_3 , which is so rapidly absorbed that the resultant high serum T_3 can cause worrisome tachycardias or arrhythmias in elderly patients or those with underlying cardiac disease. The levothyroxine products also are more stable, with a longer and more predictable shelf life. Since T_4 is converted to T_3 , ultimately near-normal concentrations of serum T_3 can be restored by the administration of thyroxine alone. In order to more closely mimic thyroidal T_3 secretion and normal blood levels, oral supplements of T_3

would need to be given in frequent divided dosage, a regimen that makes good compliance problematic. Moreover, convincing arguments or data demonstrating benefit of concomitant T_3 administration are lacking. When initially diagnosed, most patients with hypothyroidism have had the condition for some time, and there is usually (with the exception of myxedema coma) no reason to rapidly correct the thyroid deficiency with aggressive therapy. Rather, the dosage generally is gradually incremented with an initial daily dose of 25 to 50 μg thyroxine increased by 25 to 50 μg at 4- to 6-week intervals until a normal metabolic state is attained. This is especially true in elderly patients and in patients with heart disease, since a sudden increase in metabolic rate may tax cardiac or coronary reserve. The best indication that a normal metabolic state has been attained is normalization of the TSH level down to the range of 0.5 to 1.5 milliunits per liter. On average, this will equate to an ultimate full replacement dose of approximately 1.7 μg per kilogram per day.

In some circumstances a previously stable dosage of levothyroxine may need to be increased or decreased. Increases of 25 to 50 μg per day may be required during pregnancy, as evidenced by increases in serum TSH. Progressive increases in dose may be required as further atrophy of the gland occurs in patients with Hashimoto's disease or in patients with Graves' disease who have been treated with surgery or radioiodine. On the other hand, spontaneous disappearance of TSH receptor–blocking antibodies in Hashimoto's disease or increases in stimulating TSH receptor antibodies leading to evolution of autonomy in a previously treated Graves' gland can necessitate a reduction in dosage. Thyroxine absorption may be minimally reduced when taken with food or certain other pharmacologic agents that interfere with gastrointestinal absorption or enhance the metabolic clearance of levothyroxine ([Table 406.4](#)). Similarly, decreases in dosage may be required with the emergence of autonomous hyperfunction in a uninodular or multinodular goiter.

Decreased dosage requirement
T_4 production normally decreased
Androgen therapy
Decreased T_4 clearance
Older age
Remaining autonomous thyroid tissue
Graves' disease
Multinodular goiter
Increased dosage requirement
T_4 production normally increased
Pregnancy and estrogen therapy
Obesity
Decreased gastrointestinal absorption of T_4
Malabsorption and short-bowel syndromes
Therapy with agents that bind T_4 in the intestinal tract
Sucralfate, ferrous sulfate, aluminum hydroxide, cholestyramine, colestipol
Increased T_4 clearance
Younger age
Therapy with phenytoin, carbamazepine, rifampin
Decreased extrathyroidal T_4 conversion to T_3
Therapy with amiodarone
Apparent increase in dosage requirement (pseudomalabsorption)
Poor adherence

T_4 , thyroxine; T_3 , triiodothyronine.

TABLE 406.4. FACTORS ALTERING THYROXINE DOSAGE NEEDED FOR ADEQUATE REPLACEMENT THERAPY IN HYPOTHYROID PATIENTS

In known or suspected cases of pituitary or hypothalamic hypothyroidism, it is traditional not to begin thyroid hormone replacement without concomitant corticosteroid administration. This practice is based on the theoretical risk of precipitating acute adrenocortical insufficiency by augmenting the metabolism of plasma cortisol in a patient with sluggish adrenal output as a result of long-standing hypothyroidism. The exogenous steroid would be continued for perhaps 10 to 14 days or until euthyroidism was reestablished. More rapid treatment of hypothyroidism may be indicated in certain patients, such as those in whom myxedema coma is suspected (see below), and perhaps in hypothyroid patients who are being prepared for emergency surgery, out of concern for their sensitivity to anesthesia and central nervous system depressants. In these patients, intravenous administration of levothyroxine, in conjunction with the use of hydrocortisone, may be employed. Patients discovered to be hypothyroid prior to scheduled or urgent coronary artery bypass grafting or angioplasty need not be started on their thyroxine replacement urgently. There is some risk of infarction or arrhythmia with rapid hormone replacement in the setting of coronary ischemia. Outcomes are generally more satisfactory when the coronary revascularization is done first to ensure vessel patency and thyroid hormone therapy is initiated postoperatively. In such patients, special intraoperative and postoperative attention to airway and ventilation is necessary to prevent carbon dioxide retention and coma, as is attention to fluid and electrolyte balance to avoid hyponatremia. In the neonate or small child, thyroxine replacement dosage will be disproportionately greater than the 1.7 μg per kilogram per day described above, and should be begun as soon as possible to avoid impairment of normal intellectual development and growth.

Myxedema Coma

Myxedema coma represents the extreme clinical expression of hypothyroidism and constitutes a life-threatening emergency. The presentation is typically an elderly woman with a history of radioiodine therapy or surgery who had discontinued or never started thyroxine replacement. Presentation is often in winter, and the patient appears profoundly myxedematous, with hypothermia, hypotension, bradycardia, and altered mental status ranging from disorientation and confusion to somnolence and frank coma. Any patient with profound long-standing hypothyroidism is at risk for evolution into a stuporous precomatose to comatose state if left untreated, and ultimately to a fatal outcome. Even with aggressive management, mortality may average 30% to 60%, and patients should be admitted to and treated in an intensive care unit. Factors that predispose to myxedema coma include cold exposure, trauma, infection, respiratory disease, and administration of central nervous system depressants such as hypnotics, narcotics, and sedatives. With narcosis, respiratory depression occurs and CO_2 retention is an important component of the pathophysiology of the coma. Patients may present with hypothermia, hypotension, hypoglycemia, hyponatremia, hypoventilation with hypercapnia, respiratory acidosis, progressive stupor, coma, and seizures. When myxedema coma is suspected, blood should be drawn for measurements of TSH, free T_4 , and cortisol, but therapy should be initiated immediately without waiting for the results if a disastrous outcome is to be avoided. Hydrocortisone is given intravenously because of the frequency of concomitant adrenal insufficiency. The latter may be due to pituitary disease (secondary hypothyroidism and adrenocorticotrophic hormone deficiency) or to primary autoimmune adrenal insufficiency associated with Hashimoto's disease and hypothyroidism (Schmidt's syndrome). Often the patients have some underlying infection or systemic illness that may have precipitated the coma, but which also causes a reduced conversion rate of T_4 to T_3 , as in the sick euthyroid syndrome. For this reason, in addition to vigorous thyroxine therapy, supplementary small doses of T_3 may be warranted. Treatment with T_3 alone is not recommended in view of the potential for cardiovascular risk. In the comatose patient unable to take oral medications, parenteral forms of both levothyroxine and liothyronine are available. One regimen could be to immediately administer 3 to 4 μg of thyroxine per kilogram intravenously followed by 100 μg per day thereafter, along with 10 μg of liothyronine every 8 hours. Both parenteral preparations are discontinued when the patient becomes able to take oral medications. Supportive therapy is essential with special attention to ventilation. Warming should be done gently with blankets to avoid sudden peripheral vasodilatation and secondary shock. Water restriction with judicious saline administration will be required to reverse hyponatremia, which is usually related to impaired water excretion and disordered regulation of vasopressin secretion. Mental status, blood pressure, temperature, and pulse rate should improve within the first 24 hours. Treatment of any precipitating or coincident illness will be indicated as in the management of any other elderly patient with multisystemic problems. This may include treatment of any underlying infectious processes, congestive heart failure, diabetes, hypertension, and so forth. It should be kept in mind that the dosage of specific medications (e.g., digoxin for congestive heart failure) may have to be modified based on their altered distribution and slowed metabolism in profound hypothyroidism.

THYROTOXICOSIS AND HYPERTHYROIDISM

Thyrotoxicosis is the term applied to the clinical, physiologic, and biochemical findings that result when the tissues are exposed to, and respond to, excess thyroid hormone. Rather than being a specific disease, thyrotoxicosis can occur in a variety of ways ([Table 406.5](#)), and it may be temporary or permanent until treated. Of the various causes, the most important are those that lead to sustained overproduction of hormone by the thyroid gland itself ("hyperthyroidism"). Rarely, this hyperfunction results from excessive secretion to TSH by a pituitary tumor or as a result of resistance to thyroid hormone in the pituitary but not in peripheral tissues. Other than the normal thyroid stimulator (TSH), stimulators of extrapituitary origin occur as in Graves' disease, Hashimoto's disease, and trophoblastic tumors. The thyroid gland may also develop hyperfunctioning areas (or nodules) within the gland itself that are autonomous and not dependent on TSH. Thyrotoxicosis not associated with hyperthyroidism per se occurs in subacute thyroiditis and the syndrome called chronic thyroiditis with transient thyrotoxicosis. In these disorders, an inflammatory (or an autoimmune) process leads to leakage of an excess of preformed hormone from the gland. New hormone formation is decreased because of the suppression of TSH secretion by the circulating hormone excess as well as because of the inflammatory process the thyroid. Thyrotoxicosis due to thyroiditis is only a transient phenomenon because the stores of preformed hormone are eventually depleted. Recovery of hormone synthesis and secretion after the thyrotoxicosis may take weeks to months; as a consequence, the thyrotoxic state is often followed by a transient period of thyroid hormone deficiency. Thyrotoxicosis without true hyperthyroidism can also occur with exogenous sources of excess hormone, as in thyrotoxicosis factitia or the ingestion of meat contaminated with animal thyroids ("hamburger toxicosis"), or from thyroid hormone derived from follicular cells outside of the thyroid gland, such as functioning metastatic thyroid carcinoma and struma ovarii.

Graves' disease
 Multinodular goiter
 Hyperfunctioning thyroid adenoma (toxic adenoma)
 Thyroiditis

TABLE 406.5. CAUSES OF HYPERTHYROIDISM

The distinction between *thyrotoxicosis* and *hyperthyroidism* has implications for both diagnosis and treatment. Because hyperthyroidism denotes sustained hyperfunction of the thyroid gland, there is usually an increased radioiodine uptake (RAIU), whereas in the nonhyperthyroid thyrotoxic states, thyroid function (as reflected in the RAIU) is subnormal. Furthermore, treatment of thyrotoxicosis by means intended to decrease hormone synthesis (antithyroid agents, surgery, or radioiodine) is appropriate in hyperthyroidism but is inappropriate and ineffective in other forms of thyrotoxicosis. Overt hyperthyroidism will be marked by clinical signs and symptoms, elevated serum T_4 and T_3 , and suppressed serum TSH. "Subclinical" hyperthyroidism reflects a term utilized to describe early or mild thyrotoxicosis and is defined as having few signs or symptoms, normal serum total and free T_4 or T_3 , but a suppressed serum TSH. Subclinical hyperthyroidism is common and is often due to degrees of excessive thyroid hormone replacement taken by hypothyroid patients. The prevalence of all types of thyrotoxicosis may range from 5 to 20 per 1000 population, being highest in the elderly. The most common variety of true thyroid hyperfunction is Graves' disease.

GRAVES' DISEASE

Graves' disease or diffuse toxic goiter, also known as Parry's or Basedow's disease, is a disorder that in its full-blown state has three major manifestations: hyperthyroidism, diffuse goiter, and ophthalmopathy. A peculiar localized myxedema or infiltrative dermatopathy may also occur. These manifestations need not appear together. Indeed, one or two need never appear, and the three may run largely independent courses. The expression "euthyroid Graves' disease" has been applied to patients who present with clear evidence of thyroid autoimmunity, such as proptosis due to infiltrative ophthalmopathy or dermatopathy, but do not have thyrotoxicosis as indicated by normal serum levels of T_4 or T_3 . They may, however, have low serum TSH and minimal goiter.

Prevalence

Graves' disease occurs most commonly in women (6–8:1) in their third or fourth decade but can occur in men and children, and at virtually any age. Genetic factors play an important role; there is an increased incidence of haplotypes HLA-B8 and DRw3 in Caucasian, HLA-Bw36 in Japanese, and HLA-Bw46 in Chinese patients with the disease. Not surprisingly, there is a familial predisposition. In addition, among family members, a clinical and immunologic overlap exists with respect to Hashimoto's disease, primary thyrotoxic hypothyroidism, and pernicious anemia, and probably with respect to other autoimmune disorders as well. Concordance rates in monozygotic twins are high, and both Graves' disease and Hashimoto's thyroiditis occur frequently in other family members. In occasional patients the picture may change from Graves' disease to Hashimoto's disease or vice versa; rarely, patients with primary myxedema later become hyperthyroid. Thus, in view of the concordance of the two disorders in families, and their serologic and pathologic similarities, Graves' disease, Hashimoto's disease, and primary myxedema can be considered as closely related autoimmune thyroid diseases. Other than genetic predisposition, other risk factors may include smoking, female sex, and psychological or physical stress.

Pathogenesis and Pathology

The precise initiating cause of Graves' disease remains unknown, and no one factor may be responsible for the entire syndrome. With respect to the goiter and hyperthyroidism, the central cause is the production by lymphocytes of TSH receptor–stimulating autoantibodies (TSH-R-Ab; TSAb), also known as thyroid-stimulating immunoglobulins (TSIs) of the IgG class. It is speculated that exogenous initiating factors such as bacteria or retroviruses may activate an immunologic cascade leading to activation of lymphocytes in susceptible individuals with an inherited abnormality in immune surveillance. The defect allows thyroid-specific T lymphocytes to stimulate quiescent B lymphocytes to proliferate and secrete the immunoglobulins that are stimulatory to the TSH receptor. By binding to the TSH receptor and continuously stimulating thyroid hormone synthesis and release, these antibodies disrupt homeostatic mechanisms that normally control hormone secretion ([Fig. 406.3](#)) Some thyroid-directed antibodies may be of a TSH-blocking type rather than of the stimulating type and can be identified in the serum of some patients with euthyroid ophthalmic Graves' disease, occasional patients with Hashimoto's disease, and some euthyroid relatives of patients with Graves' disease. Pathologically, the thyroid is diffusely enlarged, demonstrating both hypertrophy and hyperplasia, characterized by increased epithelial height and redundant follicular walls causing papillary infoldings. The gland is soft, vascular, and infiltrated with lymphocytes. Occasional patients will show generalized lymphoid hyperplasia with enlargement of the spleen or thymus as well.

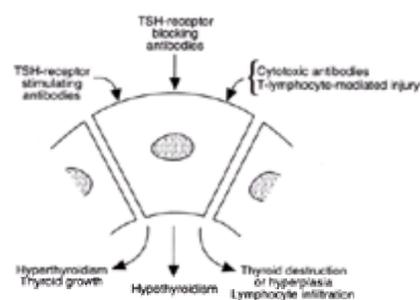

FIGURE 406.3. While the precise initiating cause of Graves' disease is unknown, the central cause of the goiter and hyperthyroidism is the production by lymphocytes of TSH receptor–stimulating autoantibodies, also known as thyroid-stimulating immunoglobulins (TSIs) of the IgG class. Bacteria or retroviruses may activate an immunologic cascade leading to activation of lymphocytes in susceptible individuals with an inherited abnormality in immune surveillance.

The pathogenesis of Graves' ophthalmopathy is even more enigmatic, but both cellular and humoral immunity may have a role. It has been suggested that an antigen in orbital tissues cross-reacts with the thyroid, and intraorbital fibroblasts produce a protein that reacts with antibodies to the TSH receptor. The T cells release cytokines or growth factors that provoke an inflammatory reaction with proliferation of more fibroblasts and production of glycosaminoglycans. On pathologic examination, there is an inflammatory infiltrate of the orbital contents, with lymphocytes, mast cells, and plasma cells. Early on, the orbital musculature is enlarged owing to infiltration with lymphocytes, mucopolysaccharides, and edema, whereas with time the muscles show degeneration and loss of striations and become more fibrotic and bound down, leading to restrictive eye movement. The increased retrobulbar fat and infiltration of the eye muscles with lymphocytes and inflammatory edema cause an increased soft-tissue volume of the orbit; with the confinement imposed by the four bony walls of the orbit, the orbital contents protrude through the orbital fissure, leading to proptosis. Even less is known about the pathogenesis of the pretibial myxedema or infiltrative dermatopathy that is characterized both by thickening of the dermis and by infiltration with lymphocytes and hydrophilic mucopolysaccharides.

Clinical Findings

Graves' disease is a multisystem disease reflecting the ubiquity of thyroid hormone receptors, and the clinical manifestations may involve virtually every tissue in the

body (Table 406.6). On presentation, often the most prominent manifestations are nervousness, tremors, frequent bowel movements, excessive sweating, emotional lability, inability to sleep, and heat intolerance. Weight loss is usual despite a well-maintained or increased appetite, but actual weight gain may occur due to the dramatically stimulated appetite. Difficulty in arising from a sitting or squatting position or in climbing stairs is a manifestation of proximal muscle weakness. In premenopausal women, infertility, loss of libido, oligomenorrhea, and amenorrhea are common. The cardiac manifestations of chronic excesses of thyroid hormone include tachycardia, palpitations, dyspnea with exertion, and, in older patients, a lowered threshold for ischemic chest pain or congestive heart failure. Symptom complexes may be age-dependent, with weight loss, atrial fibrillation, or cardiac failure more common in the elderly, and irritability, heat intolerance, and increased appetite more common in younger individuals. The nervousness, anxiety, and emotional lability will often lead to poor school or job performance, impaired decision making, volatile interpersonal relations, and rarely even to sociopathic behaviors. Paradoxically, in some older patients, the clinical picture is one of apathy rather than hyperactivity (“apathetic thyrotoxicosis”), and myopathic features may be prominent. In elderly patients, the cardiovascular manifestations predominate, and it is generally wise to evaluate any patient with atrial arrhythmias or unexplained cardiac failure thyrotoxicosis.

Symptoms
Anxiety, nervousness
Emotional lability
Easy fatigability
Increased perspiration
Heat intolerance
Palpitation
Dyspnea
Weakness
Weight loss
Increased appetite
Hyperdefecation
Signs
Hyperactivity

Thyroid enlargement
Tachycardia (>90 beats/min)
Atrial fibrillation
Tremor
Muscle weakness
Hyperreflexia
EVIDENCE LEVEL: C, Expert Opinion.

TABLE 406.6. COMMON SYMPTOMS AND SIGNS OF HYPERTHYROIDISM

On physical examination, patients appear anxious, restless, and fidgety. The hair is fine and may be thinned due to hair loss, and there may be premature graying as is also seen in Hashimoto's thyroiditis. A fine tremor of the fingers and tongue, together with hyperreflexia, is characteristic. The skin is warm and moist with a velvety texture, and patchy vitiligo and palmar erythema may be present. Separation of the fingernail from the nailbed (onycholysis, Plummer's nail) may be seen. There may be lid retraction with a characteristic stare with widened palpebral fissures, infrequent blinking, lid lag, and failure to wrinkle the brow on upward gaze. These signs result from sympathetic overstimulation; they often subside with correction of the thyrotoxicosis and should be distinguished from infiltrative ophthalmopathy. The latter, which is characteristic of Graves' disease, is marked by impaired eye muscle movement and periorbital edema, with or without proptosis. The exophthalmos may be unilateral early on but usually becomes bilateral with time. With moderate to advancing severity, the proptosis will be accompanied by varying degrees of ophthalmoplegia and congestive ophthalmopathy characterized by chemosis, conjunctivitis, and periorbital swelling. The most dreaded potential complications are corneal ulceration, optic neuritis, and optic atrophy. When exophthalmos becomes more severe and progresses rapidly to this point, it has been termed *malignant exophthalmos*. The term *exophthalmic ophthalmoplegia* refers to the ocular muscle weakness that results in impaired upward gaze and convergence and strabismus with varying degrees of diplopia. The thyroid is usually enlarged, sometimes asymmetrically; it is beefy in texture and may have an enlarged pyramidal lobe, audible bruit, and a palpable thrill. Effects on the cardiovascular system may be manifest as sinus tachycardia, atrial arrhythmias (especially atrial fibrillation), systolic flow murmurs, increased intensity of the apical first sound, cardiac enlargement, and, at times, overt heart failure. Blood pressure is usually normal but with a widened pulse pressure due to peripheral vasodilatation with reduced peripheral resistance. A to-and-fro, high-pitched sound simulating a pericardial friction rub (Means–Lerman scratch) has been described as heard best in the pulmonic area. Infiltrative dermopathy, when present, usually occurs over the dorsum of the legs or feet and has been called “pretibial myxedema.” The affected area is usually raised, plaque-like, nodular, or polypoid, and hyperpigmented with a peau d'orange appearance. Thyroid acropachy, manifest as clubbing of the fingers and toes with bony changes, may be associated with the dermopathy. Deep tendon reflexes are brisk and unsustained clonus may be seen. Choreoathetoid movements have been described. Thyrotoxic periodic paralysis appears to occur rarely, primarily in men of Asian or Latin American extraction.

Diagnosis and Laboratory Findings

In its full-blown clinical presentation as described above, Graves' disease presents little difficulty in diagnosis. Distinction of Graves' disease from other causes of thyrotoxicosis is rendered relatively easy in the presence of typical diffuse thyroid enlargement and ophthalmopathy. Absence of thyroid enlargement makes the diagnosis of Graves' disease less likely but does not exclude it. The laboratory evaluation of patients suspected of having thyrotoxicosis is described in [Chapter 418](#). Laboratory tests will confirm the diagnosis by documenting that TSH levels are undetectable by a sensitive technique and that the measured values for RAIU and serum total and free T₄ and T₃ are increased. Patients may rarely have a TSH-producing tumor with TSH-induced hyperthyroidism manifest as a measurable low-normal to normal TSH level, or so-called T₃ toxicosis in which the levels of serum T₄ and free T₄ are within normal limits but the values for total and free T₃ are elevated. Serum thyroglobulin should be elevated in endogenous hyperthyroidism of all causes, and its measurement, when found to be low, may be useful to detect exogenous or factitious thyrotoxicosis. Other aberrated laboratory parameters in thyrotoxicosis may relate to the effects of excess thyroid hormone on bone and include increases in serum calcium, urine calcium, osteocalcin, and alkaline phosphatase, with osteopenia or osteoporosis on bone densitometry. Liver function tests may be abnormal, with elevated aminotransferases, LDH, angiotensin-converting enzyme activity, and sex hormone-binding globulin. In contrast, CPK is decreased.

Differential Diagnosis

While the constellation of symptoms of tachycardia, tremulousness, irritability, weakness, and fatigue is typical of thyrotoxicosis, an anxiety state or pheochromocytoma may have to be ruled out. Pheochromocytoma and thyrotoxicosis may share symptoms of heat intolerance, sweating, tachycardia with palpitations, and a hypermetabolic state. In anxiety, the skin is usually cold and clammy rather than warm and moist. Weight loss in anxiety disorders is usually accompanied by anorexia rather than the increased appetite of thyrotoxicosis. Proptosis accompanying signs and symptoms of thyrotoxicosis invariably represents Graves' disease, particularly when the eye disease is bilateral. But apparent euthyroid Graves' ophthalmopathy must be distinguished from intraorbital or intracranial disease, such as retrobulbar tumors, cavernous sinus thrombosis, sphenoidal ridge meningioma, or pseudotumor oculi. Proptosis also may be seen in systemic disorders such as uremia, accelerated hypertension, chronic alcoholism, chronic obstructive pulmonary disease, superior mediastinal obstruction, and Cushing's syndrome. Ophthalmoplegia in the absence of infiltrative manifestations can be confused with that in diabetes mellitus or myasthenia gravis. When doubt exists about the cause of ophthalmopathy, the demonstration of significant titers of TSH receptor antibody or an immeasurably low TSH suggests that the cause is Graves' disease. Changes in the extraocular muscles characteristic of Graves' disease may be seen by ultrasonography, magnetic resonance imaging, or computed tomography of the orbit.

When the laboratory results and signs and symptoms indicate thyrotoxicosis but there are no signs of Graves' disease, such as ophthalmopathy or infiltrative dermopathy, other causes of thyrotoxicosis must be considered. Palpation of the thyroid, ultrasonography, or radionuclide scanning will disclose whether the problem is a hyperfunctioning autonomous nodule or a toxic multinodular goiter. The absence of radioactive iodine uptake by the thyroid suggests factitious thyrotoxicosis, subacute thyroiditis, or the extremely rare struma ovarii. Tenderness of the thyroid is suggestive of subacute thyroiditis, and an immeasurably low thyroglobulin is suggestive of an exogenous factitious source of thyroid hormone. In struma ovarii, the RAIU measured over the thyroid is low, since TSH secretion is suppressed, and the struma as the source of the circulating high levels of thyroid hormone can be identified by scintillation scanning over the pelvis. The unusual presentation of thyrotoxicosis due to inappropriate TSH production (associated with a pituitary tumor or resistance to feedback suppression of TSH secretion) or an abnormal stimulator of trophoblastic origin (hydatidiform mole, choriocarcinoma) may be ruled out by measurements of TSH or human chorionic gonadotropin (hCG). Demonstration of elevated titers of thyroid-stimulating immunoglobulins in the blood also provides strong evidence that Graves' disease is the cause of thyrotoxicosis.

Course and Treatment of Thyrotoxicosis

There is no cure for Graves' disease. The thyrotoxicosis may spontaneously remit, but neither the likelihood nor the duration of remission can be predicted. The principal therapy of hyperthyroidism is directed to reducing the production of thyroid hormone from the gland. For this purpose, antithyroid agents that chemically block hormone synthesis may be employed. An alternative therapy for thyrotoxicosis could be to functionally destroy the ability of the thyroid gland to manufacture hormone via the ablation of thyroid tissue by either surgical thyroidectomy or the use of radioactive iodine. With the latter therapy, advantage is taken of the fact that the thyroid normally actively traps iodine, and the uptake of iodine (or radioiodine) is further accelerated in hyperthyroidism. Based on the size of the goiter and the

measured radioiodine uptake, doses of radioactive iodine can be standardized sufficiently to ensure attainment of at least euthyroidism, and more often transformation into hypothyroidism. The transition with time into hypothyroidism after thyroidectomy or radioiodine ablation is generally deemed to be a more acceptable trade-off than the alternative of the possibility of less than permanent remissions with antithyroid drugs with subsequent exacerbation or recurrence of thyrotoxicosis. The choice of which of the three available therapies (Table 406.7 and Table 406.8) might be most appropriate in a given patient varies depending on a number of factors; it represents a decision that should be individualized after adequate discussion and education of the patient on the pros and cons of each approach. The patient should be made aware that the thyrotoxicosis of Graves' disease is often characterized by cyclic phases of exacerbation and remission, which are of unpredictable onset and duration.

Antithyroid therapy

Drugs

Methimazole (carbimazole)

Propylthiouracil

Iodide

Radioactive iodine (¹³¹I)

Subtotal thyroidectomy

Amelioration of thyroid hormone action

β-Adrenergic antagonist drugs

TABLE 406.7. THERAPY FOR HYPERTHYROIDISM

	Drug Therapy	Iodine 131
Dosage	Daily	Single dose*
Initial response	2–6 wk	8–12 wk
Side effects†	Uncommon	Rare
Hypothyroidism	Uncommon	Common
Thyroid inadequate	Uncommon	Rare
Need for continuous or repeated courses of therapy	Common	Rare
Long-term outcome	Euthyroidism or hyperthyroidism	Hypothyroidism
Outcome dependent on continued T ₄ production	Yes	No
Use during pregnancy	Indicated	Never

* If dose is small, one or more additional doses may be required.
† Toxic drug effects (rash, fever, arthralgia, arthritis, hepatitis, agranulocytosis) and radiation thyroiditis or radiation-induced exacerbation of hyperthyroidism.
T₄Ab, thyroid-stimulating hormone receptor-stimulating autoantibodies.

TABLE 406.8. FEATURES OF ANTITHYROID DRUG AND IODINE 131 THERAPY FOR HYPERTHYROIDISM CAUSED BY GRAVES' DISEASE

Antithyroid Drug Therapy

The primary advantage of antithyroid drug therapy is that patients have an opportunity to remain euthyroid after therapy is discontinued, providing that they enter a sustained remission. Since the thyrotoxicosis may recur at any time after remission, patients must be followed indefinitely or made aware of the possibility of recurrence so that they will recognize the signs and symptoms. Choices for long-term antithyroid drug therapy include either methimazole (Tapazole) or propylthiouracil (PTU) in the United States and carbimazole in Europe and elsewhere. Initial daily dosage often averages 300 to 450 µg of PTU or 30 to 45 µg of methimazole, in divided doses every 8 hours or t.i.d., but relatively mild disease can be treated with as little as 50 to 100 µg of PTU or 5 to 10 µg of methimazole daily. Some clinical improvement may be seen as early as 2 weeks, although such improvement may be due largely to the use of concomitant β-adrenergic blocking agents. Usually, it takes as long as 4 to 8 weeks to achieve clinical and laboratory evidence of euthyroidism, at which time the daily dosage can be titrated downward by as much as 50% to a lower “maintenance” dose. Adequate satisfactory control of symptoms with restoration of normal levels of T₄ and T₃ can virtually always be attained, given sufficient drug dosage and a compliant patient. Monitoring of TSH levels may be useful as well, but this should not be relied on because TSH levels can remain suppressed for months after attainment of a euthyroid state. Overdosage with serum total or free T₄ below the normal range (with or without elevated TSH) should be avoided in view of some observations of worsening ophthalmopathy when this occurs. In some patients with more severe thyrotoxicosis, doses of PTU greater than 150 mg every 6 or 8 hours may be required for initial control.

Approximately 4% to 8% of patients will have adverse side effects with either methimazole or PTU. Side effects, which tend to occur within the first month or two of therapy, are frequently dose-dependent and usually promptly reversible with discontinuation. The most serious and fortunately rare adverse reactions include agranulocytosis, aplastic anemia, hepatitis, and a lupus-like syndrome with vasculitis, arthralgias, and fever. These occur in no more than 0.1% to 0.2% of patients. Nevertheless, it may be useful to monitor blood counts during therapy with routine blood counts, including white blood cell count, differential, and platelet count obtained before commencement of thiourea drug therapy in order to distinguish between patients whose leukopenia is due to Graves' disease and those whose leukopenia is a side effect of antithyroid drug therapy. Given availability of alternative therapies, antithyroid drug therapy can be discontinued as soon as leukopenia is detected in follow-up evaluations, although a mild transient leukopenia may occur with antithyroid drugs in perhaps 10% of patients. Discontinuing a drug is often simpler than attempting to document that a leukopenia is transient by serial testing, which might allow continuation of drug therapy. Clearly, however, antithyroid medication should be discontinued when the absolute number of polymorphonuclear leukocytes reaches $\leq 1,500$ per microliter. Other more minor adverse reactions to the antithyroid drugs, such as pruritus, urticaria, or other skin rashes, often disappear with concomitant antihistamine therapy. Nevertheless, it is probably wiser to at least change to the alternative thiourea agent in the event of a sensitivity reaction. Antithyroid drug therapy should be terminated when severe sensitivity reactions occur, and radioactive iodine therapy may be the next best option.

In addition to the thiourea antithyroid drugs, there are a number of other pharmacologic agents that may be used to ameliorate the thyrotoxic state. Several different *β-adrenergic blocking agents* have been used routinely in thyrotoxicosis in view of the dramatic salutary response obtained on the adrenergic component of the thyrotoxicosis, which may include amelioration of hyperkinesia, tremor, tachycardia, insomnia, nervousness, and lid retraction. The first agent available for this purpose, propranolol, is still widely used, but usually is required to be given in divided dosage of 10 to 30 µg every 6 hours. Other, longer acting adrenergic antagonists, such as atenolol, may be equally effective in doses of 50 to 100 µg once daily, and both agents are relatively free of adverse side effects. While some studies have demonstrated reduction of T₄ to T₃ conversion by propranolol, this is only a modest effect with probably minimal clinical importance. Thus, the β-adrenergic blocking agents are very useful as adjunctive therapy while awaiting responses to antithyroid drugs or radioiodine, and may provide dramatic clinical improvement while not affecting the underlying thyrotoxicosis per se. Cautious use of these agents is recommended in patients with congestive heart failure other than rate-related failure, in whom further reduction in myocardial contractility will further compromise cardiac function. Several studies have demonstrated the utility of propranolol as the sole agent in preparation of patients for thyroidectomy. While this may rarely be necessary in patients who manifest significant allergy to all antithyroid agents, or in thyrotoxic patients with a nonthyroid surgical emergency, more routine use of propranolol alone is not recommended since its use will not eliminate the risk of thyroid storm in the perioperative period. β-Adrenergic blocking agents are particularly useful for symptomatic control during the transient thyrotoxic phase of thyroiditis.

Administration of *iodide* (100 to 200 µg per day) in the form of saturated solution of potassium iodide (50 µg per drop) or Lugol's solution will acutely inhibit proteolysis of colloid within the gland, thereby reducing release of hormone. Because the effect is virtually immediate, improvement in serum T₄ or T₃ is seen more rapidly than occurs with the antithyroid drugs that act by inhibiting hormone synthesis. An important application for the use of iodides is in life-threatening severe thyrotoxicosis (*thyrotoxic crisis*) and in patients who cannot tolerate prolonged thyrotoxicosis, such as those with underlying severe cardiac disease. Sole therapy with iodide without concomitant antithyroid drug may be hazardous because inhibition of hormone release without blockade of new-hormone synthesis allows continuing new-hormone synthesis (with the iodide substrate provided), thereby expanding intrathyroidal stores of hormone. In cases of severe thyrotoxicosis in which iodide administration may be required, *antithyroid drug therapy should be initiated first* in relatively large doses to block hormone synthesis prior to administration of iodide. Another drawback of sole therapy with iodine is that the patients will escape from the inhibitory effect on hormone secretion in 2 to 4 weeks, which can be followed by

secretion of the iodine-augmented hormone stores and worsening thyrotoxicosis. Iodide therapy also complicates subsequent management by two potential mechanisms. First, planned treatment with radioactive iodine (iodine 131, or ^{131}I) may have to be postponed pending clearance of the increased thyroidal and blood pool of stable iodine, which serves to dilute the radioactive iodine and reduce thyroid uptake; second, the increased intrathyroidal iodine resulting from iodide treatment may prolong the period of initial response to the thiourea drugs, which act in part by depleting intrathyroidal iodine. On the other hand, iodide may be administered *after* radioiodine therapy has been given in order to achieve a more rapid clinical response while awaiting the longer term destructive effect of ^{131}I . The iodide-induced inhibition of hormone release serves to retain the ^{131}I within the thyroid gland and provides a greater degree of ablation. In patients allergic to iodides, lithium carbonate is an alternative agent with much the same effect. Other agents that may be employed in cases of severe thyrotoxicosis believed to represent actual or impending thyrotoxic crisis are glucocorticoids in relatively large doses. Dexamethasone (2 mg every 6 hours) reduces the serum T_3 concentration by inhibition of T_4 to T_3 conversion, as will the iodinated x-ray contrast agent sodium ipodate. Ipodate has been given as an initial loading dose of 2 to 3 g followed by a single daily dose of 0.5 to 1.0 g. The rich iodine content of this agent also has the adjunctive effect of inhibiting thyroidal secretion of both T_4 and T_3 .

Radioactive iodine (^{131}I) Therapy

Radioiodine is generally considered to be the most efficient and cost-effective treatment for thyrotoxicosis. The usual therapeutic dose of ^{131}I for Graves' disease is approximately 5.9 MBq (160 μCi) per gram of estimated gland weight. This generally delivers 50 to 150 Gy (5,000 to 15,000 rad) to the thyroid. Significantly larger doses than those employed for thyrotoxicosis have been given for thyroid cancer, and the doses given for hyperthyroidism in adults have not been shown to lead to an increased incidence of leukemia or other malignancy later in life. However, the thyroid in children may be more susceptible to radiation-induced carcinogenesis, as was clearly shown by the marked increase in thyroid neoplasms in children exposed to radioactive fallout following the 1986 Chernobyl disaster. As a result, many physicians reserve radioiodine therapy for patients over 25 years of age. Women of childbearing age are generally advised to avoid pregnancy for at least a year following treatment. Some physicians prefer to not treat patients still desiring children even though no adverse or mutagenic effects have been shown.

The outcome after a dose of ^{131}I therapy may be post-radioiodine hypothyroidism, euthyroidism, or persistent hyperthyroidism requiring a second dose. Eventually and increasingly with time, hypothyroidism will supervene in the overwhelming majority of patients necessitating lifelong thyroxine replacement therapy. Smaller doses of approximately 3.0 to 4.5 mBq per gram (80 to 120 μCi per gram) have been given in an attempt to avoid hypothyroidism; but these lower doses merely delay the onset of hypothyroidism without reducing its frequency. Within 10 to 15 years after treatment, approximately 50% to 75% of patients will be hypothyroid. Because the insidious evolution into hypothyroidism over years may evade detection, and in view of the morbidity of untreated hypothyroidism, many expert clinicians have suggested that all patients be treated with a relatively large doses of ^{131}I to predictably achieve hypothyroidism earlier so that replacement therapy can be initiated immediately thereafter. This approach to management is particularly applicable to the elderly. Surgical thyroidectomy would be the choice for therapy in younger patients in whom it may be desirable to avoid long-term effects of radioiodine. However, younger patients can be considered candidates for radioiodine therapy in the event of recurrent thyrotoxicosis following an initial surgery, or in patients who refuse surgery or have a complicating illness that renders surgery a greater risk.

Controversy remains at present regarding whether or not patients with Graves' disease may experience an exacerbation of ophthalmopathy following radioiodine therapy. Patients who may be at greater risk include smokers, those with preexisting ophthalmopathy, and those with severe thyrotoxicosis. The theoretical basis for this phenomenon may be radiation thyroiditis with release of antigen, provoking increases in TSH receptor antibody which binds to orbital fibroblasts and muscle, thereby eliciting an inflammatory response. Studies have demonstrated less propensity to post-radioiodine worsening of ophthalmopathy when glucocorticoids are administered for approximately 2 weeks before and 6 weeks after the ^{131}I dose.

On average, the peak effect of radioiodine in regard to restoration of iodothyronine levels to normal may not be reached before 6 to 12 weeks. Most patients will be too symptomatic to wait this long for improvement, nor would it be necessarily safe to do so. As a consequence, given the latent period for radioiodine effect, the majority of patients benefit from a course of antithyroid drug therapy to render them euthyroid prior to radioiodine therapy. This serves to accelerate the attainment of a eumetabolic state and to preclude the possibility of a posttreatment radiation thyroiditis causing thyrotoxic crisis. Simultaneously, propranolol can be given to relieve the hyperadrenergic symptoms. Since the thiourea drugs will impede organic binding of the radioiodine within the thyroid and diminish its therapeutic effect, it is necessary that the drugs be discontinued approximately 2 to 3 days prior to treatment with radioiodine. In patients with a large thyroid gland and a history of moderate to severe thyrotoxicosis, resumption of antithyroid drugs after the radioiodine therapy will be necessary but should not be initiated until at least 3 days after therapy to permit adequate accumulation and retention of administered ^{131}I . It is mandatory to perform a radioiodine uptake test prior to administration of the treatment dose to ensure that the uptake is adequate for therapy, as well as to use the observed value to calculate the treatment dose. Hypothyroidism due to radiation necrosis of the gland is a virtually inevitable consequence of radioactive iodine therapy and may occur in months to years depending on the dose. Given the above doses, approximately 50% of patients will be hypothyroid within the first 6 to 9 months, and additional patients will become so at a rate of 1.5% to 2.5% per year thereafter. An alternative outcome to post-radioiodine hypothyroidism is persistent hyperthyroidism, particularly if a relatively low dose of radioiodine was administered. In such cases, a second and rarely a third therapeutic dose is required.

A post-radioiodine radiation thyroiditis may follow ^{131}I therapy (usually within a week if it occurs) that may be associated with accelerated release of hormone into the blood. Optimally, given the risk of radiation-related release of hormone into the circulation and exacerbation of thyrotoxicosis, values for serum T_4 and/or T_3 should be relatively normal prior to administration of the treatment dose. While radiation thyroiditis-related thyrotoxic crisis is rare, it appears to occur more frequently in elderly thyrotoxic patients with other systemic illness. For these reasons, patients with severe hyperthyroidism or underlying cardiorespiratory disease first should be rendered eumetabolic with antithyroid agents before therapy with ^{131}I . Large doses of ^{131}I should be used with caution in patients with large retrosternal goiters because of the potential for radiation-related tissue edema with swelling that may cause tracheoesophageal compression.

Surgery

Subtotal thyroidectomy in the hands of a skilled surgeon who is experienced in this procedure remains an effective and relatively safe choice of therapy albeit infrequently employed today for Graves' disease. Prior to the advent of radioiodine, thyroidectomy was often employed and surgeons were able to develop sufficient expertise with the procedure to avoid anticipated risks and complications. Given the few procedures performed during surgical training today, experienced surgeons tend to be confined to major medical centers, and it is these surgeons to whom patients should be referred. Complications seen following procedures done by less experienced surgeons include hemorrhage leading to respiratory obstruction, hoarseness or voice loss due to recurrent laryngeal nerve injury and vocal cord paralysis, and hypoparathyroidism necessitating lifelong calcium and vitamin D supplementation. Sufficient tissue may be left behind to cause persistent or recurrent thyrotoxicosis. Just as with radioiodine therapy, hypothyroidism is likely to occur when sufficient thyroid tissue is removed to avoid a postoperative recurrence of thyrotoxicosis, and it is simply treated with thyroxine replacement. Prior to surgery, patients should first be rendered euthyroid by means of antithyroid agents. Some surgeons prefer that iodides be administered along with the antithyroid drugs for an additional week (e.g., five drops of Lugol's solution per day), which is said to reduce the vascularity and subsequent blood loss during the procedure. Candidates for surgical therapy may include those patients who have had major allergic reactions to antithyroid drugs or who are habitually noncompliant but decline radioiodine therapy, pregnant patients who cannot tolerate antithyroid therapy or who require very large doses, and patients with unusually large goiters.

TOXIC MULTINODULAR GOITER

After Graves' disease, toxic multinodular goiter represents the next most common cause of hyperthyroidism. Thyroid hyperfunction is believed to develop as a gradual transition over years from a benign, nontoxic, or simple goiter into one with scattered foci characterized by functional autonomy (i.e., independence from control by TSH stimulation). These foci can be demonstrated by radioisotopic scan as "hot" in two general types of patterns. Usually tracer is concentrated in patchy foci diffusely throughout the gland, or less frequently the isotope will be concentrated in several discrete nodules with the remainder of the gland being essentially "cold" or nonfunctional. Studies on thyroid slices following radioiodine administration permit autoradiographic mapping of functional activity and demonstrate marked irregularity and heterogeneity of both structure and function in these glands. However, there do not appear to be specific pathologic features that distinguish nontoxic from toxic multinodular goiter. Not uncommonly, toxic multinodular goiter arises in patients residing in areas of endemic iodine deficiency. Typically, the native thyroglobulin in these glands is characterized by a relatively low iodination, due to either long-standing iodine deficiency or an intrinsically impaired ability to normally incorporate iodine. Functional hyperactivity leading to thyrotoxicosis may develop slowly over years or relatively acutely after exposure to excess iodine. The latter phenomenon (Jod-Basedow) occurs typically in patients with this type of endemic multinodular goiter, as well as those with sporadic nontoxic goiter.

The functional autonomy of this disorder does not appear to be governed by stimulation by TSH receptor antibodies as in Graves' disease. And there are several other clinical differences from Graves' disease as well. On average, Graves' patients tend to be in their third or fourth decade, whereas those with toxic multinodular goiter tend to be elderly, largely due to the years of evolution inherent to the natural history of toxic multinodular goiter. Because the latter patients are more elderly, they are more likely to manifest clinically more apparent muscle wasting, weakness, and cardiac decompensation with arrhythmias and/or congestive heart failure.

The hyperadrenergic features of Graves' disease are often lacking in these patients, and their thyrotoxicosis is not infrequently incidentally discovered by a T_4 or TSH measurement performed as part of a screen for weight loss. This has led to use of the designation "apathetic thyrotoxicosis." Importantly, the features of Graves' disease generally associated with autoimmunity and the TSH receptor antibodies are lacking in toxic multinodular goiter, such as ophthalmopathy and infiltrative dermopathy.

A definitive diagnosis of toxic multinodular goiter should not be difficult to establish in the majority of patients. If the multinodular goiter cannot be appreciated on physical examination due to the anatomy of the patient's neck or a substernal location of the gland, a radioiodine uptake and scintiscan should demonstrate both hyperfunction and the typical scan appearance. As in thyrotoxicosis of any cause, the key to the diagnosis is an immeasurably low TSH value by a sensitive assay. Serum total and free T_4 or T_3 levels may be only mildly increased, but these slight increases may be more significant in an elderly patient in view of the usually observed trend toward physiologically lower levels with aging. Serum thyroglobulin levels may be increased as well.

In regard to treatment, the age of these patients may preclude thyroidectomy as an option, particularly since the ease of administration of radioactive iodine and the absence of any contraindications in the elderly tends to make it almost invariably the treatment of choice. In contrast to Graves' disease, there is little indication for antithyroid drugs in toxic multinodular goiter other than as perhaps a therapeutic trial when the diagnosis may be uncertain, or to render the patient euthyroid prior to radioiodine treatment. Long-term use of antithyroid drugs will effectively maintain euthyroidism, but the spontaneous remission typical of Graves' disease will not occur, and lifelong use of antithyroid agents is generally not acceptable therapy. As in the thyrotoxicosis of Graves' disease, adrenergic blockers such as propranolol are useful unless contraindicated, for control of the manifestations of thyrotoxicosis both before and after radioiodine therapy, while awaiting its therapeutic effect. For therapeutic ablation with radioiodine, typically larger doses than are employed for Graves' disease are required to satisfactorily return the patient to euthyroidism. The administered dose is often as high as 600 to 1,200 MBq (16 to 32 mCi) because of the relatively lower radioiodine uptake in these glands. In contrast to the post-radioiodine hypothyroidism that is ultimately so common in Graves' patients, the thyroid gland of patients with toxic multinodular goiter is more resistant. This may be because of the heterogeneous function in differing segments of the gland, which allows those segments that were previously less functional to augment their function after the hot areas are destroyed by ^{131}I .

UNUSUAL CAUSES AND PRESENTATIONS OF THYROTOXICOSIS

Thyrotoxicosis Factitia

Many of the clinical manifestations of thyrotoxicosis are the same whether the excess circulating concentrations of T_4 or T_3 responsible for the syndrome are derived from an exogenous source, such as thyroid medications, or from endogenous hyperthyroidism. The former results from either the intentional or the inadvertent ingestion of large amounts of thyroid hormone. Commonly, the syndrome is seen in women with the mistaken belief that the excess thyroid hormone will allow them to lose weight safely. In other patients, thyroid hormone ingestion may constitute a form of Munchausen syndrome or malingering, which implies an underlying psychiatric disorder. When excessive exogenous thyroid hormone is ingested, the resultant elevation in hormone levels suppresses pituitary TSH production, thereby secondarily suppressing endogenous thyroid function. This results in low values for radioiodine uptake and serum thyroglobulin concentration. When the subject takes a preparation containing T_3 only, serum T_3 will be elevated but serum T_4 will be reduced. Since T_4 is converted to T_3 physiologically, ingestion of supraphysiologic amounts of any preparation containing T_4 will result in elevated levels of both T_4 and T_3 , and of course a suppressed TSH.

TSH-Mediated Hyperthyroidism

In animal models, continuous administration of TRH or TSH results in hyperthyroidism. In man, continuous hypersecretion of TSH from a TSH-secreting pituitary adenoma can result in thyrotoxicosis. Another form of TSH-driven hyperthyroidism results from selective resistance of the pituitary to feedback inhibition by thyroid hormone (discussed above). The distinction between resistance syndromes and a pituitary tumor may be based on evidence of a pituitary adenoma on CT scan or MRI, and presence of a higher than normal ratio of free α subunit of TSH to total assayable TSH. TRH testing may also be useful in that the TSH response to TRH will be blunted or absent with tumors.

Trophoblastic Thyrotoxicosis

Human chorionic gonadotrophin (hCG) is a thyroid stimulator, albeit a weak one, but sufficient to induce thyrotoxicosis when continuously present in relatively high serum levels. Such levels can be achieved in patients with trophoblastic tumor such as choriocarcinoma or hydatidiform mole, and patients with these tumors may demonstrate increased levels of total and free T_4 and T_3 and suppressed, immeasurable levels of TSH. These patients manifest all of the typical hyperadrenergic signs and symptoms of thyrotoxicosis as might be seen in Graves' disease, but dermopathy or ophthalmopathy is absent. The cause of the thyroid hyperfunction may be confirmed by measurement of serum hCG, whereas titers of TSH receptor antibody, if measured, will be negative. Removal of the source of origin of the hCG (the tumor) restores thyroid function tests to normal limits.

Thyrotoxicosis Ectopia

Rarely, thyrotoxicosis may result from excess circulating levels of thyroid hormone that are derived not from the thyroid gland but from an ectopic focus of thyroid tissue. One such lesion is struma ovarii, which is the presence of autonomously hyperfunctioning thyroid tissue within a benign cystic teratoma of one or both ovaries. TSH levels and, as a consequence, the thyroid gland in the neck are suppressed by the high T_4 or T_3 levels derived from the ovary, and the thyroid gland demonstrates a low radioiodine uptake and fails to be visualized on thyroid scintiscan. However, scanning over the pelvis will disclose uptake in the struma, and its surgical removal will be followed by recovery of function in the cervical thyroid. Even more rare is the occurrence of thyroid malignancy in a struma, or the coincidence of goiter or Graves' disease along with a pelvic struma. Another cause of thyrotoxicosis due to ectopic thyroid hormone production is that due to widespread functioning metastases of thyroid carcinoma. The tumor type is usually of the follicular variety, which by virtue of the sheer mass of metastases present can produce enough T_4 to cause thyrotoxicosis.

Iodine-Induced Thyrotoxicosis

As described above, the Jod-Basedow phenomenon refers to the induction of thyrotoxicosis in a previously euthyroid patient as a result of exposure to excess iodine. The thyrotoxicosis is triggered by avid uptake and hormone synthesis by thyroid tissue that either has been chronically exposed to endemic iodine deficiency or has underlying functionally autonomous tissue as in multinodular goiter or Graves' disease, or both. In addition to sanctioned dietary supplements, such as iodized salt, iodine is so ubiquitously available as to constitute an omnipresent risk of excess ingestion, at least in the United States. Iodide or other salts of iodine are in common use as a preservative in baked goods, as an antiseptic in public water supplies, in food dyes, and of course, in organic contrast agents commonly employed for radiographic procedures such as CT scans, cholecystography, myelography, pyelography, and, most commonly today, coronary angiography. Patients undergoing the latter procedures tend to be elderly and at greater risk of serious cardiovascular manifestations should they become thyrotoxic. Consequently, these sources of iodine should be avoided in patients known to have underlying autonomous function, multinodular goiter, or autoimmune thyroid disease. When pharmaceuticals containing iodine or x-ray contrast media must be employed, patients should be carefully monitored for evolution into hypo- or hyperthyroidism and promptly treated accordingly. Indeed, where risk of thyrotoxicosis is high, therapy with an antithyroid agent such as PTU (450 mg per day in divided dosage) should be considered both for a week prior to and for 1 to 2 weeks after the procedure.

Amiodarone is an antiarrhythmic drug that has effects at multiple sites in thyroid economy, in part due to its high (37%) iodine content but also due to specific effects of the drug and its metabolites on cellular receptors. Effects of the drug include inhibition of the conversion of T_4 to T_3 and displacement of T_4 from its binding sites leading to high serum T_4 levels whether or not thyrotoxicosis is also present. Due to an intrapituitary block on T_4 to T_3 conversion, TSH levels will ordinarily be normal to high-normal in euthyroid individuals. Serum total and free T_3 will be low. Thyrotoxicosis is indicated by elevated (or even merely high normal) levels of T_3 and by a suppressed TSH. The high iodine content will induce hyperthyroidism in susceptible individuals, such as those with underlying autonomously functioning glands (e.g., patients with multinodular goiters or Graves' disease). This type of amiodarone-induced thyrotoxicosis is consistent with the Jod-Basedow phenomenon and is characterized by goiter with low to low-normal values for radioiodine uptake, normal levels of interleukin-6 (IL-6), and a normal erythrocyte sedimentation rate (ESR). A second type of amiodarone-induced thyrotoxicosis represents a thyroiditic syndrome consequent to a drug-related acute inflammatory response and aspiration cytologic examination will demonstrate necrosis with polymorphonuclear cell and histiocytes. This disorder is not associated with goiter, radioiodine uptake is negligible, and IL-6 levels and ESR are elevated. Therapy should consist of discontinuation of the amiodarone, if possible, along with measures to deplete intrathyroidal iodine stores, such as the thiourea antithyroid drugs, often in conjunction with perchlorate. Short-term, moderate to high-dose corticosteroids have proven useful for the acute inflammatory type of amiodarone-related thyrotoxicosis. The high iodine content of the drug may also induce hypothyroidism in susceptible

individuals, such as those with underlying Hashimoto's disease. Clinical manifestations may rarely oscillate between hypothyroidism and hyperthyroidism constituting a therapeutic dilemma. Assuming that the amiodarone cannot be discontinued because of the underlying problem with arrhythmias, management may sometimes be resolved by thyroidectomy followed by stable-dose thyroxine replacement.

T₃ Toxicosis

In euthyroid individuals under certain conditions, such as with iodine deficiency, the thyroid gland preferentially produces more T₃ relative to T₄. In general, hyperthyroidism results in overproduction and oversecretion of both thyroid hormones T₄ and T₃. However, in almost all types of hyperthyroidism, the thyroidal T₃ production rate is relatively greater than it is in the euthyroid state. This disproportionate T₃ production can be exaggerated in some thyrotoxic states, again perhaps related to relative iodine deficiency. Excluding a binding defect such as TBG deficiency, which would cause a low serum T₄, the presence of a low serum T₄ and a relatively high T₃ in a thyrotoxic patient has been called "T₃ toxicosis." This diagnosis applies to patients with clinical manifestations of thyrotoxicosis in whom the serum T₄ and free T₄ are normal or low and the RAIU is high-normal to increased. The distinction between endogenous T₃ toxicosis due to Graves' disease or toxic nodular goiter and T₃ thyrotoxicosis factitia can be based on findings of low radioiodine uptake and low serum thyroglobulin in the latter case. Often T₃ toxicosis represents the earliest manifestation of Graves' thyrotoxicosis, either during its initial presentation or in relapse following discontinuation of antithyroid drug therapy.

T₄ Toxicosis

As described above, most patients with hyperthyroidism have elevations in both serum T₄ and serum T₃ although the ratio of T₃ to T₄ may be slightly higher than in euthyroid individuals. The higher T₃ results from increased generation both from the thyroid gland and from peripheral conversion of the relatively high serum T₄ levels in thyrotoxicosis. On rare occasions, a higher serum T₄ level relative to that of T₃ may be seen in thyrotoxicosis, or the serum T₃ may be frankly normal. This presentation of laboratory parameters has been called T₄ toxicosis. Just as T₃ toxicosis tends to occur in the setting of iodine deficiency, T₄ toxicosis is seen most commonly in a milieu of prior excess iodine exposure (which favors T₄ biosynthesis) and may be more prevalent in elderly patients.

Thyrotoxic Storm

Thyrotoxic storm or crisis is a syndrome of exaggerated signs and symptoms of thyrotoxicosis with systemic decompensation that is likely to be fatal unless vigorously treated. The diagnosis is a clinical one based on the identification of the typical cardinal manifestations, which include fever (temperature usually more than 38.5°C); tachycardia out of proportion to the fever; central nervous system signs, varying from extreme irritability, delirium, or confusion to apathy and even coma; and gastrointestinal dysfunction, which can include nausea, vomiting, diarrhea, and, in severe cases, jaundice. The earliest possible diagnosis and subsequent implementation of therapy are required to avoid a fatal outcome. Even with early diagnosis death can occur, and reported mortality rates have ranged from 10% to 75% in hospitalized patients. The syndrome may be less common today than in the past, perhaps because of earlier diagnosis and treatment of thyrotoxicosis, thereby precluding its progression to the stage of crisis. Nevertheless, it is likely that the syndrome still occurs in 1% to 2% of hospital admissions for thyrotoxicosis. It is not possible to distinguish those with thyrotoxic storm from those with uncomplicated thyrotoxicosis simply on the basis of routine function tests. Often there is a history of previously partially treated thyrotoxicosis, but the initiation of the decompensation into thyrotoxic crisis usually follows some specific precipitating event, as listed in [Table 406.9](#). The overwhelming majority of patients will have rather obvious signs and symptoms of thyrotoxicosis, including goiter and Graves' ophthalmopathy. Older patients, particularly those who may have an underlying toxic multinodular goiter rather than Graves' disease, may present as so-called masked or "apathetic" thyrotoxicosis.

Withdrawal of antithyroid drug therapy
Iodine 131 (¹³¹I) therapy
Sepsis; infection
Surgery; trauma
Iodinated contrast dyes
Hypoglycemia
Parturition
Vigorous palpation of thyroid
Emotional stress
Burn injury
Diabetic ketoacidosis
Pulmonary thromboembolism
Cerebrovascular accident; seizure disorder

TABLE 406.9. EVENTS ASSOCIATED WITH PRECIPITATION OF THYROTOXIC STORM

Treatment must be swift and aggressive to avoid a disastrous outcome and includes both supportive measures and specific therapy of the thyrotoxicosis. Supportive therapy includes treatment of dehydration and the intravenous administration of glucose and saline, vitamin B complex, and glucocorticoids. Patients should be treated in an intensive care unit and placed in a cooled, humidified oxygen tent, with a cooling blanket if hyperpyrexia is present. Digitalis or other appropriate cardiac medications are employed to control ventricular rate in those with atrial fibrillation. In addition to vigorous fluid replacement, intravenous pressor agents may be needed for hypotension. Treatment of hyperthyroidism consists of blockade of hormone synthesis by the immediate and continued administration of large doses of antithyroid agent (e.g., 100 mg PTU every 2 hours). In comatose patients unable to swallow the medication, tablets can be crushed and given by nasogastric tube or per rectum, since parenteral preparations are unavailable. Shortly after antithyroid drugs are started, stable iodine as Lugol's solution or saturated solution of potassium iodide is given to block further hormone release from the gland. Sodium ipodate can be administered (1 g per day) instead of iodine; it has the added advantage of inhibiting peripheral conversion of T₄ to T₃. In severe cases, attempts may be made to remove thyroid hormone from the peripheral circulation by peritoneal dialysis, plasmapheresis, or hemoperfusion through a resin or charcoal bed, and cholestyramine resin may be used to bind T₄ and T₃ within the gastrointestinal tract. β -Adrenergic antagonists are a critical part of the therapeutic regimen and must be used with caution in the presence of cardiac failure. Propranolol can be administered in doses of 40 to 80 mg every 6 hours. If medications cannot be taken orally, propranolol may be given intravenously. A plasma propranolol level in excess of 50 ng per milliliter may have to be maintained to establish clinical response. When used intravenously, an initial dose of 0.5 to 1 mg should be given cautiously while the patient's cardiac rhythm is continuously monitored. Subsequent doses of 2 to 3 mg may be given intravenously over 10 to 15 minutes every several hours, while one awaits the effect of the orally administered drug. Use of a Swan-Ganz catheter to monitor central hemodynamics is recommended in patients receiving high-dose propranolol, pressors, digoxin, diuretics, and fluids. A very short-acting β -adrenergic blocker, esmolol, has also been used in thyrotoxic storm with success. An initial loading dose of 0.25 to 0.5 mg per kilogram is followed by continuous infusion of 0.05 to 0.1 mg per kilogram per minute. Large doses of dexamethasone (e.g., 2 mg every 6 hours) should be administered based on the belief that there are increased glucocorticoid requirements in thyrotoxicosis and because adrenal reserve may be reduced. Steroids will also impair the peripheral generation of T₃ from T₄. With the combined use of PTU, iodine, and dexamethasone, the serum T₃ concentration generally returns to normal within 36 to 48 hours. Dexamethasone may be tapered thereafter, while antithyroid therapy and iodine must be continued until a normal metabolic state is achieved, at which time iodine is progressively withdrawn and plans are made for definitive treatment.

EUTHYROID SICK SYNDROME

The euthyroid sick syndrome is really not a syndrome at all, but the designation has become firmly entrenched in the literature and represents observed abnormalities in tests of thyroid function in patients with systemic illness. The abnormalities tend to assume a typical pattern that is seen in virtually any severe illness, or after physical trauma or physiologic stress, and is due to alterations in the peripheral transport and metabolism of the thyroid hormones, in regulation of TSH secretion, and, occasionally, in thyroid function itself. Acting alone or together, these alterations lead to changes in the concentrations of both total and free T₄ and T₃. Because the most dramatic effect is a reduction in serum T₃ concentration, the entity is also known as the low-T₃ syndrome. Given the frequency and variety of nonthyroid disease associated with changes of the euthyroid sick syndrome, it likely is a more common cause of abnormalities in thyroid function tests than is intrinsic thyroid disease.

Under normal circumstances, circulating T₄ undergoes 5'-monodeiodination (see section "[Thyroid Hormone Metabolism](#)," above) which generates 80% of circulating

T₃. With illness or any perturbation from normal physiology, activity of 5'-deiodinase is inhibited, resulting in dramatic reductions in T₃ production rates and in serum T₃, the degree of which varies with the severity of the underlying illness. The same 5'-deiodinase is responsible for the clearance of reverse rT₃, and rT₃ levels are increased as a result of the decreased activity of the enzyme. In mild to moderate illness, serum T₃ falls but T₄ remains within the normal range. Another aspect of the euthyroid sick syndrome is the presence of circulating inhibitors to hormone binding to both serum transport proteins and cellular receptors. As a result of the inhibition of binding to its transport proteins, values for the resin T₃ uptake test will be increased and unbound or free T₄ will be increased, at least initially. Thus, the low serum T₃ should not be taken to indicate hypothyroidism, particularly because serum T₃ tends to be within normal limits in most hypothyroid patients and is not a useful measurement in those patients. The designation "euthyroid sick" is based on the belief that the patients are indeed euthyroid in spite of often dramatic abnormalities in serum T₄ and T₃, and this belief is strongly supported by measured values for TSH that are normal. A euthyroid state is also implied by the serum rT₃ levels, which are increased due to slowing of rT₃ degradation but would be decreased in most (albeit not all) cases of primary or pituitary hypothyroidism. Moreover, patients with primary hypothyroidism and systemic illness tend to still have elevated serum TSH levels, although generally somewhat lower than prior to becoming ill. TSH responses to TRH administration are usually blunted, rather than being exaggerated as is seen in hypothyroidism. With more prolonged and severe systemic illness, TSH levels are more suppressed; serum T₄ levels fall as well, probably as a result of both inhibition of binding and reduced thyroidal production secondary to the low TSH levels, and to circulating cytokines such as IL-1 and tumor necrosis factor. It is controversial as to whether this stage of illness reflects some degree of hypothyroidism with inappropriately low TSH response. There is a correlation between the severity of the aberrated thyroid function tests and survival from the underlying illness. With recovery from the illness, TSH levels rise, often transiently into an elevated range of 10 to 20 milliunits per liter, and thyroid hormone production resumes. Intervention with thyroid hormone therapy is generally neither necessary nor recommended and does not improve survival, with the possible exception of patients with an extremely prolonged course of illness, such as coma.

Rarely, a variant of the euthyroid sick syndrome is seen in which the serum total T₄ is elevated, at least initially. This may be seen in critically ill patients on admission to an intensive care unit, in patients with psychiatric disorders on admission to hospital, and in patients who have received exogenous iodine. The latter may represent a transiently augmented production of T₄ relative to T₃ and must be distinguished from so-called T₄ toxicosis (see above). The high T₄ generally resolves within days to a week with treatment of the underlying critical or psychiatric illness and with no specific thyroid therapy. A thyrotoxic patient with superimposed illness may have lower than baseline values for T₄ and T₃, but in general the values for total and free T₃ will be elevated or at least be high-normal (in contrast to the low or immeasurable levels in uncomplicated illness), and TSH will be immeasurably low.

Patients with AIDS may have a pattern of thyroid function test abnormalities that do not differ significantly from other causes of the euthyroid sick syndrome except that rT₃ may not be increased. Most patients, with the exception of those who may be severely cachectic, will have normal total and free T₄ and low-normal total T₃. As the disease progresses and CD4 counts fall and other infections supervene, serum T₄ as well as T₃ will fall, but serum TSH may remain normal. Observed increases in TBG may account for maintenance of normal serum T₄ at least early in the course of the disease. Rarely, AIDS patients develop hypothyroidism due to opportunistic infections of the gland itself, such as *Pneumocystis carini* thyroiditis, or due to involvement of the thyroid by Kaposi's sarcoma.

SIMPLE (NONTOXIC) GOITER

The thyroid gland normally weighs 14 to 18 g in adults, and enlargement due to any cause may be called goiter. Although the cause of goiter may be a diffuse or generalized process, it may not result in symmetrical enlargement for the right lobe tends to be larger than the left. Goiter may be associated with increased, normal, or decreased hormone secretion, depending on the underlying process. The overwhelming majority of patients with simple or sporadic goiter are euthyroid. A focal enlargement manifested as a nodule usually implies a neoplasm, which may be benign or malignant. Any cause of goiter may lead to compression of adjacent structures in the neck or mediastinum and cause difficulty with swallowing or with breathing. Goiter may be classified as "endemic" when it is present in more than 10% of a given population, whereas the designation of "sporadic" refers to thyroid enlargement that occurs in nonendemic areas and is due to other factors. The commonly used designation of simple or nontoxic goiter is employed for any enlargement of the thyroid that is not attributable to an inflammatory or neoplastic process and is not initially associated with hypothyroidism or thyrotoxicosis, and may occur in either an endemic or a nonendemic area. On pathologic examination, there is either diffuse thyroid follicular cell hyperplasia or hyperplastic follicles and larger, quiescent ones. The goiters may change little during follow-up periods of years but may become more multinodular with time.

Pathogenesis

For most patients presenting with simple goiter, the underlying cause is never known. Occasionally, it can be documented that the goiter is being driven by an elevated TSH secondary to impaired thyroid hormone synthesis such as might be seen with iodine deficiency, ingestion of a goitrogen, or a defect in hormone biosynthesis. On the other hand, TSH levels are often perfectly within normal limits, and another goitrogenic influence will be operative. The cause is likely heterogeneous, but whatever it is, the underlying pathogenesis usually relates to factors that impair the capacity of the thyroid to secrete insufficient hormones to meet the needs of peripheral tissues.

Clinical Presentation

In simple goiter without associated hypothyroidism, the clinical manifestations are due only to the thyroid enlargement of the thyroid. In goitrous hypothyroidism, symptoms of thyroid hormone deficiency accompany those caused by thyromegaly. Early compressive symptoms may include a sensation of pressure discomfort that may be positional. As the goiter enlarges, displacement of the trachea or esophagus occurs and may cause obstructive symptoms such as dysphagia or odynophagia. Respiratory compromise can result from tracheal compression and hoarseness can result from compression of one or both recurrent laryngeal nerves. A low-lying goiter may enlarge inferiorly to below the jugular notch and sternum (substernal or retrosternal goiter) and lead to superior mediastinal obstruction and a superior vena caval syndrome. A diagnostic clinical sign of thoracic outlet obstruction by a large retrosternal goiter can be demonstrated by having the patient raise his or her arms above the head, which causes a plethoric suffusion of the face, light-headedness, and, rarely, syncope (Pemberton's sign). The sudden appearance of painful swelling in the neck with compressive symptoms is often due to hemorrhage within the goiter or within a dominant nodule in the goiter. Hyperthyroidism may supervene in long-standing multinodular goiter (see section "[Toxic Multinodular Goiter](#)") as autonomous foci of hyperfunctioning tissue may develop with time, especially after exposure to excess iodide (Jod-Basedow phenomenon).

Goitrous hypothyroidism may be present in areas of severe endemic iodine deficiency, and the children of goitrous parents in these regions are at greater risk of having cretinism. Other goitrogenic factors appear to play a role in the etiologic process of endemic goiter, since the frequency and severity of goiter will vary among persons with equally severe iodine deficiency. Nutritional or water-borne goitrogens can represent important conditioning factors, or these goitrogens may cause goiter in the absence of iodine deficiency. In parts of Africa, for example, the cassava root, which is highly goitrogenic, is a dietary staple, and a history of chronic cassava ingestion is often obtained from patients who have emigrated from Africa.

Diagnosis and Treatment

The extent of a substernal goiter may be assessed by performance of CT scan or MRI imaging, and the degree of possible upper airway obstruction should be evaluated by respiratory flow-loop studies. A diagnosis of simple goiter per se implies the presence of a euthyroid state with normal levels of serum TSH, T₄, and T₃. Not uncommonly, a multinodular goiter may be associated with normal serum T₄ and T₃ but with an undetectable TSH (see section "[Subclinical Hyperthyroidism](#)"). This is particularly the case in elderly patients in whom clinical manifestations of thyrotoxicosis may be quite subtle (see section "[Toxic Multinodular Goiter](#)"). A number of these patients have underlying Hashimoto's thyroiditis, which can be confirmed by measurement of antithyroglobulin and/or antithyroperoxidase antibodies. The radioiodine uptake test is usually within normal limits but may be increased with Hashimoto's disease or in the context of iodine insufficiency. A dominant nodule may be apparent in a multinodular goiter and should be managed no differently than a single nodule in a nongoitrous gland (see section "[The Thyroid Nodule](#)"). Such a nodule may harbor a carcinoma, and diagnosis is facilitated by fine-needle aspiration cytology. Hemorrhage within either a benign or a malignant nodule may be the cause of a sudden increase in size and, if infarction is extensive, will result in loss of radiotracer concentrating ability and the appearance of a cold nodule on scintiscan.

Treatment of goiter with thyroxine replacement is intended to diminish the size of the goiter by both inhibiting supraphysiologic TSH production and by supplying sufficient product of the thyroid gland to put the thyroid gland to rest. Exposure to known goitrogens should be eliminated and iodine deficiency addressed as applicable. While a daily dose of iodide may prove efficacious for iodine deficiency goiter, often thyroxine replacement is equally or more practical. In young patients, treatment can be initiated with a dose of 0.1 mg of levothyroxine daily, with the dose increased at four to six weekly intervals based on measurements of TSH. In older patients, a starting dose of 0.050 mg will suffice. Ultimately, no more than 0.125 to 0.15 mg per day is required (average dose 1.7 µg per kilogram per day) to achieve

a TSH level between 0.3 and 1.5 mU per liter. There is little need to administer higher doses of thyroxine to achieve complete TSH suppression (less than 0.1 milliunit per liter), which would imply risk for loss of bone mineral and possible atrial fibrillation. While measurement of TSH alone should suffice, adequacy of thyroxine dosage has been assessed as well by measurement of the 24-hour radioiodine uptake, with the desired level being less than 5%.

In many multinodular goiters of long standing, areas of functional autonomy arise that are by definition nonsuppressible. Hence, the radioiodine uptake will not decrease to less than 5%, and often these patients will have subclinical hyperthyroidism with undetectable or very low TSH levels. This constitutes the rationale for TSH measurement prior to initiation of thyroxine therapy, for if autonomy or low TSH is present, there is no point in attempting further TSH suppression. In fact, supplemental thyroxine is contraindicated because it would create overt thyrotoxicosis. In such patients, optimal management would consist of radioiodine ablation. Efficacy of thyroxine therapy in terms of goiter shrinkage varies widely. Diffuse, hyperplastic goiters in younger adults may regress in size by 50% to 70% in 3 to 6 months, whereas the multinodular goiter of the elderly rarely responds very well, with some reduction in goiter achieved in perhaps 25% of patients. Thyroidectomy may be indicated when a goiter fails to shrink with therapy, for unrelieved compressive symptoms, or when a cytology report indicates findings indicating of malignancy. While radioactive iodine has traditionally been employed for toxic multinodular goiter (or Graves' disease), several studies have shown that therapeutic doses of 60 to 100 mCi may be employed safely for large nontoxic goiters, especially when substernal and causing partial upper airway obstruction.

THYROIDITIS

The clinically most important types of thyroiditis are subacute and chronic lymphocytic thyroiditis (Hashimoto's disease) and subacute granulomatous thyroiditis. All of these disorders may be associated at some time in their course with either euthyroidism, thyrotoxicosis, or hypothyroidism. Discussion here will necessarily be brief for both acute infectious pyogenic thyroiditis and chronic fibrosing (Riedel's) thyroiditis because of their rarity. *Acute pyogenic thyroiditis* is generally the result of an acute bacterial infection in the pharynx or hypopharynx that is believed to spread via the pyriform sinuses or connecting soft-tissue planes to the thyroid gland by direct extension. The presentation is one of acute bacterial infection with fever, high white blood cell count, and erythema and warmth overlying the thyroid gland, which is enlarged and tender. The ESR may be increased, thyroid function tests in serum will be normal, but a radioiodine uptake or scan will demonstrate patchy distribution of radionuclide. A scintiscan cold area may represent an abscess, which can be imaged by ultrasonography or MRI. Therapy should be symptomatic for the pain and fever with appropriate antibiotics, usually with gram-positive and anaerobic coverage pending culture results. Cultures of the throat and of fine-needle aspirates of the thyroid may guide antibiotic choice, and incisional drainage is indicated for any abscesses or fluctuant areas within the thyroid or perithyroid tissues. Unusual organisms may cause acute thyroiditis in immunosuppressed patients, such as those on high-dose corticosteroids, or those with AIDS or cachexia due to widespread malignancy. Organisms such as *Mycobacterium tuberculosis*, *P. carinii*, cytomegalic inclusion virus, and various fungal infections have been seen. *Riedel's struma* or thyroiditis is even more uncommon, and some pathologists even doubt its existence as a distinct disorder, suggesting instead that it may be part of the spectrum of retroperitoneal and mediastinal fibrosis. The thyroid gland is entirely replaced by dense, fibrotic tissue that extends through the gland capsule into the surrounding structures of the neck. The neck is indurated and may be tender to palpation, and there may be associated mediastinal fibrosis. Biopsy is indicated to rule out primary or metastatic malignancy of the thyroid, and surgery may be required to relieve tracheal or esophageal compressive symptoms.

Subacute Granulomatous Thyroiditis

This form of thyroiditis is relatively common and is believed to usually represent a viral or postviral disorder. It is also known as de Quervain's or granulomatous giant cell thyroiditis, and the typical presentation is of a pain or pressure sensation in the thyroid gland that may involve first one lobe and then the other. The discomfort frequently radiates to the chin, jaw, ears, or mastoid area and may be associated with dysphagia orodynophagia. The painful thyroid often follows a nonspecific mild febrile illness, such as an upper respiratory infection, and constitutional symptoms may include low-grade fever, fatigue, malaise, and anorexia. Not infrequently, these symptoms are mild enough to be tolerated without medical attention, until symptoms of thyrotoxicosis such as nervousness, palpitations, and insomnia develop. On physical examination, the patient demonstrates findings of thyrotoxicosis, such as warm and moist skin, tachycardia, tremor, and so forth, but without the stigmata of Graves' disease such as ophthalmopathy or dermopathy. Depending on when in the course of the illness the patient is seen, the thyroid gland may or may not be tender. Classically, the gland will be moderately to exquisitely tender and its palpation is often not tolerated by the patient. Palpation may disclose a diffuse or multinodular goiter.

The illness is said to pass through four phases: thyrotoxicosis, transition, hypothyroidism, and, finally, recovery with euthyroidism. The thyrotoxic phase may last for 2 to 6 weeks, and patients seen after this time may have normal to low values for T_4 and T_3 depending on the stage of the illness. The hypothyroid phase of the illness is due to the latency of thyroid gland recovery based on several mechanisms. First, TSH has been suppressed by the thyrotoxicosis and may take weeks to recover. Second, the iodide-trapping mechanism of the gland was inhibited (as reflected by the low radioiodine uptake) by the inflammation and recovers slowly under stimulation by a rising TSH level. This may take several weeks, and sufficient hormone biosynthesis to generate adequate T_3 and T_4 secretion into the blood pool is the final step in the recovery process. As a consequence, the hypothyroid phase may last for 6 weeks to 6 months.

The white blood cell count may be normal or slightly increased with a lymphocytic predominance, although leukopenia typical of viral infection is common. The distinction between the thyrotoxicosis of thyroiditis and that due to diffuse or multinodular toxic goiter can best be made by performance of a radioiodine uptake measurement and an erythrocyte sedimentation rate. The radioiodine uptake will be virtually zero, and any uptake greater than 10% should raise doubt as to the diagnosis. The antiarrhythmic agent amiodarone may cause thyrotoxicosis with low radioiodine uptake as well. The mechanism may be of two types, either a Jod-Basedow phenomenon (see section "[Iodine-Induced Thyrotoxicosis](#)") or an acute, necrotic thyroiditis related to drug toxicity itself.

In most cases, aspirin or a nonsteroidal analgesic is all that is required for alleviation of the symptoms of pain and pressure in the neck. Generally all that is needed to combat the thyrotoxic symptoms is β -adrenergic blocker therapy for the duration of the thyrotoxic phase of the illness. Occasionally, patients are seen in whom the thyroid pain is not relieved by analgesics alone, and a short (7- to 10-day) course of prednisone (20 to 40 mg per day) may be required. Thyroxine therapy is indicated once the patient enters the hypothyroid phase of the illness. Although the gland ultimately spontaneously recovers, patients clearly benefit symptomatically from a short, self-limited course of thyroid hormone replacement. After 6 to 9 months, the thyroxine is gradually tapered during monitoring of serum TSH levels. Once free T_4 and TSH levels remain normal or minimal (50 μ g or less) doses of thyroxine, it should be possible to discontinue the replacement therapy.

Subacute Lymphocytic Thyroiditis

In contrast to granulocytic thyroiditis, lymphocytic thyroiditis is likely to progress to a chronic variant (Hashimoto's disease), often culminating in hypothyroidism. Early presentations of lymphocytic thyroiditis may be associated with thyrotoxicosis, of either a transient variety much like that seen in viral subacute granulomatous thyroiditis or a longer lasting variant, similar to Graves' disease, which has been called "hashitoxicosis." The short, self-limited variant differs from subacute thyroiditis in that it is painless and not associated with systemic signs of viral infection; it has been called "silent thyroiditis." Histologically, there is lymphocytic infiltration of the thyroid gland as in Hashimoto's disease, but the areas of patchy fibrosis and atrophy are lacking. Like subacute thyroiditis, there is no thyroid hyperfunction per se, and the thyrotoxicosis is due to discharge or leak of T_4 and T_3 into the circulation. There may or may not be goiter and, if so, the thyroid tends to be firm and without nodules. The radioiodine uptake is typically low, but may be normal to high in the hashitoxicosis variant, making distinction from Graves' disease difficult. Indeed, describing a distinction may be artificial, for the two disorders may represent different presentations along a spectrum of autoimmune thyroid disease. As in subacute painful thyroiditis with thyrotoxicosis, the sedimentation rate is increased, and serum total and free T_4 and T_3 , along with thyroglobulin, are elevated. Antithyroglobulin or antithyroperoxidase antibodies will be positive in modest to high titers, in contrast to subacute postviral thyroiditis in which antibodies are rarely detectable. Silent thyroiditis may occur at any age but is, like all autoimmune thyroid disease, more common in women. The pathogenesis of silent lymphocytic thyroiditis is unknown, but a postviral etiologic process has not been documented as in granulomatous thyroiditis. The reduced radioiodine uptake may be due in part to TSH suppression by high T_4/T_3 , and perhaps less so to any inflammatory process as is the case for subacute thyroiditis. Unlike Graves' disease, there is no TSH receptor antibody present to provide ongoing stimulation of the radioiodine uptake. The duration of the thyrotoxic state in lymphomatous thyroiditis varies from 6 weeks to 6 months, and, like subacute postviral thyroiditis, the thyrotoxicosis may be followed by a hypothyroid phase of the illness. Also, as in subacute thyroiditis, there is recovery and return to normal thyroid function, although it is more likely that these patients will ultimately progress to burned-out Hashimoto's disease later in life.

Postpartum Thyroiditis

Postpartum thyroiditis is a variant of lymphocytic painless thyroiditis that presents after pregnancy, usually within 2 to 6 months of delivery in 5% to 6% of otherwise normal women. It is particularly common in women with type 1 diabetes mellitus, 25% of whom will develop postpartum hypothyroidism or thyrotoxicosis, and may present with postpartum depression. There is usually a small, diffuse goiter and a family history of thyroid disease. Approximately 6% of normal pregnant women have positive antithyroid antibodies at their first prenatal visit, and about 20% of them go to symptomatic postpartum thyroiditis, which may occur as late as 6 to 8 months after delivery. Typically, the first phase of the illness is thyrotoxicosis during which patients will have the usual symptoms of fatigue, palpitations, emotional lability, and heat intolerance, and then usually transition into a subsequent hypothyroid phase, as in granulomatous thyroiditis. However, postpartum thyroiditis may present

with only hypothyroidism, or with hyperthyroidism that evolves back to euthyroidism without ever going through a hypothyroid phase. Laboratory findings may include an elevated serum level of T_4 and T_3 , suppressed TSH, elevated titers of antithyroid antibodies, and low radioiodine uptake. During the hypothyroid phase (from 4 to 8 months post partum), patients usually manifest a low serum T_4 level, elevated TSH, and high titers of autoantibodies. These patients usually require no treatment other than (a) symptomatic management or (b) β -adrenergic blockers while thyrotoxic and levothyroxine while hypothyroid until the thyroid recovers.

Chronic Lymphocytic (Hashimoto's) Thyroiditis

Chronic autoimmune thyroiditis or lymphadenoid goiter, is the most common form of thyroiditis, the most common basis for hypothyroidism, and arguably the most common of all thyroid disorders. It is a chronic inflammatory disease of the thyroid in which cytotoxic T lymphocytes and antithyroid antibodies play a prominent role. While seen in men as well, it occurs most frequently in women of middle age and is the most common cause of sporadic goiter in children, especially adolescents. The risk factors are female sex, family history or inherited susceptibility, and advancing age. There are said to be two forms of the disease, a goitrous and a nongoitrous, atrophic form, but the latter is likely only the end stage of the earlier, goitrous form. Both are characterized by lymphocytic infiltration and varying degrees of fibrosis, with the atrophic form having the most fibrosis. In the goitrous form, there is thyroid follicular cell hyperplasia, and greater degrees of lymphocytic infiltration with actual lymphoid germinal centers. The progressive atrophy is presumed to be due to both antibody- and cell-mediated injury to the follicular cells. The hallmark of the disease is the antibodies, which are now routinely measured in serum as two types: antithyroglobulin antibody, detected by the tanned red cell agglutination test, and antithyroid peroxidase (anti-TPO or antimicrosomal) antibody, detected by immunofluorescence, complement fixation, or enzyme-linked immunosorbent assay (ELISA). Cytotoxic T lymphocytes and these autoantibodies reflect and also may cause the thyroid follicular cell destruction. In addition, there may be antibodies present to the TSH receptor that inhibit the binding of TSH, thereby blocking its action. In this way, the hypothyroidism may be the result of either (or both) follicular cell destruction and impaired TSH action. Qualitative and quantitative differences in antibody production and activation of the cytotoxic T lymphocytes likely account for the extent of thyroid cellular destruction and resulting hypofunction.

In younger patients presenting with goiter, generalized thyroid enlargement is seen, which typically also involves the pyramidal lobe, and the patients are usually euthyroid. The consistency is that of rubber, but as the disease progresses, there is progressive replacement of thyroid parenchyma by lymphocytes or fibrous tissue, and hypothyroidism supervenes. At this stage, the goiter is usually smaller and finely nodular or so atrophic as to be barely palpable. Between first presentation and development of overt hypothyroidism, there may be years or even decades of falling thyroid reserve and a state described as "subclinical hypothyroidism," which represents simply early or mild thyroid failure. The hallmark of this state of the disease is the presence of an increased TSH level but normal values for circulating total and free T_4 and T_3 . Perhaps 5% to 10% progress to hypothyroidism per year of follow-up. What may appear to be paradoxical is the finding of an elevated radioiodine uptake in Hashimoto patients with mild to moderate thyroid failure. This phenomenon reflects the continued integrity of the iodide trap, particularly when under more intense TSH stimulation, while thyroid hormonogenesis is failing.

Chronic Hashimoto's thyroiditis may account for as many as 90% of cases of hypothyroidism. Clinicians may argue about whether to start levothyroxine therapy when the TSH is only mildly elevated (e.g., between 4 to 10 microunits per liter), but controlled studies indicate statistically significant improvement in profile or well-being and in objective parameters such as lipid profiles. Since the presence of positive antibodies predicts inexorable thyroid failure in patients with mild TSH elevations, our practice is to initiate treatment. A small reduction in goiter size may be seen with treatment, but the lymphocytic components to the goiter would not be expected to shrink with therapy. Presentation during pregnancy of mild hypothyroidism due to chronic thyroiditis is common, probably precipitated by the increased demands for thyroid hormone during gestation. High antibody titers are associated with a greater frequency of postpartum thyroiditis and with miscarriage. Euthyroid patients with Hashimoto's disease are sensitive to iodine exposure, which can induce a reversible form of hypothyroidism. Rarely, Hashimoto's disease may present as thyrotoxicosis, likely representing patients with an overlap autoimmune syndrome reflecting the presence of both Graves' disease and its TSH receptor antibodies and Hashimoto's disease with cytotoxic autoantibodies. This presentation has been called hashitoxicosis, and the clinical picture includes a more firm or even nodular goiter than that seen in Graves' disease, but with the same profile of laboratory tests, including elevated serum T_4 and T_3 , high radioiodine uptake, and high titers of circulating antithyroid antibodies. Equally rare is the transition of a euthyroid or even a hypothyroid patient with Hashimoto's disease to Graves' disease with thyrotoxicosis. This latter phenomenon suggests the emergence of clones of lymphocytes that produce stimulatory anti-TSH receptor antibodies. Both of these forms of autoimmune thyrotoxicosis tend to progress more readily to spontaneous remission than is seen in the usual patient with Graves' disease, probably because of the presence of intrathyroidal cytotoxic T lymphocytes. As a consequence, short-term therapy of the hyperthyroidism with antithyroid drugs is preferable to ablative therapy by either radioiodine or surgery.

THYROID NODULES AND NEOPLASMS

Epidemiology and Pathogenesis

Solitary nodules of the thyroid gland are present in about 6.4% of women and 1.5% of men. The incidence is low in children (about 1.5%), and increases with age. Many single palpable nodules thought to be solitary are actually in a multinodular thyroid gland. Autopsy studies indicate thyroid nodules in as many as 50% of consecutive necropsies, although many may be small and clinically inapparent. High-resolution ultrasonography has identified nodules in 13% to 40% of patients under evaluation for nonthyroid problems. The prevalence of nonpalpable nodules incidentally detected by ultrasonography ("incidentalomas") is 30% to 60% in autopsy studies and 19% to 67% in clinical studies, with an average risk for malignancy of 4%.

Although the cause of thyroid nodules is not known, some association with iodine deficiency and states of TSH stimulation has been noted. Radiation exposure can cause thyroid neoplasia, with a linear relationship between radiation doses up to 1,800 cGy and the incidence of thyroid nodules and cancer. Radiation exposure as a child is more likely to produce thyroid neoplasia than similar exposure at a later age, possibly related to greater cellular mitotic activity at the earlier age of insult. Among individuals in the United States receiving head and neck irradiation in childhood, palpable nodules are found in 16% to 29% and carcinoma in one-third of these nodules. Most nodules tend to occur within 10 to 20 years of exposure, but the risk may exist for more than 40 years. The increase in thyroid nodules and thyroid cancer occurring in Belarus after the 1986 Chernobyl nuclear disaster has been dramatic. Higher doses of irradiation, such as those used for Hodgkin's disease (more than 2,000 rads), and ^{131}I therapy do not appear related to subsequent thyroid carcinoma.

Diagnosis and Differential Diagnosis

The differential diagnosis of apparent thyroid nodules is indicated in [Table 406.10](#). Most (27% to 60%) true intrathyroidal nodules will represent colloid adenomas or simple follicular adenomas (26% to 40%). About 5% of thyroid nodules are classified as hot on the basis of a relative increased ability to trap iodide (see below). Hot nodules rarely represent malignancy; warm nodules carry an intermediate risk of around 5%; and cold nodules, while having the highest risk of malignancy, still represent benign pathology in more than 80% of cases. Since the morbidity of thyroid nodules is related to those lesions representing carcinoma, the diagnostic evaluation is focused on identification of those nodules that may be malignant. The single most important historical risk factor for cancer is exposure to radiation. It is important to determine the age at time of exposure, exact region of the body irradiated, and, if possible, the type and dose of radiation to the thyroid. Although women are more prone to thyroid nodules and cancer than men, the probability of cancer is higher among men with nodules. The incidence of thyroid cancer increases with age, but a higher percentage of nodules in patients younger than 20 years are malignant. Thyroid lymphoma should be considered in patients with rapid thyroid enlargement and a previous diagnosis of Hashimoto's thyroiditis, especially in women over age 50 with coincident diabetes mellitus. A family history of pheochromocytoma, hypercalcemia, mucosal abnormalities, or medullary thyroid carcinoma raises suspicion of the latter diagnosis as part of a MEN syndrome. While a family history of benign goiter may be reassuring, the rare Pendred's syndrome of familial goiter and deaf mutism is associated with a higher cancer risk. Most thyroid nodules are discovered incidentally in asymptomatic patients. As noted in [Table 406.11](#), a number of symptoms or physical findings are felt to be more common in malignant than benign nodules, although as few as 5% to 10% of patients with malignancy present with symptoms. Patients with advanced disease may present with lymphadenopathy, growth of hard nodules, thyroid pain and tenderness, and vocal cord paralysis, all of which point to the likelihood of malignancy.

Benign Thyroid Neoplasms	Nonthyroidal Lesions
Follicular adenoma	Thyroglossal duct cyst
Colloid	Lymphadenopathy
Simple	Aneurysm
Fetal	Parathyroid adenoma
Embryonal	Parathyroid cyst
Hürthle cell	Cystic hygroma
Lipoma	Lymphocyst
Papillary adenoma	
C-cell adenoma	
Teratoma	
Dermoid cyst	
Malignant Thyroid Neoplasms	
Papillary carcinoma	
Follicular carcinoma	
Metastatic carcinoma	
Medullary thyroid carcinoma	
Anaplastic carcinoma	
Lymphoma	
Sarcoma	
Other Thyroid Abnormalities	
Thyroiditis	
Thyroid cyst	
Hemorrhagic thyroid infarction	
Granulomatous disease (e.g., sarcoidosis)	

TABLE 406.10. DIFFERENTIAL DIAGNOSIS OF APPARENT THYROID NODULES

History	Physical Exam
Dysphagia	Documented growth
Rapid growth	Vocal cord paralysis
Hoarseness	Cervical lymphadenopathy
Pain	Firm-to-hard consistency
Family history of multiple endocrine neoplasia	Tenderness
History of irradiation	Fixation
Growth on levothyroxine therapy	Horner's syndrome
Respiratory obstructive symptoms	

TABLE 406.11. PHYSICAL AND HISTORICAL FEATURES SUGGESTING INCREASING RISK OF CARCINOMA IN A THYROID NODULE

Routine thyroid function tests are of little value in the evaluation of thyroid nodules. The best preoperative method to identify a malignancy is to obtain cells from the nodule for cytopathologic examination by a fine-needle aspiration (FNA) technique. The results of FNA of a thyroid nodule will be generally categorized as "benign," "suspicious," "malignant," or "inadequate for diagnosis." Use of ultrasonographically guided FNA has been shown to be effective for the detection of malignancy in nonpalpable lesions (Table 406.12). Some studies have sought to use cytometric DNA analysis to improve the predictive value of FNA. While it has not been found to be entirely successful in separating benign from malignant disease, it does correlate with outcome and survival in patients with proven malignancy. Polymerase chain reaction amplification of TSH receptor or thyroglobulin transcripts on material obtained by FNA of cervical lymph nodes has facilitated earlier diagnosis of metastatic malignancy. FNA carries no significant risk, and no cases of tumor seeding have been reported.

- Differentiation of solid vs. cystic consistency
- Detection of multinodularity
- Guidance for needle biopsy in difficult selected cases
- Monitoring nodule size, including response to suppressive therapy
- Determination of solid vs. hemorrhagic expansion in thyroid lesions showing rapid increase in size
- Monitoring irradiated thyroids
- Monitoring for local recurrence of thyroid carcinoma
- Detection of occult thyroid malignancy in cases of metastatic cervical lymphadenopathy from unknown primary

TABLE 406.12. POTENTIAL UTILITY OF ULTRASONOGRAPHY OF THYROID NODULES

Thyroid Adenomas

True adenomas, as opposed to localized adenomatous areas, are typically monoclonal, encapsulated cellular tumors that compress contiguous tissue and are composed of thyroid follicular cells. Adenomas vary in size and are classified into three histologic types: papillary, follicular, and Hürthle cell. The follicular adenomas can be subdivided, according to the size of the follicles, into colloid or macrofollicular, fetal or microfollicular, and embryonal varieties. Adenomas vary in physiologic differentiation, as judged by their ability to concentrate radioiodine. The more highly differentiated adenomas (follicular) are most likely to mimic the function of normal thyroid tissue and be responsive to TSH stimulation except when autonomous and/or hyperfunctioning. On scintiscan, an adenoma may be seen to accumulate radiotracer sufficient to constitute an area of increased density within the still functioning extranodular tissue (a warm nodule). With time, the nodule may grow larger and ultimately increase function to the point of suppressing TSH secretion. Consequently, the remainder of the gland undergoes relative atrophy and loss of function, and the scintiscan reveals radioiodine accumulation only in the region of the nodule (See section [The Hyperfunctioning \("Hot"\) Thyroid Nodule](#) below).

Management

Thyroid hormone therapy has been used for many years to reduce the size of thyroid lesions thought to be dependent on TSH stimulation. Typically, patients are given a 3- to 6-month trial of *l*-thyroxine at a dose titrated to result in TSH suppression to below the lower limit of normal of a sensitive TSH assay. Growth of a nodule or lack of reduction in size during therapy raises suspicion of malignancy. Complete responses probably occur in less than 10% of cases, whereas 50% reduction in size has been reported in an average of 30% of cases. The benefit of thyroxine therapy remains controversial, with some studies failing to show significant shrinkage and others reporting both a reduction in size and possible prevention of the appearance of new nodules. Possible risk of osteopenia after long-term suppressive doses of thyroid hormone is a concern, especially in postmenopausal women, but either replacement dosage or mild suppressive doses of thyroxine has not been shown to cause osteopenia. An elevated serum TSH indicates that dosage is insufficient and an elevated serum T₃ that it is excessive. Levothyroxine treatment is contraindicated for autonomous hyperfunctioning adenomata. FNA biopsy should be repeated immediately when a nodule is found to be enlarging on suppressive therapy, and surgical exploration should be deemed inevitable unless cystic fluid or hemorrhage with benign cytology is obtained. FNA should also be repeated when there is failure to obtain significant reduction in nodule size after 6 to 12 months of suppressive therapy. Figure 406.4 suggests an algorithm that may be useful in a practice where FNA is frequently utilized with experienced cytopathologic support.

bodies, and large pink follicular cells with large pale nuclei and nuclear inclusions ("Orphan Annie cells") with numerous nucleoli. Ultrasonography and nuclear scintiscanning may be also useful, with the former indicating a solid tumor and the latter a nonfunctioning, or cold, lesion.

When the cytologic results are equivocal, suppressive doses of thyroid hormone may be tried in an attempt to shrink the suspect nodule, or one can proceed to thyroidectomy. Candidates for surgery include those with a history of radiation to the thyroid and one or more clearly palpable nodules, as well as young men and women with solitary cold nodules, particularly nodules that are hard, nontender, and changing rapidly in size. In the remainder, thyroid hormone therapy with repeat aspiration cytology in 3 to 6 months is recommended. Opinions vary as to the preferable procedure when carcinoma is found. In skilled hands the preferred procedure may be near-total thyroidectomy, especially for lesions larger than 2 cm in view of the high incidence of multicentric tumor and the evidence that both recurrence rates and subsequent mortality are lower following this more extensive operation. Regional lymph nodes should be explored and removed if there is evidence of involvement, but radical neck dissection is not justified. When the initial surgical procedure was not a near-total thyroidectomy and the permanent sections reveal carcinoma when frozen sections failed to do so, a second surgery for a completion thyroidectomy should be undertaken. A total thyroidectomy is warranted for follicular carcinoma in view of its tendency for distant metastasis. This is so because the metastases do not concentrate adequate ^{131}I in the presence of residual normal thyroid tissue, which both competes for the ^{131}I and prevents the increase in serum TSH required to stimulate uptake by tumor cells.

The need for postoperative ablation of the thyroid remnant with radioiodine and for subsequent periodic radioisotopic scanning for residual or current disease varies with the histologic type of cancer, size of lesion, presence of metastases, and other indications of invasiveness or aggressiveness.

Total body scintiscanning with ^{131}I is the method employed to evaluate for residual normal or malignant thyroid tissue in the neck and for distant metastases, and is only done when the TSH is sufficiently elevated to stimulate good uptake and imaging. One concern is that high doses of ^{131}I (a β -particle emitter) used for diagnostic scanning may have an adverse effect on the subsequent uptake of the therapeutic dose, a phenomenon that has been called "stunning." As a precaution against stunning, ^{123}I (a pure γ -ray emitter) or $^{99\text{m}}\text{Tc}$ may be used instead for initial scans, reserving ^{131}I for actual therapy, or for scanning when the ^{123}I scan is negative but residual disease is suspected on the basis of elevated serum thyroglobulin levels. Postoperatively, the patient is not started on T_4 -thyroxine replacement and is allowed to become hypothyroid with the resultant increase in serum TSH. With the recent availability of recombinant TSH for parenteral injection, it is no longer necessary to discontinue thyroid hormone therapy for follow-up scanning. Some patients may be monitored for recurrence by measuring serum thyroglobulin only.

Patients are reexamined approximately 6 months after the initial operation and at least every 6 months for several years thereafter. At these examinations, the neck is palpated for evidence of recurrence, which often can be surgically removed. Serum thyroglobulin is measured, and elevated values in patients receiving suppressive therapy signal the presence of metastatic disease. At the initial 6-month examination, patients in whom metastases had previously been found are prepared for whole-body scan as described above. Patients with relatively small initial ("low risk") lesions, in whom no metastases have been demonstrated by earlier scan, may not require rescanning unless the serum thyroglobulin is shown to increase (either basally or after recombinant TSH administration). Patients in whom whole-body scans are positive are reentered into the therapeutic algorithm, as described above. Those in whom scans are negative continue to be reexamined and have measurements of serum thyroglobulin concentrations at regular intervals. If both serum thyroglobulin concentrations and scans fail to disclose residual tumor, patients are scanned for possibly the last time after approximately 3 to 5 years, unless serum thyroglobulin concentrations subsequently rise. In some patients, serum thyroglobulin may be elevated despite the absence of demonstrable functioning metastases, and empirical therapy has been given. Reduction in serum thyroglobulin in such patients is presumed to represent therapeutic benefit. In scan-negative patients, alternative imaging to identify tumor may be feasible by CT or MRI or other radionuclides such as fluorodeoxyglucose–polyethylene terephthalate, thallium 201 or technetium-99m MIBI to determine whether the site of the thyroglobulin-secreting metastases may be amenable to surgery or external radiation. This management program with near-total thyroidectomy, long-term suppressive therapy, and treatment of functioning metastases with radioiodine reduces the recurrence rate and prolongs survival in patients with papillary carcinoma of the thyroid. Follicular carcinoma should be treated with even greater vigor, since the outcome with this tumor is generally less favorable. Because follicular carcinoma metastasizes to lung and bone, appropriate follow-up radiography and measurements of serum thyroglobulin should be performed. Mixed differentiated tumors with both follicular and papillary elements tend to behave biologically as papillary tumors and should be so managed.

CARCINOMAS OF PARAFOLLICULAR EPITHELIUM

Medullary thyroid carcinoma (MTC) arises from the thyroid parafollicular C cells, clustered in the upper two-thirds of the thyroid lobes, and is traditionally classified as sporadic versus hereditary. There are four presentations, with the sporadic form accounting for 80% of cases, and three autosomal dominant hereditary forms, which account for the remaining 20%.

Hereditary Medullary Thyroid Carcinoma

Hereditary medullary thyroid carcinomas are thought to begin as C-cell hyperplasia and are usually multifocal. Two of the familial forms of MTC occur as MEN 2A and 2B. MEN 2A is the most common form, representing perhaps 95% of affected individuals, 50% of whom will have associated pheochromocytoma and 15% to 25% of whom will also have hyperparathyroidism. MEN 2A is rarely associated with Hirschsprung's disease or with cutaneous lichen amyloidosis. Patients with MEN 2B, the second most common syndrome, do not have hyperparathyroidism. MEN 2B includes MTC, pheochromocytoma, and ganglioneuromas of the oral mucosa and gastrointestinal tract. Familial MTC is the least common hereditary form and has no extrathyroidal (MEN) manifestations. Each of the hereditary syndromes is associated with a germ line mutation of the *ret* gene on chromosome 10. In familial forms, the disease may be diagnosed early in family members by means of screening DNA analysis of the *ret* gene, precluding the necessity for periodic tests of calcitonin secretion in family members at risk. Thyroidectomy is recommended for gene carriers starting at age 5 years.

Sporadic Medullary Thyroid Carcinoma

There is a peak incidence of the sporadic form in the sixth and seventh decades of life. At presentation, patients may already have cervical lymph node metastases, which often demonstrate calcification on routine radiographic examination of the neck. Local symptoms of dysphagia or hoarseness may be due to tissue compression or invasion of the recurrent laryngeal nerves. Paraneoplastic manifestations of flushing, secretory diarrhea, or hypercortisolism occur rarely. FNA biopsy is the diagnostic procedure of choice, and correct preoperative diagnosis is essential to screen for pheochromocytoma and plan an appropriate staging evaluation. Staging may include scintigraphic imaging of the neck and mediastinum, and CT or MRI of the neck and chest. The preoperative evaluation should also include a basal calcitonin and carcinogenic embryonic antigen level, serum calcium, and 24-hour urine catecholamines or metanephrines to rule out pheochromocytoma. The preoperative diagnosis of MTC prepares the surgeon to search for regional metastases and perform extensive lymph node dissection. Postoperatively, serum calcitonin serves as a tumor marker for residual disease, and the serum levels correlate with tumor burden.

Anaplastic Carcinoma

Anaplastic carcinoma, aggressive tumor, constitutes approximately 5% of thyroid cancers and usually occurs in the sixth or seventh decade of life. The tumor is histologically undifferentiated, composed largely of spindle and giant cells, and is fast growing and highly malignant. Despite radical surgery, the prognosis is dismal, with survival in months rather than years, although survival is slightly better in younger patients with early disease. The rapidly fatal character of the lesion is due to extensive local invasion that is refractory to both external-beam radiation therapy and radioiodine therapy (because the tumor does not concentrate iodine). The fact that many patients have coexisting differentiated carcinoma suggests that anaplastic tumors arise from the former, and metastases of papillary or follicular carcinoma have been known to undergo late malignant dedifferentiation.

Lymphoma

Primary thyroidal lymphoma constitutes about 5% of all thyroid malignancies. Of the various cell types, large-cell histiocytic (or immunoblastic) lymphoma is the most common and typically occurs in women between the ages of 55 and 75, who often have underlying chronic lymphocytic thyroiditis with positive serum antithyroglobulin or anti-TPO antibodies. Patients with Hashimoto's disease have an approximate 60-fold relative risk for developing non-Hodgkin's lymphoma of the thyroid, a risk so high that any enlarging thyroid mass in an elderly patient with Hashimoto's thyroiditis should be considered to be thyroid lymphoma until ruled out. While occasional T-cell lymphomas have been reported, primary thyroidal lymphoma is almost always of B-cell lineage. Because of histologic and prognostic similarities, some workers have grouped B-cell thyroid lymphomas with mucosa-associated lymphoid tissue (MALT) lymphomas. Molecular abnormalities reportedly associated with both thyroid and MALT lymphomas include loss of expression of *bcl-2* and increased *p53* inactivation.

Symptoms of thyroid lymphoma typically include dysphagia, odynophagia, and hoarseness (those of a rapidly enlarging goiter, with compression of surrounding structures, and substernal extension is common). Many patients also have cervical or supraclavicular lymphadenopathy. Hypothyroidism, when present, is due to both

the underlying Hashimoto's thyroiditis and possible replacement of functioning follicular tissue with the lymphoma. The tumor may completely encircle the trachea giving rise to a "donut sign" on CT. The mass will be cold on radioiodine scanning but frequently may be made visible with either gallium 67, thallium 201, or technetium 99m MIBI. The diagnosis is usually confirmed by fine needle aspiration cytology but rarely a surgical biopsy may be required. Because of the tendency of this tumor to grow rapidly, airway management is usually a principal focus of management. Prognosis depends on the cell type and the extent of disease beyond the neck. Variable success rates have been reported with combinations of surgery, radiation, and chemotherapy. External-beam radiation therapy with approximately 4,000 cGy usually provides a 5-year survival of 10% to 70%, and whether or not aggressive surgery may further benefit survival is controversial. More advanced disease may benefit from chemotherapy or combined-modality therapy.

NORMAL ADRENAL FUNCTION

The adrenal cortex is the source of three types of steroid hormones: cortisol, aldosterone, and sex steroids. Cortisol is synthesized in the zona fasciculata and its secretion is regulated by adrenocorticotropic hormone (ACTH; also called adrenocorticotropin, or corticotropin). ACTH binds to specific receptors in the adrenocortical cell membrane where it activates adenylyl cyclase. In turn, cyclic AMP activates a protein kinase that increases the activity of cholesterol esterase and the hydrolysis of cholesteryl esters, making cholesterol available to the mitochondria for initiation of steroidogenesis. The rate-limiting step in the activation of steroidogenesis by ACTH is the transport of cholesterol from the outer to the inner mitochondrial membrane, a process that is regulated by a steroidogenic acute regulatory protein (StAR). ACTH also activates the conversion of cholesterol to pregnenolone, a step catalyzed by the cholesterol side-chain cleavage enzyme. A series of four enzyme-catalyzed steps then converts pregnenolone to cortisol. The four key enzymes that regulate this process belong to the cytochrome P450 family. They are 3 β hydroxysteroid dehydrogenase-d5-4 isomerase, which catalyzes the conversion of pregnenolone to progesterone; and 17 α , 21, and 11 β -hydroxylases, which sequentially act on the various carbons to introduce hydroxyl groups and convert progesterone to 17 α -hydroxyprogesterone, 11-deoxycortisol, and cortisol, respectively. Cortisol is secreted into the blood where 94% of it is transported in association with two plasma proteins: corticosteroid-binding globulin (CBG) and albumin. The remaining 6% is a biologically active free fraction of small molecular size that is capable of moving freely across cell membranes. CBG is primarily of hepatic origin, but it may also be produced in smaller quantities in other organs, including lung, kidney, and testis. The major source of physiologic variation of CBG is pregnancy. CBG levels start to increase from 10 weeks on and a marked two- to threefold increase is observed during the last trimester. The concentration of CBG can also vary in families in which there is an inherited deficiency of CBG leading to a decrease in total cortisol level. Cortisol is metabolized in the liver by reduction and converted to dihydro and tetrahydro derivatives. Small amounts of cortisol are metabolized by hydroxylation. Cortisol metabolites are cleared through glomerular filtration. Conditions that diminish filtration, such as renal insufficiency, can alter cortisol clearance. The following situations also affect cortisol metabolism: estrogen therapy, which increases the binding capacity of CBG; thyroxine therapy, which accelerates the rate of reduction of cortisol by the liver; and liver disease, which decreases the rate of cortisol turnover.

Aldosterone synthesis takes place in the zona glomerulosa and its secretion is regulated by the renin–angiotensin system, potassium, and ACTH in the short term. The pathway of aldosterone synthesis involves the synthesis of progesterone and the subsequent hydroxylation on carbons 21 and 11 to produce 11-deoxycorticosterone and corticosterone. Aldosterone synthase catalyzes the final steps in aldosterone synthesis.

Adrenal androgen synthesis takes place in the zona reticularis under ACTH control. The main adrenal androgens produced are dehydroepiandrosterone (DHEA) and d⁴-androstenedione. Small amounts of testosterone are synthesized and secreted by the adrenal cortex.

Cortisol secretion is regulated by ACTH. In turn, ACTH secretion depends on the integrated function of the limbic system, the anteromedial hypothalamus, and the anterior pituitary gland. Activation of the hypothalamic neurons is mediated by release of serotonergic, dopaminergic, and cholinergic neurotransmitters. The various physiologic characteristics of ACTH release (basal secretion, circadian rhythm, and feedback regulation), as well as the activation or suppression of ACTH release under conditions of stress, depend on specific neuronal pathways located in the limbic system. Hypothalamic corticotropin-releasing hormone (CRH)–secreting neurons are the final common pathway for these various inputs. CRH, a 41-amino-acid peptide, is released into the hypothalamic–hypophysial portal system, through which it reaches pituitary corticotropes in the anterior pituitary gland causing the release of pro-opiomelanocortin (POMC)-derived peptides [ACTH, b-lipotrophic pituitary hormone (b-LPH), b-endorphin, melanocyte-stimulating hormone (MSH)]. This release involves CRH binding to specific receptors in the corticotrope cell membrane and activation through adenylyl cyclase and G proteins of a protein kinase, which regulates gene expression for the synthesis of POMC. POMC is processed in the pituitary corticotropes through a series of steps regulated by endopeptidases that cleave POMC into b-LPH (a 91-amino-acid peptide) and ACTH (a 39-amino-acid peptide). Two important functions of the neurohypothalamus determine the normal physiology of ACTH secretion. They are a circadian rhythm whereby ACTH reaches a peak between 6 and 8 a.m. and a nadir at midnight. In addition, the secretion of ACTH is subject to negative feedback whereby a decrease in cortisol increases ACTH secretion and a rise in cortisol suppresses ACTH release.

Renin is synthesized in the afferent arteriole of the renal glomerulus. Stretch receptors in the wall of the afferent arteriole respond to changes in arterial pressure and stimulate the release of renin. Renin, acting on renin substrate produced in the liver, generates angiotensin I, a decapeptide that is further processed in the lung under the effect of converting enzyme to the octapeptide angiotensin II. Angiotensin II has both direct pressor effects on the peripheral vasculature and endocrine effects through which it stimulates glomerulosa cells to secrete aldosterone. Factors that stimulate the secretion of renin, angiotensin, and aldosterone are volume depletion (hemorrhage, low sodium intake, dehydration, and diuretics) and assuming the upright posture. Factors that inhibit renin, angiotensin, and aldosterone secretion include those associated with volume expansion. In addition, aldosterone secretion can be directly stimulated by the concentration of potassium and ACTH reaching the adrenal cortex.

MECHANISM OF ACTION OF ADRENOCORTICAL STEROIDS

Most steroid effects involve penetration of the cell membrane by the steroid molecule and its binding to specific intracellular protein receptors. These receptors are found in the cytosol and/or nucleus of steroid-responsive cells. This initial interaction is necessary for a subsequent hormonal response. The steroid–receptor complex then binds reversibly to specific sites in the cell nucleus, resulting in transcriptional activation.

The tissue response to cortisol is catabolic in most tissues (muscle, skin, lymphoid, adipose, or connective) but anabolic in the liver where it stimulates gluconeogenesis. The general response is due to specific stimulation or inhibition of a number of individual enzymes, each of which contributes to the total catabolic or anabolic pattern. The resulting effect is protein catabolism, stimulation of gluconeogenesis and hepatic glucose production, and redistribution of fat with development of truncal obesity.

Glucocorticoids have a major anti-inflammatory and immunosuppressive role, although it is not clear if this role occurs within a physiologic range of secretion. They inhibit the initial inflammatory reaction by suppressing hyperemia, extravasation, cellular migration, and cellular permeability; they also inhibit the release of vasoactive kinins from plasma proteins and suppress the phagocytic mechanism. They decrease histamine synthesis by mast cells, which in turn inhibits the acute anaphylactic reaction based on antibody-mediated hypersensitivity. They have a suppressive effect on wound healing and scar formation.

Mineralocorticoids stimulate sodium pump activity, causing sodium retention, potassium excretion, metabolic alkalosis, and increased blood pressure. Androgens induce protein anabolism and development of male secondary sexual characteristics.

CUSHING'S SYNDROME

DEFINITION

Cushing's syndrome is the clinical expression of the metabolic effects of persistent, inappropriate hypercortisolism. The diagnosis can be precisely established by biochemical means, by noninvasive imaging of pituitary and adrenal lesions, and by selective identification of the source of ACTH in the ACTH-dependent types.

ETIOLOGIC FACTORS

The cause of Cushing's syndrome can be exogenous, resulting from the administration of glucocorticoids or ACTH, or endogenous, resulting from a primary increased secretion of cortisol or ACTH ([Fig. 407.1](#)).

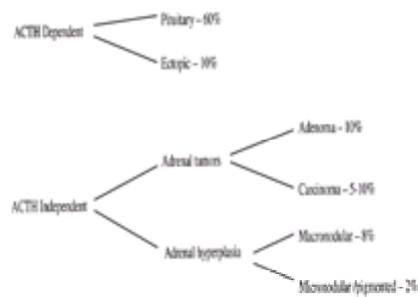

FIGURE 407.1. Etiologic classification of Cushing's syndrome.

Pituitary ACTH hypersecretion occurs in 60% of patients with Cushing's syndrome. This condition is also called Cushing's disease. About 85% of patients with Cushing's disease have pituitary microadenomas. In most cases, the microadenomas are located in the periphery of the gland and can be identified by imaging techniques or transsphenoidal pituitary exploration. Occasionally, they are located deep in the central wedge of the pituitary and can be missed on imaging or at surgery. It has been suggested that excessive ACTH secretion may develop from corticotrope hyperplasia caused by neurohypothalamic stimulation and CRH hypersecretion. Clonal analyses of the pituitary tissue obtained from patients with Cushing's syndrome show that ACTH-secreting microadenomas have a monoclonal pattern consistent with a monoclonal proliferation of a genetically altered cell. In contrast, corticotrope hyperplasia such as that seen in patients with CRH-secreting bronchial carcinoids is polyclonal. Thus, a spontaneous somatic mutation in pituitary corticotropes is the primary pathogenetic mechanism in this disorder. In the few patients in whom CRH levels have been measured in the spinal fluid, low levels have been found, suggesting suppressed CRH secretion.

The association of Cushing's syndrome with nonadrenal neoplasms is called ectopic ACTH or paraneoplastic ACTH syndrome. Typically, a rapidly developing malignancy causes the autonomous secretion of high levels of ACTH and cortisol, with clinical manifestations of Cushing's syndrome and pigmentation. Approximately 50% of these ectopic ACTH-secreting tumors are in the lung, and the remainder occur in a variety of tissues. In addition to ACTH, these tumors may contain other hormones, such as insulin, gastrin, and glucagon, which are not produced in sufficient amounts to cause a metabolic syndrome. Less frequent causes of ectopic ACTH syndrome include thymic carcinoids; gastric and appendicular carcinomas; pheochromocytomas; adrenal medullary paragangliomas; cyst adenomas of the pancreas; epithelial carcinomas of the thymus; medullary thyroid carcinomas; prostatic carcinomas; carcinomas of the esophagus, ileum, and colon; ovarian tumors; squamous cell carcinoma of the lung, larynx, and cervix; and melanomas. Although the relationship between the more commonly occurring tumors and ectopic ACTH production has been well established, the production of ACTH by the less commonly occurring tumors has not been absolutely proven. An unusual cause of ectopic ACTH production is an ectopic pituitary adenoma. In some cases, normal pituitary tissue occurs in an ectopic location and not in continuity with intrasellar pituitary tissue. Occasionally, adenomas may develop in this ectopic pituitary tissue, causing excessive ACTH production.

Ectopic CRH production can cause Cushing's syndrome. Tumors associated with ectopic CRH secretion include bronchial carcinoids, medullary thyroid carcinoma, and metastatic prostatic carcinoma.

Primary nodular hyperplasia, adrenocortical adenomas, and carcinomas, and rare cases of ectopic cortisol production by tumor, are found in 30% of patients presenting with Cushing's syndrome. Primary bilateral micronodular hyperplasia is characterized by the presence in the adrenal cortex of one or more yellow nodules visible to the naked eye and 2 to 3 cm in diameter. Its pathogenesis is unknown. Histologically, the nodules consist of clear cells arranged in acini and cords, and are occasionally encapsulated and surrounded by simple or micronodular cortical hyperplasia. The incidence of mitotic figures is low. A form of ACTH-independent micronodular adrenal disease is characterized by darkly pigmented micronodules in the presence of atrophy of the perinodular adrenal tissue, disorganization of normal zonation of the cortex, and small glands.

A condition associated with pigmented micronodular hyperplasia is Carney's complex, a form of multiple endocrine neoplasia. In addition to the adrenocortical disease, patients with this condition may have growth hormone-secreting pituitary tumors, Sertoli cell testicular tumors, atrial or ventricular myxomas, single or multiple cutaneous fibroadenomas and myxomas. A prominent feature is spotty skin pigmentation similar to that observed in several lentiginosis syndromes. The genetic defect(s) responsible for Carney's complex map(s) to the short arm of chromosome 2 (2P16). ACTH-independent macronodular adrenocortical hyperplasia is a rare cause of Cushing's syndrome in which the adrenal glands become very enlarged and occupied by multiple large cortical nodules. In some patients the masses can be extremely large and weigh close to 100 g each. Histologically the nodules are mostly composed of clear cells, and no cortical architecture has been observed in the internodular regions.

Adrenal adenomas are unilateral, well-circumscribed, brown-to-yellow tumors with a homogeneous appearance, weighing less than 30 g. Histologically, they have the characteristics of normal adrenal cortex, with compact and clear cells arranged in cords. Adrenal carcinomas are large neoplasms with irregularly shaped nodules, exhibiting areas of necrosis or hemorrhage. Histologically, the cells are small, with nuclear pleomorphism and mitotic figures, and there is evidence of capsular and angioinvasion by tumor. Adrenocortical carcinomas can develop in patients with hereditary cancer syndromes. The Li-Fraumeni syndrome is characterized by cancers involving all three types of germinal cells and includes sarcomas, brain tumors, leukemia, lymphoma, and adrenocortical carcinoma, in addition to early-onset breast cancer. Mutations in the P53 tumor suppressor gene have been identified in patients with cancer associated with the Li-Fraumeni syndrome.

PATHOGENESIS

In the ACTH-dependent types of Cushing's syndrome, ACTH is secreted by the pituitary gland or by an extrapituitary neoplasm capable of producing peptide hormones, including ACTH and CRH (see [Fig. 407.2](#)). In pituitary-dependent Cushing's disease, the feedback relationship between the pituitary and the adrenal glands is maintained but is abnormal. In the ectopic ACTH syndrome, pituitary ACTH release is suppressed by excessive production of cortisol, which is stimulated by an unsuppressible overproduction of ACTH by the ectopic source. In ectopic CRH syndrome, tumor CRH stimulates ACTH secretion by the pituitary corticotropes; this causes an excessive production of cortisol that is not sufficient to suppress ACTH secretion. In patients with ACTH-independent Cushing's syndrome, pituitary ACTH secretion is suppressed by excessive cortisol production that originates in adrenocortical tumors (adenomas or carcinomas) or in autonomous nodular hyperplastic glands.

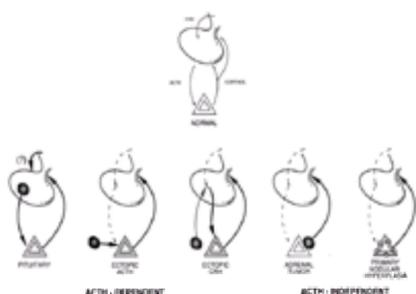

FIGURE 407.2. Changes in ACTH and cortisol secretion observed in patients with ACTH-dependent and ACTH-independent Cushing's syndrome.

The manifestations of abnormal ACTH secretion in Cushing's disease are a loss of normal negative feedback and a blunted circadian rhythm of ACTH and cortisol secretion. Unusual abnormal patterns of release of ACTH and cortisol have been described whereby episodes of hypersecretion occur periodically, lasting hours or weeks and interrupted by periods of normal secretion.

Several interesting pathogenic mechanisms have been described in patients with ACTH-independent nodular adrenocortical hyperplasia. In one case, the secretion of cortisol was stimulated by food. The patient had elevated postprandial cortisol levels that could not be suppressed with dexamethasone. Cortisol increased in response to oral glucose, a lipid-rich meal, or a protein-rich meal but not to the intravenous administration of glucose. In response to test meals, plasma gastric inhibitory polypeptide (GIP) increased in parallel to the plasma cortisol. The ability of GIP to stimulate adrenal cortisol production could be demonstrated in cell suspensions of adrenal tissue from the patient. It was postulated that nodular adrenocortical hyperplasia and Cushing's syndrome was food-dependent and resulted from abnormal responsiveness of adrenal cells to the physiologic secretion of GIP. Ectopic expression of GIP receptors in the adrenal cells was felt to mediate this disorder. A case of Cushing's syndrome secondary to ACTH-independent bilateral adrenal hyperplasia was also described that responded to catecholamines acting through ectopic adrenal β -receptors. This increased cortisol secretion was responsive to changes in posture and inhibited by β -blockade with propranolol.

CLINICAL FINDINGS

The clinical manifestations of Cushing's syndrome involve many organ systems and metabolic processes. Hypertension, obesity, diabetes, androgen-type hirsutism, and acne are commonly seen in these patients. When present, the following findings increase the suspicion of Cushing's syndrome: symptoms and signs of protein catabolism (e.g., ecchymoses, myopathy, osteopenia); truncal obesity; lanugal hirsutism; cutaneous lesions (wide, purple striae; tinea versicolor; verrucosus vulgaris); hyperpigmentation; and psychiatric manifestations (impairment of affect, cognition, and vegetative functions). In some instances, the diagnosis of Cushing's syndrome can be strongly suspected on clinical grounds alone, but confirmation of the diagnosis requires specific laboratory studies. The clinical manifestations of Cushing's syndrome are determined by the increased abnormal secretion of cortisol, ACTH, and other adrenocortical steroids under ACTH control. However, the clinical presentation varies among the different types.

Patients with pituitary ACTH-dependent disease have a history of 2- to 3-year duration. In milder cases, symptoms may be present for 5 to 10 years. Earliest symptoms include weight gain, progressive changes in physical appearance, hypertension, and glucose intolerance. Patients may have been treated for these conditions with weight reduction diets, antihypertensive drugs, and oral hypoglycemic agents. The response to diet is frequently unsuccessful. Those who do not experience actual weight gain notice redistribution of adipose tissue resulting in changes in appearance, with facial rounding, increased central adiposity, and thinning of upper and lower extremities. After 2 to 3 years of mild symptoms, additional symptoms or increased severity of the initial symptoms draw patients to the attention of the physician. Patients relate the appearance of striae, easy bruising, and increased body hair growth; women may complain of irregular menses or amenorrhea and men of gynecomastia. Proximal muscle weakness and atrophy are common, and some patients exhibit manifestations of a steroid myopathy. A history of increased skin pigmentation is uncommon in patients with pituitary ACTH-dependent Cushing's disease because ACTH levels are not sufficiently elevated to induce hyperpigmentation. Other manifestations include peripheral edema, back pain, and loss of height if patients have developed severe osteoporosis and compression fractures of their vertebrae.

The physical examination reveals plethora, a round face with pre-auricular fullness, a prominent upper lip (cupid's bow), supraclavicular fossa fullness, and a cervicodorsal fat pad (buffalo hump) disproportionate to the degree of obesity. Patients exhibit truncal obesity, with large breasts or gynecomastia and a protuberant abdomen. This protuberance is the result of an increased omental fat and relaxed abdominal muscles. The extremities are thin, with decreased muscle mass and strength and, occasionally, edema. The skin is thin, with wide, atrophic purple striae present over the abdomen, chest, and upper thighs. Other skin lesions include keratosis pilaris seen over the upper trunk, tinea versicolor over the anterior chest and back, and verruca vulgaris lesions, which occasionally are large and present in multiple locations. Hirsutism is often present, with a mixture of fine, lanugal-type hair growth over the face and trunk, and coarse, terminal-type hair over the face, trunk, and extremities. This latter type of hair is associated with increased androgen secretion.

Hyperpigmentation, when present, is associated with high ACTH levels and characterized by pigmentation of the hands, palmar creases, elbows and knees, gums, and oral mucosa. Another type of pigmentation is associated with insulin resistance and hyperinsulinemia, and is present in the neck, elbows, and dorsum of the hands with the characteristics of acanthosis nigricans. In dark-skinned individuals, a history of further darkening is suggestive of hyperpigmentation.

The duration of symptoms in patients with ectopic ACTH syndrome is usually less than with the pituitary ACTH-dependent type because the source of ACTH is a malignant neoplasm with a rapidly progressive course. Often the symptoms and signs of Cushing's syndrome appear 4 to 6 months before a diagnosis is made. Some patients exhibit minimal symptoms of Cushing's syndrome because of the short duration of hypercortisolemia. In these patients, very high cortisol levels are often associated with manifestations of mineralocorticoid excess, including hypernatremia, hypokalemia, and metabolic alkalosis. Because the levels of ACTH in these patients are 5 to 10 times higher than those with pituitary ACTH-dependent disease, hyperpigmentation of the skin and oral mucosa may be an early manifestation. Severe hypokalemia may also lead to significant muscle weakness. The manifestations of the underlying malignant neoplasm, including anorexia, weight loss, and focal symptoms of organ involvement, may occur together with manifestations of cortisol excess. Some patients with ectopic ACTH syndrome have a more protracted course. These are patients with bronchial or mediastinal carcinoids whose clinical course may last for several years before detection and whose clinical and biochemical features are similar to those with pituitary ACTH-dependent disease.

Patients with benign adrenocortical adenomas usually have a long history of manifestations of cortisol excess before a definitive diagnosis is made. Because adrenocortical adenomas are often purely cortisol-secreting tumors, the predominant clinical manifestations are those related to the protein catabolic effects of cortisol unopposed by androgen excess. These include skin and muscle atrophy, easy bruising, and osteopenia. Patients have the typical fat distribution associated with hypercortisolism, but acne and coarse, terminal-type hair growth are unusual. Patients with primary nodular adrenocortical hyperplasia are clinically indistinguishable from patients with benign adrenocortical adenomas or pituitary ACTH-dependent disease.

Patients with adrenocortical carcinoma have a history of shorter duration, typically 4 to 6 months. The severity of the clinical manifestations depends on the degree of hypercortisolemia. These patients also exhibit manifestations of androgen excess, including hirsutism, acne, scalp hair loss, and clitoromegaly. The androgen excess can moderate the severity of the catabolic effects of high cortisol levels. In particular, skin and muscle atrophy may not be as apparent. Because adrenocortical carcinomas are large, frequently greater than 100 g, they may be palpable on the abdominal examination, and hepatomegaly may be noticed if hepatic metastases are present.

LABORATORY FINDINGS

A biochemical evaluation of Cushing's syndrome is necessary for confirming the clinical diagnosis and for determining its presence in patients with an equivocal clinical presentation. A diagnostic algorithm is depicted in [Fig. 407.3](#). Preliminary testing includes the measurement of urinary free cortisol and of the ability to suppress serum cortisol levels with a low dose of dexamethasone. In patients with Cushing's syndrome, the urinary free cortisol usually exceeds 90 μg per day (radioimmunoassay reference values: 20 to 90 mg per day). Serum cortisol obtained 9 hours after the oral administration of 1 mg of dexamethasone at 23:00 hours usually fails to decrease below 10 μg per deciliter.

FIGURE 407.3. Algorithm for diagnosis of Cushing's syndrome.

EVIDENCE LEVEL: C. Expert Opinion.

Patients with Cushing's syndrome, regardless of cause or type, have high baseline urinary free cortisol, and serum cortisol levels lack normal circadian rhythm. The early-morning cortisol levels may be in the normal range, but levels obtained between 22:00 hours and midnight are higher than in normal persons. A convenient procedure to test the circadian rhythm is the measurement of salivary cortisol at 08:00 and 22:00 hours or midnight. Salivary cortisol correlates well with plasma free-cortisol levels. Patients with Cushing's syndrome have high evening salivary cortisol levels.

The pituitary response to dexamethasone is measured to detect abnormal feedback regulation of ACTH and cortisol secretion. Dexamethasone is given in doses of 0.5 mg every 6 hours for eight doses, followed by 2 mg every 6 hours for eight doses. A lack of normal suppression of cortisol with low doses of dexamethasone is found in all types of Cushing's syndrome, but most patients with pituitary ACTH-dependent Cushing's syndrome (Cushing's disease) suppress with high doses of dexamethasone to values below 50% of the baseline levels. Fewer than 10% of patients with ectopic ACTH syndrome respond in this manner. In patients with ACTH-dependent Cushing's syndrome, high ACTH levels and lack of response to dexamethasone should strongly raise the possibility of ectopic ACTH syndrome.

Benign and malignant adrenocortical tumors can be differentiated biochemically. Malignant neoplasms often have partial enzymatic deficiencies in the steroid biosynthetic pathway. When this occurs, steroid biosynthetic intermediates or other metabolites are found in increased quantity in serum or urine. Impaired activities of 3- β -hydroxysteroid dehydrogenase and 11 β -hydroxylase are the most common. These deficiencies lead to increased serum levels of pregnenolone, DHEA, and 11-deoxycortisol.

After the diagnosis of Cushing's disease is established on clinical and biochemical grounds, the presence of pituitary lesions should be further determined by magnetic resonance imaging (MRI) of the pituitary and hypothalamus. Pituitary adenomas can be found by MRI in about 70% of patients with Cushing's disease using gadolinium contrast with coronal cuts. Petrosal sinus sampling with CRH stimulation can be used to localize pituitary tumors. Through a percutaneous unilateral or bilateral femoral approach, catheters are placed in the left and right inferior petrosal sinuses, and blood for ACTH is withdrawn simultaneously from both catheters and a peripheral vein. To account for fluctuations in levels caused by the pulsatile nature of ACTH secretion, sequential samples are drawn at 2- to 5-minute intervals. A plasma ACTH concentration gradient (petrosal sinus/peripheral vein ACTH \geq 3.0) verifies the pituitary source of ACTH. A right-to-left discrepancy may also help to lateralize ACTH secretion and aids in the preoperative localization of the lesion. A lateralization of the source of ACTH by this procedure can help in cases in which a tumor is not found at the time of surgery. Partial resection of the side of the pituitary where the highest ACTH levels are recorded can result in remission of the disease.

Techniques for the anatomical localization of adrenal lesions include abdominal computed tomography (CT) scans and MRI, ultrasonography, and adrenal scintigraphy with iodine I 131 6 β -iodomethyl-19-norcholesterol. These techniques are noninvasive and provide good definition of the pathology of the adrenal glands.

Scintigraphy with iodocholesterol provides information about the structure of the adrenal gland and its function. Patients with bilateral adrenocortical hyperplasia demonstrate bilateral increased adrenal uptake of iodocholesterol. Patients with cortisol-secreting adrenocortical adenomas, which suppress pituitary ACTH secretion and the function of the contralateral gland, demonstrate unilateral concentration of the tracer. Patients with Cushing's syndrome secondary to an adrenocortical carcinoma fail to show tracer uptake on either side.

The localization of ectopic sources of ACTH involves a variety of procedures, including CT of the chest, CT or MRI of the abdomen, thyroid scan, octreotide scan, and selective venous catheterization and sampling in search of concentration gradients of ACTH. Approximately 50% of these tumors are within the thorax (e.g., small-cell carcinomas, bronchial carcinoids, thymomas), and thoracic CT scanning usually can localize the lesion. Other ACTH-secreting tumors are found in the pancreas (islet cell tumors), the thyroid (medullary carcinoma), and the adrenal medulla (pheochromocytoma). Small carcinoid tumors may escape detection by any of the available imaging procedures.

OPTIMAL MANAGEMENT

Optimal treatment of Cushing's disease depends on an accurate diagnosis of the underlying pathologic process. Four approaches are used in the management of pituitary ACTH-dependent Cushing's disease: pituitary surgery, pituitary irradiation, adrenal surgery, and drug therapy.

The treatment of choice is surgical removal of the pituitary tumor in Cushing's disease. The transsphenoidal selective resection of ACTH-secreting pituitary microadenomas is the most common treatment of Cushing's disease and comes closest to the ideal form of treatment for this condition. It is a reasonably safe procedure with a mortality rate of less than 1% and a high cure rate. The main complications are anterior pituitary insufficiency in 19% and diabetes insipidus in 18%. If a microadenoma can be identified and resected, the remaining pituitary tissue remains functional, and patients can enjoy remission without loss of endocrine function. If a specific adenoma cannot be identified during surgery, the decision must be made to perform a partial or total hypophysectomy. If preoperative inferior petrosal sinus sampling is clearly lateralizing, hemiresection of the side with the highest concentration of ACTH should be performed. If the endocrine studies strongly indicate a pituitary origin but the petrosal sinus sampling is not lateralizing and the patient does not wish to have children, a total hypophysectomy should be considered, but only after a lengthy preoperative discussion with the patient regarding this possibility. If the patient wants to have children, alternative forms of therapy including medical treatment or a total adrenalectomy must be considered. With transsphenoidal surgery, permanent anterior or posterior pituitary hormone deficiencies are rare. Transient diabetes insipidus may occur during the early weeks after surgery. Permanent diabetes insipidus and cerebrospinal fluid rhinorrhea are uncommon complications with an initial procedure but may be more common with repeated transsphenoidal surgery. Treatment failures are most common in patients with pituitary macroadenomas or in those in whom a distinct microadenoma has not been found.

When transsphenoidal surgery has failed or alternative forms of treatment are desired, pituitary irradiation is an option. The most widely used type is high-voltage fractionated irradiation provided by cobalt 60 in a total dose of 40 to 50 Gy. Remission is achieved in about 50% of patients. The best responses are observed in patients with the juvenile form of the disease or in adults younger than 40 years.

When successful, ^{60}Co irradiation has several advantages. Remission occurs with preservation of pituitary and adrenal function; panhypopituitarism develops infrequently; normal reproductive function is usually restored when the patient is in remission; corticosteroid replacement therapy is not needed; recurrence is rare; and normal cortisol secretion may be restored (circadian rhythm, normal suppressibility on dexamethasone). The major disadvantage is the slow therapeutic response; 6 to 18 months may elapse before a clinical and biochemical remission is achieved. ^{60}Co irradiation alone is not adequate in patients who have severe Cushing's syndrome. Symptoms may progress while the patient waits for remission, and severe complications may result. Heavy particle beam irradiation and Bragg peak proton irradiation therapy, which can deliver a higher radiation dose, is more effective than ^{60}Co irradiation, with a rate of improvement or remission as high as 80%. There is a higher incidence of postirradiation side effects, including radiation necrosis of the brain, with a higher dosage. Another method of focally targeted radiation therapy is stereotactic radiosurgery or gamma knife therapy. These techniques have been applied to patients with residual tumor who experience recurrence of Cushing's disease after transsphenoidal resection of pituitary adenomas.

In patients with advanced Cushing's disease in whom transsphenoidal surgery or pituitary irradiation have failed, bilateral total adrenalectomy is the preferred treatment. The major disadvantage of adrenalectomy is that it fails to remove the ACTH-secreting pituitary tumor, which may continue to grow and become locally invasive and difficult to control either by surgery or by radiation therapy. The combination of an enlarging pituitary tumor, hyperpigmentation, and very high ACTH levels is called Nelson's syndrome. This complication may occur months or years after the adrenalectomy. Laparoscopic adrenalectomy has become a common procedure for resecting benign adrenocortical tumors. In contrast, resection of an adrenocortical carcinoma should be done only through an open procedure.

Various inhibitors of adrenal function have been used to suppress cortisol secretion in patients with Cushing's syndrome. The most common are aminoglutethimide, ketoconazole, and mitotane.

Aminoglutethimide inhibits cholesterol side-chain cleavage and blocks the conversion of cholesterol to D⁵-pregnenolone in the adrenal cortex. This causes inhibition of the synthesis of cortisol, aldosterone, and androgens. It is used in adults and children in doses of 0.5 to 2 g daily. In persons with cortisol-secreting adrenocortical carcinoma, the effect of aminoglutethimide can be maintained for many months, with regression of the clinical manifestations of Cushing's syndrome. However, the drug is only transiently effective in patients with ACTH-dependent Cushing's syndrome, in whom the inhibitory effect of the drug is overcome by the high levels of

ACTH. The effect of aminoglutethimide is promptly reversed by interruption of therapy.

Ketoconazole is an imidazole derivative that inhibits mitochondrial cytochrome P450-dependent enzymes, such as 11 β -hydroxylase and the enzymes needed for cholesterol side-chain cleavage. Ketoconazole inhibits abnormal cortisol production in patients with adrenal adenoma and Cushing's syndrome. These patients respond promptly, with disappearance of the clinical and metabolic manifestations of the disease within 4 to 6 weeks of treatment. When patients are treated with ketoconazole, adrenal insufficiency is avoided by decreasing the dose sufficiently to maintain normal cortisol levels.

Mitotane inhibits biosynthesis of corticosteroids and destroys adrenocortical cells that secrete cortisol, producing a long-lasting effect. Mitotane acts on adrenocortical cell mitochondria, where it inhibits 11 β -hydroxylase and cholesterol side-chain cleavage enzymes. As a result of this inhibition, the production of cortisol, aldosterone, and DHEA is suppressed. Mitotane appears to require metabolism for its action. Under the effect of mitochondrial P450 monooxygenases, the drug is probably transformed into an acyl chloride that covalently binds to important macromolecules in the cell mitochondria. The result is destruction of the mitochondria with necrosis of the adrenal cortex. The zona reticularis of the adrenal cortex appears to be most sensitive to the action of mitotane, and the glomerulosa is the least sensitive.

A combination of ^{60}Co irradiation of the pituitary gland and selective suppression of cortisol secretion with low doses of mitotane has resulted in clinical and biochemical remission in 80% of patients with Cushing's disease.

Treatment of ectopic ACTH syndrome involves the surgical resection of the primary tumor, followed by radiation therapy or chemotherapy, depending on the type of neoplasm producing the illness. In patients whose neoplasms cannot be resected, the use of adrenal inhibitors, such as aminoglutethimide and ketoconazole, may ameliorate the clinical manifestations of Cushing's syndrome. However, the very high ACTH levels may overcome the suppressive effect of these drugs. Bilateral surgical adrenalectomy is an alternative approach but is not a practical form of treatment for patients who have rapidly progressive metastatic disease. Because the underlying tumors (bronchial carcinoids) may be slow growing, an adrenalectomy followed by replacement therapy with normal amounts of hydrocortisone can lead to remission of Cushing's syndrome.

Adrenocortical adenomas should be surgically removed. Because of suppression of the hypothalamic–pituitary–adrenal axis in these patients, adrenal insufficiency occurs postoperatively and patients require replacement therapy with physiologic doses of cortisol until recovery of the hypothalamic–pituitary–adrenal axis takes place.

Adrenal carcinomas causing Cushing's syndrome are highly malignant neoplasms resulting in a shortened life expectancy. Their treatment has not been well standardized, and the prognosis has been poor regardless of therapy.

Several approaches to therapy have been used. One method is surgical excision of the primary tumor and of large neoplastic abdominal masses. Although temporary remission of the disease frequently occurs with this approach, recurrence and eventual death from metastatic disease is the rule. Another approach is nonspecific chemotherapy, but the neoplasm is generally resistant to therapy.

PRIMARY ALDOSTERONISM

DEFINITION

Primary aldosteronism or Conn's syndrome results from a renin-independent, inappropriate hypersecretion of aldosterone. Patients with secondary aldosteronism have an increase in aldosterone production in response to volume depletion or decrease in effective renal perfusion pressure. In contrast, patients with primary aldosteronism secrete aldosterone in the presence of volume expansion and hypertension.

INCIDENCE AND EPIDEMIOLOGIC FACTORS

Hypokalemic primary aldosteronism is present in 1% to 3% of patients with hypertension. Other reports based on observations in patients with minimal hypokalemia or normal serum potassium levels suggest an incidence of up to 10% of patients with hypertension.

ETIOLOGIC FACTORS

Approximately 60% of patients with primary aldosteronism have a single, benign adrenocortical adenoma as the cause of excessive aldosterone production; 40% exhibit bilateral adrenocortical hyperplasia. Aldosterone-secreting adrenocortical carcinomas are very rare.

PATHOGENESIS

The excessive production of aldosterone by an adrenocortical tumor or hyperplasia leads to increase sodium retention and volume expansion. This causes suppression of plasma renin and decreased generation of angiotensin II. The aldosterone secretion continues in the absence of renin. The high levels of aldosterone act on the distal nephron to promote sodium reabsorption in exchange for potassium and hydrogen ions. Acting on sodium-transporting epithelial cells, aldosterone binds to the mineralocorticoid receptor and causes transcriptional activation of an aldosterone-induced protein thought to increase the apical to basal sodium flux. Aldosterone also activates Na^+, K^+ -ATPase, promoting the exchange of sodium for potassium. The consequence of these events is the development of hypertension accompanied by hypokalemia and metabolic alkalosis.

CLINICAL FINDINGS

The principal clinical findings in primary aldosteronism are hypertension and hypokalemia. Hypertension is moderate to severe and may be complicated by stroke and proteinuria. Symptoms of hypokalemia include muscular weakness and tetany; renal loss of concentrating ability due to kaliopenic nephropathy and subsequent polyuria; and changes in b-cell function which result in abnormal glucose tolerance.

LABORATORY FINDINGS

Measurement of serum electrolytes reveals hypernatremia (serum sodium 142 to 150 mEq per liter), hypokalemia (serum potassium 1.6 to 3.2 mEq per liter), and metabolic alkalosis (serum bicarbonate 28 to 38 mEq per liter). Hypokalemia is present in 90% of patients with adenoma and in 70% of patients with hyperplasia. A high aldosterone/renin ratio is diagnostic of primary aldosteronism. [Figure 407.4](#) depicts a diagnostic algorithm for patients suspected of primary aldosteronism. The aldosterone/renin ratio is greater than 50 in patients with primary aldosteronism and less than 50 in patients with essential hypertension.

FIGURE 407.4. Diagnostic algorithm for patients suspected of having primary aldosteronism.
EVIDENCE LEVEL: C. Expert Opinion.

Once the diagnosis has been established, tests are available for localization of an adrenocortical adenoma. CT or MRI of the adrenal glands usually demonstrates a small adrenocortical tumor. Adrenal scintigraphy with ¹³¹I-6b-iodomethyl-19-norcholesterol allows for detection of an aldosterone-secreting tumor. The scintigraphy is enhanced by the administration of dexamethasone that suppresses uptake by the normal adrenal cortex but not by the tumor. Occasionally, localization by these procedures is equivocal and more definitive localization requires selective adrenal venous catheterization and sampling. For this procedure, catheters are placed in the right and left adrenal veins through a transfemoral approach. Blood samples are obtained for aldosterone and cortisol. The side with an aldosterone-producing tumor will show much higher aldosterone levels than the contralateral side. This difference will not be noted in patients with primary aldosteronism secondary to bilateral adrenocortical hyperplasia.

OPTIMAL MANAGEMENT

The treatment of choice for patients with a single aldosterone-secreting adrenocortical adenoma is laparoscopic unilateral adrenalectomy. Since these tumors are usually less than 2 cm, laparoscopic surgery is ideal because of its relatively low morbidity. Removal of an aldosterone-producing adrenocortical adenoma results in cure of the hypertension in 50% to 70% of cases and the electrolyte abnormality in every case. In contrast, patients with bilateral adrenocortical hyperplasia do not benefit from a bilateral adrenalectomy. Although hypertension improves, most patients continue to be hypertensive. Treatment with high doses of spironolactone, an aldosterone antagonist, is effective. Side effects in men are gynecomastia and impotence.

ADRENAL INSUFFICIENCY

DEFINITION

Adrenal insufficiency occurs when the cessation of normal secretion of the two major adrenocortical hormones, cortisol and aldosterone, is deficient. It can develop as a consequence of destruction or suppression of the adrenal cortex (primary adrenocortical insufficiency) or as a result of failure of pituitary ACTH secretion (secondary adrenal insufficiency).

INCIDENCE AND EPIDEMIOLOGIC FACTORS

Primary adrenocortical insufficiency is uncommon; it has been reported with a prevalence rate of 4 to 6 per 100,000 population.

Adrenal insufficiency is usually sporadic, but certain forms, especially those with an autoimmune cause, occur in families in which siblings can be affected. An infectious cause is found in some patients, including tuberculosis, coccidioidomycosis, histoplasmosis, blastomycosis, and HIV-2 infection.

ETIOLOGIC FACTORS

Autoimmune primary adrenocortical insufficiency is the most common form of adrenal insufficiency in the United States. Patients with autoimmune Addison's disease show familial prevalence of this condition and other associated autoimmune endocrinopathies, including Hashimoto's thyroiditis with primary hypothyroidism (Schmidt's syndrome), Graves' disease, type 1 diabetes mellitus, idiopathic hypoparathyroidism, pernicious anemia, primary gonadal failure, and pituitary insufficiency. These patients show a statistical association with human leukocyte antigen (HLA) haplotypes, especially HLA-B8 and Dw3. Other causes of primary adrenocortical insufficiency are infectious (tuberculosis, coccidioidomycosis, histoplasmosis, and blastomycosis). Bilateral adrenal hemorrhage with consequent adrenocortical insufficiency can occur with severe sepsis, pneumonia, recent abdominal surgery, heparin therapy, and coagulopathies. These patients usually present with clinical manifestations of adrenal insufficiency and a CT scan of the abdomen showing bilateral adrenal masses that regress over time. Adrenocortical involvement can occur in patients with HIV infection. The adrenal insufficiency observed with HIV infection appears to be related to superimposed cytomegalovirus infection, which is found in 84% of autopsy cases of patients with AIDS. Infiltrative diseases involving the adrenal glands can lead to adrenocortical insufficiency. These include lymphomas, primary amyloidosis, and metastatic neoplastic disease. In some cases, adrenal insufficiency is the first manifestation of lymphoma. The involvement of the adrenals by infiltrative diseases has to be severe and bilateral to induce clinical manifestations of adrenal insufficiency. Congenital adrenocortical hypoplasia has been described in children who present with adrenocortical insufficiency. Iatrogenic diseases leading to adrenal insufficiency include bilateral adrenalectomy, treatment with adrenolytic drugs (e.g., mitotane), and administration of anticoagulants, which in the presence of severe stress lead to bilateral adrenal hemorrhage. Enzyme deficiencies are also associated with adrenal insufficiency. These may be congenital and involve 21-, 11b-, and 17a-hydroxylases or iatrogenically induced by the administration of adrenal inhibitors. The most common cause of secondary adrenocortical insufficiency is chronic suppression of ACTH secretion by chronic glucocorticoid therapy. Other causes include pituitary tumors (which destroy normal pituitary cells), pituitary infarction resulting from cerebrovascular thrombosis, or postpartum necrosis of the pituitary gland. Surgical hypophysectomy for the treatment of pituitary disease also results in panhypopituitarism and secondary adrenal insufficiency. In these cases, renin and aldosterone secretion is preserved, and patients exhibit only the clinical manifestations of cortisol deficiency. In patients with isolated renin deficiency, aldosteronopenia may be the presenting disorder. Renin deficiency is seen in patients who develop hyporeninemic hypoaldosteronism as a consequence of diabetic nephropathy, chronic renal failure, or the administration of indomethacin or angiotensin-converting enzyme (ACE) inhibitor. The main clinical expression of this deficiency is hyperkalemia. A rare familial variety of primary adrenal insufficiency is adrenoleukodystrophy, a condition in which general adrenocortical failure is present together with destruction of the cerebral white matter. This condition, which has an X-linked transmission, shows large areas of cerebral demyelination and accumulation of specific lipid-like material in the adrenocortical cells.

PATHOGENESIS

Adrenocortical insufficiency results from cessation of normal secretion of adrenocortical hormones. In primary adrenal insufficiency there is a destruction of the adrenal cortex with inability to synthesize and secrete all major adrenocortical steroid hormones. In contrast, secondary adrenal insufficiency develops as a result of either ACTH or renin deficiency, leading to isolated cortisol or aldosterone deficiency. Cortisol insufficiency leads to depletion of gluconeogenic substrates as well as suppressed gluconeogenesis and hepatic glucose production. In addition, there is increased sensitivity of the liver and peripheral tissues to the action of insulin, resulting in increased glucose transport. A clinical consequence of these changes is the development of fasting hypoglycemia with possible neuroglucopenia. Lack of cortisol also leads to decreased renin substrate production, decreased vascular sensitivity to the effect of angiotensin II and norepinephrine, and increased vasodilator prostaglandin E₂ and kallikrein. These changes lead to the development of hypotension. A decrease in the feedback suppression of pro-opiomelanocortin synthesis by cortisol leads to high ACTH and MSH levels and the development of hyperpigmentation. In addition, there are major changes that occur with aldosteronopenia, including natriuresis, iso-osmotic water loss, and increased potassium and hydrogen ion reabsorption. The clinical consequence of these changes is hyponatremia, development of extracellular fluid volume depletion and hypotension, hyperkalemia, metabolic acidosis, and cardiac arrhythmias. Volume depletion also leads to stimulation of renin release. The decrease in cortisol leads to increased arginine vasopressin secretion and a decrease in free-water clearance. While restoring volume, the water retention is likely to further depress sodium levels. Finally, a decrease in androgen production is particularly significant in women in whom there is a decrease in axillary and pubic hair growth.

CLINICAL FINDINGS

The diagnosis of primary adrenal insufficiency is suspected in patients who present with anorexia, weight loss, nausea, vomiting, chronic fatigue, and increased pigmentation of the skin. Secondary adrenal insufficiency should be considered in patients who have received therapy with glucocorticoids for long periods of time, have pituitary tumors, or have undergone pituitary surgery.

Symptoms associated with primary adrenal insufficiency, such as fatigue, pigmentation, anorexia, weight loss, and hypotension, occur in more than 90% of patients. The fatigue appears to be present constantly and is aggravated by physical activity. Patients describe profound asthenia and difficulty in getting out of bed. The pigmentation is a persistent tan over sun-exposed areas and darkening of areas not normally exposed such as nipples, scars, and genitalia. Dark-skinned individuals relate increased depth of their natural skin pigmentation. Occasionally, patients have vitiligo. Dizziness is most prominent when patients are upright and when they change from the recumbent to the standing position. Generalized muscle and joint pains and abdominal pain are also described. Patients with secondary adrenal insufficiency have similar symptoms, except for the absence of pigmentation and postural dizziness. In fact, patients may notice decrease in skin pigmentation and ability to tan when exposed to sunlight. Associated with symptoms of adrenal insufficiency are symptoms related to the deficiency of other pituitary hormones, including amenorrhea in women, impotence in men, dry skin, cold intolerance, and increased lethargy.

Patients with primary adrenal insufficiency may have associated endocrine deficiencies caused by autoimmune pluriglandular failure. Thus, clinical findings of

hypothyroidism and hypogonadism in patients with adrenal insufficiency do not necessarily indicate panhypopituitarism. In contrast to the hypopigmentation observed in patients with panhypopituitarism, those with autoimmune pluriglandular failure are usually hyperpigmented.

LABORATORY FINDINGS

Laboratory findings include manifestations of aldosterone and cortisol deficiency. Prominent manifestations of aldosterone deficiency are hyponatremia, hyperkalemia, metabolic acidosis, and urinary sodium excretion in excess of 20 mEq per liter. Because of intravascular volume contraction, serum urea and creatinine are increased. The most severe electrolyte and renal changes are observed in patients with chronic adrenal failure who have developed acute adrenal insufficiency as a consequence of stress with vomiting and diarrhea. Patients with secondary adrenal insufficiency who have normal aldosterone secretion may also develop hyponatremia as a result of impaired free-water clearance. Cortisol deficiency is associated with hematologic changes, including normochromic normocytic anemia, leukopenia with relative lymphocytosis, and eosinophilia. Fasting hypoglycemia is seen in patients who have been eating poorly.

Radiographic examination reveals a small heart. Adrenal calcifications can be seen on a plain radiograph of the abdomen in patients in whom the cause of the adrenal insufficiency is granulomatous disease. Abdominal computerized CT scanning shows small adrenals in patients with autoimmune disease and enlarged adrenals or adrenal masses in patients with either granulomatous disease or adrenal hemorrhage.

Figure 407.5 depicts a diagnostic algorithm for the evaluation of patients suspected of having adrenal insufficiency. Hormonal measurements reveal low serum and urine cortisol levels in all patients with adrenocortical insufficiency. Serum aldosterone levels are low in patients with primary adrenal insufficiency and normal or low in patients with secondary adrenal insufficiency. When aldosterone levels are low, plasma renin levels are usually high. In the presence of low cortisol levels, the level of plasma ACTH defines the type of adrenal insufficiency. Patients with primary adrenal insufficiency have high ACTH levels, whereas levels are low in patients with adrenal insufficiency secondary to hypopituitarism.

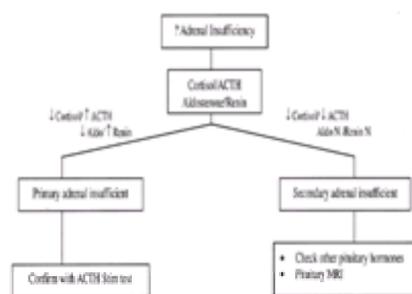

FIGURE 407.5. Diagnostic algorithm for patients suspected of having adrenal insufficiency.

EVIDENCE LEVEL: C. Expert Opinion.

Patients whose clinical features suggest adrenal insufficiency should have biochemical confirmation and a definitive diagnosis established prior to institution of long-term therapy. Since this biochemical confirmation may take some time before it is completed and severe adrenal insufficiency may develop while the patient is awaiting results, therapy should be initiated immediately and either continued or discontinued once a definitive diagnosis has been made. A diagnosis of primary adrenal insufficiency is based on the finding of low random cortisol and aldosterone levels together with high ACTH and renin levels. This combination of findings is unique for primary adrenocortical insufficiency. Other conditions that increase ACTH, such as stress, also increase cortisol levels, whereas those that increase renin, such as a low-sodium diet, will correspondingly increase aldosterone levels. Conversely, low cortisol levels obtained in the late evening hours are associated with low ACTH levels whereas low aldosterone levels in patients on high sodium intake are associated with correspondingly low renin values. Immediately after obtaining a basal sample, patients should receive 250 µg of synthetic corticotropin intravenously. Blood samples for cortisol are obtained 30 and 60 minutes thereafter. A peak value above 20 µg per milliliter usually rules out adrenal insufficiency.

Patients who have been on chronic glucocorticoid therapy have suppressed ACTH and cortisol levels and may develop secondary adrenal insufficiency when corticosteroid therapy is discontinued. A diagnosis of concomitant primary adrenocortical insufficiency in such patients is difficult and may require the demonstration of failure to respond to prolonged ACTH stimulation. In such cases, a corticotropin stimulation test should be performed by administering 250 µg of synthetic corticotropin over a 12-hour period on 2 to 3 consecutive days. Patients with suppressed ACTH levels secondary to glucocorticoid therapy exhibit a gradually increasing cortisol response, whereas patients with primary adrenal insufficiency fail to respond.

Additional studies can be performed to evaluate the cause of adrenal insufficiency. This includes imaging of the adrenals by CT scanning, thyroid function tests and a serum calcium and phosphorus to investigate for associated autoimmune endocrinopathies, and a combined pituitary function test to evaluate for panhypopituitarism.

OPTIMAL MANAGEMENT

Chronic Adrenal Insufficiency

Treatment of chronic adrenal insufficiency requires the administration of cortisol in physiologic replacement amounts. The most commonly used preparation is hydrocortisone given in amounts of 20 to 30 mg daily in unequally divided doses to mimic the normal circadian rhythm of cortisol secretion. The largest dose of 10 to 15 mg is given upon arising and the smallest dose, 5 mg, is given shortly before bedtime. Larger doses given at bedtime may cause insomnia. Alternatively, patients may be treated with two doses daily, with the largest dose being given in the morning and the other dose in the evening. The optimal replacement dose of cortisol may be established by measuring urinary free-cortisol levels, which should be in the mid-normal range. Cortisol replacement is preferable to other synthetic glucocorticoid analogs with low sodium retention activity because it helps maintain a better sodium balance. In addition to cortisol, patients with primary adrenal insufficiency require replacement with fludrocortisol, a preparation similar to aldosterone in its mineralocorticoid activity. The usual dose is 0.05 to 0.2 mg daily, adjusted according to serum electrolyte and blood pressure response. The dose given should be sufficient to eliminate orthostatic hypotension or tachycardia, but hypokalemia or hypertension should be avoided. Patients with essential hypertension may have an exaggerated sensitivity to mineralocorticoids and develop sodium retention and hypertension. In those patients, the dose of fludrocortisol should be reduced. Patients with associated endocrinopathies or hypopituitarism may require concomitant replacement with thyroxine and gonadal hormones.

Patients with secondary adrenal insufficiency usually require replacement therapy with cortisol alone. Occasionally, prolonged ACTH deficiency can cause marked adrenocortical atrophy and impaired aldosterone secretion. In those cases, replacement therapy with fludrocortisol is also indicated.

Acute Adrenal Insufficiency

Acute adrenal failure is a medical emergency. It may develop as a result of progression of undiagnosed or untreated chronic adrenocortical insufficiency, or it may occur in patients with chronic adrenal insufficiency who develop acute stress for which appropriate adjustments in cortisol therapy have not been made. Frequently, these patients have suffered intercurrent infection, trauma, or acute surgical stress. Undiagnosed patients present with nausea, vomiting, rapid weight loss, and hypotension. The presence of hyperpigmentation in this setting should raise suspicion of primary adrenal insufficiency. Laboratory studies should be obtained immediately, including serum electrolytes, urea, creatinine, cortisol, aldosterone, ACTH, and renin. An intravenous line is then established through which patients receive an infusion of a 5% dextrose in 0.9% sodium chloride solution at a rate sufficient to deliver 1 liter over the next hour. Simultaneously, a dose of 250 µg of synthetic corticotropin is injected as an intravenous bolus and blood samples for cortisol are obtained 30 and 60 minutes later. Once the samples have been obtained, patients should receive hydrocortisone, 100 mg, followed by a continuous infusion with hydrocortisone to be administered at a rate of 10 mg per hour for the next 5 hours. Patients may require additional intravenous fluids as needed to restore intravascular volume and correct the abnormal electrolyte findings. Restoration of normal blood pressure and heart rate should be the goal of this replacement therapy. Patients with more severe hyperkalemia whose serum potassium levels are greater than 6 mEq per liter may require, in addition to hydrocortisone, glucose and insulin or potassium-binding resins in order to rapidly lower serum potassium.

21-hydroxylase deficiency, the 17 α -hydroxyprogesterone response to ACTH is greater than 2 SD above the normal mean response or 1,200 mg per deciliter. Similarly, in patients with 11 β -hydroxylase deficiency, the serum 11-deoxycortisol and the 11-deoxycortisol/cortisol ratio response is greater than 2 SD above the normal mean response.

OPTIMAL MANAGEMENT

Treatment of patients with CAH involves suppression of ACTH and the abnormal cortisol steroidogenic pathway with corticosteroids. Dexamethasone, in doses of 0.5 mg at bedtime, or prednisone, in doses of 5.0 to 7.5 mg daily, suppresses endogenous ACTH and excessive androgen secretion. Caution should be used in selecting doses of glucocorticoids that do not result in Cushing's syndrome. Occasionally, patients develop these side effects while receiving standard physiologic doses. Patients with the salt-losing form of CAH should also be treated with mineralocorticoids. Patients in whom hirsutism is the main concern can be treated with oral contraceptives and spironolactone in a manner similar to that for idiopathic hirsutism. Because of the side effects that may occur with even low doses of glucocorticoids, this type of therapy should be reserved for patients who do not respond optimally to other types of antiandrogen therapy. Androgen receptor antagonists, such as spironolactone, cyproterone acetate, flutamide, and 5 α -reductase inhibitors such as finasteride, may be preferable to glucocorticoids as primary treatment of mild 21-hydroxylase deficiency. Ovarian suppression with the GnRH analog leuprolide has been effective in patients with nonclassic CAH, but this type of treatment requires injections and is expensive. Patients with pseudohermaphroditism require corrective surgery of their ambiguous genitalia.

INCIDENTALLY FOUND ADRENAL MASSES

DEFINITION

Adrenal masses are discovered radiographically during the evaluation of nonspecific abdominal complaints. These masses are not usually uncovered as a result of investigation for symptoms associated with adrenal hormone production.

INCIDENCE AND EPIDEMIOLOGIC FACTORS

Various reports place the prevalence of such masses at 1% to 3% of abdominal CT scans. This figure is consistent with the finding of nonfunctioning adrenocortical adenomas or nodules in 1.45% to 2.85% of autopsies. Adrenal tumors can be found in 71% of patients with non-classic CAH. Occasionally, these patients reach older age undiagnosed and are found to have incidentally discovered adrenal masses in the course of investigation for other unrelated complaints.

ETIOLOGIC FACTORS

Adrenal masses are (a) benign or malignant adrenocortical tumors, (b) pheochromocytomas, (c) myelolipomas, and (d) cysts and hematomas.

CLINICAL FINDINGS

While the great majority of incidentally discovered masses are clinically silent, 20% to 30% are hormone-secreting and associated with subtle symptoms of hormone excess. Approximately 7% of these hormone-secreting masses secrete cortisol. The clinical manifestations are nonspecific, such as generalized obesity, hypertension, abnormal glucose tolerance, and depression. The daily amount of cortisol produced is within normal limits, but secretion is ACTH-independent, without a normal circadian rhythm, and resistant to suppression with dexamethasone. This combination of clinical and biochemical findings has been called subclinical Cushing's syndrome.

Autonomous aldosterone production by otherwise clinically silent, incidentally found adrenal masses is rare. Some patients have been described who are either normotensive or hypertensive but without hypokalemia. Pheochromocytomas may also present as a silent mass, without a history of hypertension or typical symptoms of catecholamine excess.

LABORATORY FINDINGS

Preliminary studies to determine if the adrenal mass is functioning or silent should include measurement of cortisol and ACTH levels, serum electrolytes, plasma renin and aldosterone, and urinary metanephrines and normetanephrines.

Normal cortisol with suppressed ACTH levels is consistent with subclinical Cushing's syndrome. Characteristically, these patients have normal urinary free cortisol, similar 8 a.m. and midnight cortisol levels, and undetectable or low ACTH levels. Cortisol levels following a 1-mg overnight dexamethasone suppression test exceed 3 mg per deciliter. Patients with aldosterone-secreting tumors have low renin concentrations, but aldosterone levels are not in a diagnostic range and fail to suppress with fludrocortisol. Patients with pheochromocytomas, even if not hypertensive, have elevated urinary metanephrine and normetanephrine levels.

The major concern in the evaluation of an incidentally discovered adrenal mass is to determine if the mass is malignant and requires surgical resection. Primary adrenocortical carcinomas are rare, and many of the lesions that are malignant are metastatic from extra-adrenal neoplasms. Adrenocortical adenomas are 60 times more common than primary adrenocortical carcinomas. Size is a significant factor in determining the probability that a lesion is benign or malignant. There is consensus that most benign lesions are smaller than 3 cm, whereas most malignant lesions are larger than 6 cm. Uncertainty remains for masses measuring 3 to 6 cm. The importance of determining if a small tumor is benign or malignant has to do with the fact that patients with primary adrenocortical carcinomas have the best life expectancy when subject to curative resection in MacFarlane stage 1, when the tumor is less than 5 cm. The malignant or benign character of a lesion can be defined by CT, MRI, adrenal scintigraphy with ³¹I-6 β -iodomethyl-19-norcholesterol and CT or ultrasonographically guided fine-needle biopsy (FNB). CT and MRI of the adrenal mass can help determine if the mass is lipid-rich or lipid-poor. Lipid-rich masses have a high probability of being benign, whereas lipid-poor masses have a high probability of being malignant. Occasionally, a benign adrenocortical adenoma is lipid-poor and may be confused with a malignant lesion. With unenhanced CT, an attenuation of less than 10 Hounsfield units is consistent with an adenoma, whereas nonadenomas have unenhanced attenuation of greater than 30 Hounsfield units. With contrast enhancement, a major distinguishing characteristic appears to be a different retention of contrast by benign and malignant lesions. Benign lesions exhibit more than 50% wash-out of contrast within the first 15 minutes after injection, while malignant lesions tend to retain the contrast with a much slower wash-out phase. Using chemical-shift MRI, lipid-rich adenomas show a decrease in relative signal intensity of 34%, whereas nonadenomas show no significant change in relative signal intensity. Benign tumors appear to be homogeneously enhancing, while malignant tumors are inhomogeneous because of areas of necrosis. Ultrasonographic scanning of an adrenal mass may help distinguish cystic from solid masses. A homogeneous mass with a thin, noncomplex wall is consistent with a benign adenoma. ¹³¹I-6 β -iodomethyl-19-norcholesterol scintigraphy can be combined with CT to evaluate eoadrenal masses of less than 4 cm. Concordant images (increased uptake on the side of the mass) are 100% benign, whereas discordant images (uptake contralateral to the mass) are frequently associated with malignant lesions. Metaiodobenzylguanidine scintigraphy is highly specific for the detection of pheochromocytomas.

FNBs of adrenal masses may be helpful, particularly in the detection of metastatic disease to the adrenal. Occasionally, the primary tumor is unknown, but the adrenal metastasis is found incidentally and can direct attention to the site of the primary neoplasm. Neoplasms that frequently metastasize to the adrenal are lung cancer, renal cell carcinoma, melanoma, and breast, prostate, and pancreatic carcinoma. Of importance is that the cytologic characteristics of the metastases are similar to those of the primary tumor and help to determine the origin of the primary tumor. FNB can be useful in documenting metastatic disease and determining resectability of the primary lesion. A potential serious complication of FNB in patients with suspected primary adrenocortical carcinoma is tracking and seeding neoplastic cells along the path of the needle, with consequent dissemination of the tumor. If based on size or imaging characteristics a mass is likely to be malignant, the approach should be to have the mass surgically removed. FNB should not be necessary.

OPTIMAL MANAGEMENT

The following strategy ([Fig. 407.7](#)) can be used in managing incidentally found adrenal masses: (a) remove hormone-secreting or large (more than 6 cm) masses; (b) follow masses smaller than 3 cm if they are silent; (c) follow masses 3 to 6 cm in size if patients are 50 years of age or older; (d) consider surgical resection in younger patients with masses between 3 and 6 cm; (e) masses between 3 and 6 cm can be further evaluated with FNB. However, other radiographic and scintigraphic techniques can be used to determine whether a mass is benign or malignant.

CHAPTER 408: ADRENAL MEDULLARY DISORDERS

BRAHM SHAPIRO AND MILTON D. GROSS

[Underlying Physiologic Principles](#)
[Specific Disorders of the Sympathoadrenal System: Pheochromocytoma](#)

UNDERLYING PHYSIOLOGIC PRINCIPLES

EMBRYOLOGY AND ANATOMY

In fetal life, neural crest cells migrate to form sympathetic and other ganglia, and they invade the adrenal cortex to form the adrenal medulla. This sympathochromaffin system, which includes the carotid bodies, aortic arch, paravertebral sympathetic ganglia, aortic bifurcation (Zuckermandl's organ), and vagus nerve ganglia, is one component of the neuroendocrine system derived from the neural crest that has amine precursor uptake and decarboxylation (APUD) properties.

PHYSIOLOGY OF CATECHOLAMINE SYNTHESIS, STORAGE, RELEASE, AND METABOLISM

Amines with the 3,4-dihydroxyphenyl structure are termed *catecholamines* and include dopamine, norepinephrine, and epinephrine. Within the central nervous system, they act as neurotransmitters; norepinephrine is the neurotransmitter of peripheral adrenergic axons. Both norepinephrine and epinephrine from the adrenal medulla are true hormones.

Catecholamines are synthesized from tyrosine derived from the diet or converted from phenylalanine ([Fig. 408.1](#)). Tyrosine hydroxylase converts tyrosine to dihydroxyphenylalanine (dopa) and is rate limiting. The enzyme is stimulated by acetylcholine and inhibited by its own product. Aromatic L-amino acid decarboxylase (ALAAD) converts dopa to dopamine. Dopamine β -hydroxylase acts on dopamine to form norepinephrine, the final product in sympathetic and central noradrenergic neurons. Phenylethanolamine-*N*-methyltransferase (PNMT) promotes methylation of norepinephrine to form epinephrine and is induced by glucocorticoids, which the adrenal medulla receives in high concentrations from the adrenal cortex.

FIGURE 408.1. Biosynthesis of catecholamines and the metabolic pathways for their degradation.

Tyrosine hydroxylase and ALAAD are cytoplasmic enzymes in chromaffin cells and postganglionic neurons. Dopamine formed by their action is transported by a specific uptake mechanism into storage vesicles, where it is converted to norepinephrine by dopamine β -hydroxylase. Where conversion to epinephrine occurs, PNMT is present in the cytoplasm, norepinephrine leaves the vesicle, and epinephrine is then taken up.

Catecholamine release occurs by exocytosis, whereby vesicle contents are discharged into the extracellular space adjacent to a capillary, in the case of the adrenal medulla, or into the synapse in neurotransmission. This requires an influx of calcium mediated by an acetylcholine-induced action potential.

In neurotransmission, after release, a small fraction of the catecholamines binds to the postganglionic receptors and produces the effect appropriate to the specific receptor. Some is metabolized and some enters the circulation (thus, plasma norepinephrine is an index of sympathetic neuronal function), but most is taken into the preganglionic neuron by a specific energy-dependent mechanism (uptake I) and stored in cytoplasmic vesicles.

Catecholamines have a short half-life in plasma (1 to 2 minutes) because of either cellular uptake or enzymatic degradation ([Fig. 408.1](#)). The major pathways are catalyzed by catechol *O*-methyltransferase (COMT) and monoamine oxidase (MAO). COMT converts epinephrine to metanephrine, norepinephrine to normetanephrine, and dopamine to 3-methoxytyramine. The former are converted by MAO and aldehyde oxidase to 3-methoxy-4-hydroxymandelic acid [or vanillylmandelic acid (VMA)]. Alternatively, MAO first converts norepinephrine and epinephrine to 3,4-dihydroxymandelaldehyde, and aldehyde oxidase converts this to 3,4-dihydroxymandelic acid, which is converted via COMT methylation to VMA. Another pathway is by COMT and alcohol dehydrogenase on 3,4-dihydroxymandelaldehyde to yield 3-methoxy-4-hydroxyglycol, much of which is metabolized to VMA. In the case of dopamine, the final product is 3-methoxy-4-hydroxyphenylacetic acid (or homovanillic acid). Conjugation, primarily to sulfates, also occurs. The concentrations of conjugated catecholamines excreted in urine are several fold greater than those of free catecholamines.

Catecholamines act through cell surface receptors. These are divided into α_1 -, α_2 -, β_1 -, and β_2 -adrenergic and D_1 - and D_2 -dopaminergic receptors on the basis of responsiveness to agonist and antagonist drugs. Norepinephrine, epinephrine, and dopamine are all mixed agonists. Adrenergic receptors are subject to down- and up-regulation in the presence of high and low catecholamine levels, respectively. Receptors are also classified by location: *prejunctional* (presynaptic) receptors, on the axonal terminal itself, which autoregulate catecholamine release; *postjunctional* (postsynaptic) receptors in the synapse opposite the axonal terminal; and *extrajunctional* receptors on noninnervated cells, where catecholamines act as true hormones.

Agonist binding to receptors does not result in hormonal action directly but induces second messengers. For β_1 and β_2 receptors, there is linkage by a guanine nucleotide-regulatory protein to a cell membrane adenylate cyclase, and a rise in intracellular cyclic adenosine monophosphate induces a series of protein kinase activations resulting in hormone action. D_1 receptors are linked to stimulation of adenylate cyclase, and D_2 receptors are linked to its inhibition. The β_2 receptors are linked to an inhibitory guanine nucleotide regulatory protein and inhibit adenylate cyclase. For α_1 receptors, the coupling to intracellular events is not yet elucidated but results in calcium influx.

Upright posture, pain, anxiety, exercise, hypovolemia, hypotension, sodium depletion, and hypoglycemia all elevate the catecholamine levels, as does acute myocardial infarction, diabetic ketoacidosis, surgical trauma, burns, and chronic processes, including cardiac failure, anemia, respiratory failure, and hypothyroidism. Decreased levels (especially in response to normal stimuli) occur in autonomic neuropathy, after depletion of stores by reserpine, inhibition of synthesis by methylparatyrosine, and reduction of central sympathetic tone by clonidine.

Hemodynamic effects include vasoconstriction (α), vasodilatation (β_2), and positive chronotropic and inotropic effects on the heart (β_1). Norepinephrine causes generalized vasoconstriction, systolic and diastolic hypertension, and reflex bradycardia. Epinephrine, by β_2 effect, causes vasodilatation, systolic hypertension, and diastolic hypotension, and cardiac rate and output are increased. Dopamine increases cardiac output and systolic blood pressure with little effect on diastolic blood pressure, and (at low concentrations) causes renal and mesenteric vasodilatation. Peripheral infusion of norepinephrine must achieve concentrations greater than 1,000 pg per milliliter to cause significant metabolic and hemodynamic effects. With epinephrine, 50 to 200 pg per milliliter is required. Metabolic effects include increased glycogenolysis and gluconeogenesis by liver and muscle; reduced glucose utilization outside the central nervous system; stimulation of lipolysis, hepatic

ketogenesis, and amino acid release from muscle; and increased thermogenesis. Hypokalemia and hypophosphatemia result from cellular potassium and phosphate uptake. Smooth-muscle relaxation of bronchi and uterus is mediated by β_2 receptors. Other effects are mydriasis (α) and reduction of gastrointestinal motility (β_1). Catecholamines modulate the secretion of hormones, including insulin (suppressed by a α_2 effect and to a lesser degree stimulated by β_2). Stimulation of glucagon (β), growth hormone (α), and renin (β_1) dopamine receptors has been reported. Stimulation of the pituitary reduces prolactin secretion.

SPECIFIC DISORDERS OF THE SYMPATHOADRENAL SYSTEM: PHEOCHROMOCYTOMA

Only the tumorous hypersecretion of catecholamine is considered in this section. A functional increase in sympathetic tone may play a role in essential hypertension and defective catecholamine release in autonomic neuropathy, which is discussed elsewhere in this text.

DEFINITION

Catecholamine-secreting tumors derived from the adrenal medulla or sympathetic autonomic paraganglia frequently stain brown with chromium salts, leading to the name *pheochromocytoma*. There are two nomenclatures. "Pheochromocytoma" may be used for all catecholamine-secreting tumors, adrenal and extra-adrenal; alternatively, the term "pheochromocytoma" is reserved for adrenal lesions, and extra-adrenal tumors are termed *functional paragangliomas*. The embryologically related, highly malignant neuroblastoma occurs almost exclusively in childhood.

INCIDENCE AND EPIDEMIOLOGY

Pheochromocytomas are not rare tumors. The true incidence is not known, but such tumors may be present in 0.1% to 0.5% of hypertensive patients. Ten percent to 20% of patients have associated neurocristopathies ([Table 408.1](#)). No age group is exempt, and 10% of cases occur in childhood.

Syndrome	Component Features
Multiple endocrine neoplasia type 2a	Medullary thyroid carcinoma, hyperparathyroidism, pheochromocytoma (usually bilateral intraadrenal)
Multiple endocrine neoplasia type 2b	Medullary thyroid carcinoma, ganglioneuromatosis, pheochromocytoma (usually bilateral intraadrenal)
von Hippel-Lindau disease	Retinal hemangiomas, cerebellar hemangioblastomas, visceral tumors and cysts including pheochromocytoma
von Recklinghausen's neurofibromatosis	Cafe-au-lait spots, neurofibromata, plexiform neuromas and occasional pheochromocytoma
Simple familial pheochromocytoma	Familial pheochromocytoma without other lesions

TABLE 408.1. NEUROCRISTOPATHIC SYNDROMES ASSOCIATED WITH PHEOCHROMOCYTOMA

ETIOLOGIC FACTORS

Most cases are sporadic with unknown cause. The responsible regulatory genes for a number of the autosomal dominant familial syndromes have been identified, e.g., the *RET* oncogene in multiple endocrine neoplasia type 2 (MEN 2) syndromes, which provides a tool for early diagnosis, family screening, and insights regarding cause of disease.

PATHOGENESIS

Pheochromocytomas may arise from chromaffin tissue anywhere from the base of the skull to the bladder. Most (90%) are intra-adrenal. The most common extra-adrenal site is the organ of Zuckerkandl near the aortic bifurcation. In addition, tumors may arise in the urinary bladder; paravertebral and celiac ganglia; sympathetic jugular chain; paracardiac, aortic, and carotid bodies; and the glomus jugulare. They are typically chromaffin-positive and stain for neuron-specific enolase and chromogranin. Characteristic dense-core granules are observed on electron microscopy. As in other endocrine neoplasms, it is difficult to distinguish benign from malignant lesions in the absence of frank metastasis.

Catecholamine hypersecretion accounts for most symptoms and signs in pheochromocytoma. The relative proportions of epinephrine and norepinephrine affect the clinical presentation. Excessive epinephrine, usually from an intra-adrenal lesion, leads to tachycardia, diastolic hypotension, and cardiac arrhythmia. Metabolic effects, including increased metabolic rate, glucose intolerance due to decreased insulin secretion, and insulin resistance, are common, but frank diabetes is unusual. More commonly, norepinephrine secretion predominates and accounts for most symptoms and signs. A number of manifestations are not explained by catecholamine excess, including hypercalcemia and polycythemia. Many neuropeptides have been described in pheochromocytomas and may contribute to the individual symptom complex. Ectopic adrenocorticotrophic hormone production occasionally leads to Cushing's syndrome.

CLINICAL FINDINGS

Hypertension is the cardinal abnormality. In many patients it is sustained, whereas in the remainder baseline hypertension is associated with paroxysms of greater severity. Truly intermittent hypertension is unusual. Rarely, hypotension may alternate with hypertension, usually with epinephrine-secreting neoplasms. Other features of the hypertension include severity, early onset, resistance to conventional therapy, and exacerbation by β blockers. Hypertension may lead to all the complications of elevated blood pressure. In addition, paroxysms occur, characterized by various combinations of throbbing headache, anxiety, drenching sweats, tachycardia, palpitations, chest and abdominal pain, nausea and vomiting, syncope, tremor, and blanching followed by flushing. These episodes may occur spontaneously or after exercise, meals, or other provocative stimuli. Bladder lesions are associated with hematuria in 50% of patients, and paroxysmal headache, hypertension, or other symptoms are related to micturition. Glomus jugulare tumors invade the base of the skull. Extra-adrenal primary tumors have a greater tendency to metastasize than intra-adrenal lesions. Metastases spread to bone, lymph nodes, and liver, where they lead to local symptoms. Diagnostic physical signs in pheochromocytoma are few. The most important sign is hypertension during and between typical episodes. Hypertension may follow abdominal palpation. Intravascular volume constriction may lead to postural hypotension. Hypertensive changes and, in von Hippel-Lindau disease, angiomas may be observed in the retina. Other signs include neurofibromas and cafe(c) au lait spots in neurofibromatosis. Goiter due to medullary carcinoma of the thyroid occurs in all types of MEN. Hypertrophy of corneal nerves and ganglioneuromatosis occur in MEN type 2b.

The clinical features of pheochromocytoma are protean and overlap with those of many other disorders, including essential, secondary, and paroxysmal hypertension (e.g., after withdrawal of medications, clonidine, or adverse reactions to MAO inhibitors). Other manifestations may overlap with thyrotoxicosis, anxiety states (including panic attacks), carcinoid syndrome, mastocytosis, paroxysmal tachycardia, vasodilatory headaches, intracranial lesions, atypical diencephalic seizures, and hypoglycemia. Also included in the differential diagnosis are related tumors, including neuroblastoma, ganglioneuroblastoma, and ganglioneuroma.

Pheochromocytoma may go unrecognized for years and is often not diagnosed in life. Left untreated, it may lead to chronic complications of hypertension or, rarely, sudden death. Unanticipated, potentially lethal presentation may occur with anesthesia, pregnancy and delivery, or trauma. Multifocal pheochromocytomas, most commonly bilateral intra-adrenal, may present simultaneously or evolve over decades, warranting lifelong surveillance. Malignancy is uncommon, occurring in about 10% of cases. The natural history of these lesions is highly variable, and if the effects of catecholamine excess are controlled, patients may tolerate large tumor burdens for extended periods. Death may then occur from local invasion of critical organs.

LABORATORY FINDINGS

Plasma catecholamines are labile, and samples must be obtained in the fasting, rested, and supine state via an indwelling needle. Because of a multitude of potential interferences and alterations due to drug use, studies should be performed with subjects in a drug-free state whenever possible. Many drugs may interfere with assays of catecholamines depending on the methodology used. Twenty-four-hour urine collections serve to integrate the overall daily excretion; 12-hour overnight

collections have the advantage of excluding the effect of upright posture.

PLASMA AND URINARY MEASUREMENTS

Once clinically suspected, the diagnosis of pheochromocytoma is made by demonstrating excessive catecholamine secretion. The choice of biochemical studies is controversial, with much depending on availability, quality, and costs of assays at a given institution. Urinary catecholamines or metabolites (e.g., metanephrines or VMA) provide a logistically convenient index. Only the free fraction of urinary catecholamines should be determined. Many consider a single, spot, unfractionated urine metanephrine to be an adequate screen for hypertensive persons without typical symptoms. Plasma catecholamine measurements, performed under appropriate conditions, provide a sensitive alternative. About 80% of patients with pheochromocytoma have unequivocal elevations (e.g., more than 2,000 pg per milliliter of norepinephrine), but some, especially those with paroxysmal patterns or asymptomatic patients at risk due to familial syndromes, may have normal or borderline values. In these cases, multiple determinations or provocative or suppressive tests are indicated. In the absence of the characteristic clinical picture, the yield from biochemical investigations is low, and false positives are common.

SUPPRESSION TESTS

Clonidine reduces sympathetic tone and plasma catecholamine levels. The autonomous hypercatecholaminemia of pheochromocytoma is not suppressed by clonidine (oral dose of 300 µg with blood samples both before and 0.5, 1, 1.5, and 2 hours later). The test is superfluous when plasma catecholamines exceed 2,000 pg per milliliter. Tyramine-, glucagon-, and histamine-provocative tests are potentially dangerous, have high false-negative and false-positive rates, and are obsolete.

PREOPERATIVE TUMOR LOCATION

Accurate preoperative identification of all pheochromocytoma deposits is a prerequisite for curative surgery. Localizing procedures are justified only when a clinical and biochemical diagnosis has been made. Plain radiography, intravenous urography, retroperitoneal air insufflation, and ultrasonography are obsolete. Angiography and venography with sampling are invasive, may trigger crisis, and, while effective, have in most cases been replaced by computed tomography (CT), magnetic resonance imaging (MRI), and scintigraphy with metaiodobenzylguanidine (MIBG). CT is highly effective in adrenal pheochromocytomas (greater than 95% sensitivity) but is less so for extra-adrenal lesions (75% sensitivity). Adequate technique requires the use of modern scanners, thin sections, and oral contrast agents. CT may fail in thin patients and in the presence of metallic clips and other postoperative artifacts. With MRI the high T2-weighted signal from pheochromocytoma permits distinction from adrenocortical lesions but not from metastases. MIBG and radiolabeled somatostatin analogs both permit noninvasive scintigraphy of the entire body in a single procedure and are effective in locating pheochromocytomas of all types (sensitivity 88%, specificity 98%). Both radiopharmaceuticals are now available commercially in the United States.

OPTIMAL MANAGEMENT

Preoperative Management

Acute crisis is best managed with 1 mg intravenous phentolamine followed by an infusion, titrated against blood pressure. An alternative is a nitroprusside infusion. The only definitive cure for pheochromocytoma is surgical extirpation. To achieve acceptable morbidity and mortality requires meticulous preoperative preparation. Radiologic procedures requiring contrast media need similar preparation. The time-honored agent is phenoxybenzamine, an oral, noncompetitive α -adrenergic blocker. The full effect occurs 12 hours after administration, and action accumulates over several days. An initial dose of 10 mg twice daily is increased by 10 mg every other day. The goal is control of hypertension without symptomatic postural hypotension. If paroxysms predominate, the dose should be that which eliminates or significantly blunts attacks without causing symptomatic postural hypotension. Nasal congestion and failure of ejaculation are common side effects of a blockade. Prazosin is an alternative with shorter action that may be titrated more rapidly. An α blockade for about 2 weeks permits reexpansion of the contracted plasma volume; β blockade is only occasionally required for tachycardia or tachyarrhythmia. Either a nonspecific β blocker (propranolol) or a β_1 -selective blocker (metoprolol) may be used. Although risks have probably been overemphasized, β blockade should not be induced before an α blockade because this can lead to severe, even lethal, hypertensive crisis as a result of unopposed α -adrenergic agonism. Occasionally, adrenergic blockade cannot control symptoms, and inhibition of catecholamine synthesis by α -methylparatyrosine is required. It is seldom completely effective but permits lower doses of α blockers. Calcium channel antagonists may also be effective. Heart failure sometimes encountered with pheochromocytoma responds to a blockade and α -methylparatyrosine, and diuretics and digitalis are seldom indicated.

Presentation in Pregnancy

Pheochromocytoma may present as a crisis during pregnancy or delivery, and it carries a poor prognosis for both infant and mother even when recognized. It must be distinguished from eclampsia. Rapid induction of an α blockade and the use of nitroprusside infusion with delivery by cesarean section are required.

Intraoperative Management and Surgery

The purpose of surgery is total extirpation and requires close collaboration between anesthesiologist and surgeon. A rapid, stress-free induction of anesthesia is best achieved with pentobarbital and succinylcholine followed by methoxyflurane or enflurane, oxygen, and nitrous oxide. Endotracheal intubation, muscle relaxation, and mechanical ventilation are essential. Electrocardiographic monitoring and intra-arterial pressure and urinary output measurement are mandatory, and a central venous pressure or Swan–Ganz catheter may be required. Preoperative α blockade is seldom complete, and intraoperative tumor manipulation frequently leads to hypertension, best managed by gentle dissection, phentolamine, or nitroprusside. Tachycardia or supraventricular arrhythmia is controlled by β blockers, and ventricular arrhythmia by lidocaine. When venous drainage from the tumor is interrupted, catecholamines and blood pressure may fall precipitously. This is minimized by preoperative α blockade and liberal administration of intravenous fluids. Pressors are seldom required. Intra-abdominal lesions require an anterior abdominal approach with thorough exploration of the entire retroperitoneum. Laparoscopic surgery is currently gaining popularity and speeds recovery. Bladder lesions require partial cystectomy with ureteric reimplantation. Posterior mediastinal lesions are approached through posterior thoracotomy, whereas paracardiac lesions require median sternotomy and, often, cardiopulmonary bypass.

Postoperative Follow-up

Catecholamine levels fall within minutes of tumor resection. Complete return to normal requires as long as 2 weeks because of large amounts of catecholamines stored in peripheral sympathetic nerve endings. Failure to do so indicates residual, second primary, or metastatic tumor. The histology of the primary tumor may not predict long-term behavior. Even lesions that are not strictly malignant may not be resectable. Up to one-third of patients are left with some sustained hypertension despite normal catecholamine levels, probably because of damage to renal vasculature. All patients require lifelong follow-up because metastases or second primary tumors may manifest after long periods. Control of hypercatecholaminemia effects by long-term adrenergic blockade or methylparatyrosine is the mainstay of management. This controls most disabling and potentially life-threatening effects; tumor growth, though unaltered, is often slow and may be tolerated for years with good quality of life. Painful skeletal metastases may be palliated by radiation therapy. Experimental therapy with large doses of iodine 131-labeled MIBG has been attempted with some success. Large doses of indium 111- or yttrium 90-labeled somatostatin analogs may also be effective. The combination of vincristine, cyclophosphamide, and dacarbazine (a commonly used combination for the embryologically related neuroblastoma) has shown promise.

CHAPTER 409: DISORDERS OF THE REPRODUCTIVE CYCLE IN WOMEN

ROBERT L. BARBIERI

[Hormonal Control of Female Fertility](#)
[Postcoital Contraception](#)
[Prevention of Menses](#)
[Dysmenorrhea](#)
[Treatment of Hypoestrogenic States](#)

The reproductive endocrine environment of the female depends on the complex interaction of hypothalamic, pituitary, ovarian, and uterine events. In contrast to the male, the critical and unique aspect of this system is cyclic ovarian function, which is responsible for the production of gametes and the sex steroids, estradiol and progesterone. An inherent feature of the female reproductive system is that depletion of gametes and cessation of estrogen and progesterone production usually occurs by 55 years of age. The resulting hypoestrogenic state is associated with important changes in lipid and bone metabolism. Common clinical problems requiring intervention to alter the production and action of estradiol and progesterone are discussed in this chapter.

HORMONAL CONTROL OF FEMALE FERTILITY

The major structural components of the female reproductive system and their functions are the hypothalamus, which controls the pulsatile release of gonadotropin-releasing hormone (GnRH); the pituitary, which controls the pulsatile release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH); the ovary, which controls follicular development, with cyclic secretion of estradiol and progesterone, and gamete maturation; and the uterus, which controls cyclic endometrial growth, maturation, and shedding in response to ovarian estradiol and progesterone secretion ([Fig. 409.1](#)).

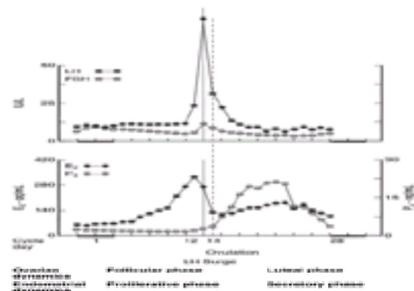

FIGURE 409.1. Circulating luteinizing hormone (LH), follicle-stimulating hormone (FSH), estradiol (E_2), and progesterone (P_4) throughout the normal ovulatory menstrual cycle.

The most widely used reversible birth control method remains the combined estrogen–progestin (E-P) oral contraceptive. The E-P oral contraceptive contains a synthetic estrogen and a synthetic progestin. Ethinyl estradiol is the synthetic estrogen in most E-P contraceptives. Many E-P contraceptives contain a synthetic progestin related to norethindrone or norgestrel. The synthetic progestins norethindrone acetate and ethynodiol diacetate are converted to norethindrone in vivo. Norethindrone and norgestrel are structurally related to progesterone and testosterone and have progestogenic and androgenic properties. More recently, three “nonandrogenic” synthetic progestins have become available: desogestrel, norgestimate, and gestodene. Unlike norgestrel, these nonandrogenic progestins do not suppress hepatic sex hormone–binding globulin or high-density lipoprotein (HDL) cholesterol production.

The most commonly used E-P oral contraceptives are available in packages containing 28 pills. Twenty-one pills contain the synthetic E-P hormones and seven pills contain inert ingredients. Menses usually occurs while the user is taking the seven inert pills owing to the withdrawal of E-P hormones. E-P contraceptives prevent conception by inhibiting hypothalamic GnRH secretion, inhibiting pituitary response to GnRH, preventing normal endometrial maturation, and blocking sperm entry to the upper reproductive tract by producing a hostile cervical mucus. Because E-P contraceptives block fertility by redundant and overlapping mechanisms, they are extremely efficacious and have failure rates in the range of one to two pregnancies per 100 woman-years of use.

The major serious side effects of the birth control pill are cerebrovascular accidents (thromboembolic stroke, subarachnoid hemorrhage), myocardial infarction, and venous thrombosis with pulmonary embolism. In women younger than 35 years of age who do not smoke, these life-threatening complications of oral contraceptives are exceedingly rare. Women younger than 35 years who do not smoke have a fourfold greater risk of dying of a pregnancy than of dying as the result of a complication of oral contraceptive use. Women older than 35 years of age who smoke should not be prescribed oral contraceptives. Activated protein C resistance caused by factor V Leiden mutation is an important risk factor for venous thromboembolism in women using oral contraceptives. Other medical problems that can be associated with oral contraceptive use include hepatic adenoma, gallbladder disease, elevated blood pressure, and increased risk of cervical dysplasia.

Studies suggest that oral contraceptives *decrease* the risk of development of endometrial cancer, ovarian cancer, pelvic inflammatory disease, and breast cysts. Oral contraceptives appear to decrease the risk of development of endometrial cancer by 60%. It is likely that the continuous exposure of the endometrium to the synthetic progestins contained in the pill, which prevent endometrial growth (mitosis), accounts for this effect. Oral contraceptives decrease the risk of ovarian cancer in both low-risk and high-risk women by approximately 50%. For example, in women with the *BRCA1* mutation (high risk for ovarian cancer) oral contraceptive use reduced the risk of ovarian cancer by 50%. Epidemiologic studies suggest that ovarian cancer is related to both elevated gonadotropin levels and incessant ovulation. Oral contraceptives may decrease the risk of development of ovarian cancer by decreasing gonadotropin secretion and preventing ovulation.

POSTCOITAL CONTRACEPTION

Women who are the victims of sexual assault or who have a failure of a barrier contraceptive method (e.g., condom rupture) may be offered postcoital contraception. Pregnancy can often be prevented in women with unprotected intercourse at midcycle by administering 100 μ g ethinyl estradiol and 0.5 mg levonorgestrel immediately and repeating the dose in 12 hours. The failure rate is approximately 1%. Human chorionic gonadotropin should be assayed before therapy, and therapy must be instituted within 72 hours of exposure. These high doses of E-P appear to prevent pregnancy by disrupting endometrial maturation and implantation. Many experts recommend that all women at risk for pregnancy (e.g., sexually active, using a barrier contraceptive) should be prescribed a postcoital contraceptive to keep in their home, so that they have easy access to this form of contraception should a failure of a nonhormonal contraceptive occur. Economic modeling suggests that preemptive prescription of postcoital contraceptives to all sexually active women using a barrier contraceptive can save health care resources by preventing undesired pregnancies.

PREVENTION OF MENSES

In many clinical settings, such as severe thrombocytopenia, cyclic uterine bleeding is undesirable. Hormones can be used to stabilize the endometrium and prevent menses. Four hormonal agents are available to prevent or delay menses: E-P contraceptives used in a “pseudopregnancy” regimen, danazol, high-dose progestin, and GnRH agonist analogs. Each cycle of E-P contraceptives contains 21 hormone pills and 7 inert pills. Menses can often be prevented by the continuous administration of one hormone pill daily for 3 to 12 months without using the inert pills (pseudopregnancy regimen). The main complication of this regimen is irregular uterine spotting or bleeding. Danazol at doses of 800 mg per day, medroxyprogesterone acetate at doses of 30 to 100 mg per day, and leuprolide acetate at doses of 3.75 or 7.5 mg by intramuscular injection every 4 weeks can also prevent menses.

For the thrombocytopenic patient who is already bleeding, E-P contraceptives, one to four pills per day, until bleeding is controlled, can be instituted. Before initiating hormone therapy, the possibility of pregnancy or a structural abnormality of the uterus should be assessed.

DYSMENORRHEA

Dysmenorrhea is often divided into two broad categories: primary and secondary. Primary dysmenorrhea is the presence of painful menstruation in the absence of a demonstrable pelvic pathologic process. Secondary dysmenorrhea is the occurrence of painful menstruation due to a pelvic lesion, such as endometriosis, chronic pelvic inflammatory disease, or uterine leiomyomas. In primary dysmenorrhea, the pain characteristically begins with the onset of menstruation and lasts for 12 to 72 hours. The pain is usually confined to the lower abdomen and is most intense in the midline. It is often described as crampy and intermittent in intensity. Evidence suggests that prostaglandin F_{2a} and prostaglandin E_2 released from the endometrium at the time of menstruation cause primary dysmenorrhea. Prostaglandins induce smooth-muscle contraction in many tissues. Prostaglandin-induced uterine contractions can last many minutes and may produce intrauterine pressures greater than 60 mm Hg. When uterine pressure exceeds mean arterial pressure for a prolonged period, uterine ischemia may occur.

In a woman with dysmenorrhea, a history consistent with primary dysmenorrhea, and a negative pelvic examination, a trial of antiprostaglandins or E-P contraceptives is warranted. Initial therapy for dysmenorrhea consists of ibuprofen at doses up to 2,400 mg daily. Therapy is initiated just before menses, for those women who can accurately predict the onset of menses, or at the onset of menses. Therapy usually lasts for 3 or 4 days. If ibuprofen (an arylpropionic acid derivative) is not effective, a trial with a drug in the fenamate class (mefenamic acid) or an E-P contraceptive may be warranted. Nifedipine at doses of 20 to 40 mg daily has also been demonstrated to be effective in the treatment of primary dysmenorrhea. If aggressive therapy for primary dysmenorrhea fails, the patient should be evaluated by a gynecologist to consider if laparoscopy is warranted.

TREATMENT OF HYPOESTROGENIC STATES

The rapid aging of the population is one of the most dramatic demographic changes occurring in developed countries. In the United States, about 30% of women are postmenopausal. From an epidemiologic viewpoint, menopause describes the permanent cessation of menses. From a biologic perspective, menopause occurs when the ovaries are surgically removed or when the ovary is depleted of all follicles. In virtually all menopausal women, serum FSH is elevated. Ovarian follicular depletion results in a 95% decrease in estradiol production. Before ovulation, estradiol production is 400 μ g per day, and circulating estradiol concentrations are 300 pg per milliliter. In the menopausal woman, estradiol production is about 20 μ g per day and circulating estradiol 15 pg per milliliter. The major changes associated with hypoestrogenism are accelerated trabecular and cortical bone loss; increased low-density lipoprotein cholesterol and decreased HDL cholesterol; amenorrhea; vasomotor symptoms (hot flashes); sleep disturbances; and atrophy of secondary sexual characteristics. Hormone replacement therapy (HRT) may be able to reverse or prevent many of these changes. Before considering HRT in a postmenopausal woman, a history and physical examination should be combined with appropriate screening procedures: Pap smear, stool guaiac, mammography, measurement of cholesterol and HDL cholesterol, and measurement of trabecular bone density, if indicated to assess major health risks. HRT is contraindicated in women with estrogen-dependent cancers, such as breast cancer or advanced endometrial cancer. Relative contraindications to HRT are thromboembolism, porphyria, severe liver disease, hypertension, and cholelithiasis.

Prospective, randomized, controlled studies fully delineating the risks and benefits of HRT have not yet been completed. Until such studies are completed, recommendations concerning HRT must rely on clinical judgment and the results of large prospective cohort studies. Most prospective cohort studies conclude that estrogen treatment increases life expectancy, on average, by 1 to 3 years. The benefit of estrogen replacement is greatest for women at risk for cardiovascular disease. For a woman with a uterus, estrogen-only HRT is associated with an increased risk of development of endometrial cancer. Therefore, women with a uterus should receive both an estrogen and a progestin. A typical cyclic regimen consists of conjugated equine estrogens, 0.625 mg every day of the year, and medroxyprogesterone acetate, 5 mg per day for calendar days 1 to 12 of each month (Fig. 409.2). Most women younger than 70 years can expect to have uterine bleeding each month, typically lasting 3 to 5 days and occurring sometime between day 9 and day 17 of the month. Many menopausal women dislike the resumption of menses produced by cyclic HRT. An alternative continuous regimen is conjugated equine estrogens, 0.625 mg, and medroxyprogesterone 2.5 or 5 mg every day of the year. About half of women become amenorrheic on this regimen. Unfortunately, the others have irregular menses. Endometrial biopsy is warranted in any menopausal woman, on or off HRT, who has irregular or heavy uterine bleeding.

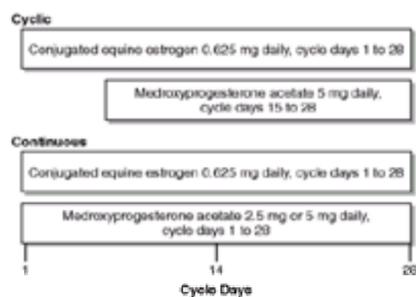

FIGURE 409.2. Cyclic and continuous hormone replacement therapy.

Epidemiologic studies suggest that estrogen plus progestin HRT is associated with a decreased risk of development of coronary heart disease (relative risk of 0.6). HRT also appears to decrease the rate of bone loss that occurs in aging hypoestrogenic women. Long-term HRT may be associated with a small increase in risk of development of breast cancer. These data are controversial and require confirmation.

The discovery of selective estrogen receptor modulators (SERMs) has opened a new era in hormone replacement. SERMs interact with the estrogen receptor but can act as estrogen agonists in some tissues and estrogen antagonists in other tissues.

In hypoestrogenic women, the SERM raloxifene is an estrogen agonist in the liver (decreases LDL cholesterol) and bone (decreases osteoclast activity), but is an estrogen antagonist in the breast. In menopausal women, raloxifene treatment (60 mg daily) decreases the risk of osteoporotic fracture and appears to decrease the risk of breast cancer. Raloxifene treatment does not cause uterine bleeding.

CHAPTER 410: DISORDERS OF GONADAL FUNCTION IN MEN

PETER J. SNYDER

[Normal Male Reproductive Endocrinology](#)
[Male Hypogonadism](#)
[Androgen Resistance](#)

NORMAL MALE REPRODUCTIVE ENDOCRINOLOGY

The male gonads are the testes, whose two major functions are production of testosterone by the Leydig cells and production of sperm in the seminiferous tubules. Testosterone secreted into the systemic circulation affects many tissues, mostly by binding to the androgen receptor, and the cumulative effect is to produce a phenotypic male. Testosterone within the testes is the principal hormonal stimulus to sperm production. Both functions of the testes are controlled by the gonadotropins, luteinizing hormone (LH), and follicle-stimulating hormone (FSH), which are secreted by the gonadotroph cells of the pituitary gland. LH stimulates the Leydig cells to secrete testosterone, and FSH stimulates the Sertoli cells of the seminiferous tubules. LH and FSH, in turn, are both stimulated by gonadotropin-releasing hormone (GnRH), which is secreted by the hypothalamus into the hypothalamic–pituitary portal circulation. Testosterone inhibits the gonadotroph cell from secreting both LH and FSH. Inhibin, secreted by the Sertoli cells, also inhibits FSH secretion ([Fig. 410.1](#)).

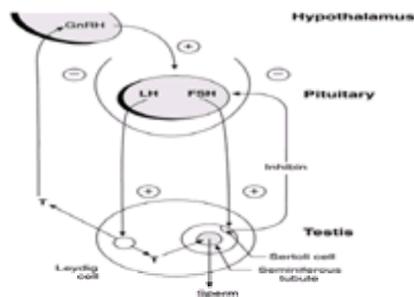

FIGURE 410.1. The hypothalamic–pituitary–testicular axis. The hypothalamus secretes gonadotropin-releasing hormone (GnRH) into the portal circulation, and GnRH stimulates the gonadotroph cells of the pituitary to secrete luteinizing hormone (LH) and follicle-stimulating hormone (FSH). LH stimulates the Leydig cells of the testes to secrete testosterone into the systemic circulation, and testosterone within the testes is also the principal hormonal stimulus to spermatogenesis. FSH stimulates the Sertoli cells of the seminiferous tubules to secrete inhibin and other peptides, which also stimulate spermatogenesis. Testosterone inhibits GnRH secretion and thereby LH and FSH secretion, and inhibin inhibits FSH directly.

SYNTHESIS AND SECRETION OF GONADOTROPINS AND THEIR CONTROL

FSH and LH are both synthesized in the gonadotroph cells of the pituitary. Both are heterodimeric glycopeptides, consisting of a common α subunit and a unique β subunit. The α subunit has two aspartic acid (Asp)–linked oligosaccharide chains, and both β subunits have one.

Both LH and FSH are stimulated by GnRH, a decapeptide that is cleaved from a larger precursor peptide, which is synthesized in the arcuate nucleus of the hypothalamus. GnRH is released into the hypothalamic–pituitary portal circulation and binds to specific cell-surface G-protein-coupled receptors, which triggers a cascade of intracellular signaling pathways and stimulates LH and FSH release. GnRH cannot be measured readily in the portal or peripheral circulation of humans, but its secretion is thought to be pulsatile because secretion of LH is pulsatile. In addition, administration of GnRH to men who are unable to secrete it by themselves increases LH secretion to normal if the GnRH is administered in pulses, but not if it is administered continuously, and continuous administration of GnRH to men whose own secretion is normal decreases LH secretion to subnormal.

TESTOSTERONE SYNTHESIS, SECRETION, TRANSPORT, AND ACTION

LH stimulates testosterone synthesis by binding to a cell-surface receptor on the Leydig cells and activating a cyclic adenosine monophosphate (cAMP)–mediated mechanism that increases cholesterol side-chain cleavage and conversion to pregnenolone and, eventually, to testosterone. Daily synthesis of testosterone is 5 to 7 mg.

Testosterone secreted into the systemic circulation is 98% to 99% bound, about half to sex hormone–binding globulin (SHBG) with high affinity and half to albumin with low affinity. Testosterone bound to SHBG is not available to tissues, but that bound to albumin probably is. SHBG synthesis is stimulated by estrogens and decreased by androgens and obesity.

The actions of testosterone appear to be mediated on a cellular level in three ways: directly and by conversion to dihydrotestosterone (DHT) or estradiol. The direct effect of testosterone on cells is mediated by its passive diffusion into cells, binding to the androgen receptor, binding of the testosterone–androgen receptor complex to DNA, and stimulation of messenger RNA (mRNA) and protein synthesis. This mechanism appears to be responsible for the effects of testosterone on stimulation of the wolffian ducts to become the male internal genitalia during embryonic development, inhibition of gonadotropin secretion, and probably stimulation of erythropoiesis, growth of muscle, and increase in linear bone growth and bone mineral density. In other tissues, testosterone acts by conversion to DHT in the target cell cytoplasm by the enzyme 5 α -reductase. DHT is then bound to the androgen receptor, and the DHT–receptor complex binds to DNA, stimulating mRNA and protein synthesis. DHT binds to the androgen receptor with greater affinity than does testosterone and so has a greater effect. This mechanism appears to be responsible for the effects of testosterone in male sexual differentiation of the external genitalia in utero, enlargement of the external genitalia during puberty, and the development of sexual hair during puberty. Testosterone may also act in some tissues through conversion to estradiol by the enzyme aromatase, which is found in greatest concentrations in some hypothalamic nuclei, adipose tissue, and liver. This mechanism appears to mediate the effect of testosterone on epiphyseal closure, since the epiphyses of males who have mutations either of the gene coding for the estrogen receptor or the aromatase enzyme do not close. This mechanism appears to partially mediate the inhibition of LH secretion, since administration of an aromatase inhibitor to men increases their serum LH concentrations.

SPERMATOGENESIS

Spermatogenesis occurs in the seminiferous tubules of the testes. The principal hormonal stimulus of spermatogenesis is testosterone, whose concentration in the testes is 100 times that in the peripheral circulation. This relatively high testosterone concentration, which is essential for spermatogenesis, is likely the consequence of both the LH-stimulated production of testosterone nearby in the Leydig cells and the binding of testosterone by androgen-binding protein, produced by the Sertoli cells of the seminiferous tubules. FSH stimulates the Sertoli cells to secrete androgen-binding protein and also inhibin, which inhibits FSH secretion by the pituitary, and activin, which stimulates spermatogenesis. Maturation of a spermatogonium to a mature spermatozoon takes approximately 75 days, and passage through the epididymis, where motility is acquired, takes another 14 days—a total of approximately 3 months.

THE AGES OF MAN: IN UTERO, PUBERTY, SENESCENCE

The preceding description of male reproductive function is that found in the young adult. The development of adult function occurs primarily in utero and during puberty, and that function declines in the male senescence.

In Utero

During the first trimester in utero, sexual differentiation occurs. In the presence of the sex-determining region of the Y chromosome, SRY, the indifferent gonads become testes. The Sertoli cells of the testes secrete anti-müllerian hormone, which suppresses the müllerian ducts so that they do not become female internal genitalia. The Leydig cells of the testes, stimulated by human chorionic gonadotropin from the placenta, secrete testosterone, which stimulates the nearby wolffian ducts to become the male internal genitalia (vas deferens and seminal vesicles). In addition, testosterone is converted to DHT by the anlage of the external genitalia, and DHT influences them to become the penis, scrotum, and prostate. During the third trimester in utero, LH from the fetal pituitary stimulates the fetal Leydig cells to secrete testosterone, which results in penile growth. During the first few months post partum there is a third testosterone elevation, but the consequences of this elevation are not known. Thereafter, the serum testosterone concentration falls to relatively low values until puberty.

Puberty

Puberty in boys begins at a mean age of 11.4 ± 1.1 years with an increase in the secretion of LH and FSH by the gonadotroph cells of the pituitary, presumably stimulated by an increase in GnRH secretion by the hypothalamus. The initial consequence is an increase in testicular length, from 2 cm to, eventually, 4 to 7 cm. The increase in LH stimulates an increase in testosterone secretion; causes an increase in the size of the phallus; growth of pubic, axillary, and, eventually, body and facial hair; and regression of temporal scalp hair. Testosterone also causes an increase in long-bone growth and height, thickening of the vocal cords and lowering of the voice, and increase in hemoglobin concentration. Most of these changes are completed within 4 to 5 years, but full development of body hair and beard may take several more years, and temporal scalp hair regression continues for decades.

Senescence

As men age, their serum total testosterone concentration decreases and their estradiol increases, increasing their SHBG. The consequence is that their free-testosterone concentration decreases to a greater degree than the total, so that by age 80 years the free testosterone is one-half to one-third of that at age 20 years (Fig. 410.2). The cause appears to be both decreased LH secretion and decreased responsiveness of the Leydig cells. These changes, unlike the female menopause, occur very slowly. What is uncertain is whether the decrease in testosterone causes any deleterious effects. Because some of the changes that occur in the male senescence are similar to those that occur in male hypogonadism, such as decreases in libido, energy, muscle mass and strength, and bone mineral density, testosterone deficiency could be a cause of these changes during the male senescence.

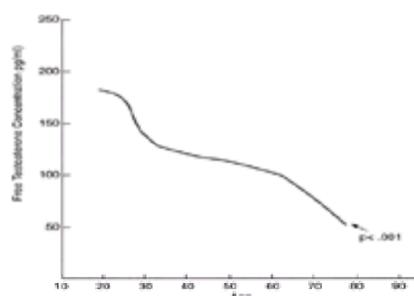

FIGURE 410.2. Serum free testosterone concentrations throughout adult life. (Adapted from Purifoy FE, Koopmans LH, Mayes DM. Age differences in serum androgen levels in normal adult males. *Hum Bio.* 1981;53:499–511.)

MALE HYPOGONADISM

DEFINITION

Abnormalities of reproductive function in a genetic male can occur as a consequence of diseases of the testes, called primary hypogonadism, or of the pituitary or hypothalamus, called secondary hypogonadism. The physician suspects the diagnosis of hypogonadism on the basis of certain symptoms and signs and confirms it by laboratory tests. Treatment of testosterone deficiency is usually satisfactory whether the hypogonadism is primary or secondary, but treatment of spermatogenesis is satisfactory only if the hypogonadism is secondary.

CLINICAL FINDINGS

The clinical features of hypogonadism depend on whether spermatogenesis alone is impaired or testosterone secretion is also impaired. The one clinical feature of decreased spermatogenesis is infertility. In contrast, the clinical features of testosterone deficiency vary widely, depending on when the deficiency is manifested (Table 410.1). When testosterone deficiency is manifested in the first trimester in utero, male sexual differentiation is incomplete. Complete lack of testosterone during this period results in female external genitalia (clitoris and labia). Incomplete testosterone deficiency causes partial virilization, from posterior labial fusion when testosterone deficiency is severe to hypospadias when testosterone deficiency is mild. When testosterone deficiency is not manifested until the third trimester in utero, the result is normal male sexual differentiation but microphallus at birth. When testosterone deficiency is manifested before the anticipated onset of puberty, the result is incomplete puberty.

Age	Effects of Testosterone Deficiency
First trimester in utero	Incomplete virilization of external genitalia; incomplete development of wolffian ducts and therefore of male internal genitalia
Third trimester in utero	Micropenis
Prepubertal	Incomplete pubertal maturation
Postpubertal	Decrease in energy, mood, and libido; decrease in hemoglobin and hematocrit; decrease in muscle mass, strength, and bone mineral density

TABLE 410.1. EFFECTS OF TESTOSTERONE DEFICIENCY BY AGE

When testosterone deficiency does not occur until after puberty, some pubertal changes regress, but even of those that do, most do so slowly. Although decreases in energy and libido can be recognized within days to weeks of the decrease in testosterone and a decrease in hemoglobin and hematocrit within a few months, decreases in sexual hair, muscle mass, and bone mineral density are usually not recognized for several years.

PHYSICAL EXAMINATION

Physical examination focuses primarily on whether sexual development is consistent with the patient's age. If the patient is an adult, the testes should be 4 to 7 cm in

length (20 to 25 mL in volume), musculature should be normal for a man, pubic hair should be dense and in a diamond pattern, chest and other body hair should be present, and temporal scalp hair should be receding appropriately for the patient's age and family pattern. If the patient is an adolescent, development should be appropriate for his age. If a child, the testes should be descended and no hypospadias present.

Physical examination should also include evaluation of the possibility of eunuchoid proportions and gynecomastia. An adult male usually has an upper body segment approximately equal to his lower segment and an arm span equal to his height. The absence of testosterone and the continued presence of growth hormone during puberty causes a delay in epiphysial closure and increased length of the long bones, so that the lower body segment is longer than the upper and the arms are longer than the legs, a relationship known as eunuchoid proportions. This relationship persists even after testosterone treatment, so when an adult of any age has a heel-to-pubis measurement more than 2 cm longer than his pubis-to-crown measurement and when his arm span is more than 2 cm longer than his height, he was probably hypogonadal during adolescence. Gynecomastia, the presence of glandular breast tissue in a man, may occur as a consequence of many abnormalities (see [Chapter 395](#)), one of which is hypogonadism, especially primary hypogonadism.

LABORATORY FINDINGS

Although hypogonadism can be suspected on the basis of symptoms, and strongly suspected on the basis of signs, the diagnosis can be confirmed only by documenting decreased production of sperm or testosterone. If hypogonadism is confirmed, supranormal serum concentrations of LH or FSH indicate primary hypogonadism, and "inappropriately normal" or subnormal values indicate secondary hypogonadism.

Spermatogenesis

Sperm production can be assessed most readily by counting how many sperm are present in an ejaculated semen specimen. Normal men produce at least 20×10^6 sperm per milliliter of ejaculate and at least 40×10^6 sperm per ejaculation. More than 60% of the sperm in a fertile man are motile. A severely subnormal sperm count (e.g., less than 5×10^6 sperm per specimen) can occur as a consequence of either primary or secondary hypogonadism. A normal or mildly subnormal sperm count (e.g., 35×10^6 sperm per specimen) associated with a markedly abnormal sperm motility is most likely the result of a primary spermatogenic abnormality and almost certainly not a result of secondary hypogonadism.

Testicular biopsy can also provide information about the status of the seminiferous tubules, but usually no more than number and motility of ejaculated sperm because the variety of histologic responses of the testes to injury is limited. The one situation in which testicular biopsy may be helpful is when there are no sperm in the ejaculated semen but testicular size and the serum concentrations of testosterone, LH, and FSH are normal. This situation could occur as a consequence of obstruction of the ejaculatory outflow or of damage to the seminiferous tubules sufficient to impair spermatogenesis but not sufficient to elevate the serum FSH concentration. A testicular biopsy showing normal seminiferous tubules would favor the former diagnosis and suggest that the next step in diagnosis be evaluation of the patency of the ejaculatory outflow.

Testosterone Concentration

Testosterone secretion is most readily evaluated by measuring the serum concentration of total testosterone because the total testosterone usually reflects accurately the free testosterone and because current assay techniques for free testosterone are usually not as accurate as those for total testosterone. Measurement of free testosterone and SHBG may be helpful in situations where the total testosterone does not accurately reflect the free testosterone, such as obesity.

Gonadotropins

If the testosterone concentration is subnormal, the finding that the serum LH and FSH concentrations are supranormal indicates that the patient has primary hypogonadism, and the finding that they are not supranormal indicates that he has secondary hypogonadism. If the sperm count is distinctly subnormal but the serum testosterone is normal, a supranormal FSH and normal LH indicates that there has been damage to the seminiferous tubules but that the Leydig cells have not been affected. If the hypogonadism is secondary, magnetic resonance imaging of the sellar region will show if the cause is a mass lesion and, if so, whether it is in the pituitary or hypothalamus, or is a parasellar lesion. Measuring the LH responses to a single dose of exogenous GnRH, however, does not distinguish between a pituitary and a hypothalamic lesion. The reason for this is that a normal LH response to GnRH depends on normal up-regulation of GnRH receptors on the gonadotroph cells, which in turn requires the episodic exposure of the cells to GnRH. Severe hypothalamic disease leads to diminished GnRH secretion and therefore to down-regulation of GnRH receptors, so that there is a poor LH response to a single-bolus dose of exogenous GnRH, just as occurs in severe pituitary disease. Repeated administration of exogenous GnRH for many days leads to a normal LH response to a single-bolus dose of GnRH in patients who have hypothalamic disease, but not in patients who have pituitary disease.

DISEASES THAT CAUSE HYPOGONADISM

Once a patient's hypogonadism has been identified as primary or secondary, the specific cause can be sought.

Primary Hypogonadism

Taken together, the causes of primary hypogonadism ([Table 410.2](#)) are more common than those of secondary hypogonadism ([Table 410.3](#)). Of the congenital abnormalities that cause primary hypogonadism, the most common is Klinefelter's syndrome, which occurs in approximately 0.2% of newborns. It is the phenotypic presentation of a male with an extra X chromosome. The most common genotype is 47, XXY, but additional X chromosomes (e.g., 48, XXXY) and mosaics (e.g., 46,XY/47,XXY) have also been reported. The 47,XXY genotype occurs from the nondisjunction of the sex chromosomes of either parent during meiotic division. Mosaicism probably results from nondisjunctive mitotic division after conception. The phenotypic consequences usually are more severe the greater the number of extra X chromosomes. The gonadal consequence is usually severe damage to the seminiferous tubules and variable damage, from minimal to severe, to the Leydig cells. Individuals who have this syndrome therefore usually have very small testes, no sperm in the ejaculate, infertility, and markedly high serum FSH concentrations. Their serum testosterone concentrations vary from normal to subnormal, so that their virilization varies from normal to subnormal and their serum LH from normal to supranormal. Persons with this condition also usually exhibit behavioral and long-bone abnormalities not directly related to the gonadal abnormalities. The behavioral abnormality causes difficulty in social interactions that are recognized in childhood and leads to problems in school and eventually in work. The long-bone abnormality is increased length of the legs, but not the arms, and occurs independently of increased length of both the arms and legs due to testosterone deficiency. The diagnosis can usually be made by determining the karyotype of the peripheral leukocytes. Testosterone deficiency, if present, can be treated as described later. The behavioral abnormality cannot be treated satisfactorily, but a support group can be helpful to the person's family, and school counselors should be advised of the diagnosis.

Congenital
Chromosomal abnormalities
Klinefelter's syndrome
46,XX male
Noonan's and male Turner's syndrome
Cryptorchidism
Disorders of androgen biosynthesis
Myotonic dystrophy
Acquired
Orchitis (e.g., mumps)
X irradiation
Drugs
Alkylating agents
Ketoconazole
Cyclophosphamide
Alcohol
Trauma
Torsion
Autoimmune damage
AIDS

TABLE 410.2. CAUSES OF PRIMARY HYPOGONADISM

Congenital
 Isolated gonadotropin-releasing hormone deficiency
 With anovula (Kallmann's syndrome)
 With other abnormalities (Prader-Willi, Lawrence-Moon-Biell syndrome)
 Without other abnormalities
 Mutations of *LH2* and *GNRH1* genes
 Multiple hypothalamic and pituitary hormone deficiencies

Acquired
 Benign tumors and cysts:
 Pituitary adenomas
 Craniopharyngiomas, dysembryomas, Rathke's pouch cysts
 Malignant tumors:
 Metastases from lung, breast, and other malignancies
 Adenocarcinoma, gliomas
 Lymphomas
 Infiltrative diseases (e.g., sarcoidosis, Langerhans' cell histiocytosis, hemochromatosis)
 Infectious diseases (e.g., tuberculosis, histoplasmosis)
 Infections of the pituitary (e.g., Sheehan's syndrome)
 Lymphocytic hypophysitis
 Trauma
 Surgery
 Radiation
 Aneurysm of the internal carotid artery
 Systemic illness (starvation, anorexia, acute and chronic illness)
 Medications (glucocorticoids, megestrol acetate, suramin)
 Drugs (opioids)
 Hypogonadotropic hypogonadism
 Isolated acquired gonadotropin-releasing hormone deficiency
 Delayed puberty (hypogonadism)

TABLE 410.3. CAUSES OF SECONDARY HYPOGONADISM

Cryptorchidism, or undescended testes, is also associated with damage to the testes, as well as with greater damage to the seminiferous tubules than to the Leydig cells. More than one mechanism may cause the damage; damage or testosterone deficiency in utero may cause the lack of descent, and the heat of the abdomen may cause further damage to the testis that has not descended. Some clinical consequences depend on whether one or both testes are undescended. If only one, the chances are 25% to 33% that the sperm count will be subnormal and the serum FSH slightly high. If both, the sperm count is likely to be severely subnormal and the patient infertile, and he may have a subnormal serum testosterone and be undervirilized as well. A neoplasm is also 50 times more likely to develop in cryptorchid testes. The diagnosis is made by failing to palpate a testis that is within the scrotum or that can be manipulated manually from the inguinal canal into the scrotum by 1 year of age. The initial treatment is administration of small doses of human chorionic gonadotropin or a GnRH agonist, based on the rationale that descent depends on testosterone. If this treatment is unsuccessful, the next step is orchiopexy (surgically bringing the testis into the scrotum and attaching it there). This procedure is performed before the age of 2 years in an attempt to minimize testicular damage, although there is little evidence that early surgery reduces the amount of testicular damage or the risk of testicular neoplasm. Securing the testis within the scrotum allows it to be palpated more readily.

The possibility that a varicocele, which is a varicosity of the venous plexus within the scrotum, can cause damage to the seminiferous tubules has been considered for decades, and varicoceles of infertile men are often ligated in an attempt to improve their fertility. The proposed mechanism by which a varicocele causes infertility is increased blood flow, which in turn causes a higher than normal temperature in the scrotum, and the higher than normal temperature impairs spermatogenesis. However, since infertile men who do not have varicoceles have scrotal temperatures similar to those with varicoceles, and infertile men are not much more likely to have a varicocele than fertile men, it is not certain that varicocele is a cause of infertility. More important, when men who are infertile and have a varicocele are randomized to ligation and no-treatment groups, eventual fertility in the ligated group is no better than in the no-treatment group. Therefore, varicocele ligation cannot be recommended to improve fertility.

Congenital deficiency of testosterone production can also result from mutations of genes that encode enzymes necessary for androgen biosynthesis. These disorders are rare. Two of them, deficiencies of the cholesterol side-chain cleavage enzymes b-hydroxysteroid dehydrogenase and 17 α -hydroxylase, occur in the adrenal as well as in the testes, and so lead to deficient cortisol secretion as well. Deficiency of 17 β -hydroxysteroid oxidoreductase occurs only in the testes. All three disorders result in deficient testosterone secretion beginning in the first trimester in utero, resulting in incomplete virilization. The degree of incompleteness, especially of phallic development, influences the sex of rearing. The testosterone deficiency itself can be treated as testosterone deficiency of any other cause.

Many acquired illnesses also cause primary hypogonadism. One is various infections, including mumps orchitis. Mumps usually does not cause orchitis, but when it does the testes initially become markedly swollen and severely painful, followed by gradual atrophy. Diminished sperm production is common; decreased testosterone secretion is less common. Diagnosis is made by eliciting a history of painful swelling of the testes during systemic mumps infection.

Treatment of neoplasms by chemotherapeutic drugs, especially by alkylating agents or by radiation therapy to the inguinal lymph nodes, often damages the seminiferous tubules and, less often, the Leydig cells. Radiation causes damage in spite of shielding of the testes because of radiation scatter. The degree of damage is usually proportional to the extent of treatment and, in cases of less extensive treatment, the damage may be reversible. However, no specific treatment is available. Other drugs that damage the testes include alcohol, the antifungal agent ketoconazole, and the nematocide dibromochloropropane.

HIV infection and AIDS wasting are commonly associated with hypogonadism, and more than one mechanism appears to be involved. Some men who have AIDS and subnormal serum testosterone concentrations have inappropriately low serum concentrations of LH, which may be the result of concomitant illnesses and drugs, such as malnutrition, opiate use, and megestrol acetate administration, which are known to cause secondary hypogonadism. Other men with AIDS who do not have those associated illnesses have elevated serum concentrations of LH, indicating primary hypogonadism.

Trauma to the testes can sometimes be sufficiently severe as to damage them. Bilateral castration is a treatment for bilateral testicular cancer, and, unlike castration for prostatic cancer, there is no reason not to withhold testosterone treatment.

More men who have primary hypogonadism have no identifiable cause than do all of those who have one of the known causes given here. Presumably, many causes are yet unknown.

Secondary Hypogonadism

When a man has secondary hypogonadism, it is especially important to identify the cause because the cause of secondary hypogonadism, unlike that of most primary hypogonadism, often can be treated specifically (Table 410.3). Pituitary adenomas, other benign tumors and cysts of the sellar area, and malignancies that metastasize to the hypothalamus or parasellar area can usually be detected by magnetic resonance imaging. Infiltrative diseases can usually be detected by their simultaneous presence elsewhere. Tumors, cysts, and infiltrative lesions are often accompanied by deficiencies of other hypothalamic or pituitary hormones.

Secondary hypogonadism that is not associated with any other hormonal abnormalities (isolated) is probably caused by deficiency of GnRH secretion by the hypothalamus and can be either congenital or acquired. When congenital, it may or may not be an aspect of Kallmann's syndrome. Kallmann's syndrome is the association of deficient GnRH secretion with, variably, anosmia, cryptorchidism, red-green color blindness, and long-bone and urogenital tract abnormalities. It may occur sporadically or in families, and when familial can be inherited in an autosomal dominant pattern with expression mostly limited to males, or in an X-linked recessive pattern. The genetic defect responsible both for the deficiency in GnRH secretion and for anosmia in some patients who have the X-linked recessive form of Kallmann's syndrome is a mutation in the *KAL-1* gene, which encodes the neural cell adhesion protein anosmin. Without this protein during embryogenesis, GnRH-secreting neurons do not migrate from the olfactory placode to the olfactory bulb and then to the hypothalamus, resulting in both anosmia and hypogonadotropic hypogonadism. Other causes of a congenital inability to secrete LH include a mutation of the *LHb* gene and a mutation of the *DAX-1* gene.

Any systemic illness or hyperprolactinemia inhibits gonadotropin secretion, but reversibly. The effect of medications and drugs, such as glucocorticoids, suramin, and opiates, is also reversible. Damage to the pituitary from surgery or radiation, in contrast, is usually permanent.

Delayed puberty differs from all other causes of secondary hypogonadism in that it is always transient. The difficulty in making the diagnosis is in knowing when an adolescent male whose pubertal development is delayed more than 2 standard deviations from the mean has one of the previously mentioned diseases or merely a delay in the onset of puberty that will eventually correct itself spontaneously. The degree of hypogonadism is usually not helpful in making this distinction, nor is any biochemical test. A family history of delayed puberty or constitutional short stature increases the chance of delayed puberty. The finding of anosmia, symptoms of a chiasmal lesion, or other indications of a specific hypothalamic or pituitary disease increases the chance of an organic lesion.

Subnormal serum testosterone concentration due to no recognizable cause other than aging can be considered another form of secondary hypogonadism, and administration of testosterone to elderly men who have subnormal serum testosterone concentrations may increase their bone mineral density and lean body mass. Whether or not this treatment will increase their risk of prostate disease, however, has not yet been determined.

OPTIMAL MANAGEMENT

Testosterone Replacement

Testosterone can be replaced whether the hypogonadism is primary or secondary. Testosterone itself cannot be readily replaced orally because after it is absorbed into the portal circulation it is rapidly catabolized during its first pass through the liver. Several derivatives of testosterone that are alkylated in the 17a position were introduced several decades ago to obviate such rapid hepatic catabolism, and they do, but they appear to lack the full virilizing effect of testosterone. In addition, they may cause hepatic toxicity, including cholestatic jaundice, a cystic condition of the liver called peliosis, and, possibly, hepatocellular carcinoma. For all of these reasons, and because the other preparations described below are preferable, the 17a alkylated androgens rarely should be used to treat testosterone deficiency.

Long-acting esters of testosterone, enanthate, or cypionate, produced by esterifying the hydroxyl group in the 17b position with a fatty acid, have also been available for decades. These produce full virilization. They are usually administered in 150- to 200-mg doses by deep intramuscular injection every 2 weeks. This regimen results in peak serum testosterone values within a day or two after the injection and fall to a nadir just before the next injection (Fig. 410.3). These fluctuations are noted by some patients as fluctuations in energy, mood, and libido.

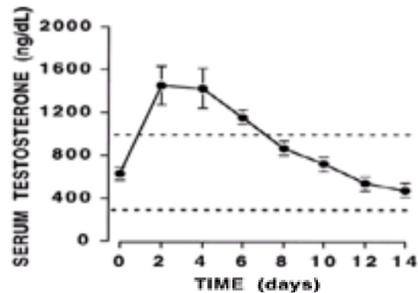

FIGURE 410.3. Serum testosterone concentrations during the 14 days following an injection of a 200-mg dose of testosterone enanthate to hypogonadal men. The serum testosterone concentration was highest just after the injection and lowest just before the next injection. The dashed lines represent the range of normal. (Adapted from Snyder PJ, Lawrence DA. Treatment of male hypogonadism with testosterone enanthate. *J Clin Endocrinol Metab* 1980;51:1335–1339.)

A new way of replacing testosterone is by transdermal means, using patches, gels, or creams that contain testosterone. These preparations usually produce serum testosterone concentrations that are within the normal range in most hypogonadal men and that fluctuate no more than is physiologically normal (Fig. 410.4). These relatively stable serum testosterone concentrations result in relative stability of energy, mood, and libido.

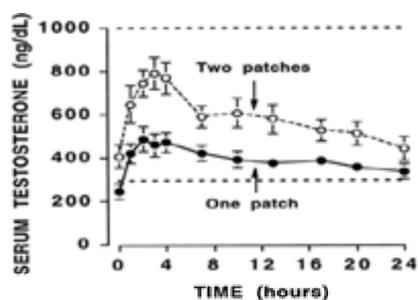

FIGURE 410.4. Serum testosterone concentrations during a 24-hour period in hypogonadal men treated with testosterone transdermally. One or two testosterone patches increased the mean serum testosterone concentration to within the normal range, which is indicated by the dashed lines. (Adapted from Yu Z, Gupta SK, Hwang SS, et al. Testosterone pharmacokinetics after application of an investigational transdermal system in hypogonadal men. *J Clin Pharmacol* 1997;37:1139–1145.)

Men who are being treated with testosterone should be monitored for efficacy and side effects. Efficacy should be monitored by measurement of the serum testosterone concentration, which should be midnormal midway between injections of testosterone esters or at any time after application of a transdermal preparation. Men who are older than 40 years should be monitored for testosterone-dependent diseases, such as prostate cancer, benign prostatic hyperplasia, and erythrocytosis. No evidence yet presented, however, shows that testosterone administered exogenously is more likely to exacerbate any of these conditions than is testosterone produced endogenously.

Stimulation of Spermatogenesis

When sperm production is impaired by damage to the seminiferous tubules, no treatment can improve it, although any mature sperm produced may be used for in vitro fertilization. When sperm production is subnormal due to diseases of the pituitary or hypothalamus, it can be stimulated by administration of exogenous gonadotropins if the cause is pituitary or hypothalamic disease, or by administration of gonadotropin-releasing hormone if the cause is hypothalamic disease.

ANDROGEN RESISTANCE

Not surprisingly, generalized tissue resistance to the action of androgens results in abnormalities similar to those of testosterone deficiency. Two kinds of biochemical abnormalities can prevent testosterone from having its usual effects: an abnormal androgen receptor and an abnormal 5a-reductase type 2 enzyme, so that testosterone cannot be converted to DHT. Both conditions result from genetic mutations, both are rare, and both result in incomplete virilization of the external genitalia.

Many different mutations of the androgen receptor gene have been described, and most are limited to a single family. These mutations lead to several kinds of abnormalities in the androgen receptor. Some of the receptor abnormalities result in absent or subnormal binding of androgen to the receptor and others in lack of binding of the androgen–receptor complex to DNA. The clinical presentations of the different receptor abnormalities also vary but do not correlate with the receptor abnormality. In the most severe clinical presentation, called complete testicular feminization, the affected person is born with testes in the inguinal canals, no internal genitalia, and female external genitalia. At puberty the serum testosterone concentration increases to high-normal or slightly higher than normal, but sexual hair does not develop because of the absence of functional androgen receptors. Breasts develop because testosterone can still be converted to estradiol. In the next most severe form of the disorder—incomplete testicular feminization—there is partial fusion of the posterior labial folds, but the genitalia are still more female than male; in Reifenstein's syndrome, a greater degree of labial fusion occurs, so that the genitalia are more appropriately called incompletely male. The least severe form of androgen resistance is manifested only by infertility and, perhaps, gynecomastia. Serum testosterone and LH concentrations are high-normal to slightly high in all of these forms of androgen resistance.

Many different mutations of the 5a-reductase type 2 gene also lead to incomplete virilization of the external genitalia because virilization requires conversion of testosterone to DHT. At birth, the external genitalia are usually predominantly female, so that the sex of rearing is usually female. At puberty, the serum testosterone

concentration increases and overcomes to some degree the lack of DHT by binding to the androgen receptor to cause phallic enlargement and development of sexual hair in an adult male pattern. If the sex of rearing is female, the testes should be removed before the anticipated age of puberty to prevent these events. Subsequently, estradiol should be administered.

CHAPTER 411: DIABETES MELLITUS, TYPES I AND II

JAY S. SKYLER

- [Classification and Diagnosis](#)
- [Pathophysiology of Hyperglycemia](#)
- [Type I Diabetes](#)
- [Type II Diabetes](#)
- [Acute Complications](#)
- [Chronic Complications](#)
- [Other Complications](#)
- [Perspective](#)

Diabetes mellitus is a chronic metabolic syndrome. The metabolic dysregulation is a consequence of relative or absolute deficiency of insulin. Diabetes mellitus is recognized when there are elevated levels of plasma glucose (hyperglycemia) and is monitored by means of measurement of variations in glycemia. The metabolic dysregulation is pervasive, involving deranged metabolism of carbohydrates, fats, and proteins. As a function of time and the metabolic disruption, many patients with diabetes have chronic complications of the disease, including accelerated vascular disease, neurologic deficits, and other organ-specific, particularly retinal and renal, degenerative disorders.

Diabetes mellitus is an important public health problem. Worldwide, more than 120 million persons have diabetes. One in every 20 Americans has diabetes—an estimated 15.7 million persons. Five million of these cases of diabetes are undiagnosed. Approximately 10% of the population has either an impaired fasting glucose or an impaired glucose tolerance state, in which glucose homeostasis is disrupted. These conditions often are harbingers of the overt clinical syndrome of diabetes. Diabetes, with its complications, is the seventh leading cause of death of disease in the United States. Persons with diabetes are two to four times more likely to have coronary and cerebral vascular disease than the general population. In the United States, the economic burden of diabetes in 1995 was estimated at \$92 billion in direct health care costs and \$138 billion in combined direct and indirect costs.

CLASSIFICATION AND DIAGNOSIS

CLASSIFICATION

Diabetes mellitus is a heterogeneous syndrome. The primary manifestation, hyperglycemia, can have from various causes. The currently used classification of diabetes was revised by an expert committee of the American Diabetes Association (ADA) and a World Health Organization (WHO) consultation group ([Table 411.1](#)). It divides primary diabetes mellitus into two major categories. These are type I diabetes mellitus, which accounts for 5% to 10% of cases of diabetes in the United States, and type II diabetes mellitus, which accounts for 90% to 95% of cases of diabetes in the United States. These two main clinical patterns of the diabetic syndrome are distinct in terms of etiology, pathogenesis, clinical presentation, and treatment.

Category	Sub-category	Specific Etiology		
Type I Diabetes Mellitus	Immune-mediated	Autoimmune		
		Idiopathic		
	Other	Genetic		
		Infectious		
		Drugs		
		Endocrine		
		Neurological		
		Other		
		Type II Diabetes Mellitus	Obese	Insulin resistance
				Insulin deficiency
Non-obese	Genetic			
	Infectious			
	Drugs			
	Endocrine			
	Neurological			
	Other			

TABLE 411.1. ETIOLOGIC CLASSIFICATION OF DIABETES MELLITUS

Type I diabetes is characterized by immune-mediated pancreatic islet b-cell destruction, absolute insulin deficiency, and dependence on insulin therapy for the preservation of life. The previous term *insulin-dependent diabetes* denoted the dependence on daily insulin administration for survival. Because of absolute insulinopenia, patients with type I diabetes are prone to ketosis and possibly ketoacidosis even under basal conditions. In the past the disease had been called *ketosis-prone diabetes*. In most cases of type I diabetes the b-cell destruction is caused by an immune attack and thus is called *immune-mediated type I diabetes*. This form of type I diabetes is most common among Europeans. However, a minority of patients with type I diabetes, particularly those of other than European ancestry, have no evidence of autoimmunity, and the disease is classified as *idiopathic type I diabetes*. This includes a variant that occurs most often among young blacks, labeled *atypical diabetes*, in which there are some features of both type I and type II diabetes and fluctuation in b-cell function.

The onset of type I diabetes usually is in the first two decades of life. The peak incidence is between 10 and 13 years of age (hence the previous name *juvenile-onset diabetes*) but may occur at any age. A slowly evolving variant of type I diabetes is called *latent autoimmune diabetes among adults*.

Type II diabetes is the common form of diabetes caused by defects in insulin secretion, almost always with a major contribution from insulin resistance. One subclassification divides this entity into obese and nonobese subtypes. Most patients (80% to 90% in the United States) are obese. The characteristics of type II diabetes are altered insulin secretory dynamics but retention of endogenous pancreatic insulin secretion; absence of ketosis (the disease therefore in the past has been called *ketosis-resistant diabetes*); and insulin resistance caused by diminished target cell action of insulin. Patients with type II diabetes usually are not dependent on insulin for prevention of ketosis or maintenance of life (hence the previous term *non-insulin-dependent diabetes*), but insulin may be necessary to control symptoms or correct disordered metabolism. Temporary insulin therapy can be used to re-regulate glycemic control. Type II diabetes usually begins after the age of 40 years (hence the previous name *maturity-onset diabetes*), and the frequency increases with aging, although the disease is increasingly making its appearance in adolescence and early adulthood, especially among obese sedentary persons at high genetic risk.

A number of other specific types of diabetes are caused by genetic defects in insulin secretion or insulin action. The best characterized of these are a group of mutations in which diabetes is caused by monogenetic defects in b-cell function. These familial autosomal dominant forms of diabetes frequently are characterized by onset of mild hyperglycemia at an early age (generally before 25 years) and were previously called *maturity-onset diabetes of the young*. These forms of diabetes are characterized by impaired insulin secretion with minimal or no defects in insulin action. Abnormalities at several genetic loci on different chromosomes have been identified, including mutations on chromosome 12 in a hepatic transcription factor (HNF-1a) gene region, mutations on chromosome 7p in the glucokinase gene, and mutations on chromosome 20q in a hepatic transcription factor (HNF-4a) gene region.

Gestational diabetes mellitus (GDM) begins or is first recognized during pregnancy, although it is possible that glucose intolerance may antedate the pregnancy but have been previously unrecognized. Almost all women with GDM have normal glucose tolerance after parturition but are at markedly increased risk of future diabetes. Women with known diabetes who become pregnant do not have GDM.

Secondary diabetes mellitus refers to hyperglycemia caused by another condition, such as pancreatic surgery, chronic pancreatitis, chronic liver disease, or various forms of endocrinopathy, such as Cushing's syndrome, acromegaly, pheochromocytoma, or aldosteronism, or by medication use, such as chronic glucocorticoid therapy. Diabetes mellitus also is associated with a number of relatively uncommon genetic conditions.

Impaired fasting glucose (IFG) and *impaired glucose tolerance* (IGT) refer to abnormalities in glucose homeostasis with glucose values intermediate between normal and overt diabetes. Persons with these conditions are at increased risk of overt diabetes and of coronary artery disease. Results of serial testing may show worsening

to diabetes, improvement toward normal, or no change.

Metabolic syndrome (insulin resistance syndrome, deadly quartet) is a precursor of diabetes that confers increased risk of coronary disease and atherosclerosis. The components are as follows: impaired glucose regulation or diabetes; insulin resistance (under hyperinsulinemic euglycemic conditions, glucose uptake below lowest quartile for background population under investigation); high arterial pressure (more than 140/90 mm Hg); dyslipidemia (plasma triglyceride level more than 150 mg per deciliter or high-density lipoprotein cholesterol level less than 35 mg per deciliter for men, less than 39 mg per deciliter for women); central obesity (more than 120% ideal body weight, body mass index [mass in kilograms divided by square of height in meters] greater than 30, or waist to hip ratio more than 0.90 for men or more than 0.85 for women); and microalbuminuria (urinary albumin excretion rate more than 20 µg per minute). Although there is no international standard for the definition of *metabolic syndrome*, WHO suggests as a working definition, which does not imply causal relations, the following: glucose intolerance (IGT, IFG, or diabetes mellitus) or insulin resistance, or both, with two or more of the other components.

DIAGNOSTIC CRITERIA

Diabetes mellitus is recognized on the basis of elevated plasma glucose levels. The criteria for diagnosis of diabetes are as follows:

- Unequivocal symptoms (polyuria, polydipsia, polyphagia, unexplained weight loss) *and* casual (any time of day without regard to time since last meal) plasma glucose levels of 200 mg per deciliter or more; *or*
- Fasting (no caloric intake for at least 8 hours) plasma glucose (FPG) level 126 mg per deciliter or more; *or*
- Two-hour plasma glucose level 200 mg per deciliter or more during an oral glucose tolerance test (OGTT; ingestion of 75 g glucose)

In the absence of unequivocal hyperglycemia with acute metabolic decompensation, such as ketoacidosis, these criteria should be confirmed through repetition of the test on a different day. The preparation and procedure for an OGTT are summarized in [Table 411.2](#).

Preparation
If the patient has not consumed sufficient dietary carbohydrate before the test, the insulin secretory response to the oral glucose stimulus may not be as great as it should be, and the test results may be unreliable. Therefore the patient must consume a high-carbohydrate diet for a minimum of 3 full days before testing. The requirements are as follows:
• High-carbohydrate (> 150 g) diet for at least 3 days before the test
• 10–16 hour fast
• 10 hour abstinence from coffee, tea, caffeine-containing drinks, cigarettes, alcohol, vigorous exercise
• Water consumption
The patient should remain seated during the test. The test is started the morning after a night's sleep (9:00–10:00 a.m.). Patients may not work the night before the test. The test should be postponed at least 1 week after any intercurrent infectious illness or other stress.
Procedure
Oral glucose is administered to adults in a dose of 1.75 g/kg body weight to a maximum of 75 g and to children as a solution in a concentration no greater than 35 g/dL of flavored water consumed within 5 min. A fasting baseline blood sample is obtained before glucose is consumed (0 min). Blood samples are obtained 30, 60, 90, and 120 minutes after glucose consumption for measurement of plasma glucose.

TABLE 411.2. ORAL GLUCOSE TOLERANCE TEST

Persons with IFG and IGT are recognized as intermediate groups in whom glucose levels, although not meeting criteria for diabetes, are too high to be considered normal. IFG is defined as FPG levels more than 110 mg per deciliter but less than 126 mg per deciliter. IGT is defined as 2-hour OGTT values greater than 140 mg per deciliter but less than 200 mg per deciliter during an OGTT involving ingestion of 75 g glucose.

Because 35% to 40% of cases of type II diabetes are undiagnosed, screening is an important public health measure. Testing for diabetes among persons without symptoms is recommended by the ADA for everyone older than 45 years. If FPG level is normal, the test should be repeated within 3 years. FPG testing at a younger age and more frequently and follow-up OGTT testing should be considered by persons who have any risk factors of diabetes. These factors are IFG or IGT; parents or siblings with diabetes; obesity (more than 120% ideal body weight or body mass index of 27); high-risk ethnicity (African American, Hispanic, Native American); hypertension (blood pressure 140/90 mm Hg or more); dyslipidemia (plasma triglyceride level more than 150 mg per deciliter or high-density lipoprotein cholesterol level less than 35 mg per deciliter for men, less than 39 mg per deciliter for women); and for women, a history of GDM or giving birth to an infant weighing more than 9 pounds (4 kg).

Because GDM endangers the fetus, it is recommended that all or most pregnant women undergo screening for abnormal glucose levels at approximately 26 to 28 weeks' gestation. The ADA recommends starting with a screening test to measure plasma glucose 1 hour after consumption of 50 g glucose. Values of at least 140 mg per deciliter on the screening test warrant a full OGTT. The ADA still advises use of the 100-g OGTT during pregnancy and interprets the results according to the O'Sullivan criteria (pregnancy protocol and interpretation; [Table 411.3](#)). The WHO criteria are the same as those for nonpregnant adults.

Procedure
Oral glucose is administered in a dose of 100 g (adults). A fasting baseline blood sample is obtained before glucose is consumed (0 min). Blood samples are obtained 60, 120, and 180 min after glucose consumption for measurement of plasma glucose.
Interpretation
Gestational diabetes mellitus is diagnosed if two or more values equal or exceed the following:

Time	Glucose
Fasting	105 mg/dL (5.8 mmol/L)
1 h	190 mg/dL (10.6 mmol/L)
2 h	165 mg/dL (9.2 mmol/L)
3 h	145 mg/dL (8.1 mmol/L)

TABLE 411.3. DIAGNOSTIC CRITERIA: GESTATIONAL DIABETES MELLITUS

PATHOPHYSIOLOGY OF HYPERGLYCEMIA

Insulin is a protein hormone of approximately 5,800 kd synthesized in the b-cells of the pancreatic islets. The insulin molecule consists of two peptide chains, a 21-amino-acid A chain connected by two disulfide bridges to a 30-amino-acid B chain. There also is a third disulfide bond within the A chain. Insulin is produced from proinsulin, a high-molecular-weight, single-chain precursor molecule, in which the A and B chains are linked by an additional 31-amino acid sequence, C-peptide. Proinsulin is packaged into secretory granules, where specific peptidases cleave it into insulin and C-peptide. These are released into the circulation concomitantly when the secretory granules liberate their contents, a process known as *exocytosis*.

Glucose is the primary physiologic stimulus for insulin secretion. Asynchronous biphasic secretion of insulin occurs after a glycemic challenge ([Fig. 411.1](#)). The first phase of insulin secretion is from a pool that can be rapidly mobilized. Second-phase release is from a larger compartment that is replenished by newly synthesized insulin if the stimulus is prolonged. Other factors that influence insulin secretion include gastrointestinal hormones, protein ingestion, and neural control mechanisms. The important physiologic event is that in response to nutrient ingestion there is substrate-mediated (particularly glucose-mediated) insulin secretion. Insulin secretion is timely, occurring in concert with glycemic challenge, and decreases abruptly as glycemia diminishes and the signal abates ([Fig. 411.2](#)). Nevertheless, in the absence of substrate stimulation, insulin secretion is not absent but continues at a low basal rate (basal insulin secretion) that is crucial in modulating intermediary metabolism, particularly in maintaining hepatic glucose production equivalent to non-insulin-mediated basal glucose utilization, principally in the brain and nervous system.

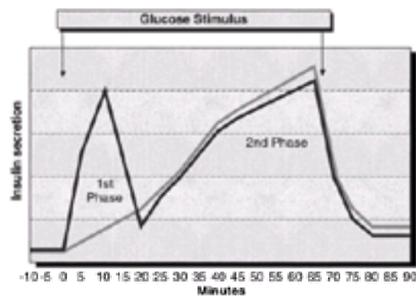

FIGURE 411.1. Insulin secretory response to intravenous glucose. *Dark line*, normal biphasic response. *Light line*, response typical of both type II diabetes and evolving type I diabetes during the prediabetic phase.

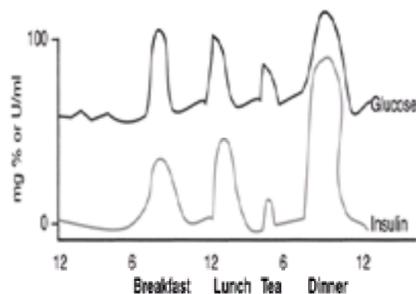

FIGURE 411.2. Schematic representation of 24-hour plasma glucose and insulin profiles of a hypothetical person without diabetes.

Circulating insulin concentration is the primary regulator of fuel metabolism. It coordinates the mobilization of fuel into and out of the various fuel storage depots to meet the needs of the organism depending on the availability or lack of fuel in the environment. The net effect of insulin action is facilitation of utilization and storage of substrates. Decrements in insulin secretion allow mobilization of depot substrate at precisely the rate needed by the body. Such precision is modulated in part by continued basal insulin secretion, which dampens the rate of substrate mobilization. In addition, several hormones have biologic effects directly or indirectly antagonistic to the effects of insulin. These are the so-called glucose counterregulatory hormones, including glucagon, catecholamines (epinephrine and norepinephrine), growth hormone, and cortisol. Collectively these hormones counteract the effects of insulin, prevent hypoglycemia, and maintain adequate substrate availability in the fasted state.

In the diabetic state, the normal adaptations to fasting are amplified. Relative or absolute insulin deficiency leads to aberrations in fuel metabolism during periods of eating and of fasting. With milder degrees of insulin deficiency, the abnormalities may be manifest only during the fed state, when plasma insulin levels are normally high. With more severe degrees of insulin deficiency, the normal effects of insulin in the fasted state (modulation of hepatic glucose production and inhibition of catabolism) are impaired and the metabolic derangement is more severe.

TYPE I DIABETES

PATHOGENESIS

The pathogenesis of type I diabetes involves, first, a genetic predisposition, conferred principally by “diabetogenic” genes in the major histocompatibility complex (MHC) on the short arm of chromosome 6, although multiple other genetic loci modulate disease risk; second, nongenetic (environmental) factors that appear to act as triggers in genetically susceptible persons; and third, activation of immune mechanisms targeted against pancreatic islet b-cells. The initial immune response appears to engender secondary and tertiary immune responses, which collectively cause progressive destruction of pancreatic islet b-cells and consequent development of type I diabetes. The insidious process of immune-mediated destruction of the pancreatic islet insulin-secreting b-cells may precede the overt expression of clinical symptoms by many years, because these effects become apparent only when most of the b-cells have been destroyed ([Fig. 411.3](#)).

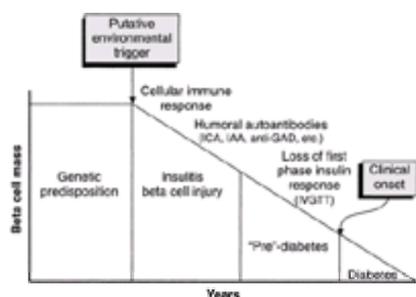

FIGURE 411.3. Schematic representation of the slow, progressive loss of b-cell mass during the development of type I diabetes. The process is divided into four phases: genetic predisposition, b-cell injury (insulinitis), prediabetes, and overt diabetes. Accompanying features include an anti-b-cell cellular immune response, the appearance of humoral markers (antibodies), and loss of first-phase insulin response. *GAD*, glutamic acid decarboxylase; *IAA*, insulin autoantibodies; *ICA*, islet cell antibodies; *IVGTT*, intravenous glucose tolerance test.

Genetics

The familial predisposition to type I diabetes has long been known. A specific mode of genetic transmission has not been established. There is a higher concordance rate for type I diabetes between monozygotic twins (35% to 50%) than between dizygotic twins (5% to 10%). The empirical risk of type I diabetes is higher among first-degree relatives of probands with the disease. Among whites in the United States, the overall risk is 0.2% to 0.4%. However, among siblings of probands with type I diabetes, the risk is about 5%. Offspring of diabetic parents have a 3% risk if the mother has the disease and 6% risk if the father has the disease.

About 40% to 50% of the genetic predisposition to type I diabetes is conferred by genes on the short arm of chromosome 6, either within or close to the class II human leukocyte antigen (HLA) region of the MHC. It has been suggested that at least a dozen other loci are involved, the largest contribution (about 10% of the genetic predisposition) accounted for by the flanking region of the insulin gene on chromosome 11.

The relation between type I diabetes and specific HLA region alleles is complex. There is a strong positive relation with HLA-DR3 and HLA-DR4 and a strong negative relation with HLA-DR2. More than 90% of whites with type I diabetes are HLA-DR3 or HLA-DR4. There is an even stronger relation with type I diabetes when DQ loci

(DQa and DQb) are considered with DR loci. That is, the predisposition to type I diabetes among whites is associated with HLA-DR3, DQB1* 0201 and with HLA-DR4, DQB1*0302, the strongest association being the DQaDQb combination DQA1*0501–DQB1*0302. Other DQ alleles appear to confer protection from type I diabetes; for example, DQA1*0201–DQB1*0602 provides protection even in the presence of DQ susceptibility alleles. This suggests that protection is dominant over susceptibility. Because class II MHC genes regulate the immune response, the susceptibility and protective alleles could be involved differentially in antigen presentation of peptides that establish and maintain tolerance or influence the immune response.

Environmental Factors

The role of environmental factors in type I diabetes among humans is uncertain. It has been argued that the substantial discordance between identical twins mandates that environmental factors play a role. However, the potential genetic diversity between such “identical” twins eliminates the need to include environmental events in the disease sequence. Yet the prevailing view is that environmental factors at least influence the probability of development of type I diabetes in a given person. One potential environmental influence is nutrition in the neonatal period and early infancy. There is a reciprocal relation between breast-feeding and frequency of type I diabetes. A Finnish study suggests that exclusive breast-feeding may reduce the likelihood of development of disease. It has been proposed that consumption of cow's milk proteins, particularly early in life, may lead to initiation of the immunologic attack against pancreatic islet b-cells and increase susceptibility to type I diabetes. Another theory is that consumption of breast milk may lead to disease protection.

Several chemical toxins can destroy b-cells, including nitrosourea compounds such as streptozotocin and the rodenticide Vacor (*N*-3-pyridimethyl-*N*-*p*-nitrophenyl urea). Results of one study suggested that maternal consumption of nitrates and nitrites around the time of conception may influence eventual development of type I diabetes. A developing embryo exposed to toxins may suffer an initial b-cell insult, enhancing the risk of diabetes, which appears years later.

Exposure to a variety of viruses may influence development of type I diabetes. A number of viral infections contracted by humans can damage b-cells in vitro. The role of viruses in disease pathogenesis is unclear. However, type I diabetes develops in 10% to 15% of children with congenital rubella. As with maternal periconceptual nitrate and nitrite consumption, exposure is remote in time from the clinical onset of diabetes. It is not clear whether this is a direct effect of the virus, whether the virus initiates an immune mechanism, or whether involvement is magnified because exposure occurs during embryonic and fetal development. Whether or not viruses initiate the disease sequence, viral infection may bring type I diabetes to clinical recognition without playing a specific role in b-cell destruction.

Environmental factors may influence the immune response through molecular mimicry. There is homology between glutamic acid decarboxylase and coxsackievirus protein P2-C; insulin and a retrovirus sequence; a 52-kd islet protein and a rubella protein; b-cell protein IA-2 and a rotavirus sequence; and the b-cell surface protein ICA-69 and a 17-amino-acid sequence of bovine serum albumin.

Immunologic Factors

Specific cell-mediated T-lymphocyte immune processes appear responsible for the destruction of b-cells, although the exact mechanisms have not yet been clearly defined. Immune activation seems to involve presentation of a diabetogenic peptide to the immune system and activation of a helper subset (T_H1) of CD_4^+ T lymphocytes. The cytokines produced by T_H1 cell activation, interleukin- $_2$ and interferon- $_g$, activate cytotoxic T lymphocytes and macrophages to kill b-cells. The killing mechanism involves oxygen free radicals, nitric oxide, destructive cytokines (interleukin- $_1$, tumor necrosis factors a and b , and interferon- $_g$), and CD_8^+ cytotoxic T lymphocytes that interact with a b-cell autoantigen–MHC class I complex. Once initial immune destruction begins, secondary and tertiary immune responses are activated, compounding interpretation of the sequence of events.

The cell-mediated immune reaction is seen as a mononuclear cell infiltration of islets (insulinitis) and is a pathognomonic lesion in pancreases examined near time of onset of type I diabetes. However, at the time of diagnosis of type I diabetes, only a few islets show the insulinitis lesion. Some normal islets and rarely a hyperplastic islet can be seen. Most islets are pseudoatrophic small islets, devoid of b-cells and without mononuclear infiltration but with intact glucagon-secreting a -cells and somatostatin-secreting d cells. It is presumed that these islets already have had their b-cells destroyed and that the immunologic attack has abated. Type I diabetes appears when enough b-cells are destroyed that glucose tolerance can no longer be maintained.

Because b-cell destruction is immunologically mediated, attempts have been made to interdict the disease by means of immune intervention in new-onset type I diabetes in an effort to preserve any residual b-cell function that may be present. Although immune intervention does alter the course of the disease, providing compelling support that immune mechanisms are important in disease pathogenesis, studies of new-onset diabetes have failed to show convincing long-term benefit. It may be that at this stage in the disease it is already too late to preserve sufficient b-cell function to be clinically important.

A number of circulating autoantibodies to islet cell markers are detected at diagnosis of type I diabetes, including cytoplasmic islet cell antibodies, antibodies directed against insulin, glutamic acid decarboxylase, b-cell protein IA-2, and a variety of others. These antibodies usually are not thought to mediate b-cell destruction through humoral mechanisms. Rather it is likely that as b-cells are destroyed, multiple antigens are exposed to the immune system and antibodies directed against these components are generated. Thus these antibodies serve as markers of immune activity or of b-cell damage and are useful in heralding the disease through the appearance of various antibodies several years before the onset of overt clinical hyperglycemia and type I diabetes. Because b-cell function is lost and total diabetes evolves, antibodies tend to decrease in titer or disappear.

Persons destined to have type I diabetes have a progressive metabolic defect measured as a decline in b-cell function detected by a decrease in early first-phase insulin release during an intravenous glucose tolerance test. Thus it is possible to predict development of type I diabetes through identification of genetic, immunologic, and metabolic markers in persons without symptoms. Screening programs are in place for identifying such individuals among relatives of persons with type I diabetes, because empiric risk of type I diabetes (about 3% to 6% among first-degree relatives) is 10- to 20-fold that in the general population (prevalence about 0.3%). This has led to a strategy aimed at prevention or delay of disease among susceptible persons by means of alteration of the pathogenetic sequence early in its course, before clinical manifestation of type I diabetes. Such intervention is contingent on effective case finding. This involves screening of persons at high risk, such as relatives of persons with type I diabetes. In the United States and Canada, the Diabetes Prevention Trial–Type 1 is designed to test whether antigen-based therapies can prevent or delay the development of clinical diabetes among such persons. As predictive models are confirmed and screening for genetic markers in the general population becomes feasible, screening and intervention studies may be expanded to society as a whole.

THERAPY

Therapy for type I diabetes is discussed in [Chapter 399](#).

TYPE II DIABETES

PATHOGENESIS

Two major pathogenetic mechanisms are operative in type II diabetes: impaired islet b-cell function (impaired insulin secretion) and impaired insulin action (insulin resistance or decreased insulin sensitivity). Although type II diabetes is a heterogeneous disorder, there is invariable impairment in insulin secretion, almost always with a major contribution from impairment in insulin action. However, different patients manifest variable degrees of insulin resistance and impairment in b-cell function. Current thinking is that separate genetic defects are responsible for each of these. In addition, environmental factors cause further insulin resistance. There is progressive decrease in insulin sensitivity with age, and insulin resistance is induced by adiposity and a sedentary lifestyle. It is not surprising that the incidence of type II diabetes increases after 40 years of age and that there is a higher prevalence among older patients, particularly those who are overweight or sedentary. Yet there are growing numbers of younger persons, even adolescents, with type II diabetes, a manifestation of the modern lifestyle characterized by low levels of physical activity and high levels of adiposity. In addition, hyperglycemia per se can further impair both b-cell function and the action of insulin, creating a vicious circle that aggravates hyperglycemia.

Impaired Islet b-Cell Function

Impairment in b-cell function is manifest in at least three ways. First, there is blunted or absent first-phase insulin response to glucose (see [Fig. 411.1](#)), so that insulin secretion is delayed and fails to restore prandial glycemic excursions in a timely manner. The first phase of the normally biphasic insulin response is the critical determinant of the magnitude of hyperglycemia after carbohydrate intake. The decrease in first-phase insulin secretion results in an overall delayed insulin secretory

response to glucose. Although variable, in most circumstances the second-phase insulin response is sufficient to restore postprandial plasma glucose excursions to basal (preprandial) levels before the next meal, albeit after a prolonged interval. Second, the sensitivity of the insulin response to glucose decreases such that hyperglycemia may not trigger an appropriate insulin response. The insulin response to glucose is attenuated so that the b-cells have a relative blindness to hyperglycemia and do not generate an adequate insulin response. The blindness is selective for glucose in that the b-cells respond to nonglucose stimuli, such as amino acids (e.g., arginine), glucagon, secretin, sulfonylureas, theophylline, and isoproterenol. Third, there is a progressive decline in overall insulin secretory capacity, particularly in severe type II diabetes. This declining insulin response is illustrated by Starling's law of the pancreas (Fig. 411.4). There is compensatory insulin release in response to increasing hyperglycemia among persons without diabetes and among patients with IGT but a decreased insulin response to increasing hyperglycemia once type II diabetes is present.

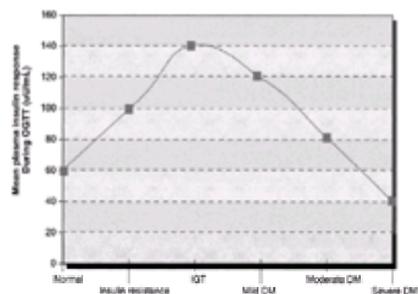

FIGURE 411.4. Mean plasma insulin response during oral glucose tolerance test (OGTT) for six groups of subjects: nondiabetic insulin-sensitive (normal), nondiabetic insulin resistant, impaired glucose tolerance (IGT), mild type II diabetes, moderate type II diabetes, and severe type II diabetes. DM, diabetes mellitus.

The impairment in insulin secretory response is not static. It is dynamic such that chronic hyperglycemia may itself aggravate the impairment in insulin secretion, so-called glucose toxicity. Thus with progressive hyperglycemia in type II diabetes, there is concomitant deterioration in insulin secretory response. Moreover, and most important, when hyperglycemia is corrected, there is some reversal of the impairment in endogenous insulin response to a meal challenge, that is, there is demonstrable improvement in insulin secretion. Attainment of glucose control therefore facilitates maintenance of glucose control.

At the cellular level, mutations in the glucokinase gene on chromosome 7 have been found in about 60% of families with maturity-onset diabetes of the young. Because the mutant enzyme has a low affinity for glucose, glucose-stimulated insulin secretion is impaired. Glucokinase mutations do not appear to be involved in typical type II diabetes. Likewise, normal coding sequences for the insulin gene on chromosome 11 and the predominant glucose transporter in islets, GLUT2, have been found in typical type II diabetes. Thus the genetic basis of altered b-cell function in typical type II diabetes remains to be defined.

Impaired Insulin Action

Patients with type II diabetes have impaired insulin action (insulin resistance) at target cells. Insulin resistance may be defined as being present whenever normal concentrations of insulin elicit a less-than-normal biologic response. Among persons without diabetes, insulin resistance is recognized through the presence of hyperinsulinemia in the absence of hypoglycemia. In anyone insulin resistance can be demonstrated through a subnormal response to exogenous insulin. Most insulin resistance is a consequence of impaired insulin action at the level of target cells (hepatocytes, adipocytes, myocytes). This is the case for the most common causes of insulin resistance, obesity and type II diabetes.

Insulin action may be quantified in vivo with measurement of the biologic response to exogenous insulin under controlled conditions. A number of protocols have been devised to standardize the conditions for insulin administration (the challenge) and to provide uniformity of measurement of the response variables. One of the most commonly used methods to assess insulin action is the insulin clamp technique, in which insulin is infused at a fixed rate designed to achieve a steady-state plasma insulin concentration. Plasma glucose level is kept constant (clamped) at a predetermined level (usually either euglycemia or the basal plasma glucose level, depending on the protocol) by means of continuous infusion of a variable amount of glucose, the amount determined by measurement of plasma glucose every 5 minutes. Once steady-state glucose infusion rates are achieved, these are considered a measure of insulin action, because the glucose infusion rate equals the rate of glucose metabolism (less any urinary glucose losses). If clamping is performed at basal glucose concentration, glucose clearance (glucose infusion rate divided by plasma glucose level) reflects insulin action. With the insulin clamp technique, decreased insulin action (insulin resistance) has been demonstrated among persons with type II diabetes, among those with IGT, and among many first-degree relatives of persons with type II diabetes although they have normal glucose tolerance. Chronic hyperglycemia may of itself aggravate the impairment in insulin action (glucose toxicity). With decompensation of glycemic control, there is a concomitant decrease in the action of insulin. When hyperglycemia is corrected, there is some reversal of the impairment in insulin action.

Quantitatively, impairment of insulin-stimulated glucose uptake principally affects skeletal muscle, specifically the nonoxidative pathway of glucose metabolism. The result is diminished glucose storage (glycogen synthesis). To a lesser degree, glucose oxidation is reduced, the liver resists the action of insulin, and enhanced hepatic glucose production is not inhibited by insulin.

The sequential steps in the action of insulin at the cellular level are depicted in Fig. 411.5. The first step in the action of insulin at target cells is binding of insulin to its cellular receptor. The receptor spans the plasma membrane of the cell and is a tetrameric protein composed of two a subunits responsible for insulin binding and serving a regulatory function and two b subunits with inherent kinase activity responsible for transmembrane signaling. The receptor itself undergoes autophosphorylation and causes phosphorylation of insulin receptor substrates (IRS-1 and IRS-2). IRS-1 and IRS-2 serve as docking proteins, intracellular ligands that bind noncovalently to other specific proteins, including phosphatidylinositol-3-kinase, which phosphorylates phosphatidylinositol-2-P to phosphatidylinositol-3-P, which appear to be involved in translocation of the glucose transporter GLUT4 (stored in cytoplasmic vesicles) to the cell surface in skeletal muscle and adipose cells; SHPTP2, a phosphotyrosine phosphatase potentially capable of dephosphorylating the insulin receptor IRS-1 or IRS-2 to modulate the insulin signal; and growth factor receptor-binding protein 2 (GRB2), which links IRS-1 and IRS-2 to the Ras signaling pathway, activating a cascade that includes the mitogen-activated protein kinases, which initiate a sequence resulting in glycogen and lipid synthesis and transcriptional expression of enzymes stimulated by insulin.

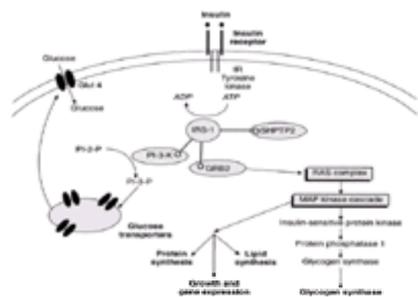

FIGURE 411.5. Cellular scheme of action of insulin. Circulating insulin binds to the insulin receptor (IR), which spans the plasma membrane. The IR then functions as a tyrosine kinase, first phosphorylating itself, and then as insulin receptor substrate-1 (IRS-1), which serves as a docking protein for several molecules important in the action of insulin. These include SH protein tyrosine phosphatase 2 (SHPTP2), growth factor receptor-binding protein 2 (GRB2), and phosphatidylinositol-3-kinase (PI-3-K), which further propagate insulin signaling. ADP, adenosine diphosphate; ATP, adenosine triphosphate; GLUT4, glucose transporter 4; MAP, mitogen-activated protein.

Among patients with type II diabetes, defects have been identified in insulin receptor binding of insulin, in receptor tyrosine kinase activity for both autophosphorylation and for phosphorylation of substrates, in translocation of GLUT4 glucose transporters from their intracellular pool to the plasma membrane and their activation therein, and in the total number of glucose transporters per cell. However, most of these defects are at least partly reversible with one or another intervention. In addition to these, some patients have been found to have increased levels of either a member of the Ras superfamily named *Raa* or a membrane glycoprotein inhibitor of insulin tyrosine kinase action named *PC-1*. Whether the increased levels of these factors have a role in the pathogenesis of type II diabetes is not yet known. Thus the primary cellular mechanisms responsible for insulin resistance in type II diabetes and other conditions are still being clarified.

THERAPY

Therapy for type II diabetes is discussed in [Chapter 399](#).

ACUTE COMPLICATIONS

DIABETIC KETOACIDOSIS

Diabetic ketoacidosis (DKA) is acute, life-threatening metabolic acidosis, the most extreme result of uncontrolled diabetes mellitus. DKA is most commonly a complication of type I diabetes and occasionally occurs as the initial manifestation of undiagnosed diabetes. DKA occurs infrequently in type II diabetes, particularly when the patient is decompensated by severe intercurrent illness.

Pathophysiology

Diabetic ketoacidosis develops as a consequence of severe insulin deficiency and an excess of the glucose counterregulatory hormones (glucagon, the catecholamines, cortisol, and growth hormone). The result is a disturbance of glucose and fatty acid metabolism. Insulin deficiency decreases glucose uptake and utilization. Insulin deficiency combined with glucagon excess increases glucose production because glucagon promotes glycogenolysis and gluconeogenesis in the liver. Insulin deficiency enhances proteolysis and causes muscle breakdown and release of amino acids, which are used by the liver for gluconeogenesis. Glucose overproduction is perpetuated, and concomitant urinary nitrogen loss occurs. Hyperglycemia and hyperosmolality develop, and water shifts from the intracellular to the extracellular compartment. Glycosuria occurs, as does osmotic diuresis accompanied by large urinary losses of potassium and phosphorus and hypovolemia. This process can have several consequences, including tissue hypoxia, which produces both lactic acidosis and loss of cellular potassium; hypotension and decreased blood flow; hyperviscosity; and in rare instances, thrombosis. Decreased renal blood flow leads to acidosis and without intervention, anuria. Decreased cerebral blood flow leads to stupor and contributes to coma.

Insulin deficiency also leads to lack of inhibition of lipolysis and mobilization of free fatty acids and glycerol. In the presence of severe insulin deficiency and availability of free fatty acids, glucagon stimulates gluconeogenesis and ketogenesis. In the liver, free fatty acids are activated to their fatty-acyl-coenzyme A derivatives, transported by carnitine into the mitochondria, and oxidized to acetyl-coenzyme A, with coupling to form acetoacetate. Acetoacetate can diffuse into the circulation or be reduced to b-hydroxybutyrate or spontaneously to decarboxylate to form acetone. With the rapid oxidation of free fatty acids, dihydronicotinamide adenine dinucleotide (NADH) accumulates, so that most of the acetoacetate is converted to b-hydroxybutyrate. Although acetoacetate, b-hydroxybutyrate, and acetone are used for energy by many tissues, in severe insulin deficiency the rate of production exceeds the capacity of extrahepatic tissues to use them. The consequence is ketonemia and severe acidosis. Hyperpnea ensues in a compensatory attempt to eliminate both carbon dioxide and acetone. Ketonuria develops and aggravates osmotic diuresis and the consequences described earlier.

Diagnostic Criteria

The cardinal diagnostic features of DKA are hyperglycemia (250 mg per deciliter or greater), ketosis (ketonemia or ketonuria), and acidosis (arterial pH less than 7.3 and serum bicarbonate concentration less than 15 mEq per liter). DKA is metabolic acidosis with an elevated anion gap. Volume depletion frequently is present. A quick diagnosis can be made at the bedside by means of demonstrating hyperglycemia and ketonemia in a patient with evidence of volume depletion and Kussmaul's respirations, from which acidosis can be inferred. It is not always appreciated that the degree of hyperglycemia need not be great—a large proportion of patients with DKA have glucose concentrations less than 350 mg per deciliter.

Therapy

Therapy for DKA is discussed in [Chapter 399](#).

HYPEROSMOLAR HYPERGLYCEMIC NONKETOTIC COMA

Hyperosmolar hyperglycemic nonketotic coma (HHNC) is an acute syndrome that may occur with uncontrolled type II diabetes. The hyperglycemia, hyperosmolality, and dehydration of HHNC usually are more severe than those of diabetic ketoacidosis, and there is no ketosis.

Pathophysiology

The increased severity of hyperglycemia, hyperosmolality, and dehydration is probably related to a more prolonged period of osmotic diuresis. Perhaps because there are no symptoms of ketosis and acidosis, the syndrome is not readily recognized. Insulin levels usually are somewhat higher than those of persons with ketoacidosis, and they may be sufficient to suppress lipolysis and ketogenesis. Some researchers have postulated that the dehydration and hyperosmolality per se may have antilipolytic effects. The elevations of growth hormone and cortisol usually are less than those that occur with ketoacidosis. Changes in mental status associated with lesser degrees of hyperosmolality also occur and comprise a range of hyperosmolar hyperglycemic nonketotic states that can be called *hyperosmolar hyperglycemic syndrome*. HHNC develops most often among older patients with or without a known history of type II diabetes. Patients at risk often are elderly and often have other underlying medical problems, including cardiac and renal disease. HHNC frequently is precipitated by infection, which augments fluid losses. Patients become severely hyperglycemic and profoundly dehydrated because of osmotic diuresis and inadequate fluid replacement. Extreme hyperosmolality leads to brain dehydration. This may account for focal neurologic deficits and hallucinations, which are frequent. Marked dehydration and postural hypotension occur, and the mortality is high.

Diagnostic Criteria

The diagnosis of HHNC is made when a patient with abnormal mental status has severe hyperglycemia (usually 600 to 1200 mg per deciliter), elevated serum osmolality (more than 350 mOsm per kilogram), and minimal or absent ketonemia or ketonuria.

Therapy

Therapy for HHNC is discussed in [Chapter 399](#).

CHRONIC COMPLICATIONS

The chronic complications of diabetes include accelerated vascular disease, neurologic deficits (diabetic neuropathy), and other organ-specific degenerative processes. The vascular disease is of two types. *Microangiopathy* is a disease of the capillaries specifically associated with diabetes, characterized by thickening of capillary basement membranes, and clinically manifested principally in the retina and kidney. *Macroangiopathy* is the accelerated frequency and severity of atherosclerotic disease of the arteries clinically manifested principally in the coronary arteries, cerebral arteries, and peripheral vessels of the lower extremities.

EFFECTS OF GLYCEMIC CONTROL

Over the years, extensive evidence has mounted suggesting that careful control of glycemia can reduce the risk of diabetic complications, particularly retinopathy,

nephropathy, and neuropathy. The beneficial effects and effect of effective glycemic control on chronic complications of type I diabetes were firmly established with the results of the Diabetes Control and Complications Trial (DCCT) and the Stockholm Diabetes Intervention Study (SDIS). The overall results of the DCCT dramatically exceeded all expectations. Clinically important progression of diabetic retinopathy was reduced by more than 70%. The incidence of clinical renal disease (proteinuria) was reduced 54%, of early renal damage (microalbuminuria) 39%, and of clinically significant neuropathy 64%.

The United Kingdom Prospective Diabetes Study (UKPDS) also demonstrated the effect of effective glycemic control on chronic complications among patients with type II diabetes. In the UKPDS, intensive treatment decreased the risk of any diabetes-related end point 12%, of microvascular end points 25%, and of myocardial infarction 16%. The small Kumamoto Study in Japan showed similar results.

Epidemiologic studies, such as the Wisconsin Study, point to a relation between glycemia and diabetic complications for both type I and type II diabetes. The results of all of these studies have resolved the long-standing debate on whether glycemia is important. Now the debate focuses on the best means of attaining effective glycemic control and on the therapeutic targets that should be sought. It is ironic that the goal articulated by the DCCT investigators of maintaining glycemic status as close to normal as safely as possible is identical to that recommended in 1923, soon after the discovery of insulin.

MECHANISMS LEADING TO COMPLICATIONS

A variety of pathways contribute to the pathogenesis of one or more of the major complications.

Protein Glycation

Nonenzymatic glycation of proteins occurs at both N-terminal amino groups and at β -amino groups of intrachain amino acids, such as lysine, with the slow, continuous addition of glucose to protein by means of a reaction that is a function of the duration of contact between the reactants and the integrated glucose concentration during the time of contact (Fig. 411.6). The first product is an aldimine, or Schiff base, which undergoes internal rearrangement of the double bond, an Amadori rearrangement, to form a ketoamine, a relatively irreversible reaction. The nonenzymatic glycation reaction occurs in essentially all tissues, leading to the genesis of many functional abnormalities. There may be further essentially irreversible transformation by cross-linking of glycated proteins to form advanced glycation end products (AGEs). This results in profound alteration of protein function and structure and leads to diabetic complications. Glycation reaction inhibitors (GRIs), such as aminoguanidine and its derivatives, have been shown to block the cross-linking that results in AGEs. Clinical trials with GRIs are underway.

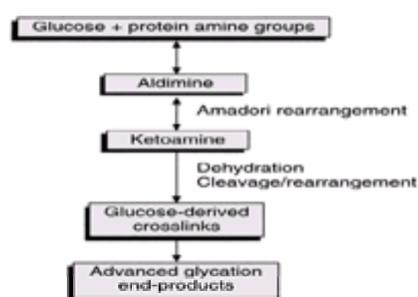

FIGURE 411.6. Steps in pathway of nonenzymatic glycation, with subsequent cross-linking to form advanced glycation end products.

Dicarbonyl Pathway

Another potential mechanism of complications is generation of dicarbonyl compounds to form methylglyoxal and 3-deoxyglucosone. Methylglyoxal is produced by means of fragmentation of triose phosphates, and 3-deoxyglucosone is formed from 3-phosphofructose or fructose-lysine. These reactive α -dicarbonyls are extremely reactive as glycation agents for collagen, enzymes, and other important cellular components and have been shown to be toxic to cultured cells. They are thought to contribute to diabetic complications either as direct toxins or as precursors for AGEs, because their effects include inhibition of cell growth, inhibition of cell DNA synthesis, mutagenic effects on DNA, inhibition of cell enzymatic activity, protein fragmentation, protein cross-linking, and precursors of AGE formation. Methylglyoxal and 3-deoxyglucosone are elevated in the plasma of persons with diabetes and are found in increased levels in patients who have evidence of early diabetic nephropathy and retinopathy.

Polyol Pathway Activity

Glucose is converted to its sugar alcohol, sorbitol, by the enzyme aldose reductase (Fig. 411.7). In cells where insulin-mediated glucose transport is not rate limiting, and glucose is freely permeable, the presence of the polyol pathway enzymes aldose reductase and sorbitol dehydrogenase leads to intracellular accumulation of sorbitol and fructose in direct proportion to the degree of hyperglycemia. The result is a high intracellular glucose concentration. The reaction also consumes dihydronicotinamide-adenine dinucleotide phosphate (NADPH), resulting in a change in intracellular redox potential. Sorbitol accumulation has osmotic effects in the lens and is associated with changes in nerve function, mediated through alteration of $\text{Na}^+\text{-K}^+$ -adenosine triphosphatase ($\text{Na}^+\text{-K}^+$ -ATPase) activity, depletion of intracellular myoinositol, impairment of nerve conduction, and nerve fiber loss. In addition, hyperglycemia causes competitive inhibition of sodium-dependent myoinositol uptake, reduces the intracellular level of myoinositol, decreases membrane content of phosphatidylinositol, and further reduces $\text{Na}^+\text{-K}^+$ -ATPase activity. The altered redox potential in vasa nervorum (from NADPH depletion) decreases local vasodilatation and reduces blood flow to the nerves and other tissues. All these abnormalities may be reversible with the use of aldose reductase inhibitors, which are in clinical trials.

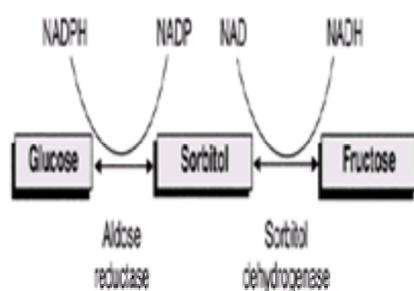

FIGURE 411.7. Polyol pathway by which glucose is converted to sorbitol and then slowly to fructose. Thicknesses of arrows and lines are proportional to reaction rates.

Endothelial Cell Proliferation

The activation of protein kinase C (PKC) and increase in diacylglycerol (DAG) levels initiated by hyperglycemia are associated with many vascular abnormalities in retinal, renal, and cardiovascular tissue. The glucose-induced activation of PKC has been shown to increase production of extracellular matrix and cytokines; to enhance contractility, permeability, and vascular cell proliferation; to induce activation of cytosolic phospholipase A₂; and to inhibit $\text{Na}^+\text{-K}^+$ -ATPase. PKC activation

may also regulate vascular permeability and neovascularization through expression of growth factors, such as vascular endothelial cell growth factor (VEGF), which interacts with endothelial cell membrane receptors to initiate a series of events, including activation of intracellular PKC, that result in endothelial cell mitosis and proliferation. The level of VEGF–vascular permeability factor (VPF) is increased in the ocular fluid of patients with diabetes. This substance has been implicated in the neovascularization of proliferative retinopathy. Production of VEGF by hypoxic retinal tissue leads to neovascularization.

In the kidney, expression of transforming growth factor b (TGF-b) has been shown to be increased in the glomeruli of patients with diabetes and those of experimental animals. The secondary metabolic products of glucose, such as glycation products and oxidants, also can increase DAG-PKC, suggesting that the activation of DAG-PKC may be a common downstream mechanism by which multiple by-products of glucose exert their adverse effects. In experiments, inhibitors of PKC block endothelial tube formation in vitro and block intraocular neovascularization caused by retinal ischemia. Clinical trials are being conducted to test the effects of an orally effective b-isoform-selective inhibitor of PKC.

Enzymatic Glycosylation of Basement Membranes

The hallmark of diabetic microangiopathy is thickening of capillary basement membranes. Hyperglycemia enhances the rate of biosynthesis of capillary basement membranes. Renal glomerular capillary basement membranes contain increased carbohydrate in two types: complex heteropolysaccharide and disaccharide (galactose and glucose) bound to hydroxylysine. There is an increased proportion of disaccharide units in diabetic tissue.

Platelet and Endothelial Function

Alterations in platelet or endothelial function, including increased platelet aggregation, increased platelet metabolism of arachidonic acid, decreased platelet survival, decreased prostacyclin production by endothelial cells, diminished fibrinolytic activity, increased levels of plasminogen activator inhibitor-1 (PAI-1), and increased levels of von Willebrand's factor, may contribute to the vascular complications of diabetes. Hyperglycemia may influence arachidonic acid metabolism through inhibition of myoinositol uptake and reduction of membrane phosphatidylinositol and other membrane phospholipids, of which arachidonic acid is a component. The availability of arachidonic acid for prostaglandin or prostacyclin synthesis is decreased, resulting in an imbalance between these substances. Antiplatelet agents, such as salicylates, dipyridamole, and similar agents, decrease platelet aggregation and may reduce vascular risk.

Hemorheologic Abnormalities

Vasodilatation is limited. The viscosity or fluidity of blood is a limiting factor in perfusion and oxygen delivery to tissues. Factors contributing to fluidity include erythrocyte aggregation and deformability, whole blood viscosity, and plasma viscosity, which is determined from levels of high-molecular-weight plasma proteins, such as fibrinogen, levels of which are increased among persons with diabetes. When fluidity is lost, erythrocyte deformability is decreased. Pentoxifylline and its congeners may influence the rheologic characteristics of blood and improve flow.

Hemodynamic Alterations

Hemodynamic alterations in the microcirculation (hyperfiltration) are important in initiating and perpetuating diabetic nephropathy. Moderate hyperglycemia increases blood volume, glomerular plasma flow rate, and perfusion, causes hyperfiltration, and increases glomerular transcapillary hydraulic pressure. The high capillary pressures and flows, if sustained, cause direct cellular injury, increase mesangial matrix, and cause proteinuria and glomerulosclerosis. Progressive renal injury causes selective changes in the glomerular barrier and aggravate proteinuria. Factors that lessen the effect of hyperfiltration include careful control of hyperglycemia; aggressive control of systemic blood pressure; selective efferent arteriolar dilation with angiotensin-converting enzyme (ACE) inhibitors, which decrease trans-glomerular capillary pressure; and restriction of dietary protein, because high protein intake increases renal perfusion rate.

Growth Factors

Decreases in nerve growth factor may have a role in diabetic neuropathy. Studies with animals show improvement in nerve function with administration of nerve growth factor. Retinal neovascularization develops as a consequence of retinal hypoxia, which liberates a local vasoproliferative or angiogenesis factor. There may be an imbalance between retinal vasoproliferative factors and their inhibitors.

MANIFESTATIONS AND MANAGEMENT OF COMPLICATIONS

Diabetic Retinopathy

Diabetic retinopathy is the leading cause of blindness in the United States among working-age adults (20 to 65 years of age). An estimated 24,000 persons lose vision each year as a consequence. The National Eye Institute estimates that 90% of such blindness is preventable.

The earliest clinically apparent manifestations of diabetic retinopathy are classified as nonproliferative or background diabetic retinopathy ([Table 411.4](#)). At this stage, there may be microaneurysms, dot and blot hemorrhages, hard and soft exudates, venous dilatation and beading, and intraretinal microvascular abnormalities. These changes do not impair vision. Background diabetic retinopathy affects 80% of patients with type I diabetes 10 years after onset and almost 100% of patients with type I diabetes 15 to 20 years after onset. Background diabetic retinopathy affects 50% to 80% of patients with type II diabetes 15 to 20 years after onset. The more severe form of diabetic retinopathy is classified as proliferative diabetic retinopathy (PDR) because of the presence of neovascularization as the hallmark of this type of retinopathy. There also may be fibrous proliferation and preretinal and vitreous hemorrhages. After 20 to 25 years of diabetes, 50% to 60% of patients with type I diabetes and 15% to 20% of patients with type II diabetes have PDR. PDR is relentlessly progressive and impairs vision, causing blindness if not treated. The mainstay of treatment is panretinal laser photocoagulation. Vitrectomy has become an important therapeutic modality for advanced diabetic eye disease, in which there is severe vitreous hemorrhage or fibrosis, often with retinal detachment. The eye disease eventually becomes quiescent, a stage called *involutional retinopathy*.

Background (nonproliferative) retinopathy
Microaneurysms
Venous dilatation
Hemorrhages
Exudates
No effect on vision
Background with maculopathy
Macular edema
May impair central vision
Focal laser photocoagulation effective
Proliferative retinopathy
Neovascularization (cardinal feature)
Fibrous proliferation
Preretinal hemorrhage
Vitreous hemorrhage
Panretinal laser photocoagulation effective
Advanced diabetic eye disease
Vitreous opacities (hemorrhage and fibrous tissue)
Retinal detachment
Vitrectomy effective
Retinal reattachment possible
Involutional retinopathy
Residual scarring from previously active proliferative retinopathy
No treatment indicated

TABLE 411.4. CLASSIFICATION OF DIABETIC RETINOPATHY

A separate subtype of retinopathy is diabetic maculopathy, in which severe macular edema impairs central vision and for which focal laser photocoagulation may be effective.

Glycemic control has been shown to be important in slowing the course of diabetic retinopathy. The DCCT and the UKPDS showed that intensive therapy has major beneficial effects on type I and type II diabetes. In the DCCT, the rate of clinically important progression of diabetic retinopathy (a sustained three-step change on the quantitative grading scale) was significantly reduced 70.3% overall, 78.5% among patients with no retinopathy at enrollment, and 64.5% among those with some retinopathy at enrollment. In the cohort with some retinopathy at entry, the rate of progression of retinopathy to proliferative or severe nonproliferative retinopathy (necessitating referral to an ophthalmologist for evaluation and treatment) was significantly reduced 60.8% overall. The rate of need for laser photocoagulation, an index of progression to vision-threatening retinopathy, was significantly reduced 56% overall. The rate of initial appearance of any retinopathy in the cohort with no

retinopathy at enrollment was significantly reduced 27%. In the UKPDS, the rate of retinal photocoagulation was reduced 29%, of cataract extraction 24%, and of deterioration in retinopathy 21% after 12 years of follow-up study.

A number of pharmacologic therapies have been assessed, but none has been shown beneficial in controlled clinical trials. Both aspirin and the aldose reductase inhibitor sorbinil were found to be without benefit.

The Diabetic Retinopathy Study (DRS) demonstrated the dramatic effects (more than 50% reduction in visual loss) of laser photocoagulation on preventing vision loss due to diabetic retinopathy. The DRS results defined criteria for high risk in which generalized panretinal laser photocoagulation is indicated. These high-risk criteria are PDR with new vessels on disc greater than 25% of the disc diameter; new vessels on disc with preretinal hemorrhage; or new vessels elsewhere with preretinal hemorrhage. Because panretinal photocoagulation is associated with side effects, such as decreased peripheral vision and decreased night vision, it should not be used routinely unless criteria of high risk are present.

The Early Treatment Diabetic Retinopathy Study (ETDRS) showed that focal laser photocoagulation, in which only the vessels responsible for leakage are destroyed, was effective (more than 50% reduction in visual loss) therapy for diabetic maculopathy with clinically significant macular edema. For advanced diabetic eye disease not amenable to photocoagulation, the Diabetic Retinopathy Vitrectomy Study (DRVS) established guidelines for the timing of pars plana vitrectomy by showing that early vitrectomy reduces approximately 50% the 1-year rate of blindness from vitreous hemorrhage or retinal detachment.

The effect of diabetic retinopathy may be minimized and blindness prevented with a strategy that includes careful glycemic control; aggressive control of coexisting hypertension; and annual, comprehensive, dilated eye and vision examinations by an ophthalmologist for all patients 12 years and older who have had diabetes for 5 years, all patients older than 30 years, and any patient with visual symptoms or abnormalities. It is recommended that such examinations be performed by ophthalmologists because of the difficulty in assessing diabetic retinopathy. In one study the rate of serious errors in assessment was 52% for general internists, 50% for medical residents, and 33% for diabetologists but only 9% for general ophthalmologists and 0% for retinal specialists. Underlying this strategy is the aggressive use of argon laser photocoagulation when criteria of high risk are detected.

Diabetic Nephropathy

Diabetic nephropathy is the leading known cause of end-stage renal disease (ESRD) in the United States. It accounts for an estimated 28,000 new cases of ESRD per year. However, most if not all future ESRD from diabetic nephropathy is preventable. Diabetic nephropathy affects 20% to 40% of patients with type I diabetes 20 years after onset. Although a lower percentage (less than 20%) of patients with type II diabetes have nephropathy, still about one-half of patients with ESRD and diabetes have type II diabetes. Although diabetes accounts for more than 40% of cases of ESRD in the United States, patients with diabetes consume 75% of ESRD costs, principally because the renal disease is associated with other complications. Data from Denmark suggest that the increased mortality risk for type I diabetes may be confined to patients with nephropathy. The risk of nephropathy increases with duration of diabetes to 25 to 30 years' duration (after which this complication rarely begins) and with family history of essential hypertension. Some authorities contend the appearance of diabetic nephropathy is the result of the combination of diabetes and genetic predisposition to hypertension.

The course of diabetic nephropathy is slow. It once was thought that there was a long silent period in which no changes were demonstrated. Now, through demonstration of an increased albumin excretion rate, so-called *microalbuminuria* (urine albumin levels of 30 to 300 mg per 24 hours), it is possible to identify diabetic nephropathy during this period, a stage known as *incipient diabetic nephropathy* (Table 411.5). During this stage, there may be hyperfiltration or blood pressure elevation as well. This is followed by the development of clinical-grade proteinuria (urine albumin levels more than 300 mg per 24 hours, also detectable with standard reagent dipstick tests for protein), which defines the presence of overt diabetic nephropathy and is usually accompanied by the appearance of hypertension. Advanced diabetic nephropathy is defined by a progressive decline in renal function (declining glomerular filtration rate [GFR] measured according to decreases in creatinine clearance and increases in serum levels of blood urea nitrogen and creatinine), progressive proteinuria, and hypertension. Progression to ESRD is recognized with the appearance of uremia, the nephrotic syndrome, and the need for renal replacement therapy (transplantation or dialysis).

Incipient diabetic nephropathy
Increased albumin excretion rate (microalbuminuria)
Hyperfiltration possible
Blood pressure elevation
Early (overt) diabetic nephropathy
Clinical-grade proteinuria
Hypertension
Advanced diabetic nephropathy
Progressive proteinuria
Hypertension
Declining glomerular filtration rate (decreased creatinine clearance, increased blood urea nitrogen and creatinine levels)
End-stage renal disease
Uremia
Nephrotic syndrome
Need for renal replacement therapy (transplantation or dialysis)

TABLE 411.5. CLASSIFICATION OF DIABETIC NEPHROPATHY

Glycemic control has been shown to be important in slowing the evolution of diabetic nephropathy. The DCCT showed that intensive therapy yields a 39% reduction in development of microalbuminuria and a 54% reduction in development of clinical-grade proteinuria. The UKPDS showed that glycemic control resulted in a 33% reduction in microalbuminuria after 12 years of follow-up study. Pancreatic transplantation accompanied by normoglycemia has been shown to prevent the recurrence of diabetic nephropathy in kidney grafts. Other interventions also may slow the appearance or progression of nephropathy, particularly aggressive, effective control of coexisting hypertension, which slows the rate of decline in GFR in early (overt) or advanced nephropathy. Dramatic slowing has been achieved with ACE inhibitors. For patients with microalbuminuria, the European Microalbuminuria Captopril Study showed a 66% reduction in rate of progression to clinical-grade proteinuria with an ACE inhibitor. Among patients with proteinuria, the U.S. Collaborative Study Group found that with an ACE inhibitor there was a 48% reduction in the rate of doubling of serum creatinine level and a 50% reduction in the rate of death, dialysis, or transplantation. Angiotensin receptor blockers probably share these effects. Use of calcium channel blockers also has reduced the rate of microalbuminuria. Restriction of dietary protein may delay the decline in GFR that occurs with diabetic nephropathy. Aldose reductase inhibitors may decrease or prevent an increase in albumin excretion rate. Cross-link blockers, such as aminoguanidine, have been effective in slowing renal disease in animal models of diabetes and are in clinical trials as therapy for diabetes among humans. In a provocative but uncontrolled study, pentoxifylline was found to decrease albumin excretion rate.

It may be possible to prevent diabetic nephropathy with a strategy that includes careful glycemic control and aggressive control of coexisting hypertension. Routine urinalysis should be performed yearly for adults. Postpubertal patients who have had diabetes for 5 years should undergo annual measurement of either albumin excretion rate in a timed urine collection specimen (24 hours or overnight) or albumin-to-creatinine ratio. If abnormal albumin or protein excretion is detected, serum creatinine or urea nitrogen concentrations should be measured and GFR assessed. There should be appropriate use of dietary protein restriction, early use of ACE inhibitors, and potential use of other emerging strategies.

As renal disease progresses, careful attention should be paid to all aspects of the medical renal plan, particularly that aimed at prevention of renal osteodystrophy. Protein intake for patients with evidence of nephropathy should be no more than 0.8 g per kilogram per day, or approximately 10% of daily calories. The presence of diabetes is not a contraindication to dialysis, as once was asserted. Chronic ambulatory peritoneal dialysis has been advocated by some authorities, but experience is limited. The most effective therapy for ESRD due to diabetes is renal transplantation, which often is performed at an earlier stage than with other forms of renal disease because of the accelerated catabolism that occurs when diabetes and uremia coexist. These patients ideally should undergo simultaneous renal and pancreatic transplantation, which reduces the risk of recurrent nephropathy in the transplanted kidney and takes advantage of the need for immunosuppression to prevent renal allograft rejection to allow reversal of the hyperglycemic state by the pancreatic graft.

Diabetic Neuropathy

Diabetic neuropathy may be manifested both by peripheral neurologic deficits and by autonomic dysfunction, which may involve a variety of organ systems, including

the cardiovascular, gastrointestinal, and genitourinary systems. A variety of clinical syndromes occur ([Table 411.6](#)). The nature of the clinical syndrome dictates treatment.

Peripheral Neuropathy
Distal symmetrical neuropathy
Sensory loss with numbness
Osteoarthritis
Paresthesia
Muscle pain
Neuropathic foot ulceration
Neuroarthropathy (Charcot's joint)
Mononeuropathy
Cranial neuropathy
Compression or entrapment neuropathy
Neuropathy multiplex
Neuropathy
Diabetic truncal neuropathy or radiculopathy
Autonomic Neuropathy
Cardiovascular autonomic neuropathy
Cardiac denervation syndrome
Postural hypotension
Gastrointestinal neuropathy
Gastroesophageal reflux disease
Diabetic diarrhea
Fecal incontinence
Constipation
Genitourinary neuropathy
Erectile dysfunction
Female sexual dysfunction
Subnormal spermatogenesis
Pupillary abnormalities

TABLE 411.6. CLASSIFICATION OF DIABETIC NEUROPATHY

Glycemic control has been shown to be important in slowing the evolution of diabetic neuropathy. The DCCT showed that intensive therapy yields a 64% overall reduction in the 5-year incidence of clinically significant neuropathy, defined as concordance between clinical diagnosis by a certified neurologist plus either peripheral nerve conduction abnormalities or autonomic nerve testing abnormalities. Aldose reductase inhibitors slow the progression of neuropathy. Other strategies aimed at interdicting the pathways leading to neuropathy also seem to show promise.

Peripheral Neuropathy

Distal Symmetrical Neuropathy

The most common of the diabetic neuropathies is diabetic peripheral sensorimotor polyneuropathy. This is usually distal symmetrical neuropathy. Although it involves all nerves, this condition manifests in a glove-and-stocking distribution. Motor or sensory loss may occur. Distal symmetrical neuropathy can be divided clinically into three stages—early, symptomatic, and severe or disabling. Early neuropathy usually is asymptomatic, although a careful neurologic examination may elicit sensory loss. Neurologic electrophysiologic abnormalities can be demonstrated to establish the diagnosis.

The hallmark of the clinical presentation of the symptomatic stage of peripheral neuropathy is clinically detectable sensory loss with numbness. Other possible symptoms include dysesthesia, paresthesia, and muscle pain. Tendon reflexes may be diminished. Sensory loss is detectable at clinical examination, usually in a stocking-and-glove distribution. Intervention at this stage is designed to relieve symptoms, such as to manage pain, and to halt disease progression. Therapies aimed at the pathophysiologic alterations may transiently worsen symptoms because of nerve cross-talk during regeneration.

In the severe stage of peripheral neuropathy, symptoms can be disabling. Neuropathic foot ulceration and neuroarthropathy (Charcot's joint) may occur, both of which are caused by injury from sensory impairment. Progressive ulceration may lead to potential loss of limb. In this stage, the diagnosis is obvious. Therapy is directed at relieving symptoms, preventing loss of limb, and providing appropriate rehabilitation to overcome disability.

Diabetic neuropathy may lead to amputation, often in collaboration with coexisting peripheral vascular disease. Diabetes is the leading cause of nontraumatic amputations in the United States. An estimated 67,000 limbs are lost each year as a consequence of diabetes. The ADA, however, estimates that 75% to 85% of such limb loss is preventable through use of a primary care strategy that includes patient education in foot care, regular inspection of the feet by patients and health care providers, use of appropriate shoes and footwear, careful glycemic control, podiatric and pedorthic referral, aggressive early management of foot ulcers, and use of vascular surgical intervention if needed.

Current management of neuropathy is aimed at improving symptoms. Prevention and education constitute the first line of treatment. The patient should be educated about methods for and the importance of preventing foot injury. Improving glycemic control often provides some relief. Management of painful neuropathy depends on the type of pain present—dysesthesia, paresthesia, or muscular pain. Dysesthetic pain, induced by contact with objects that do not usually cause pain, such as bed sheets or clothing, can be managed with gabapentin or tricyclic antidepressant drugs, such as amitriptyline, often in high doses. Dysesthesia also can be relieved with capsaicin cream, a topical treatment that depletes the pain-modulating neurotransmitter substance P from type C nociceptive fibers.

Paresthetic pain, manifested as a burning sensation or pins and needles, also can be relieved with gabapentin or tricyclic antidepressants, such as amitriptyline or imipramine, or with mexiletine. If these approaches fail, carbamazepine should be tried. Muscular pain, manifested as shooting pain, aching night cramps, or a band-like feeling, can be relieved with physical therapy (stretching exercises) perhaps accompanied by a nonsteroidal anti-inflammatory drug or skeletal muscle relaxant. For severe pain, analgesics may be needed, but narcotics should be avoided at all costs because of the high risk of addiction in this setting and a predictable loss of effectiveness due to tachyphylaxis.

Mononeuropathy

Other types of peripheral diabetic neuropathy are focal and multifocal neuropathy. These types are characterized by neurologic deficits confined to the distribution of single or multiple nerves (mononeuropathy or mononeuropathy multiplex), brachial or lumbosacral nerve plexuses (plexopathy), or nerve roots (radiculopathy).

Isolated cranial neuropathy is not rare among elderly patients with diabetes. Cranial nerves, particularly III, IV, and VI, often are affected by mononeuropathy (cranial neuropathy). Characteristic third cranial nerve palsy occurs with diabetic ophthalmoplegia (unilateral pain, diplopia, and ptosis with pupillary sparing). Management of cranial neuropathy is palliative because of its self-limited nature.

Diabetic truncal neuropathy or radiculopathy manifests as bandlike thoracic or abdominal pain often misdiagnosed as an acute intrathoracic or intra-abdominal emergency. Diabetic femoral neuropathy results in both motor and sensory deficits at the sacral plexus and femoral nerve. Some types of mononeuropathy mimic compression or entrapment neuropathy, such as carpal tunnel syndrome. Compression and entrapment palsy responds to standard conservative management or a surgical release procedure. Diabetic plexopathy is a diagnosis of exclusion. Other causes must be carefully excluded in consultation with a specialist.

All of these focal neuropathic syndromes mimic similar neurologic conditions of nondiabetic origin. Mononeuropathy tends to occur among older patients with diabetes, is relatively uncommon, and usually has an acute clinical onset. Management of mononeuropathy is essentially supportive. Recovery (complete or partial) usually occurs, so these syndromes usually but not always are self-limited. The acute onset and complete or partial recovery suggest a vascular or traumatic basis.

Autonomic Neuropathy

A multitude of clinical syndromes compose diabetic autonomic neuropathy. Management of autonomic neuropathy depends on the manifestations.

Cardiovascular Autonomic Neurby

Cardiovascular autonomic neuropathy manifests as increased heart rate, altered heart rate control (a fixed heart rate of 80 to 90 beats per minute that does not respond to stress, mild exercise, sleep, or postural changes), and the possibility of exercise intolerance, postural hypotension, or cardiac denervation syndrome.

Cardiac Denervation Syndrome

Cardiac denervation syndrome manifests as silent myocardial ischemia and painless myocardial infarction, increased incidence of sudden death, increased incidence of cardiac arrhythmia, poor exercise tolerance, a higher incidence of cardiovascular lability during anesthesia, denervation hypersensitivity to autonomic drugs or medicines that contain autonomic drugs (e.g., procaine hydrochloride with epinephrine), poor survival after myocardial infarction, increased morbidity during pregnancy, and poor prognosis for 5-year survival. There is no therapy for cardiac denervation syndrome. However, it is important to ascertain whether a patient has this problem, particularly before surgical anesthesia or before commencement of an exercise program. Measurement of R-R variation and evaluation of heart rate responses to the Valsalva maneuver (during which the patient blows against a standardized pressure) are simple, reliable, and noninvasive tests with which to screen patients for cardiovascular autonomic neuropathy. An exercise stress test should be performed before patients with autonomic neuropathy begin an exercise program. Patients may fatigue easily or have painless ischemia. Painless ischemia precludes participation in strenuous exercise.

Postural Hypotension

A severe manifestation of cardiovascular sympathetic neuropathy is postural hypotension. Overt postural hypotension is uncommon and usually appears as a late complication. Postural hypotension is defined as a decrease in systolic blood pressure greater than 30 mm Hg or any fall in diastolic blood pressure on standing. The clinical definition is any decrease in arterial blood pressure soon after standing that produces symptoms such as blurry vision, pain in the neck, light-headedness, or transient loss of consciousness. Two additional factors may precipitate hypotension among patients with autonomic failure. First, meals lower blood pressure dramatically among patients with autonomic failure and may provoke symptomatic postprandial postural hypotension. Second, insulin lowers blood pressure among patients with diabetes and autonomic neuropathy. The presence of postural tachycardia usually indicates that the postural hypotension may be caused by potentially reversible factors, such as hypovolemia or pharmacologic agents.

Postural hypotension from cardiovascular neuropathy can be managed with mechanical maneuvers (head-up tilting of the bed during the night, use of waist-high custom-fitted elastic support stockings during the day), increased salt intake, fludrocortisone, and in rare instances, short-acting pressor agents. It may be necessary to give vasodilators, such as hydralazine, minoxidil, or transdermal nitrates, at bedtime. Patients who take these agents should be advised against getting up during the night without assistance.

Gastrointestinal Neuropathy

Diabetic neuropathic involvement of the gastrointestinal tract, mostly causing motility disturbances, extends from the esophagus to the anorectum. In addition, acute hyperglycemia, especially with ketoacidosis, may inhibit gastrointestinal motility with resulting anorexia, nausea, vomiting, and abdominal pain, all of which resolve as the metabolic derangements are controlled.

Esophageal motor disorders are rare. For most patients, esophageal dysfunction is mild and nonspecific and does not produce symptoms. Some patients may have dysphagia, chest pain, and gastroesophageal reflux.

Gastroparesis can be detected among as many as one-fourth of persons with diabetes. In most patients it is clinically silent. However, severe diabetic gastroparesis can be quite debilitating. Typical symptoms include anorexia, early satiety, nausea, vomiting, abdominal bloating, and epigastric discomfort. A classic symptom is postprandial vomiting of undigested food, although morning nausea or dry heaves also may occur. Disruption of nutrient delivery to the small intestine upsets the relation between glucose absorption and insulin administration, with resulting wide swings of glucose levels and unexpected episodes of postprandial hypoglycemia. Diagnosis is made with upper gastrointestinal endoscopy when retained food is found in the stomach after an 8- to 12-hour fast in the absence of obstruction or with a nuclear solid-phase gastric emptying study. Treatment is careful attention to blood glucose control, a low-fat diet, and several small meals throughout the day. Pharmacologic therapy involves prokinetic agents, such as metoclopramide, bethanechol, and cisapride.

Intestinal autonomic neuropathy may cause diarrhea through effects on motility or on enterocyte absorption. Diarrhea among patients with diabetes typically is frequent and watery and may be persistent, intermittent, or alternating with constipation. Fecal incontinence among these patients also is caused by neuropathic damage with loss of internal sphincter control and anorectal sensation. Constipation is the most common gastrointestinal symptom and is assumed to be caused by generalized autonomic neuropathy.

Management of diabetic diarrhea depends on the specific cause, but the common bacterial overgrowth syndrome often responds to rotating antibiotics, which should be used if bacterial overgrowth is found or cannot be ruled out. A hydrophilic fiber supplement (psyllium) may be useful if diarrhea alternates with constipation. Synthetic, nonaddicting anti-diarrheal opiates, such as diphenoxylate or loperamide, can be tried. The long-acting somatostatin analog octreotide may be effective in the care of patients with severe refractory symptoms. Management of fecal incontinence should include sphincter-strengthening exercises. Clonidine, an α_2 agonist, may reverse adrenergic nerve dysfunction and improve diarrhea and particularly fecal incontinence. Constipation can be managed with adequate hydration and a high-fiber diet supplemented with a hydrophilic colloid such as psyllium or perhaps with a promotility drug. Patients with more severe symptoms may need intermittent use of saline or osmotic laxatives.

Genitourinary Neuropathy

Diabetic Cystopathy

Diabetic neuropathy affects the genitourinary system, particularly the urinary bladder (diabetic cystopathy), and involves a spectrum of voiding dysfunction. Initial symptoms usually are related to impaired bladder sensation, which causes a gradual change in voiding pattern—increased intervoiding interval, voiding only once or twice a day, the need to strain abdominally with resulting slow urinary stream and terminal dribbling, and increased difficulty in initiating or maintaining micturition with possible urinary incontinence. As decreased bladder sensation progresses, there are incomplete emptying, impaired bladder contractility with increased bladder capacity, an increased amount of postvoid residual urine, impaired urinary flow rate, and proneness to infection. Management of diabetic cystopathy entails scheduled voiding (voiding every 3 to 4 hours), double or triple voiding to reduce large postvoid residual volumes, abdominal straining (Crede(c)'s maneuver), intermittent self-catheterization, and use of cholinergic agents, such as bethanechol, to stimulate bladder contractility.

Erectile Dysfunction

Erectile dysfunction is one of the most common problems among men with diabetes. Erectile dysfunction may be psychogenic or organic in origin, the latter usually caused by both neurologic and vascular impairment. Autonomic neuropathy decreases penile smooth-muscle relaxation. Arterial stenosis, particularly of the internal pudendal artery, venous leaks, and microvascular abnormalities may be present. Psychological factors may contribute to erectile dysfunction among men with diabetes as they do in the general population. In addition, fear of diabetic erectile dysfunction may induce erectile dysfunction. In rare instances, testosterone deficiency may cause erectile dysfunction.

The onset of organic erectile dysfunction is gradual and progressive, beginning with decreased rigidity and reduced frequency of erection and followed by incomplete tumescence and eventually by complete erectile dysfunction. Libido usually remains unchanged. In contrast, the most obvious symptom of psychogenic erectile dysfunction is sudden onset or problems related to isolated situations or persons. Monitoring of nocturnal penile tumescence may be useful in determining whether a man is capable of having an erection.

Theoretical treatment depends on the cause of erectile dysfunction. However, many clinicians start treatment with a therapeutic trial of sildenafil, which is straightforward, provided the patient does not have coronary artery disease and is not using nitrates. Improved glycemic control may improve erectile function among patients with very poor control. Psychogenic erectile dysfunction often can be successfully treated by a therapist with expertise in sexual dysfunction. Vascular surgery may improve blood supply or repair venous leaks, when present. Injection directly into the corpora cavernosa of vasodilators (phentolamine, prostaglandins) produces an erection. A variety of mechanical vacuum devices can produce an erection, and there are several types of penile prostheses.

Female Sexual Dysfunction

Sexual problems among women with diabetes include inadequate vaginal lubrication; alteration in desire, arousal, or orgasm; and pain during sexual intercourse. Poor lubrication most closely parallels erectile dysfunction among men in that both depend on genital vasocongestion during sexual arousal. Along with vaginal dryness and lack of expansion, inadequate genital vasocongestive responses can cause poor vaginal lubrication with vaginal irritation or painful intercourse. Older

women with type II diabetes have more problems than do healthy women in terms of low sexual desire, poor vaginal lubrication, dyspareunia, and difficulty reaching orgasm.

It often is easy to manage the arousal-phase problem of poor vaginal lubrication. For women with low estrogen levels, estrogen replacement should be prescribed as a pill, patch, or vaginal cream. Estrogen replacement can improve vaginal elasticity and lubrication, but additional supplementation with androgens is more likely directly to increase sexual desire. Clinical trials of sildenafil are in progress. For premenopausal women and postmenopausal women who have risk factors that prevent estrogen replacement, vaginal lubricants are useful. For sexual activity, a water-based gel lubricant may be used. For severe dryness, a vaginal suppository inserted before foreplay can be helpful.

Probably the most common causes of sexual problems among women with diabetes are psychological, such as depression, anxiety about attractiveness, poor sexual communication, relational conflict, or a history of a traumatic sexual experience. Loss of desire for sex often is related to depression. Antidepressant drugs and brief symptom-focused psychotherapy are effective. Many women can be successfully treated by a therapist with expertise in sexual dysfunction.

Sudomotor Dysfunction

Sudomotor dysfunction occurs because the sweat glands are innervated by autonomic nerves, and function may be compromised by diabetic neuropathy. Longer nerves tend to be impaired before shorter nerves are, resulting in anhidrosis in the lower extremities, with compensatory hyperhidrosis in the upper body. The main symptom of sudomotor dysfunction is excessive perspiration on the torso and face. There also may be gustatory sweating during eating. Anhidrosis in the lower extremities may contribute to the development of foot and leg ulcers. Loss of the ability to regulate core temperature may cause heat exhaustion and heat stroke. The most important aspect of treatment is education about the causes of the increased upper-body sweating and awareness of the risk of heat exhaustion and heat stroke.

Pupillary Abnormalities

Sympathetic nerves dilate the pupil, and parasympathetic nerves constrict the pupil; thus pupil adapts to the level of illumination. Autonomic neuropathy reduces pupil size and inhibits the ability of the pupil to adapt to changes in illumination. Symptoms include night blindness and poor adaptation to darkness. Decreased pupil diameter also is associated with reduced anterior chamber depth and is a predisposition to glaucoma.

OTHER COMPLICATIONS

SKIN LESIONS

Diabetic Dermopathy

Diabetic dermopathy, also known as *shin spots* or *pigmented pretibial patches*, usually occurs on the extensor surfaces of the distal lower extremities. It is characterized by multiple, asymptomatic, hyperpigmented, oval or circular macules, which may be atrophic or scaly. No treatment is needed.

Necrobiosis Lipoidica Diabeticorum

Necrobiosis lipoidica diabeticorum is a relatively rare form of atrophic degeneration of dermal and epidermal tissue. It occurs most commonly on the shin. This condition is characterized by shiny, transparent skin with reddish-brown to violet plaques that frequently become yellow in the center; dermal vessels can be seen under the plaques. The lesions may ulcerate. Treatment is difficult, but has been attempted with intralesional glucocorticoids, pentoxifylline, dipyridamole, and salicylates.

INFECTIONS UNIQUE TO DIABETES

Malignant Otitis Externa

Malignant otitis externa is a chronic, potentially fatal erosive infection of the soft tissue and cartilage around the external auditory canal; it is caused by *Pseudomonas aeruginosa*. The infection is characterized by pain, purulent drainage, and progressive destruction of the temporal, petrous, and mastoid bones that ultimately reaches the cranial nerves (V, VII, or VIII), meninges, or sigmoid sinus. Treatment involves vigorous debridement of necrotic tissue and a prolonged course (at least 4 weeks) of antibiotics.

Mucormycosis

Rhinocerebral mucormycosis is a phenomenally rapid necrotizing invasive process caused by the mycelia of the genera *Mucor*, *Absidia*, *Rhizopus*, and *Cunninghamella*. The organisms are essentially nonpathogenic in a healthy host because they are unable to regenerate if ingested by normal macrophages. In the presence of high concentrations of glucose and in an acid environment, however, these fungi grow remarkably rapidly. The process may extend from a small eschar on the nasal septum to the paranasal sinuses, orbit, and brain. The infection erodes into the nerves and blood vessels. It often is lethal. Diagnosis requires aggressive surgical biopsy. Treatment includes vigorous repeated debridement and aggressive antifungal therapy with amphotericin B.

PERSPECTIVE

A patient with diabetes mellitus lives with a number of impositions. Not the least of these is simply having to contend with daily administration of treatment and monitoring therapy while walking the tightrope of metabolic balance. A well-educated patient with type I diabetes who responds appropriately to early cues of impending metabolic decompensation can avert diabetic ketoacidosis. Likewise, the increased susceptibility to infection and the retardation of growth and maturation characteristic of uncontrolled diabetes can be obviated with careful metabolic control. Although the chronic complications of diabetes are related wholly or partly to metabolic control, they remain an immutable threat to persons with diabetes. The leading cause of death among patients with diabetes with onset of disease before age 20 years is diabetic nephropathy. An analysis of mortality factors for patients with diabetes applying for life insurance between 1951 and 1970 revealed an actuarial projection of 33 years' life expectancy from onset of disease if younger than 30 years at onset of disease. It is doubtful that such a bleak projection now applies. Therapy has improved, and there is clearer recognition of the effect of glycemic control on risk of complications and on mortality, which was 2½ times greater in among patients with poorly controlled diabetes than among those with well-controlled disease. With further therapeutic advances likely, one can be optimistic that risk will be lessened further.

Patients with diabetes, particularly those with type I diabetes, still are targets of discrimination in employment. Although there is a rational basis for excluding persons who may have unexpected hypoglycemic episodes from occupations such as commercial pilot or truck driver, patients with diabetes can engage in most occupations successfully and need not be excluded from employment solely because they have diabetes. Educational opportunities for patients with diabetes are unlimited. Patients with diabetes can successfully pursue athletics. Diabetes per se should not be a reason for exclusion from many activities, and a person with diabetes can do almost anything a person without diabetes can with very little restraint, provided attention is paid to not sabotaging diabetes therapy.

Although the threats inherent in diabetes persist, there is reason for optimism that progress in medical research will continue to improve approaches to therapy for diabetes, lessen the impact of the disease, and ultimately eradicate it.

Treatment of patients with diabetes and their families requires that physicians muster all of their skills and resources and that they recruit nurse educators, dietitians, psychologists, and physician assistants to become part of the comprehensive management team. The expenditure of time and effort can be enormous, but the results of such expenditure make it worthwhile.

CHAPTER 412: METABOLIC BONE DISEASE

DOLORES SHOBACK AND COLEMAN GROSS

[Normal Skeleton](#)
[Metabolic Bone Disease](#)

NORMAL SKELETON

STRUCTURE

The skeleton is composed of several tissues, including bone, cartilage, and bone marrow. Bone itself is a highly organized and complex connective tissue made up of many cell types and a noncellular matrix (osteoid) rich in collagenous and noncollagenous proteins. Bone is unique among the connective tissues in that it undergoes a regulated and organized process of mineralization. Two principal types of bone are present in the skeleton—cortical and trabecular (also called *cancellous*). Although cortical bone and trabecular bone are composed of the same cellular and noncellular components, there are many differences between the two bone types. Cortical bone is compact mineralized tissue, whereas trabecular bone is composed of a rich latticework of bone struts. The axial skeleton is mainly trabecular bone, and the long bones of the peripheral skeleton are predominantly cortical bone.

FUNCTION

Trabecular bone and cortical bone are made up of the same cellular and noncellular components. The functional differences between these two types of bone are largely related to differences in structure. Cortical bone is highly compact; approximately 90% of its volume is calcified. Only 15% to 25% of the trabecular bone volume is calcified. The mechanical function of the skeleton is to provide sites for ligamentous attachment of muscles and to protect the viscera. The skeleton also serves an important metabolic function. It is the main reservoir for exchangeable calcium, phosphorus, and buffering molecules. The rich latticework of trabecular bone increases the surface area in contact with the marrow space and available for remodeling. As a result trabecular bone is highly metabolically active. Because of its compact structure, cortical bone is less metabolically active than trabecular bone, but it plays a critical mechanical role. Because it constitutes 80% of the skeletal mass, cortical bone makes a substantial contribution to the metabolic activity of the skeleton.

BONE MODELING AND REMODELING

Skeletal growth begins during fetal life and continues through the second decade. The skeleton is modeled by a variety of processes that include endocrine, paracrine, and mechanical factors. Bone formation occurs by means of endochondral ossification at the epiphyseal growth plates in the long bones or by means of intramembranous ossification from mesenchyme in the flat bones such as the skull, ribs, and pelvis.

Even though skeletal growth ceases in adults, bone remodeling continues in a regulated and organized way. The process of remodeling includes cyclic phases of bone resorption and formation. The temporal and spatial coordination of these two phases of the remodeling cycle has been called *coupling*. Under normal physiologic conditions, resorptive activity is essentially equally balanced by formative activity through this coupling mechanism. The relative constancy of bone mass during life under normal steady-state physiologic conditions attests to this fact. The processes that regulate resorptive and formative activities and their coupling are not clearly understood. A growing body of data implicates a large variety of factors, including steroid hormones, peptide hormones, prostaglandins, growth factors, and cytokines.

Osteoblasts are responsible for the production of osteoid and its subsequent mineralization to form new bone. Osteoblasts synthesize and secrete the various substances that compose osteoid, such as collagen. The osteoblast then directs the initial process of mineralization several days after initial deposition of osteoid matrix. During this time, several changes occur in the matrix, such as cross-linking of collagen fibrils, which facilitate the mineralization process. Under normal circumstances, the process of mineralization of newly formed osteoid takes several days. The mineralization lag time can be greatly increased in certain metabolic derangements, such as vitamin D deficiency (see later). The fate of the osteoblast is “sealed”; a large proportion of these cells encase themselves in newly formed mineralized bone and become osteocytes. These cells have numerous processes that penetrate bone within canaliculi. It is thought that these tubules may participate in cell–cell communication, may constitute a nutrient network, and may sense mechanical strain in bone. Another portion of osteoblasts appears to undergo apoptosis, which is a highly regulated process of programmed cell death.

The primary bone-resorbing cell of the skeleton is the osteoclast, a multinucleated giant cell derived from the monocyte-macrophage lineage. Its ability to resorb mineralized bone is the result of several highly specialized characteristics. Activated osteoclasts are polarized such that a portion of their membrane forms a ruffled border, which consists of deep folds of the plasma membrane. This membrane is anchored to the bone surface through specific interactions between integrin receptors in the osteoclast plasma membrane and collagen in bone matrix. Bone is resorbed through the action of hydrogen ions and proteolytic enzymes secreted by the osteoclast into the secondary lysosome formed by the osteoclast membrane on one side and the surface of bone on the other.

Metabolic bone disorders often occur when remodeling activity is altered from underlying pathophysiologic conditions. In healthy persons, the proportion of skeleton undergoing remodeling at any one time is regulated and on the order of 2% to 4%. Removal of old bone is a normal process necessary to maintain the structural integrity of bone. The resorption pit, or Howship's lacuna, is produced by the osteoclast and reaches a depth of approximately 50 μm after 7 to 10 days. After the resorption phase, osteoblasts begin the process of bone formation with the production of matrix, which starts mineralization 10 days later. The process of formation takes 3 to 4 months. The signals responsible for recruitment of osteoblasts to areas of resorption are poorly understood, yet it is clear that this is a tightly regulated process. A variety of signaling molecules have been suggested as potential coupling factors, including the newly described osteoprotegerin and its ligand.

METABOLIC BONE DISEASE

Metabolic bone disease consists of a diverse group of disorders. These conditions arise as a result of disordered bone formation, resorption, or mineralization. Often multiple defects occur as part of the pathophysiologic mechanism of a particular disease. The pattern of defects in any given disease is the result of the initial derangement and the metabolic and hormonal response to it.

The concept of bone turnover is helpful in understanding and categorizing metabolic bone diseases. *Turnover* refers to the balance of rates of formation and resorption. In metabolic disorders of bone, turnover may be increased or decreased often with relative uncoupling of the rates of formation and resorption which leads to increments or decrements in bone mass. Defective mineralization may be the predominant derangement, as in vitamin D deficiency osteomalacia, or it may be a minor histologic feature.

Osteoporosis is the most common metabolic bone disease. It is a multifactorial disease in which bone resorption exceeds formation (see [Chapter 465](#)). The focus of this chapter is on the other common forms of metabolic bone disease: osteomalacia, rickets, renal osteodystrophy, Paget's disease, and osteosclerosis.

RICKETS AND OSTEOMALACIA

Definition

Rickets and osteomalacia describe a clinical, radiographic, and histologic phenotype caused by a variety of disorders the pathophysiologic mechanisms of which decrease mineralization of cartilage and osteoid. Rickets affects children and is caused by abnormal calcification of epiphyseal cartilage and osteoid. Osteomalacia, the counterpart of rickets among adults because of the absence of longitudinal growth, is caused by a defect in mineralization of osteoid.

Incidence and Epidemiology

In the early part of this century, vitamin D deficiency was by far the most common cause of rickets and osteomalacia. Over the last 80 years, rickets and osteomalacia have greatly decreased in incidence in industrialized western countries. This decreased incidence is largely the result of understanding of the role of vitamin D in the prevention of this disease and the fortification of foodstuffs. In the developing world, however, rickets continues to be a serious public health problem. The incidence may be as high as 20%. This high incidence is caused primarily by inadequate access to fortified foods, limited exposure to sunlight because of cultural practices, and dark racial pigmentation that limits cutaneous production of vitamin D. Recent immigrants to western countries may have a high incidence of rickets because of adherence to cultural practices.

In recent years, it has become increasingly appreciated that subclinical vitamin D deficiency is common in western countries, particularly among the elderly. Dietary restrictions (avoidance of dairy products), limited access to nutritious meals, limited mobility, and an age-related decline in cutaneous vitamin D production are contributing factors. Subclinical vitamin D deficiency may have a role in as many as 50% of hip fractures.

With the decrease in incidence of rickets in western nations, attention to other, heretofore less common types of osteomalacia has increased ([Table 412.1](#)). These disorders have diverse pathophysiologic mechanisms and include acquired and genetic disorders. Many of these diseases have similar clinical signs and symptoms. The challenge for the clinician is to dissect out the pertinent findings that lead to the precise diagnoses and ultimately to tailored therapy.

Vitamin D deficiency	Phosphon	Genetic
Dietary deficiency	Phosphoridol	Wilson disease
Ineffective endogenous production	Impaired 1 α -hydroxylation	Cystinosis
Lack of vitamin D and metabolites	Resorcyl-vitamin D-resistant rickets	Scurvy
Nephrotic syndrome	Chronic renal failure	Acquired
Postrenal failure	Impaired 25-hydroxylation	Multiple myeloma
Colorectal deficiency	End-stage liver disease	Ameloblast
Nutritional calcium deficiency	Target tissue resistance to vitamin D	Nephrotic syndrome
Dietary calcium deficiency	Hereditary vitamin D-resistant rickets	Drugs and toxic agents
Hypocalemia	Hypophosphatasia	Heavy metals
Vitamin D malabsorption	Dietary	Aluminum
Gastrointestinal disorders	Low phosphate intake	Mercuripolymia
Gastroenteritis, partial or total	Phosphate-binding agents	Endocrine hyperparathyroidism
Intestinal bypass	Scurvy	Anticoagulants
Celiac disease	X-linked hypophosphatasia: vitamin or	Osteomalacia of chronic renal disease
Inflammatory bowel disease	hypophosphatasia	Bony metastases: breast
Renal insufficiency	Hereditary hypophosphatasia: vitamin	hypophosphatasia
Hyperparathyroid disease	with hypocalcemia	Drugs
Blunt trauma	Autosomal dominant	Fluoride
Chondrocalcinosis	Hypophosphatasia: vitamin	Estrogens, food preservatives
Alcoholic liver disease	Acquired	Anticoagulants
Celiac disease	Unrecognized osteomalacia	Defective bone matrix synthesis
Drugs	Specific hypophosphatasia	Phosphonate inhibitors: etidronate
Disordered vitamin D metabolism	Generalized	Warfarin
Increased catabolism of vitamin D	Renal tubular disorders (Fanconi's	Antineoplastic drugs
metabolites	syndrome)	Total parenteral nutrition

Table 412.1. CAUSES OF RICKETS AND OSTEOMALACIA

Etiology and Pathogenesis

Rickets and osteomalacia are caused by inadequate mineralization of epiphyseal cartilage or bone matrix. The diseases that lead to osteomalacia and rickets are extensive and are listed in [Table 412.1](#). Although the process of mineralization is complex and still poorly understood, it is clear that adequate local concentrations of calcium and phosphorus are an absolute requirement for formation of hydroxyapatite crystals, the predominant form of calcium phosphate in bone. Increasing evidence suggests an important role for osteoblasts in mineralization. Alkaline phosphatase produced locally by osteoblasts cleaves inorganic phosphate from phosphoproteins and pyrophosphate, a natural inhibitor of mineralization. In the process, inorganic phosphate levels are increased locally, and the increase contributes to a milieu conducive to the formation of hydroxyapatite crystals $[Ca_{10}(PO_4)_6(OH)_2]$. Other requirements include a neutral pH and type I collagen that has been properly matured by means of formation of cross-links and other modifications.

Other noncollagenous proteins also may play an important role in the regulation of mineralization. The elongated hydroxyapatite crystals are deposited linearly along collagen fibrils. Diminished supply of either calcium or phosphorus limits normal mineralization. Under such conditions, osteoid is no longer mineralized at the normal rate, and the amount of osteoid that accumulates and covers the surface of bone increases. The histomorphometric appearance indicates prolongation of mineralization lag time—the time required for mineralization of newly formed osteoid ([Fig. 412.1](#)).

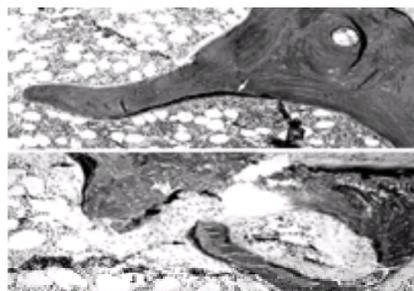

FIGURE 412.1. Specimen of trabecular bone, Goldner stain. *Top*, Normal bone. *Arrowhead* indicates osteoid, which appears darker than mineralized bone in black and white photograph. Goldner staining makes mineralized bone appear green, and unmineralized bone, orange. *Asterisk* indicates a collection of osteocytes. Cuboidal osteoblasts are visible along the mineralizing surface. Lamellar organization of bone is apparent. *Bottom*, biopsy specimen shows findings of osteomalacia with widened osteoid seams (*arrowhead*) that cover a larger amount of bone surfaces than normal.

Although increased amounts of osteoid may be present in states of high bone turnover, such as hyperthyroidism and hyperparathyroidism, because of accelerated bone formation, the presence of defective mineralization occurs only in osteomalacia. In addition to the presence of increased osteoid, the diagnosis of osteomalacia also requires abnormal mineralization. A presumptive diagnosis of osteomalacia can be based on clinical and laboratory findings (see later). Establishing the presence of this condition often necessitates histologic examination of a bone biopsy specimen.

Vitamin D has long been thought to play a central role in mineralization of bone and thus prevention of osteomalacia and rickets. More specifically, the active hormonal form of vitamin D, 1,25-dihydroxyvitamin D (1,25(OH) $_2$ D $_3$ or calcitriol), has been thought to have a central role in mineralization. Recent evidence from a variety of sources suggests that vitamin D may play a more permissive role in mineralization and may act predominantly by increasing intestinal absorption of calcium and phosphorus and enhancing mineralization. Children with a genetic form of rickets due to mutations in the nuclear receptor for vitamin D may have their bony abnormalities cured with intravenous infusions of calcium. The bony abnormalities associated in the vitamin D receptor gene disruption mouse model likewise may be rescued by a high calcium diet. Calcium treatment of children with nutritional rickets has been shown to be as effective as vitamin D and calcium. These data do not diminish the importance of vitamin D in bone homeostasis but indicate a complex and somewhat redundant system reminiscent of other hormonal axes.

Clinical Findings

Rickets generally becomes apparent by the age of 2 years. The children have short stature, delayed motor development, and skeletal abnormalities. Hypotonia and proximal muscle weakness may be present, and children often are listless and irritable. Tetany may be caused by profound hypocalcemia.

Because rachitic bones are soft, they bow under mechanical loads. This causes the typical deformities of the long bones—bowed legs (genu varum) and knock-knees (genu valgum). A characteristic prominence of the costochondral junction, the rachitic rosary, may be caused by widening of the growth plate of the anterior ribs. Because of chest wall deformities and muscle weakness, respiratory compromise and pneumonia can occur in severe cases of rickets. Calvarial deformities also can

occur; they include softening of the skull (craniotabes), frontal bossing, and basilar invagination.

The clinical findings of osteomalacia are more subtle than those of rickets. Bone pain and proximal muscle weakness may predominate. Pressure on bony areas may elicit tenderness. Lower back pain is a common symptom of osteomalacia, and spinal abnormalities such as absence of normal lordosis may occur. A waddling gait may be caused by weakness and bony abnormalities, which can include the pelvis. In severe cases, hypocalcemia can occur and cause paresthesia and tetany.

Radiographic Findings

The characteristic radiologic findings of rickets are caused by disordered mineralization in the hypertrophic zone of epiphyseal cartilage. The expansion of cells in this zone widens the growth plate. Inadequate mineralization produces irregular margins at the metaphysis and causes a frayed appearance on radiographs. Cupping of the metaphysis can be caused by continued expansion of the cartilaginous growth plate into the soft metaphysis, and metaphyseal widening occurs (Fig. 412.2). The epiphyseal bone also may have a similar appearance with irregular edges. These abnormalities are most common in areas of greatest growth, such as the knees, wrist, anterior ribs, proximal femur, and distal tibia. The bones usually are osteopenic. Because of weakness, bowing deformities may occur and predominate in the weight-bearing bones. Scoliosis may be present, as may slipped epiphyses, protrusio acetabuli, and a triradiate pelvis. Other radiographic changes include characteristic osteomalacic changes in mature bone (see later).

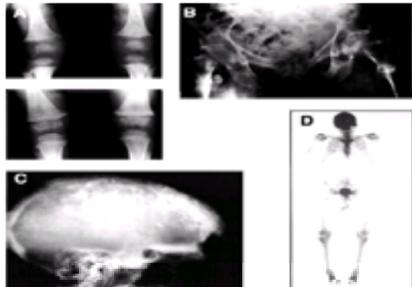

FIGURE 412.2. Radiographic findings in metabolic bone disorders. **A:** Epiphyseal fraying, cupping, and widening in rickets. **B:** Pseudofracture (Looser's zone) of the femur in osteomalacia. **C:** Cotton wool appearance and osteoporosis circumscripta in the skull in Paget's disease. **D:** Bone scintigraphy in Paget's disease showing increased uptake in the skull and spine.

The radiographic findings of osteomalacia are caused by excessive amounts of poorly mineralized osteoid. Lucent areas that appear as linear areas of rarefaction perpendicular to the cortical surface of the bone may be present and are known as *Looser's zones* or *pseudofractures* (Fig. 412.2). These areas are caused by accumulation of osteoid, often are symmetric, and occur at the medial aspect of long bones such as the femur near the femoral head or neck. Trabecular bone may appear to be coarsened and fuzzy. Vertebral collapse can occur and produce a biconcave appearance (codfish deformity) caused by pressure exerted by the intervertebral disks. Softening of the bone may cause basilar invagination, protrusio acetabuli, and a triradiate pelvis. In general, the bones are osteopenic and susceptible to fracture. Skeletal changes of secondary hyperparathyroidism such as brown tumors of osteitis fibrosa cystica may be seen.

Laboratory Findings

The laboratory findings of rickets and osteomalacia reflect the underlying pathophysiologic condition. A useful framework is to consider the abnormalities associated with the calciopenic and phosphopenic disorders. The calciopenic disorders are largely caused by nutritional deficiencies of calcium, vitamin D, or both or by inborn errors of vitamin D metabolism. Characteristic of these conditions are frankly low or low normal serum calcium and phosphate concentrations. In the presence of vitamin D deficiency, 25-hydroxyvitamin D (25-OHD) levels are low. Although 25-OHD levels of 4 ng per milliliter or less can cause osteomalacia, levels in the lower range of normal can be associated with histologic evidence of osteomalacia. Because of an increase in renal 1 α -hydroxylase activity due to low serum levels of phosphorus or compensatory increases in parathyroid hormone (PTH) levels, serum levels of calcitriol are typically normal. In severe vitamin D deficiency, in which 25-OHD is very limited, calcitriol levels may be low. The compensatory normalization of calcitriol levels and elevated PTH level may result in normal serum calcium and low serum phosphate levels, which may contribute to osteomalacia (see later). The bone-specific isoform of alkaline phosphatase is elevated in both rickets and osteomalacia.

Phosphopenic disorders usually are caused by primary or secondary renal defects that cause abnormal transport of phosphate in the nephron and thus cause phosphate wasting. These disorders include X-linked hypophosphatemic rickets, Fanconi's syndrome, and tumor-induced osteomalacia. Renal phosphate wasting leads to hypophosphatemia. Serum levels of calcium, PTH, and 25-OHD are characteristically normal. Levels of calcitriol also are within the normal range. They are said to be inappropriately normal because of the attendant hypophosphatemia, which normally increases renal 1 α -hydroxylase activity and raises calcitriol levels (see later).

Strategies for Optimal Care

Therapy for rickets and osteomalacia depends on an accurate diagnosis of the particular disease or syndrome that causes the skeletal abnormalities. When possible, efforts should be to remove or ameliorate precipitating causes of the disease. This is not always possible, because the etiologic factor can be elusive, genetic, or structural. Several syndromes may necessitate adjunctive surgical procedures to restore function. Many of the diseases that cause rickets or osteomalacia necessitate treatment with high doses of vitamin D, calcium, or phosphorus, and toxicities may occur in the course of therapy. To limit toxicity, pharmacologic intervention should be initiated at low doses and titrated upward guided by biochemical measurements, such as serum levels of vitamin D metabolites and PTH. The length of treatment can vary from a few months to a lifetime and must be based on the underlying pathophysiologic mechanism and clinical response.

RACHITIC AND OSTEOMALACIC DISORDERS

Vitamin D Deficiency

Natural sources of vitamin D are mainly limited to fish liver products and egg yolks. Fortified dairy products, however, are the main sources of dietary vitamin D. The best measure of nutritional vitamin D status is serum level of 25-OHD, the main circulating vitamin D metabolite. In general, rickets or osteomalacia is associated with a decrease in 25-OHD level to less than 5 ng per milliliter. At this level, other associated metabolic derangements are present, including secondary hyperparathyroidism and decreased serum calcium levels. Levels of 25-OHD toward the lower end of the normal range (10 to 20 ng per milliliter) also may be associated with the histologic changes of osteomalacia. Numerous commercial clinical laboratories provide reliable assays for measuring this vitamin D metabolite, thus making a diagnosis of vitamin D deficiency straightforward.

Several therapeutic regimens for rickets and osteomalacia have been evaluated and found to be effective. Vitamin D (ergocalciferol or cholecalciferol) is the agent of choice. Therapy usually consists of 5,000 to 15,000 international units (IU) of vitamin D daily for 3 or 4 weeks. Normalization of calcium, phosphorus, and PTH levels occurs within a few weeks, as does evidence of healing of rickets. Other changes, such as elevations in alkaline phosphatase level, may lag. Oral doses of vitamin D at higher doses once a month or periodic intramuscular injections are used less frequently, and only in specific cases. Once vitamin D stores have been normalized, adequate maintenance therapy should be supplied (400 IU daily or greater). Adults with osteomalacia likewise should have vitamin D stores normalized to effect a cure. Adequate vitamin D supplementation (400 to 800 IU per day) can be effective in preventing bone loss and fracture among elderly persons at risk of vitamin D deficiency. Calcium supplementation also should be provided.

Nutritional Calcium Deficiency

It has become increasingly clear that dietary calcium deficiency may cause rickets and osteomalacia. Both environmental and dietary practices, such as

vegetarianism, contribute to low calcium intake and absorption, particularly among some African and Asian populations. The diets of these cultural groups tend to be low in calcium but may be rich in substances that interfere with the absorption of calcium, such as phytate. Unlike persons with the vitamin D deficiency form of rickets and osteomalacia, those with calcium-deficiency rickets often have normal or near normal levels of 25-OHD. Serum calcium level is frankly low among these patients, and there is a compensatory increase in PTH level. Serum phosphorus level is variable and may not be decreased as it is in vitamin D deficiency rickets. Urinary excretion of calcium is low. It has been suggested that the muscular weakness associated with vitamin D deficiency is absent in calcium-deficiency rickets. Patients with this condition have radiographic evidence of osteopenia and hyperparathyroidism and have the typical metaphyseal changes of children, although the latter finding is variable. Management of this form of rickets or osteomalacia is centered on restoring calcium balance to normal. Vitamin D replacement is advisable (400 to 800 IU daily) to enhance calcium absorption, although recent evidence indicates healing of rickets with calcium supplementation alone.

Vitamin D Malabsorption

Severe gastrointestinal and hepatobiliary diseases may cause malabsorption of vitamin D. As a result of impaired mucosal integrity or biliary function, the lipid-soluble vitamin is poorly absorbed from the proximal small intestine, and osteomalacia may develop. Because substantial amounts of vitamin D are derived from cutaneous synthesis, malabsorption of vitamin D plays a lesser role in vitamin D economy. Other factors associated with these diseases may limit a person's exposure to sunlight, and dietary sources of vitamin D become more important. In such a scenario, malabsorption of limited dietary vitamin D plays a greater role in leading to metabolic bone disease.

It had been thought that impairment of enterohepatic circulation of vitamin D was the putative factor leading to vitamin D deficiency and osteomalacia in these disorders. Now, however, the etiologic importance of such a circulatory route is being questioned. Although metabolites of vitamin D can be recirculated, they are largely inactive. It is more likely that biliary secretion of vitamin D is the main excretory pathway for this molecule and limits toxicity from high doses of vitamin D. Another alternative mechanism is that increased production of calcitriol increases turnover of 25-OHD and eventually exhausts this substrate for the production of active hormone. In this scenario, vitamin D malabsorption decreases 25-OHD and calcitriol levels, decreases intestinal calcium absorption, and causes secondary hyperparathyroidism. The increase in PTH level accelerates calcitriol synthesis from the limited substrate 25-OHD and stimulates catabolism of 25-OHD. Although calcium absorption improves temporarily, ultimately the active hormone, calcitriol, becomes insufficient for adequate calcium and phosphorus absorption, and osteomalacia develops. Potential problems with this construct include the fact that calcitriol levels circulate at 1/100th to 1/1,000th the concentration of 25-OHD and that calcitriol levels often are normal in persons with osteomalacia caused by gastrointestinal and hepatobiliary diseases. Whatever the proximate mechanism, PTH levels often are increased and the effects of secondary hyperparathyroidism on the skeleton are severe in these diseases.

Gastrectomy

In recent years therapy for peptic ulcer disease has changed dramatically because of the introduction of potent drugs that inhibit gastric acid secretion and because *Helicobacter pylori* has been recognized as an etiologic agent. As a result, the role of surgical management of ulcer disease is decreasing. Nonetheless, large numbers of patients have undergone gastrectomy and are at increased risk of metabolic bone disease, such as osteoporosis and osteomalacia. Osteomalacia develops several years after gastrectomy and may occur among as many as 20% of patients. Because many patients with bone disease associated with gastric resection are elderly, the signs and symptoms often are complicated by the presence of osteoporosis.

Vitamin D deficiency, secondary hyperparathyroidism, and calcium malabsorption have pathophysiologic roles in the development of osteomalacia after gastrectomy. Therapy should be directed at normalizing the biochemical abnormalities. Vitamin D may have to be supplemented at high oral doses (1,000 to 5,000 IU daily) to overcome limited absorption. An alternative is parenteral administration of vitamin D. Levels of 25-OHD should be maintained in the normal range with such therapy. Calcium should be supplemented at 1 to 2 g daily. Adequate vitamin D and calcium nutrition can be gauged by following the decline of elevated PTH levels to normal. When osteoporosis coexists, antiresorptive therapy with a second-generation bisphosphonate can be considered. Intravenous dosing may be needed because of the inherently poor absorption of these agents.

Ileocecal Bypass

Ileocecal bypass surgery has been used to manage morbid obesity. This procedure is associated with several morbidities, including osteomalacia, which may develop after several years. Absorption of calcium and vitamin D, which occurs in the proximal small intestine, is disturbed, and the disturbance contributes to the development of osteomalacia. Management is similar to that of postgastrectomy osteomalacia, but parenteral administration of therapeutic agents is necessary more often because of the absence of functional proximal small intestine.

Celiac Disease

It is now appreciated that celiac disease is commonly associated with decreased bone mass and osteoporosis. As many as 26% to 36% of persons with celiac sprue may have osteoporosis, and many patients with osteoporosis have asymptomatic sprue. Because of the involvement of the duodenum and jejunum, vitamin D malabsorption can cause osteomalacia. Defective calcium absorption also is caused by vitamin D deficiency and villous atrophy. Levels of 25-OHD are low among persons with osteomalacia, but not all persons with sprue and low bone mass have frank vitamin D deficiency. Secondary hyperparathyroidism usually is present. Management of the underlying condition with a gluten-free diet should resolve the metabolic abnormalities of vitamin D absorption. Some patients may remain in a state of secondary hyperparathyroidism, indicating a defect in calcium absorption. If metabolic derangements persist after gluten restriction, vitamin D and calcium supplementation may be necessary. PTH may be a guide to monitoring of therapy.

Inflammatory Bowel Disease

Metabolic bone disease is associated more commonly with Crohn's disease than it is with ulcerative colitis because of the relative sparing of the small intestine in the latter disease. Nonetheless, glucocorticoids used in the management of both conditions may cause osteoporosis. Even in the absence of glucocorticoid therapy, osteoporosis is common in Crohn's disease. It may occur among as many as 30% of persons with this disease. Because the proximal small bowel commonly is affected, malabsorption of vitamin D and calcium occur in Crohn's disease and may cause osteomalacia. Levels of 25-OHD are low in approximately 65% of patients with Crohn's disease and can be in the osteomalacic range (<10 ng per milliliter) in as many as 25% of patients. Persons who undergo small-bowel resection may have additional derangements in vitamin D and calcium absorption that complicate their care. Patients with osteomalacia from inflammatory bowel disease should be treated in the same way as those with other skeletal disorders due to gastrointestinal diseases.

Hepatic Osteodystrophy

Metabolic bone disease is common among patients with hepatic diseases such as cholestatic liver disease, especially primary biliary cirrhosis, alcoholic liver disease, and chronic active hepatitis. The most common abnormality is osteoporosis. However, osteomalacia can occur with primary biliary cirrhosis and alcoholic liver disease. Biliary atresia has been reported to cause rickets among children. Bile facilitates absorption of vitamin D, and disruption of the enterohepatic circulation of vitamin D has been suggested to be the cause of the low 25-OHD levels that sometimes are encountered (see earlier). The 25-hydroxylation of vitamin D, which occurs in hepatocytes, is maintained until very late in the stage of hepatic disease and likely does not have a central role in the pathophysiologic mechanism of hepatic osteodystrophy. The use of cholestyramine decreases the availability of vitamin D by binding the vitamin in the intestine. Decreased cutaneous synthesis of vitamin D, because of jaundice and avoidance of sunlight, also may contribute to vitamin D deficiency. Persons with alcoholism may have poor overall nutrition and vitamin D deficiency. Management of osteomalacia should be directed at correcting the vitamin D deficiency by means of supplementation with vitamin D or one of its hydroxylated metabolites. 25-OHD is more polar than vitamin D and is more readily absorbed. It may be useful in some cases. Serum 25-OHD levels should be maintained in the normal range (20 to 45 ng per milliliter) with either form of vitamin D therapy. Adequate calcium nutrition should be supplied with supplements if necessary.

Disorders of Vitamin D Metabolism

Drugs

Commonly used medications may interfere with the absorption and metabolism of vitamin D and contribute to vitamin D deficiency and metabolic bone disease. Bile acid sequestrants such as cholestyramine impede vitamin D absorption. Use of these agents to treat persons otherwise not at risk of vitamin D deficiency and osteomalacia is not expected to cause clinically significant deficiency. Other agents may interfere with vitamin D metabolism primarily by increasing its catabolism.

The anticonvulsants phenytoin and phenobarbital induce hepatic cytochrome P450 enzymes, which catabolize 25-OHD. Osteomalacia and rickets have been reported to occur among patients living in institutions who take these drugs and have been associated with increased fracture risk during seizures. On the other hand, osteomalacia rarely is a complication of outpatient anticonvulsant therapy. Nonetheless, monitoring 25-OHD levels for patients taking phenytoin or phenobarbital is prudent, and vitamin D supplementation should be considered.

Pseudo–Vitamin D Deficiency Rickets

Also called *vitamin D–dependent rickets type I*, pseudo–vitamin D deficiency rickets is caused by an inborn error of metabolism in which 25-OHD is not converted to the active hormonal form of vitamin D, calcitriol. The gene encoding 25-hydroxyvitamin D 1 α -hydroxylase, the enzyme responsible for this conversion, has been cloned. Mutations have been identified in this gene in families with this disease, confirming the molecular pathogenesis of this disorder long predicted with clinical observation. The genetic defect is transmitted as an autosomal recessive trait, and affected children are homozygous for mutations in the 1 α -hydroxylase gene. At an early age these children come to medical attention with hypocalcemia, secondary hyperparathyroidism, and rickets. Growth retardation, hypotonia, tetany, and respiratory compromise may complicate the clinical course. Serum 25-OHD levels are normal in untreated patients, and calcitriol levels are very low. PTH level is elevated to compensate for hypocalcemia and the low calcitriol level, which has an inhibitory effect on PTH secretion. Normal replacement doses of calcitriol (0.25 to 1.0 μ g daily) are sufficient to manage the bone disease.

Hereditary Vitamin D–Resistant Rickets

Hereditary vitamin D–resistant rickets, also called *vitamin D–dependent rickets type II*, manifests in a manner similar to that of pseudo–vitamin D deficiency rickets. In contrast to children with pseudo–vitamin D deficiency rickets. The patient is resistant to calcitriol because of mutations in the gene that codes for the nuclear vitamin D receptor. As a result, these persons have cellular resistance to vitamin D at the target tissue level (e.g., intestine, kidney) and cannot respond to even supraphysiologic doses of calcitriol. Affected persons are homozygous for the autosomal trait and often are the products of consanguineous parents. Children come to medical attention at an early age with hypocalcemia and rickets. Tetany, muscular weakness, and dental abnormalities occur as they do in pseudo–vitamin D deficiency rickets. Alopecia totalis often occurs, but the pathogenesis is not understood. Unlike in pseudo–vitamin D deficiency rickets, in hereditary vitamin D–resistant rickets, calcitriol levels are elevated if the person is not treated. This finding reflects the increase in 25-hydroxyvitamin D 1 α -hydroxylase activity in response to hyperparathyroidism and hypophosphatemia. Some patients with this disorder have responded to treatment with very high doses of vitamin D (40,000 IU vitamin D, 20 μ g calcitriol daily) indicating a milder defect in the vitamin D receptor than is present in patients who do not respond to any amount of the vitamin. High-dose oral calcium (3 to 4 g daily) or long-term intravenous infusion of calcium has been shown to improve clinical status.

Phosphate Depletion

Chronic phosphate depletion may cause rickets and osteomalacia. Although hypophosphatemia can be caused by decreases in intake or absorption or by increases in urinary losses, metabolic bone disease caused by disordered phosphate economy usually is caused by defects in renal proximal tubular function. These diseases may be caused by a congenital or an acquired defect, which causes renal phosphate wasting and hypophosphatemia. Unlike the calciopenic causes of rickets and osteomalacia, the hypophosphatemic disorders are characterized by the absence of secondary hyperparathyroidism among untreated persons. Patients also may have quantitatively normal bone mass, but because of the mineralization defect, the skeleton is susceptible to deformity and fracture. [Table 412.1](#) lists disorders of phosphate depletion that cause metabolic bone disease.

X-linked Hypophosphatemic Rickets

X-linked hypophosphatemic rickets, also called *hypophosphatemic vitamin D–resistant rickets* is inherited as an X-linked dominant trait. The disease is most robustly expressed among hemizygous boys who come to medical attention with impaired growth, rachitic skeletal deformities, and hypophosphatemia. The patients usually have hypophosphatemia at birth. Skeletal deformities usually develop later, when the child begins weight bearing. The expression of the disease is quite variable. It ranges from isolated hypophosphatemia to severe rickets and osteomalacia. Among untreated persons, serum levels of 25-OHD are normal, and levels of calcitriol are low-normal. Because of hypophosphatemia, which would otherwise induce 1 α -hydroxylase, calcitriol concentrations are inappropriately normal among these patients. This suggests abnormal regulation of 1 α -hydroxylase, which is an important aspect of this disease. A large body of work with HYP mice, a murine homologue of this disease, has greatly contributed to an improved understanding of the pathogenesis of X-linked hypophosphatemia and phosphate conservation.

Genetic linkage studies and positional cloning strategies have led to the isolation of a candidate gene called *PEX* or *PHEX*. Mutations in the human gene have been identified among persons with X-linked hypophosphatemia. The gene codes for a membrane-bound endopeptidase. It has been suggested that this enzyme is normally responsible for proteolytic inactivation of a phosphate-lowering factor called *phosphatonin*. Among persons with X-linked hypophosphatemia, the *PHEX* gene product does not function normally and is unable to inactivate phosphatonin, and renal phosphate wasting occurs. This hypothesis is being addressed in several laboratories. Sporadic mutations may cause a nonfamilial form of X-linked hypophosphatemia. Similar disorders, such as hereditary hypophosphatemic rickets with hypercalciuria and autosomal dominant hypophosphatemic rickets, have similar physiologic mechanisms.

Tumor-induced Osteomalacia

Several patients have been described who had hypophosphatemia, hyperphosphaturia, and osteomalacia that reversed after resection of a tumor. These tumors were generally of mesenchymal origin, were benign, and often had vascular features. In rare instances the syndrome has been reported to be part of a paraneoplastic process associated with breast cancer, prostate cancer, small-cell carcinoma, and hematologic malignant disease. As in X-linked hypophosphatemia, the tubular maximum for phosphate reabsorption is abnormally reduced, and the deficiency causes renal phosphate wasting and hypophosphatemia. Patients often have bone pain, muscle weakness, and fractures. Rickets and decreased growth velocities may be present in children. The diagnosis may be delayed for several years because of the lack of awareness of the syndrome, small size and obscure location of the tumor, such as popliteal or nasopharyngeal tumors. Most patients are middle-aged when the condition is diagnosed; however, persons of any age can be affected. The diagnosis of this condition is confirmed when hypophosphatemia and osteomalacia reverse after resection of the tumor. A phosphaturic substance from tumor tissue of patients with this disorder has been isolated and partially characterized as a polypeptide. It is believed that tumor tissue in this disease is responsible for ectopic production of phosphatonin, which increases the phosphate excretion that underlies the pathophysiologic mechanisms of this disorder.

Fanconi's Syndrome

Fanconi's syndrome is generalized tubulopathy that occurs in association with inherited metabolic disorders or is acquired as the result of a toxic insult to the proximal nephron. Offending agents include toxic protein products associated with diseases such as amyloidosis, nephrotic syndrome, and myeloma; heavy metal exposure; and various drugs such as ifosfamide, aminoglycosides, and mercaptopurine. The tubulopathy of this disorder is characterized by phosphate wasting; defective reabsorption of glucose, amino acids, bicarbonate, uric acid; and proteinuria. Calcium also may be excreted in excess. Hyperphosphaturia, which leads to hypophosphatemia, may end in osteomalacia. Attendant acidosis and hypercalciuria also have a detrimental effect on the skeleton. In some forms of the syndrome, levels of calcitriol are low or low-normal, which may signify abnormal 1 α -hydroxylase regulation reminiscent of X-linked hypophosphatemia.

Strategies for Optimal Care

Therapy for tumor-induced osteomalacia centers on resection of the tumor. Calcitriol and phosphate supplementation may be a useful adjunct until the tumor is removed. For Fanconi's syndrome, the offending agent is removed if possible. Often the syndrome is not reversible. Therapy should provide oral phosphate supplementation of 1 to 4 g per day in divided doses with a neutral phosphate preparation. If levels of calcitriol are inappropriate, supplementation with calcitriol is advisable. Acidosis should be controlled. These measures often improve the clinical signs and symptoms of metabolic bone disease. Therapy for X-linked hypophosphatemia among children centers on phosphate supplementation. This usually requires 1 to 3 g of phosphorus a day in several divided doses. Vitamin D also is given, primarily as a means to prevent hypocalcemia from the increased phosphate load and to prevent secondary hyperparathyroidism. Calcitriol is the preferred form of vitamin D, and generally is provided at 1 to 3 μ g daily. Because of concern about nephrocalcinosis with this regimen, periodic renal ultrasonography and urinary calcium measurements are prudent. Therapy often is associated with improvement in signs and symptoms. Improving growth rates is an important therapeutic end point. Recent data suggest a benefit from recombinant human growth hormone therapy. The importance of continuing therapy through adult life is debatable, but therapy probably provides ongoing skeletal benefit.

RENAL OSTEODYSTROPHY

Definition

Uremic osteodystrophy represents the inevitable skeletal complications of end-stage renal disease. Because patients are surviving for many more years because of improvements in dialysis techniques and medical management, nearly all patients with chronic renal failure encounter some form of skeletal complications. Uremic osteodystrophy comprises the syndromes of secondary hyperparathyroidism, osteomalacia, aluminum overload, adynamic bone disease, and mixed lesions.

Incidence and Epidemiology

Uremic osteodystrophy is a common metabolic complication of uremia. All patients in whom renal functional capacity begins to decline experience the skeletal consequences of the reduced capacity to excrete dietary phosphate and ability to make the active form of vitamin D, calcitriol. The different clinical characteristics of an individual patient influence the type of presentation and the underlying histologic lesions present.

Etiology and Pathogenesis

Broadly defined, uremic osteodystrophy comprises high- and low-turnover forms of bone disease. The pathogenetic mechanisms responsible for the wide spectrum of bone histomorphometric findings and clinical and laboratory alterations in the forms of renal bone disease are complex. These mechanisms include the following physiologic derangements directly or indirectly caused by decreases in renal mass and function.

Phosphate Retention

Declining nephron function causes inability to excrete dietary phosphorus, a predominant component of dietary protein. This is evident as soon as renal function decreases to a glomerular filtration rate less than 50 mL per minute. As serum phosphate level increases, serum calcium level declines, and the serum calcium deficiency stimulates PTH secretion to maintain serum calcium homeostasis. The eventual result of hyperphosphatemia is the development of secondary hyperparathyroidism.

Calcitriol Deficiency

As glomerular filtration rate decreases to less than about 40 mL per minute, the ability of the kidney to produce calcitriol declines. This is further exacerbated by hyperphosphatemia, which suppresses calcitriol formation. The calcitriol deficiency impairs intestinal calcium absorption, which further decreases calcium availability.

Secondary Hyperparathyroidism

Low serum calcium concentrations and the calcitriol deficiency promote PTH secretion and parathyroid gland hyperplasia. Under normal physiologic circumstances, calcitriol exerts a negative effect on the transcription and translation of the PTH gene. Once parathyroid gland mass expands chronically, the calcium-nonsuppressible component of PTH secretion becomes progressively dominant. As the parathyroid glands grow, nodular hyperplasia can occur, as can clonal outgrowths of nodules that express mutations in growth-controlling genes such as cyclins.

Aluminum Accumulation

The aluminum present in dialysate and in phosphate-binding antacids can accumulate in bone along mineralizing surfaces and in parathyroid tissue. Aluminum accumulation in bone suppresses bone formation and produces a low turnover state. In the parathyroid glands, this impairs hormone secretion. The deficiency of PTH, which stimulates bone formation, is considered to be a key etiologic factor in low turnover states.

Acidosis

Progressive renal dysfunction is accompanied by the inability to buffer endogenously generated acid. Bone, because it is a reservoir of ions, is affected by acidosis. Physicochemical dissolution of bone matrix occurs and releases bicarbonate, carbonate, and phosphate anions as well positively charged calcium ions. Bone mineral is progressively lost if acidosis is not addressed through dialysis or dietary supplementation.

Resistance to Parathyroid Hormone

Resistance to parathyroid hormone has been ascribed to the chronically high levels of PTH resulting from the other derangements in mineral metabolism (hypocalcemia and perhaps phosphate retention) that accompany uremia. PTH receptors in bone are thought to be down-regulated by the chronically high hormone levels.

Other Uremic Toxins

In addition to aluminum, iron deposits can be present in the bone of uremic patients and have been implicated in the pathogenesis of low-turnover bone disease. Iron deposits in the parathyroid gland may induce a state of PTH insufficiency. Patients with diabetes mellitus, without stainable aluminum or iron, often have low-turnover bone disease. The pathogenesis of this condition is unknown, although roles for hyperglycemia and PTH suppression have been suggested. Deposition of b-2-amyloid can occur in patients uremia, especially after many years of dialysis, and predisposes these persons to fractures, bone cysts, arthropathy, and carpal tunnel syndrome.

High-turnover bone disease, the classic skeletal lesion of uremia, typically manifests in its early stages with mild secondary hyperparathyroidism. It progresses, if unaddressed, to full-blown osteitis fibrosa cystica. Along with this progression is a steady increase in serum intact PTH levels. The pathogenetic mechanisms cited earlier likely contribute to the development of this disorder along with a decrease in the number of calcitriol receptors in uremic parathyroid tissue.

Low-turnover bone disease in uremia can have several causes, such as aluminum intoxication. Because aluminum has been eliminated from dialysates, and long-term therapy with aluminum-containing antacids is rarely used, this form of low-turnover bone disease is now rare. In the past, before the central role of the kidney in the production of calcitriol was appreciated, patients with low-turnover bone disease had osteomalacia caused by vitamin D deficiency. The last type of low-turnover disease is an adynamic bone lesion of unknown causation. This form of low turnover often is associated with diabetes mellitus and is more common among elderly persons undergoing long-term dialysis than it is among other persons.

Mixed uremic osteodystrophy is a combination of low- and high-turnover bone lesions. The pathogenesis is uncertain. One suggestion has been that dietary deficiencies of calcium and phosphate can alter the composition of the bone formed. In such a situation, even under the influence of secondary hyperparathyroidism, the bone matrix is undermineralized. The appearance of the bone biopsy specimen in such a would include features of high-turnover bone disease along with poorly mineralized osteoid, which is characteristic of low turnover. Some patients with mixed lesions may have partially treated examples of both aluminum toxicity and secondary hyperparathyroidism.

Clinical Findings

Differentiating low- from high-turnover renal bone disease on the basis of clinical findings is challenging. Patients with most forms of renal osteodystrophy may have bone pain, weakness, and fractures. Bone pain occurs especially in the lower extremities and with weight bearing. Especially in cases of osteomalacia and low turnover, the muscle weakness accompanying renal osteodystrophy can be profound. That along with the bone pain can produce a waddling gait and great difficulty with walking. Patients with secondary hyperparathyroidism, especially in its severe forms, may report intractable itching. Depending on the magnitude of the calcium to phosphate product, especially if greater than 70, persons with uremia may have ectopic calcifications. These can occur in any soft-tissue site, including the peri-articular areas, lung, and heart and can be painful and even life threatening depending on the location. The most severe form of ectopic calcification is

calciophylaxis. This condition usually affects the digits, is caused by severe vascular calcification, and can cause ischemic necrosis of the involved digits. Fractures also can occur in any form of renal osteodystrophy, especially if it is severe. In osteomalacia and low-turnover bone disease, pseudofractures can be present ([Fig. 412.2](#)). Any site weakened by high-turnover bone disease or replaced by cystic lesions or fibrous tissue instead of normal bone can fracture with minimal trauma.

Laboratory Findings

The laboratory abnormalities in a given patient with uremic bone disease reflect the duration of chronic renal failure, the therapy used, and the underlying bone histologic lesions present. Patients with uremia may have reduced serum levels of total and ionized calcium, especially after many years of renal failure, when resistance to PTH and decreased production and action of calcitriol are evident. Hypocalcemia often occurs with severe secondary hyperparathyroidism before dialysis and therapy become effective. Because of underlying parathyroid hyperplasia and autonomy, some patients have hypercalcemia after dialysis becomes effective. Patients with low-turnover bone disease often maintain normal calcium levels, are very sensitive to therapy with calcitriol and calcium salts, and can have hypercalcemia.

Serum phosphorus level usually is in the normal or high-normal range early in renal insufficiency and may increase progressively with the decrease in glomerular filtration rate. Phosphorus level can be lowered through dialysis, judicious reduction of dietary protein intake, and the use of calcium salts as phosphate-binding therapy.

The measurement of plasma intact PTH levels is critical in the assessment of all forms of renal osteodystrophy. Early in renal functional decline, PTH levels begin to increase. Unless carefully controlled, these levels increase progressively to concentrations greater than tenfold normal. Several investigators have examined the relation between plasma PTH levels and underlying histomorphometric characteristics of bone in patients with chronic renal failure. In general, the highest PTH levels are related most closely to the presence of osteitis fibrosa and secondary hyperparathyroidism at bone biopsy and to a lesser extent with mixed bone lesion. Patients with low-turnover bone disease have the lowest PTH levels among patients with renal failure. Lowering these levels further with dialysis and calcium and calcitriol therapy has been implicated in the exacerbation of the low turnover–adynamic bone formation state. These general predictions hold for measurements of intact PTH. If only midregion or carboxyterminal PTH assays are available for clinical use, then the degree of elevation in PTH values is much more difficult to relate to the underlying bone lesion. This is because fragments of PTH detected with such assays accumulate progressively with renal functional decline.

Aluminum toxicity can be investigated for persons who have received aluminum-binding antacids. Serum aluminum levels or the response in aluminum 24 or 48 hours after an infusion of deferoxamine can be measured. The aluminum content of bone can be estimated in bone biopsy specimens and is typically elevated in states of aluminum excess.

An elevated level of serum alkaline phosphatase, an osteoblast-derived enzyme, usually indicates the presence at bone biopsy of increased bone turnover, as occurs in secondary hyperparathyroidism. The degree of elevation usually reflects the severity of the hyperparathyroidism. Alkaline phosphatase measurements are neither sensitive nor specific. Marked elevations in alkaline phosphatase are unlikely, however, to be found among patients with adynamic bone disease.

Histomorphometric analysis of bone by means of bone biopsy is the definitive means by which the underlying skeletal lesion and its severity can be best assessed for patients with chronic renal failure. This study is best performed after tetracycline labeling to assess rates of bone formation and mineralization. Proper analysis of bone biopsy specimens can be performed only at centers equipped for histomorphometry. Bone biopsy, although invasive, may be the only way to exclude aluminum osteodystrophy with certainty and to enable definitive therapy.

Radiologic Findings

A variety of radiologic features can be seen on images of patients with uremic osteodystrophy, although few signs are pathognomonic. Osteosclerosis, typified by “rigger jersey” spine, usually is caused by high-turnover bone disease and chronic excessive secretion of PTH. Pseudofractures are typical of osteomalacia and low-turnover bone disease but occur infrequently ([Fig. 412.2](#)). Subperiosteal resorption of bone, typically detected in the phalanges and distal clavicles, can occur at a variety of sites and is not confined to secondary hyperparathyroidism. b-2-Amyloid deposition often is accompanied by cystic changes in bones such as the femur, humerus, hands, and tibia. Osteitis fibrosa cystica, a once common skeletal presentation among patients with end-stage renal disease, is now seen in only the most severe cases of secondary hyperparathyroidism. It is manifested by multiple cystic lesions (brown tumors) throughout the skeleton at which pathologic fractures can occur.

Strategies for Optimal Care

Successful management of renal osteodystrophy involves a combination of dietary measurements, drug therapy, and dialysis. The spectrum of renal bone disease has a complex pathogenesis and can evolve over time, rendering this complication of uremia highly challenging for physicians to control. The goals of treating these patients can be broadly stated as follows: to maintain serum calcium and phosphorus levels as close to normal as possible; to regulate the level of parathyroid activity such that substantial increases in intact PTH and parathyroid hyperplasia are prevented; to maintain adequate vitamin D levels so that mineralization, given the proper complement of calcium and phosphorus, can proceed normally; and to avoid the accumulation of aluminum in bone and parathyroid glands.

Despite our understanding of the pathogenesis of several aspects of uremic osteodystrophy, successful therapy for this condition is difficult. Early in renal failure, dietary efforts should be made to ensure adequate calcium intake (1,500 mg per day) and restrict phosphorus ingestion (1,000 mg per day). Calcium carbonate or calcium acetate taken with meals can be used effectively to reduce serum phosphorus concentrations should the former maneuvers not be successful. Sevelamer hydrochloride (Renagel), a calcium- and aluminum-free phosphorus binding gel can be used to reduce serum phosphorus levels.

Vitamin D metabolites, particularly calcitriol, can be used to boost intestinal calcium absorption if dietary supplements are less than satisfactory. Calcitriol therapy in oral or intravenous bolus dosage forms has been used widely to control extant secondary hyperparathyroidism among patients with uremia. Calcitriol can effectively suppress PTH levels through either route of administration. Extremely judicious follow-up care of these patients is needed to prevent serious elevations in calcium–phosphorus product, extraskeletal calcifications, and frank hypercalcemia. Less calcemic analogs of calcitriol have become available for use in suppressing PTH secretion.

Patients with low-turnover bone disease caused by aluminum and symptoms related to accumulation of aluminum are best treated by means of chelation therapy with deferoxamine infusion. Relief from bone pain and muscle weakness, a decrease in the bone burden of aluminum, and improvement in bone formation rate can be achieved with this therapy. PTH levels also often increase after this therapy.

OSTEOSCLEROSIS

Definition

Osteosclerosis comprises a group of disorders that increase bone mass. Many of these disorders cause diffuse thickening of the bone in trabecular sites. Others cause localized sclerotic lesions or predominantly affect cortical sites (hyperostosis). The types of osteosclerosis are listed in [Table 412.2](#). Paget's disease of bone is relatively common, but many other types of osteosclerosis are quite rare and poorly characterized. The pathophysiologic mechanism of osteosclerosis involves excessive formation of new bone or decreased resorption of previously formed bone. When new bone formation is rapid, the newly deposited bone is woven. The new bone can be so voluminous that it occupies the medullary space and compromises hematopoiesis.

N-telopeptide. Because of the coupling of bone resorption and formation, markers of bone formation, such as alkaline phosphatase activity and osteocalcin, also are increased in Paget's disease. Osteocalcin is a highly specific protein product of osteoblasts. Measures of bone formation and resorption generally increase and correspond to disease activity and the extent of bone involvement. The values are elevated more typically in polyostotic disease and more variably in a monostotic presentation. Which value to measure has been a subject of debate. It has become clear that follow-up evaluation of disease activity and the effect of treatment can be accomplished with serial measurement of alkaline phosphatase activity in combination with clinical, radiologic, and scintigraphic assessment of disease activity.

Paget's disease does not typically alter serum calcium levels. Immobilization, however, for a patient with active bone remodeling can cause hypercalcemia (and hypercalciuria) and is an indication for therapy. A patient with Paget's disease who is found to have hypercalcemia should be evaluated for the presence of primary hyperparathyroidism. Secondary hyperparathyroidism can occur among patients with active Paget's disease. The elevation in PTH level in this situation presumably is caused by the intense stimulus to calcium accretion at sites of highly active bone formation and the inability of dietary calcium intake and intestinal absorption to meet the needs of the overactive bone remodeling state. Such patients need calcium supplementation to compensate for the increased calcium demand, and specific therapy for Paget's disease also should be provided. Because of the increased frequency of vitamin D deficiency among elderly patients, who are the typical patients with Paget's disease, it is sound practice to assess vitamin D sufficiency by measuring the 25-OHD levels of patients with secondary hyperparathyroidism and Paget's disease. Specific therapy can be directed at achieving vitamin D sufficiency for these persons and potentially better healing of the osseous lesions.

Radiographic Findings

The radiographic findings of Paget's disease often are characteristic and readily suggest the diagnosis. Skull involvement can cause osteoporosis circumscripta or a "cotton wool" appearance of intense blastic involvement with thickening of the bony cortex ([Fig. 412.2](#)). Involvement of long bones, for example, can be seen in the tibia and spare the adjacent fibula. Often the entire shaft of a long bone is affected. The radiographic findings are mixed areas of lucency and sclerosis. The entire bone typically is enlarged with thickened cortices and clear-cut bowed deformity. Pagetic involvement of the pelvis includes thickening of the iliopectineal (Brimmer's sign) and ilioischial lines and typical sclerosis, trabecular accentuation and thickening, and expansion of the bones. Paget's disease in the spine can affect several contiguous vertebral bodies but often is isolated to one level. The dense, sclerotic radiographic appearance of these bones has led to use of the term *ivory vertebrae* because of the striking radiodense appearance.

Scintigraphic studies can be quite helpful in assessing the extent of involvement and the level of disease activity and should be performed in the initial evaluation of all patients. Isotopic bone scanning can direct the clinician to the affected bones, which can then be assessed radiographically for features of Paget's disease ([Fig. 412.2](#)). The bone expansion and deformity and typical pattern of bone involvement can be readily appreciated on bone scans. A typical disease pattern often is helpful in differentiating other pathologic entities from Paget's disease.

The diagnosis of Paget's disease is made on the basis of a compatible history, physical examination, laboratory tests, radiographs, and bone scan. Radiographic findings often are characteristic of Paget's disease and sometimes are enough to confirm the diagnosis. Elevated alkaline phosphatase activity in the absence of liver disease provides strong support for the diagnosis. The level of alkaline phosphatase activity corresponds roughly with disease activity but is low in the presence of burned-out Paget's disease. The value can be only mildly abnormal or even normal in the presence of monostotic disease. Other differential diagnoses to consider are metastasis to bone, especially from carcinoma of the prostate, and fibrous dysplasia of bone, which does not share the osteoblastic or osteosclerotic appearance of Paget's disease.

Strategies for Optimal Care

Therapy for Paget's disease is becoming increasingly effective as new agents are developed that have enhanced therapeutic efficacy. The agents used include calcitonin, bisphosphonates, and nonsteroidal anti-inflammatory agents.

Calcitonin, an agent that selectively inhibits osteoclastic bone resorption, has been used in therapy for Paget's disease for more than 20 years. At present, the only form of calcitonin available in the United States is salmon calcitonin, which must be administered parenterally. It is given as a subcutaneous injection once a day (100 IU). Improvement in symptoms can occur within the first several weeks of therapy, and treatment usually is continued at this level for 6 months. On average, 60% to 70% of patients have 50% reduction in a measure of disease activity, such as an elevated alkaline phosphatase activity. After evidence of disease amelioration, the dose of calcitonin is reduced to 50 or 100 IU three times a week. Many patients continue with this dose for 1 to 2 years or indefinitely. It can be expected that once the medication is discontinued, relapse will occur that may or may not respond to repeated cycles of calcitonin therapy. It has been widely observed that patients readily become resistant to the effects of calcitonin and that all the abnormal biochemical indexes of active disease recur. In the past, calcitonin has been helpful in preparing patients with active Paget's disease for elective bone or joint surgery. This drug rapidly diminishes bone vascularity and the accelerated remodeling characteristic of the disease. Advantages of calcitonin therapy include a relatively low toxicity and rapid onset of action. The major disadvantages include parenteral administration and risk of resistance to the agent. Side effects include itching, flushing, nausea, and headache. These troublesome effects can occur among 10% to 20% of patients.

Therapy for Paget's disease has been revolutionized by several potent bisphosphonate compounds. These agents inhibit bone resorption and can expeditiously achieve biochemical and clinical remission of disease in a high proportion of patients. The first bisphosphonate used for management of Paget's disease was etidronate. This agent, at a dose of 400 mg per day (5 mg per kilogram) for 6 months, is as efficacious as calcitonin, producing approximately 50% reductions in alkaline phosphatase activity. Therapy with this agent must be cycled every 6 to 12 months because of the risk of inducing a mineralization defect in normal bone due to the deposition of etidronate in bone matrix. Etidronate is well tolerated except for occasional diarrhea.

Many patients with extensive polyostotic disease respond only partially to either etidronate or calcitonin. Such persons need more potent bisphosphonates. These needs have been met to a considerable extent by intravenous administration of pamidronate and oral preparations of alendronate and risedronate. These second- and third-generation bisphosphonates are potent antiresorptive agents and are effective at reducing biochemical measures of disease activity, such as alkaline phosphatase activity, to normal in most cases. Pamidronate is given as an intravenous infusion, typically at doses of 60 mg over 3 to 4 hours. Therapy can be given weekly for 3 or 4 weeks or monthly for 3 to 6 months and must be individualized because several regimens are effective and no single regimen has achieved universal acceptance. Alkaline phosphatase activity usually is carefully monitored because levels may decrease, even after one infusion, into the normal range and remain normal for as long as 1 year. The main adverse effect of pamidronate is precipitation of flulike symptoms within 24 to 48 hours of drug administration. This effect is self-limited and occurs among fewer than 10% of patients. Leukopenia and lymphopenia, which are self-limited, also can occur.

The oral bisphosphonates alendronate and risedronate are much more heavily used than all of the other therapies because of ease of administration by the oral route and greater efficacy. Alendronate, given at a dose of 40 mg per day for 3 months, has been shown to induce biochemical remission, defined as normalization of biochemical markers among 50% of patients, with an average decrease of 72% from baseline in alkaline phosphatase activity. Gastrointestinal side effects are the main adverse events. Risedronate, administered at 30 mg per day for 3 months, lowers alkaline phosphatase activity 65% to 70% with normalization among 50%. It also ameliorates bone pain among patients with moderate to severe Paget's disease. These agents have made it possible to achieve striking control of disease and clinical symptoms for most patients. Nonsteroidal anti-inflammatory agents can be combined with antiresorptive therapy for pain control.

An important clinical issue is which patients should be treated. Most clinicians treat patients with congestive heart failure, hypercalcemia, a neurologic syndrome or symptom due to Paget's disease, deformity of a weight-bearing limb, or bone pain referable to a pagetic lesion. Patients also are treated in preparation for a surgical procedure on an affected bone, if they have polyostotic disease, and if long-term bed rest is anticipated after surgery. Most clinicians treat patients at risk of complications such as compression syndromes or deformity because of the sites of involvement. The availability of potent therapies enables more rapid and durable therapeutic responses than were achievable only 10 years ago.

Osteopetrosis

Osteopetrosis comprises a group of related disorders. An autosomal dominant form of the disease often manifests among adults and has few if any symptoms. It is also called a *benign* form of the disease. The other well-characterized form is the autosomal recessive infantile type of the disease. This form of the disease often is fatal and has been called *malignant*. An intermediate form of osteopetrosis is caused by carbonic anhydrase II deficiency and can be associated with renal tubular acidosis.

Etiology and Pathogenesis

The pathogenesis of osteopetrosis is markedly diminished bone resorption caused by qualitative or quantitative osteoclast defects. Evidence from gene disruption

experiments on mice indicates that numerous genes can contribute to the osteopetrotic phenotype. This view is supported by the clinical diversity of osteopetrosis among humans. Osteoblast function also is likely important in the pathogenesis of some forms of this disease, perhaps through both direct and indirect mechanisms. It is becoming increasingly clear that control of osteoclast activity and number depends on paracrine signals from osteoblasts, and specific defects in osteoblast gene expression cause osteopetrosis in some animal models.

At histologic examination the absence of osteoclastic bone resorption is characteristic of osteopetrosis. The number of osteoclasts can be low, high, or normal, and normal ruffled borders are absent. Because of defective bone resorption, woven bone is common. Because bone formation rates are preserved in osteopetrosis, the defect in osteoclast function increases bone mass. This can increase the amount of bone in the marrow space and may cause obliteration and functional compromise of the space. Evidence of unresorbed mineralized cartilage within mature bone often is evidence of lack of bone resorption during modeling. The cortex is thickened with disorganized bone. Although the quantity of bone increases, the bone is structurally abnormal, fragile, and susceptible to fracture. Large amounts of osteoid also may be present in some patients with the infantile form of the disease, suggesting the presence of rickets and or osteomalacia.

Clinical Findings

Children with infantile (malignant) osteopetrosis come to medical attention at birth or during infancy. Initial symptoms include nasal congestion due to enlargement of the bony structures of the nose, cranial nerve palsy, including deafness and ophthalmic problems caused by narrowing of the cranial foramina and failure to thrive. Hydrocephalus also can occur. The encroachment of bone into the marrow space causes extramedullary hematopoiesis and hypersplenism. As a result, anemia, bleeding disorders, and increased susceptibility to infection are commonly encountered. Fractures are a common occurrence, often from minimal trauma. If the patient is not untreated, infantile (malignant) osteopetrosis generally is fatal after the first year of life.

The adult-onset form of osteopetrosis usually is a mild disease. It often is asymptomatic and is diagnosed when radiographs obtained after a low-trauma fracture show increased bone mass. Some patients have cranial nerve entrapment that causes facial palsy and hearing and vision loss.

Carbonic anhydrase II deficiency is an intermediate form of osteopetrosis. Patients may have short stature, failure to thrive, or fractures in childhood. Cranial nerve palsy occurs as with the other forms of the disease. Renal tubular acidosis complicates the disorder. Fractures are a common complication.

Several patients have been described who had hepatitis C and osteosclerosis. A diffuse osteopetrotic skeleton was characteristic. It is likely that cytokines produced as a result of the hepatic infection were responsible for the increase in bone mass. Other forms of osteopetrosis include a variety of rare disorders with varied presentations.

Radiographic Findings

Generalized increased density of bone is the primary radiographic finding of osteopetrosis. Both trabecular and cortical components of the skeleton appear thickened. Although the bones are diffusely dense, alternating areas of lucency and density can be seen, particularly in the long bones. The diaphyseal and metaphyseal portions of the long bones may be widened, giving rise to an Erlenmeyer flask deformity. Thickening of the cranium is visible and is particularly notable at the skull base. The rugger-jersey spine sign is caused by thickening of the cortical end plates of the vertebrae. Evidence of previous fractures is commonly encountered.

Laboratory Findings

Levels of calcitropic hormones usually are normal in patients with osteopetrosis, but abnormalities have been described and include elevations in PTH level, hypocalcemia, hypophosphatemia, and low calcitriol levels. Patients with carbonic anhydrase deficiency have evidence of metabolic acidosis. Patients with the infantile form of the disease often have the hematologic abnormalities described earlier.

Strategies for Optimal Care

The goal of treatment of patients with osteopetrosis is to increase bone resorption. Glucocorticoids, low-calcium diets, and high doses of calcitriol have been tried but have met with limited benefit and serious side effects. Bone marrow transplantation has been an important advance in the management of infantile osteopetrosis. Because osteoclasts are of the monocyte macrophage lineage, this therapy reverses the underlying defect in the most serious form of this disease. Because engraftment may not occur in patients with advanced disease in which there is substantial bony crowding of the marrow space, early transplantation is more likely to be successful. Correction of acidosis should be attempted in the care of patients with carbonic anhydrase deficiency. The mild adult form of the disease does not necessitate specific care. Fracture prevention should be part of the general care of patients with osteopetrosis.

CHAPTER 413: DISORDERS OF ENDOCRINOLOGY, METABOLISM, AND GENETICS

STANTON SEGAL

[Disorders of Galactose Metabolism](#)
[Disorders of Fructose Metabolism, Including Defects in Gluconeogenesis](#)
[Glycogen Storage Disease](#)

The disorders of carbohydrate metabolism that are inherited in a mendelian fashion include disorders of galactose metabolism; disorders of fructose metabolism and gluconeogenesis; and glycogen storage disease (GSD). All are rare biochemical genetic diseases with incidences of no more than 1 in 20,000 births. Diabetes mellitus, the most common disorder of metabolism and a result of both environmental and genetic factors, is considered in [Chapter 411](#). These inborn errors of carbohydrate metabolism are all inherited as autosomal recessive traits, except for the X-linked form of phosphorylase kinase deficiency, a GSD. The GSDs may affect liver, striated muscle, or both tissues. The most common GSDs are glucose-6-phosphatase, debrancher, and phosphorylase kinase deficiencies, which are forms that affect the liver and may result in hypoglycemia. Glucose-6-phosphatase deficiency is not only a hepatic glycogenosis but a disorder of gluconeogenesis. Other examples of the latter include fructose-1,6-bisphosphatase deficiency and, from a functional perspective, hereditary fructose intolerance. The most common inborn error of galactose metabolism is galactose-1-phosphate uridylyltransferase deficiency. Diagnosis of most of these disorders requires enzyme analysis in circulating blood elements or affected tissues. In some instances, a molecular diagnostic approach is available. For many of these disorders, prenatal testing can be performed. For any of these testing modalities, consultation with a metabolic specialist is essential.

DISORDERS OF GALACTOSE METABOLISM

The galactosemias are toxicity syndromes exhibited by patients with an inherited inability to metabolize the sugar galactose, a constituent of the disaccharide lactose found in milk and milk products. There are three disorders, each resulting from a deficiency of one of the enzymes that catalyze the normal conversion of galactose to glucose. Galactokinase catalyzes the reaction of galactose with adenosine triphosphate (ATP) to form galactose 1-phosphate, which is reacted with uridine diphosphate glucose by galactose 1-phosphate uridylyltransferase to form uridine diphosphate galactose and glucose-1-phosphate. The latter is then converted to uridine diphosphoglucose by the enzyme uridine diphosphoglucose. Deficiencies of these enzymes are all autosomal recessive genetic disorders whose genes have been located on chromosomes 17, 9, and 1, respectively. Homozygotes exhibit absent or very little enzyme activity, whereas obligate heterozygotes express about 50% normal activity. The uridylyltransferase gene has been cloned and sequenced, revealing a number of mutations responsible for single amino acid substitutions, the most prevalent being the Q188R, occurring in about 70% of alleles in the white population.

Uridyltransferase deficiency occurs in about 1 in 40,000 births and galactokinase in about 1 in 500,000. Epimerase deficiency is extremely rare; a benign form has been found in the African American, Swiss, and Japanese populations, and a symptomatic form, similar to the transferase deficiency described, has been reported in two Pakistani patients.

Cataracts are the principal finding in children with galactokinase deficiency who are otherwise healthy. Opacities have developed in some carriers. People younger than 40 years with cataracts may have lower-than-normal red blood cell galactokinase levels. Uridyltransferase deficiency usually manifests itself shortly after birth or within the first few weeks of birth with growth failure, vomiting, diarrhea, jaundice, hepatomegaly, proteinuria, and renal Fanconi's syndrome. Cataracts, although not easily seen with an ophthalmoscope, may be found by slit-lamp examination. Infants may die in the first few days of life from overwhelming *Escherichia coli* sepsis before other symptoms appear. Severely affected infants die of inanition and liver failure unless galactose is eliminated from the diet.

Galactokinase deficiency should be suspected in an infant or child with cataracts and the diagnosis confirmed by assaying red blood cell galactokinase. The constellation of abnormalities of transferase as well as severe epimerase deficiency also requires enzyme assay of red blood cells or fibroblasts. More than 40 states and some foreign countries screen newborns for galactosemia by analysis of blood spots on filter paper. Non-glucose-reducing substances in urine should make these disorders suspect. A great confusion in differential diagnosis is the distinction between transferase deficiency and primary liver disease because the liver is the major organ for galactose metabolism. Any disruption in hepatocellular function, or diversion of portal blood flow, may result in galactosemia and galactosuria.

A galactose-free diet is the cornerstone of treatment, and early elimination results in resolution of the toxicity syndrome seen in transferase deficiency, with regression of cataracts and jaundice. There is no indication that an ability to metabolize galactose appears with increasing age, so dietary restriction of milk and milk products as well as foods cooked with milk should not be relaxed in older children.

Dietary galactose restriction does not ensure a normal outcome. Despite excellent treatment, many patients with transferase deficiency have below-average mental development with learning defects. More than 60% have speech abnormalities, including verbal dyspraxia, and 80% of girls have hypergonadotropic hypogonadism. An ataxic neurologic syndrome may develop in older patients. Outcome does not differ in patients treated at birth before neonatal symptoms occur and in those recognized to have acute galactose toxicity syndrome within the first several weeks of life. This enigma remains to be unraveled.

DISORDERS OF FRUCTOSE METABOLISM, INCLUDING DEFECTS IN GLUCONEOGENESIS

HEREDITARY FRUCTOSE INTOLERANCE

The ingestion of fructose as the disaccharide sucrose is an important dietary habit of industrialized societies. Fructose in large amounts, particularly when administered intravenously, is not necessarily an innocuous dietary constituent, and the metabolic disease known as hereditary fructose intolerance underscores its potential toxicity. The clinical phenotype is variable, and this hereditary disease is thought often to escape detection. The incidence in different countries and in various ethnic groups is unknown, but the incidence in Switzerland was reported to be as high as 1 per 20,000 births.

The deficient enzyme is aldolase B (fructose 1,6-bisphosphate aldolase) located in liver, renal cortical, and small intestinal tissues. The human aldolase B gene has been cloned and is located on chromosome 9. Patients are unable to metabolize fructose beyond fructose 1-phosphate, which accumulates in the previously mentioned tissues. Clinical and laboratory findings depend on the rate of fructose ingestion. Hypoglycemia is secondary to an inhibition of both glycogenolysis and gluconeogenesis. The toxicity of fructose 1-phosphate accumulation is supported by the fact that patients with the rare entity known as essential fructosuria secondary to fructokinase deficiency manifest increased levels of fructose in blood, urine, and tissues but fail to manufacture fructose 1-phosphate and have no clinical abnormalities.

Hereditary fructose intolerance may be manifest as an acute toxicity syndrome in infants, children, or adults or as a chronic disease. In the latter instance, growth failure may dominate the clinical picture in infancy. However, the full-blown syndrome in infants chronically ingesting fructose consists of poor feeding, recurrent vomiting, jaundice, hepatomegaly, hemorrhage, and renal Fanconi's syndrome. Hypoglycemia usually occurs after acute ingestion of fructose. Acute exposure may result in sweating, tremulousness, dizziness, nausea, vomiting, lethargy, coma, and convulsions. Within 30 minutes, patients given fructose as part of a challenge test experience a depression in blood glucose and serum phosphorus and a rise in serum urate. Subsequently, some patients may display a rise in serum alanine transaminase (ALT), aspartate transaminase (AST), and bilirubin, proteinuria, and a generalized aminoaciduria. These are the chronic albeit intermittent laboratory findings in patients with hereditary fructose intolerance. Liver histologic examination shows steatosis, patchy necrosis of hepatocytes, fibrosis, and, sometimes, frank cirrhosis. Renal findings include dilatation of proximal tubules and possible vacuolization of cells.

The history, particularly as it relates to dietary sucrose or fructose ingestion, and laboratory findings suggest the diagnosis of hereditary fructose intolerance. Occasionally, the clinician may learn that the onset of symptoms occurred after first exposure of an infant to fruits or after administration of a sucrose-containing, soy-based infant formula, or that there is a peculiar aversion to fruits and sweets in the older patients. When the diagnosis is suspected, all exogenous sources of fructose and sucrose should be eliminated. An intravenous fructose tolerance test may reproduce some clinical and laboratory findings. Oral fructose loading should not be performed because of the severe acute reaction referable to gastrointestinal fructose "poisoning." The enzyme may be reliably assayed in liver tissue. Molecular analysis of DNA may establish this diagnosis in most patients. Two point mutations in the aldolase B gene account for 90% of the gene defects in the white population of North America.

The other rare disorders of metabolism that primarily affect gluconeogenesis include fructose-1,6-bisphosphatase, pyruvate carboxylase, and phosphoenolpyruvate carboxykinase deficiencies. Patients with fructose-1,6-bisphosphatase deficiency usually present in infancy with hypoglycemia, lactic acidosis, and ketosis associated with lethargy or coma, seizures, and hyperventilation. Although pyruvate carboxylase is a key enzyme in gluconeogenesis, most patients do not present with hypoglycemia. The most common presentation of this uncommon disease is that of a progressive neurodegenerative disorder with lactic acidosis. Only a few cases of phosphoenolpyruvate carboxykinase deficiency have been reported; some of these patients have displayed liver disease in addition to hypoglycemia and lactic acidosis.

GLYCOGEN STORAGE DISEASE

The liver glycogenoses include type I (glucose-6-phosphatase deficiency or von Gierke's disease), type III (glycogen debrancher enzyme deficiency), type IV (branching enzyme deficiency), and type VI (liver phosphorylase or phosphorylase kinase deficiency) GSDs. The muscle glycogenoses include type II (lysosomal α -1,4-glucosidase deficiency or Pompe's disease), type V (muscle phosphorylase or McArdle's disease), and type VII (phosphofructokinase [PFK] deficiency) GSDs. All of these diseases are rare. Types I, II, III, and VI account for most cases of GSD.

TYPE I GLYCOGEN STORAGE DISEASE

Type I GSD was first described by von Gierke in 1929. Four individual causes of hepatic glycogen storage secondary to defective function of glucose-6-phosphatase have now been reported. The first, termed type Ia, refers to a primary defect in the enzyme. Type Ib refers to defective transport of glucose-6-phosphate into the interior of liver microsomes, where glucose-6-phosphatase resides. Types Ic and Id refer to disorders of microsomal transport of phosphatase and glucose, respectively, which secondarily result in defective glucose-6-phosphatase activity. Defective activity results in glycogen accumulation in liver, kidney, and intestinal mucosa. In the liver, however, neutral lipid accumulation is even more prominent than that of glycogen. Clinical or laboratory findings include poor growth, marked hepatomegaly, hypoglycemia, lactic acidosis, hyperuricemia, and hyperlipidemia. Type Ib is unique in that there is also evidence of recurrent bacterial infections secondary to neutropenia and impaired neutrophil function. Of importance, many patients do not come to clinical attention until after the neonatal period. Hypoglycemia may not be readily detectable, although hypoglycemic seizures after 3 months of age are not uncommon. Physical findings may suggest the disease; the children may manifest doll-like facies with excess adipose tissue in the cheeks, a protuberant abdomen, an accentuated lumbar lordosis, relatively thin extremities, and short stature. Hypoglycemia associated with a rise in blood lactate may occur 4 to 6 hours after a meal. The serum almost always appears lipemic. Liver histologic findings include distention of hepatocytes with glycogen and fat. Long-term complications sometimes develop in the second and third decade of life.

The most important complications include hepatic adenomas and chronic renal disease. The latter is preceded by renal glomerular hyperfiltration, microalbuminuria, and, as in early diabetic nephropathy, histologic evidence of increased glomerular mesangium and focal glomerulosclerosis. Hyperuricemia is also a problem and affects the kidney. Patients may begin to show signs of gout near puberty, which often is delayed. The diagnosis can be suspected based on the clinical presentation and increased levels of blood lactate and serum lipids. A liver biopsy should be performed to demonstrate glycogen accumulation, quantitate its content, and obtain fresh or frozen tissue for glucose-6-phosphatase activity for differentiation of type Ia from the others.

Treatment centers around maintenance of normal blood glucose concentrations. Most of the secondary metabolic abnormalities, such as metabolic acidosis, ketosis, lactic acidosis, hyperuricemia, and severe hypertriglyceridemia, can be eliminated or retarded by maintaining blood glucose levels in the normal range. The use of nocturnal nasogastric infusion of glucose and orally administered, uncooked cornstarch has had a significant impact on metabolic control. These feeding regimens can be used in conjunction with regular formula or meal ingestion.

TYPE III GLYCOGEN STORAGE DISEASE

Most patients with debrancher deficiency have both liver and muscle glycogen accumulation. Clinical findings include hepatomegaly, short stature, variable skeletal myopathy, and cardiomyopathy. However, there is a spectrum of disease involvement. Hypoglycemia, hyperlipidemia, and elevated serum transaminases are usually detected in affected children. Hepatic findings usually abate after puberty. Conversely, skeletal myopathy may become more severe with time. Although hemodynamically significant cardiomyopathy is rare, biventricular hypertrophy with electrocardiographic abnormalities is frequently detected. Serum creatine kinase may be elevated. Liver histologic findings include glycogen accumulation with hepatocytes and fibrosis. Rarely, micronodular cirrhosis is detectable.

The diagnosis is suggested by these findings but, unlike type I GSD, blood lactate elevation is not prominent and there may be evidence of striated muscle dysfunction. In addition, glucagon administration after a meal may result in a rise in blood glucose, whereas in the fasting state the rise is usually absent. In type I disease, it is negative under both conditions. A liver biopsy allows for the demonstration of abnormal glycogen and deficient debrancher enzyme activity. Skin fibroblasts and blood lymphocytes or erythrocytes may also be helpful in measuring enzyme activity, as well as assessing debrancher protein or glycogen content. In particular, with both liver and muscle involvement, the muscle debrancher enzyme activity is also low in muscle biopsy specimens. The human muscle debrancher copy DNA (cDNA) has been cloned and the gene is located on chromosome 1.

As in type I disease, treatment consists of frequent meals with cornstarch supplementation or nocturnal glucose infusions. This regimen usually does not need to be as strict as that in von Gierke's disease.

TYPE IV GLYCOGEN STORAGE DISEASE

Patients with the branching enzyme deficiency accumulate long, unbranched glycogen molecules, which lack the α -1 to 6 side chains in cells or tissues that use glycogen as a storage form of glucose. The features include presentation in early infancy with poor growth and hepatosplenomegaly associated with cirrhosis and portal hypertension, hypotonia, muscle weakness and atrophy, decreased or absent deep tendon reflexes, and cardiomyopathy. Hypoglycemia is not a usual feature. Histologic examination of liver, muscle, heart, skin, intestine, brain, spinal cord, and peripheral nerve reveals the accumulation of abnormal, amylopectin-like material in cells. Presumably, this storage material results in progressive cell or tissue damage, such as diffuse interstitial fibrosis of the liver. Diagnosis requires analysis of a biopsy sample for demonstration of this abnormal glycogen-like species. Enzyme analysis of branching activity can also be performed. The cDNA for the branching enzyme has been cloned and the gene is on chromosome 3. There is no specific therapy. Although liver transplantation may be effective therapy for the end-stage liver disease, the long-term consequences of extrahepatic tissue involvement remains unknown.

TYPE VI GLYCOGEN STORAGE DISEASE

In this group of disorders, patients have a defect in either the hepatic phosphorylase enzyme itself or one of the four subunits of its regulatory enzyme, phosphorylase kinase. Only a few patients with the former type, which selectively involves the liver and has a relatively mild phenotype, have been reported. The liver phosphorylase gene has been cloned and is on chromosome 14. The most common form is the X-linked liver phosphorylase kinase deficiency. It typically presents in children with hepatomegaly, the characteristic protuberant abdomen of a hepatic glycogenosis, poor growth, and mild elevation of serum lipids and AST and ALT. Although ketosis is prominent during fasting, hypoglycemia is mild or absent. In general, the disease is not very severe and, except for the permanent effect on growth, most of the clinical and laboratory findings abate with age. Liver histologic analysis reveals glycogen accumulation in hepatocytes, but the appearance is somewhat different from that of types I or III GSD. Fibrosis with some inflammatory changes may also be seen. Usually the enzyme deficiency can be detected in erythrocytes, leukocytes, and skin fibroblasts, as well as in liver tissue. A high-carbohydrate diet with frequent feedings is usually sufficient for this type of GSD, which in general has a good prognosis. Other genotypic and phenotypic variants exist. For example, several patients with an autosomal recessive type of phosphorylase kinase deficiency have both liver and skeletal muscle involvement. There are other, rare variants in which the deficiency is restricted to either skeletal muscle or the heart. The basis for these disorders presumably is a specific alteration in one of the four subunits, which perturbs the formation of a tissue-specific phosphorylase kinase isozyme.

TYPE II GLYCOGEN STORAGE DISEASE

A deficiency of lysosomal acid α -glucosidase is the cause of Pompe's disease, which is therefore also a lysosomal storage disease. Disease primarily stems from the involvement of striated muscle tissue. Clinical onset may vary from the first weeks of life to adulthood. In the infantile form, cardiomyopathy and generalized myopathy are evident within the first 6 months of life. The heart, liver, and tongue are enlarged. The electrocardiogram usually shows the characteristic short PR interval and large QRS complexes. Patients usually succumb to cardiopulmonary disease by 2 years of age. In the juvenile and adult forms, skeletal muscle involvement usually dominates the clinical picture. It is a slowly progressive muscular disorder involving the proximal and respiratory muscles. Involvement of the latter is the usual cause of death. The electromyogram shows pseudomyotonic discharges. The serum creatine phosphokinase may be elevated. Histologic studies reveal glycogen

accumulation. The α -glucosidase deficiency may be ascertained in skin fibroblasts and in muscle and liver tissue. Several mutations have been described in the gene, which has been cloned and localized to chromosome 17. There is no effective treatment for Pompe's disease.

TYPE V GLYCOGEN STORAGE DISEASE

McArdle's disease is caused by a muscle glycogen phosphorylase deficiency. This is primarily a disease of adults, who present with exercise intolerance associated with muscle cramps and, frequently, rhabdomyolysis with myoglobinuria. Muscle fiber injury and secondary complications, such as acute renal failure, appear to correlate with the intensity of exercise. With mild to moderate sustained exercise, the "second-wind" phenomenon is often recognized, presumably the consequence of certain types of muscle fiber being able to sustain or upgrade the aerobic oxidation of fatty acids after increased muscle blood flow. Some patients have been known to complain of weakness and easy fatigability since childhood. Serum creatine phosphokinase is usually normal but increases after exercise. The electromyographic findings may be interpreted as those of a myositis. An ischemic exercise test may lend further support for the diagnosis: blood lactate levels fail to rise in the venous samples that drain an actively contracting muscle bed. Phosphorus (^{31}P) magnetic resonance spectroscopy may also be helpful in establishing the diagnosis. Analysis of a muscle undergoing isometric exercise by this technique fails to show the normal decrease in intracellular pH (acute glycogenolysis should increase lactic acid levels) and reveals an exaggerated decrease in levels of the high-energy compound phosphocreatine. Biochemical analysis of a muscle biopsy sample usually shows extremely low or undetectable phosphorylase activity and glycogen accumulation. As with the phosphorylase kinase enzyme discussed later, phosphorylase also exists in multiple tissue-specific isoforms. The muscle form is the only type found in the muscle of both children and adults. The gene for the muscle type has been cloned and is on chromosome 11. Several mutations have been identified. Approximately half of total enzyme in heart, one-fourth of that in brain, but none in liver is made up of the muscle isoform. There have been rare reports of disease in newborn infants, children, or elderly persons. The most important form of therapy for most patients with McArdle's disease is to avoid moderate to severe exercise. Ingestion of glucose or sucrose may increase exercise capacity in some affected individuals.

TYPE VII GLYCOGEN STORAGE DISEASE

Exercise intolerance in patients with the rare condition known as muscle PFK deficiency, which presents in childhood with muscle pain and easy fatigability, usually is more severe than that in type V GSD. These patients also usually manifest a subclinical hemolytic anemia; the residual enzyme activity in erythrocytes may be reduced, but only to 50% of normal. Carbohydrate intake is of no avail in this glycolytic defect in which muscle glucose cannot be metabolized to lactate and accumulates as glucose-6-phosphate and fructose-6-phosphate. These compounds may be detected in elevated amounts in the exercising muscles of patients using in vivo ^{31}P magnetic resonance spectroscopy. Because of impaired muscle ATP regeneration, serum urate levels may rise markedly during exercise. Histologic analysis of a muscle biopsy sample reveals the presence of an abnormal periodic acid-Schiff-positive, diastase-resistant polysaccharide material, presumably glycogen of long chain length. The mature muscle enzyme exists as a homotetramer of M subunits, the activity of which is decreased in a muscle biopsy specimen. The gene has been cloned and is on chromosome 1. Gene defects have been described, one of which is prevalent in people of Ashkenazic Jewish ancestry. There is also a relatively high prevalence of type VII GSD in the Japanese. A liver isoform of PFK has also been described, with the gene for the L subunit being present on chromosome 21. Erythrocytes express both the M and L subunit with five potential isozyme structures. The PFK activity is therefore not totally absent in erythrocytes because of the presence of the L_4 isoform. Avoidance of strenuous exercise is the only treatment advice that can be provided to these patients.

CHAPTER 414: DISORDERS OF ENDOCRINOLOGY, METABOLISM, AND GENETICS

ROBERT J. SMITH

[Defects in Amino Acid Catabolism](#)
[Storage Diseases](#)
[Membrane Transport Defects](#)
[Conclusion](#)

Amino acids, imino acids (proline and hydroxyproline), and a number of chemically related substances, such as taurine and γ -aminobutyric acid, are a large group of nitrogen-containing compounds that have important structural and metabolic functions in the body. In addition to their roles in protein and peptide structure, amino acids have multiple metabolic functions. To cite a few examples, glutamic acid and glycine are neurotransmitters; glutamine is an important substrate for renal ammoniogenesis pathways that are essential for acid–base balance; alanine and several other amino acids are endogenous sources of glucose (through gluconeogenesis); tryptophan is a precursor of bioactive amines such as serotonin (5-hydroxytryptamine); methionine is one of the major methyl group donors in the body and thus a precursor for choline, acetylcholine, creatine, and epinephrine; and the nonprotein amino acid ornithine is a key intermediate in the conversion of toxic ammonia to the nontoxic waste product urea.

The provision of adequate quantities of amino acids to serve their diverse metabolic functions is ensured by efficient gastrointestinal absorption (especially important for essential amino acids), resorptive transport of filtered amino acids in the renal tubules, and regulated biosynthetic pathways (in the case of nonessential amino acids). Pools of free amino acids are maintained in the plasma and intracellular compartments. The size of the reserve pools in specific tissues such as skeletal muscle and the transfer of amino acids between pools are determined by regulation of membrane transport and intracellular metabolic processes. The excess accumulation of individual amino acids is prevented by control of flux through the synthetic and catabolic pathways.

Heritable defects in amino acid metabolic and transport pathways account for nearly 100 clinical disorders, most of which occur as rare diseases with autosomal recessive inheritance. Although these disorders occur at increased frequency in consanguineous matings, clinical disease often is a consequence of inheritance from unrelated parents of two alleles with distinct mutations. [Table 414.1](#) is a list of selected disorders and their characteristics. Specific diseases most often have been detected through measurement of elevated amino acid or metabolite levels in the urine or plasma. The former are often referred to with the suffix *-uria* (e.g., iminoglycinuria) and the latter with the suffix *-emia* (e.g., hyperprolinemia). Disorders of amino acid metabolism can be catastrophic. They cause early fetal death; they can cause less severe metabolic disturbances compatible with transient or prolonged survival; or they can be associated with no apparent clinical sequelae. For disorders that cause clinical disease, early diagnosis is often important, because specific dietary therapy or pharmacologic agents may diminish the accumulation of amino acids or their toxic metabolites enough to prevent irreversible tissue injury.

TABLE 414.1. INHERITED DISORDERS OF AMINO ACID METABOLISM

For comprehensive discussions of the many known disorders of amino acid metabolism and transport, a specialized text should be consulted (see Bibliography). This chapter describes representative examples of different types of heritable amino acid disorders.

DEFECTS IN AMINO ACID CATABOLISM

EXAMPLE: PHENYLKETONURIA

Hyperphenylalaninemia is a group of heritable disorders characterized by impaired oxidation of the essential amino acid phenylalanine. Although phenylalanine is an essential amino acid and thus is not synthesized endogenously, levels in body pools depend on a balance between dietary intake and rate of conversion to tyrosine and other products. As shown in [Fig. 414.1](#), phenylalanine is oxidized to tyrosine by the hepatic and renal enzyme phenylalanine hydroxylase (PAH). More than 100 mutations in the PAH gene have been described that result in a deficiency of the enzyme and hyperphenylalaninemia. If the enzyme deficiency is severe and the disease is not controlled, toxic effects of phenylalanine lead to the syndrome of phenylketonuria, which is characterized by progressive central nervous system damage.

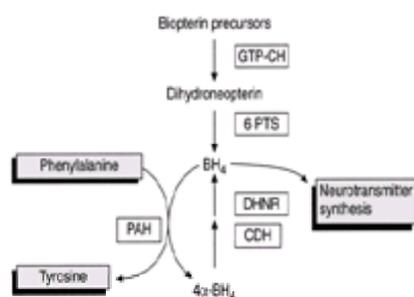

FIGURE 414.1. Pathways of phenylalanine catabolism. Enzymes are *PAH*, phenylalanine hydroxylase; *DHNR*, dihydropteridin reductase; *CDH*, 4a-carbinolamine dehydratase; *6PTS*, 6-pyruvoyl tetrahydropterin synthase; and *GTP-CH*, guanosine triphosphate cyclohydrolase. Mutations in each of these enzymes represent known or putative causes of hyperphenylalaninemia.

PAH activity requires molecular oxygen and a reduction in tetrahydrobiopterin (BH_4) cofactor ([Fig. 414.1](#)). This same BH_4 cofactor is required for synthesis of neurotransmitters (dopamine, norepinephrine, and serotonin) from tyrosine and tryptophan. In addition to PAH defects, mutations in the BH_4 recycling enzyme dihydropteridine reductase (DHNR) and the synthetic enzyme 6-pyruvoyl tetrahydropterin synthase (6PTS), as well as presumed mutations in the synthetic enzyme guanosine triphosphate cyclohydrolase (GTP-CH), lead to hyperphenylalaninemia. Central nervous system degeneration with these BH_4 defects tends to be more severe than with PAH mutations, probably because of combined effects of phenylalanine toxicity and neurotransmitter deficiency. Mutations in the 4a-carbinolamine dehydratase (CDH) BH_4 recycling enzyme have been shown to be responsible for occasional cases of hyperphenylalaninemia that are mild and transient, because

this reaction can occur to some extent nonenzymatically.

Most patients with PAH deficiency are homozygotes with two different allelic mutations affecting the enzyme. It is likely that clinical heterogeneity is explained by the effects of different mutations. Some heterozygotes have mild hyperphenylalaninemia, which may be caused by a dominant-negative effect of the mutant allele on the normal gene product. Although homozygous PAH deficiency is uncommon, the incidence of 1 in 10,000 births indicates an unexpectedly high gene frequency of mutations at close to 1%. This suggests the possibility of a heterozygote advantage, which has not been defined.

Although the various forms of phenylketonuria are rare autosomal recessive disorders, most newborns in the United States and Europe are screened for hyperphenylalaninemia because of the severity and lack of reversibility of the central nervous system damage. Early implementation of a phenylalanine-restricted diet can essentially eliminate appreciable central nervous system damage among patients with PAH deficiency. Supplemental therapy with orally administered, recombinant phenylalanine ammonia lyase is being investigated as a means of increasing dietary phenylalanine tolerance. Patients with BH₄ deficiency may need not only a restricted diet but also treatment with levodopa, 5-hydroxytryptophan, carbidopa, or folinic acid.

STORAGE DISEASES

EXAMPLE: ALKAPTONURIA

Alkaptonuria is a rare autosomal recessive inherited disorder caused by mutations in the gene that encodes homogentisic acid oxidase. Deficiency of this enzyme, which functions in a pathway of tyrosine metabolism, leads to accumulation and urinary excretion of the metabolic intermediate, homogentisic acid. Fresh urine appears normal initially, but after the urine stands, homogentisic acid becomes oxidized and imparts a characteristic black color to the urine. The presence of homogentisic acid in the urine appears to have no clinical consequences, but gradual deposition of homogentisic acid and its oxidation products in articular cartilage and certain other tissues ultimately causes progressive tissue damage. Pigmented oxidation products impart a bluish-black color to involved tissues that together with the characteristic degenerative arthritis results in the syndrome designated *ochronosis*.

Clinical features include bluish-black discoloration of the sclerae and ears; pigment deposits near the lateral rectus attachment sites in the sclerae; pigmented deposits in the heart valves, larynx, and tympanic membranes; darkening of the skin; and occasional pigmented renal or prostatic calculi. There is a probable increase in degenerative cardiovascular disease among older patients, but the dominant clinical finding is degenerative arthritis that manifests in the fourth and fifth decades with especially marked involvement of the lumbosacral intervertebral disks, dense calcification of disk spaces, fusion of vertebral bodies, and a remarkable absence of osteophyte formation or calcification of intervertebral ligaments. In many patients, the urinary abnormalities are not detected, and the diagnosis is made only during evaluation for arthritis.

Among patients with suspected alkaptonuria, the simplest diagnostic procedure is to alkalinize a urine sample. This accelerates oxidation of the homogentisic acid and generates a bluish-black pigment within several hours. Confirmation of the diagnosis then requires direct assay of homogentisic acid with one of several methods. The only truly effective therapy is nonspecific management of osteoarthritis supplemented with anti-inflammatory agents during episodes of acute arthritis. With the recent proof that mutations in homogentisic acid oxidase cause alkaptonuria, it can be anticipated that efforts will be made to correct this enzymatic deficiency with various approaches to gene therapy.

MEMBRANE TRANSPORT DEFECTS

EXAMPLE: CYSTINURIA

Cystinuria, with a prevalence of about 1 case per 7,000 persons, is the most common of about 10 known disorders of amino acid transport. The renal transporter for resorption of dibasic amino acids in the proximal convoluted tubule is defective. As a result, there is excessive urinary excretion of cystine, lysine, arginine, and ornithine. Cystine is the least soluble of all commonly occurring amino acids. As the urine becomes concentrated, cystine precipitates and forms renal, ureteral, and bladder calculi. More than 30 mutations in the dibasic amino acid transporter gene (*r BAT*) have been related to cystinuria. It is possible that the disease can be caused by mutations in other proteins as well. The inheritance pattern is recessive but complex because of the apparent occurrence of different allelic mutations.

Cystine stones, which account for 1% to 2% of all urinary tract calculi, are responsible for the only known consequences of cystinuria. Clinical features include hematuria, flank pain, obstructive uropathy, urinary tract infection, and for some patients, renal failure. Although there is also a defect in intestinal amino acid transport, adequate amino acid absorption appears to occur through alternative routes. Tissue uptake of dibasic amino acids is mediated by unrelated transporters, so plasma and tissue concentrations of cystine and other amino acids are normal.

The diagnosis of cystinuria should be considered for all patients with urinary tract stones. The diagnosis can be confirmed with the demonstration of typical hexagonal crystals in the urine, cystine excretion in the range of 0.6 to 1.8 g per day, and cystine in urinary stones. In evaluating patients with renal calculi, it should be recognized that stones of mixed composition often occur in cystinuria and that there is an absence of measurable cystine in some stones. The primary treatment is directed at prevention of stone formation by increasing fluid intake and urine volume. Although cystine solubility increases if the urinary pH is greater than 7.5, vigorous measures are needed to achieve this degree of alkalization with a consequent risk of calcium stone formation or nephrocalcinosis. Dietary restriction has little effect because of endogenous cystine synthesis, but there should be an effort to avoid diets high in the cystine precursor methionine. Penicillamine can be used to treat patients who do not respond to hydration alone. This drug is excreted in the urine, where it forms a mixed disulfide with cystine that has greatly increased solubility. Because the metabolic defect responsible for stone formation is localized to the kidney, patients with renal failure who receive transplants do not have recurrent disease.

CONCLUSION

Although there are many heritable amino acid disorders, acquired diseases of amino acid metabolism or transport rarely occur, presumably reflecting the adaptive capacity of normal pathways. Selected examples of inherited disorders are discussed to illustrate the types of defects and the spectrum of clinical syndromes. As the molecular basis of inherited disorders is better defined, it will undoubtedly become apparent that multiple distinct genetic mutations can cause similar syndromes, perhaps with minor alterations in clinical outcome that may contribute to disease heterogeneity. With better definition of the heritable defects in amino acid pathways, more specific and effective forms of nutritional and pharmacologic therapy have been developed. This has led to improved survival for many patients and a greater need for internists to understand the principles of management of disorders of amino acid metabolism. With the promise of gene therapy, it can be anticipated that the treatment of patients with inherited metabolic defects will become a much more important part of adult medicine.

CHAPTER 415: MULTIPLE ENDOCRINE NEOPLASIA

STEPHEN J. MARX

[General Clinical Features](#)
[Pathogenesis](#)
[Multiple Endocrine Neoplasia Type 1](#)
[Multiple Endocrine Neoplasia Type 2](#)

Multiple endocrine neoplasia (MEN) is the occurrence of two or more endocrine tumors in a patient. It has several causes, including chance. Two syndromes stand out, and only these are discussed ([Table 415.1](#)). MEN type 1 (MEN1) includes tumors of the parathyroid glands, enteropancreatic neuroendocrine tissue, and anterior pituitary gland. MEN type 2 (MEN2) includes tumors of the calcitonin-secreting thyroid cells (C-cells), the parathyroid glands, and adrenal medulla with three subtypes. The most common subtype of MEN2 is MEN2a with C-cell malignant growth, pheochromocytoma, and hyperparathyroidism. A second syndrome (MEN2b) consists of C-cell malignant growth, pheochromocytoma, ganglioneuromas, and a characteristic body and facial appearance. A third type is familial medullary thyroid cancer only (FMTC).

Feature	Multiple Endocrine Neoplasia Type 1	Multiple Endocrine Neoplasia Type 2 (three subtypes)
Gene and mechanism	MEN1 tumor suppressor	RET tumor activator (oncogene)
Tissue affected	Parathyroid glands Enteropancreatic neuroendocrine (gastrinoma, insulinoma, etc.) Anterior pituitary Carcinoid of foregut Lipoma, angiolipoma, collagenoma	1. Parathyroid glands 2. Calcitonin-producing parafollicular cells of thyroid (C-cells) 3. Adrenal medulla 4. Cutaneous skin amyloidosis 5. Ganglioneuroma, neurofibromatosis
Surgery to prevent or control malignant growth	No good method	Effective at young age for C-cell cancer
Mutation testing	Limited role	Important to prevent malignant growth

*Labeled tissues are numbered within MEN2 and grouped among the following three MEN2 subtypes: multiple endocrine neoplasia type 2a (MEN2a) 1, 2, 3, 4; multiple endocrine neoplasia type 2b (MEN2b) 2, 3, 5; familial medullary thyroid cancer only (FMTC) 2.

TABLE 415.1. COMPARISONS BETWEEN MEN1 AND MEN2

MEN1 and MEN2 are rare syndromes with disproportionate importance because of their implications for cancer causation and prevention and because of their genes' relevance to some common tumors. Each has a prevalence of about 1 case per 30,000 persons. A substantial fraction of all persons with endocrine tumors has hereditary MEN1: 25% with gastrinoma, 5% with prolactinoma, and 2% with primary hyperparathyroidism.

GENERAL CLINICAL FEATURES

MEN1 or MEN2 can be inherited in an autosomal dominant manner. In general the age of onset is earlier for tumors in MEN1 or MEN2 than for the same tumors in sporadic cases. Another prominent feature in MEN1 or MEN2 is tumor multiplicity. *Multiplicity* means multiple tissues and multiple tumors, which includes bilaterality in a tissue. As in several other multiple neoplasia syndromes, some tumors in MEN1 or MEN2 can become malignant.

PATHOGENESIS

The *MEN1* gene is on chromosome 11; it encodes a nuclear protein that binds to at least one transcription factor (JunD). The *MEN1* gene is a tumor suppressor gene, like the main genes for retinoblastoma, breast cancer, and intestinal polyposis. A tumor suppressor gene contributes to tumors after sequential inactivation of both copies of the gene frees one cell to grow into a clonal tumor.

MEN2 is caused by a gene, *RET*, on chromosome 10 and unrelated to the *MEN1* gene. *RET* encodes a plasma membrane–spanning tyrosine kinase. Unlike *MEN1*, *RET* encodes a direct-acting oncogene that becomes oncogenic by mechanisms of overactivation. Mutation of only highly select *RET* codons can cause *RET* kinase activation and consequently MEN2. There also is a strong relation between the codon of a *RET* mutation and the resulting phenotype. In general, *RET* activation by germ line mutation of codons in a small cysteine-rich extracellular domain causes MEN2a, whereas *RET* germ line mutation at one intracellular codon (methionine to threonine at codon 918) causes MEN2b. A more heterogeneous group of *RET* mutations, overlapping largely with those in MEN2a, occurs in FMTC.

The *RET* gene participates in several other important but only remotely related disorders. *RET* was first discovered because it can be overexpressed from a splicing rearrangement. This is not found in MEN2 but is a frequent contributor to common (nonhereditary) papillary thyroid cancer. *RET* is one of several genes, the inactivation of which can cause aganglionosis of the intestines (Hirschsprung's disease). It is thus paradoxical that MEN2a and Hirschsprung's disease occasionally coexist.

The *MEN1* and *RET* genes each contribute through somatic (nonhereditary) mutation to development of many sporadic tumors of the sorts that occur with the respective hereditary syndrome. For example, somatic inactivation of both copies of *MEN1* is the most frequent mutation in common parathyroid adenoma or in gastrinoma.

MULTIPLE ENDOCRINE NEOPLASIA TYPE 1

PARATHYROID GLANDS

MEN1 or MEN2 tumors are similar to common solitary tumors. This chapter focuses on important differences. Hyperparathyroidism is the most common and usually the first endocrine expression of MEN1. The earliest onset is at approximately 8 years of age with a peak onset at 20 to 25 years (the peak onset of sporadic parathyroid adenoma occurs at 55 years of age). There is approximately 95% expression by 50 years of age. Hyperparathyroidism progresses slowly. At early ages, the main surgical indications are degree of elevation of calcium and parathyroid hormone levels and likelihood of urolithiasis. Surgery is more difficult than for sporadic parathyroid adenoma because of tumor multiplicity and likely postoperative recurrence (50% rate of recurrence at 8 to 10 years), quite specific for MEN1. Thus the indications for parathyroid surgery for MEN1 should be somewhat more stringent than those for surgery for sporadic adenoma. The recommended operation is subtotal parathyroidectomy. Some centers cryopreserve fragments of the most normal tumor for possible autograft if hypoparathyroidism develops.

ENTEROPANCREATIC NEUROENDOCRINE TISSUE

Multiple enteropancreatic tumors develop in almost all patients with MEN1 in an age-dependent manner. Almost all MEN1 pancreatic islet tumors stain positively for one or more peptide hormones. The most common are insulin, glucagon, and pancreatic polypeptide. Synthesis of a peptide does not necessarily imply oversecretion of that peptide (for example, clinical glucagonoma is rare in MEN1).

Approximately 40% of patients with MEN1 have Zollinger–Ellison syndrome, the expression of gastrinoma. MEN1 gastrinoma typically develops at 35 years of age, one decade earlier than sporadic gastrinoma. The typical symptoms are those from excess gastric acid: peptic pain, reflux, diarrhea, and altered bowel habits. Hyperparathyroidism, common in MEN1, exacerbates gastrin hypersecretion while euparathyroidism and hypoparathyroidism decrease it. Diagnosis is from a combination of measurement of basal gastrin, secretin-stimulated gastrin, basal acid output, and endoscopy. Achlorhydria is a major differential diagnosis for hypergastrinemia.

Endoscopic examination of patients with MEN1 should include evaluation of the stomach for gastric carcinoids. With gastrinoma, somatostatin receptor imaging is helpful to grade tumor extent and the possibility of hepatic metastasis. Most or all gastrinomas are malignant, though often indolent. The gastrinomas of MEN1 usually are multiple, small, submucosal nodules mainly in the duodenum. Gastrinoma in MEN1 is highly difficult to improve, much less cure, with gastrointestinal surgery. Treatment in most cases should be pharmacologic because drug therapy is highly effective for the humoral component. Pharmacologic treatment is with gastric acid secretion blockers such as omeprazole. Therapy should be monitored with periodic measurements of gastric acid.

Insulinoma with a prevalence of 15% is less common than gastrinoma in MEN1. Insulinoma in MEN1 is usually benign, usually caused by only one tumor, and is imaged poorly with somatostatin receptor scintigraphy. The treatment is surgery. Nonfunctioning tumors are those that do not oversecrete a hormone. They may synthesize but not secrete a hormone, or they may oversecrete a nonhormonal peptide (pancreatic polypeptide or chromogranin A). Nonfunctional tumors are not recognized as often as they occur because they become clinically apparent only when they become large or metastatic. Very uncommon pancreatic endocrine tumors in MEN1 include glucagonoma, vasoactive intestinal peptide–secreting tumor (VIPoma), and growth hormone releasing hormone–secreting tumor (GRH-oma). When recognized, these tumors are generally malignant, large, and metastatic.

ANTERIOR PITUITARY GLAND

Anterior pituitary tumors occur in 30% of cases. Most are prolactinoma, followed by growth hormone or growth hormone–prolactin, then corticotropin, and so-called nonfunctional tumors. The features and management of pituitary tumors in MEN1 are similar to those of sporadic tumors.

OTHER FEATURES

Carcinoid of the foregut (thymus, bronchus, or stomach) occurs in 10% of cases and is frequently malignant. However, it does not cause carcinoid syndrome or ectopic corticotropin syndrome. As a preventive measure, thymectomy is usually done through the neck at initial parathyroid surgery for MEN1. Lipoma occurs in one-third of cases. Subtle skin tumors (angiofibroma and collagenoma) are very common in MEN1. These can contribute to the diagnosis of MEN1 and are best recognized by an experienced dermatologist.

PREVENTION AND MANAGEMENT OF MALIGNANT GROWTH

Approximately half of patients with MEN1 have a malignant MEN1 tumor, but only one-fourth of the tumors grow or metastasize rapidly. Gastrinoma is most frequent, and the rest are other enteropancreatic tumors and foregut carcinoid tumors. About one-third of deaths of MEN1 are caused by these malignant lesions. Unlike the effective malignancy prevention of MEN2, there is no effective prevention or cure of the malignant tumors of MEN1. A common strategy is resection if a pancreatic nodule larger than 2 to 2.5 cm is imaged. Other treatment considerations include debulking surgery, somatostatin analogs to inhibit hormone secretion, interferon- α , and chemotherapy.

DIAGNOSIS OF MEN1 AND FOLLOW-UP CARE

In a sporadic case, the standard criteria for diagnosis are tumor in two of the three major tissues (parathyroid, enteropancreatic, anterior pituitary). Other features, such as multiple parathyroid tumors, render *MEN1* mutation more or less likely. In a family, the clinical criteria for diagnosis are one case with MEN1 plus a first-degree relative with tumor in one of the three major tissues. The principal conditions in differential diagnosis are familial hyperparathyroidism, which can be an expression of MEN1, familial hypocalciuric hypercalcemia, or several less common disorders. Cost-effective biochemical ascertainment can include ionized calcium, parathyroid hormone, and prolactin, measured at 3- to 5-year intervals between the ages of 5 and 50 years. Nonhormonal markers (pancreatic polypeptide and chromogranin A) are not useful. Robust *MEN1* mutation testing could obviate much of this biochemical ascertainment testing.

Follow-up care of an affected patient or carrier is complex. Each tissue must be handled independently. New tumors will arise, and removed ones can recur. A program must be designed to strike a balance of cost and efficacy.

MULTIPLE ENDOCRINE NEOPLASIA TYPE 2

CALCITONIN-PRODUCING PARAFOLLICULAR THYROID CELLS (C-CELLS)

C-cell cancer accounts for only 10% of all thyroid cancers; of this minority, 10% to 20% are associated with MEN2. Sporadic tumor is typically recognized around the age of 50 years as a palpable nodule and with metastases. Sporadic MEN2 can have a similarly advanced presentation. Most cases of familial MEN2 are recognized by means of prospective screening, excepting MEN2b, half of which is from new mutation.

The normal C-cells or parafollicular cells are dispersed between the thyroid follicular cells and their basement membranes. The earliest C-cell lesions in MEN2 are benign clumps of C-cells, called *C-cell hyperplasia*. Malignant growth progresses with age. It is expressed subclinically in virtually all cases by 30 years of age but is expressed clinically in only one-third of patients by 70 years of age. C-cell cancer is multifocal and consequently bilateral in MEN2. Calcitonin immunohistologic testing or assay of an aspirated specimen can be specific. The malignant growth spreads to local nodes and occasionally to the liver at a late stage. Although it is a hormone, calcitonin even at high levels in blood causes no symptoms. Thus calcitonin is more correctly considered a useful tumor marker in this context. Almost all C-cell cancers cause hypercalcitoninemia at early stages. Unstimulated calcitonin has limited value for diagnosis because there are many false-positive findings, including some other malignant neoplasms.

Biochemical screening can be conducted by means of measurement of calcitonin after brief infusion of a bolus of pentagastrin, a synthetic secretagogue for calcitonin. However, experience has shown excessive numbers of false-positive results even with careful attention to normal control ranges. The standard of diagnosis is not tumor but *RET* germ line mutation (see later). Tumors are most aggressive in MEN2b and least aggressive in FMTC.

Therapy for C-cell cancer in MEN2 is thyroid surgery. An early operation for prevention is total thyroidectomy with removal of central nodes and with an attempt to preserve parathyroid function. When the likelihood or extent of metastases is higher, the extent of lymph node removal should increase. Calcitonin should be used as a tumor marker for follow-up care. Once C-cell cancer persists or recurs after an extensive operation, gains or even cure from further resection are sometimes still possible.

PHEOCHROMOCYTOMA

Pheochromocytoma, usually benign, occurs in 50% of cases of MEN2a or MEN2b. Pheochromocytoma is functionally similar in MEN2 and in sporadic cases. However, in MEN2 the tumors secrete a higher fraction of epinephrine and are often bilateral. The age at onset is earlier and syndrome dependent: 25 years for MEN2b, 40 years for MEN2a. A danger specific to MEN2 is hypertensive crisis during labor or during thyroidectomy. Pheochromocytoma, because of its unpredictable course and metabolic severity, remains an important cause of mortality due to MEN2. In MEN2, pheochromocytoma can be screened with urine epinephrine and norepinephrine testing. This test should be supplemented with imaging by means of computed tomography or magnetic resonance imaging. Treatment is surgery; experienced teams are divided between unilateral and bilateral adrenalectomy.

PARATHYROID DISORDER

Hyperparathyroidism is a component of MEN2a but not of MEN2b or FMTC. Hyperparathyroidism is uncommon (10–40%) and generally mild and asymptomatic in MEN2a. There may be one or two parathyroid tumors, as opposed to three or four in MEN1. The indications for surgery are the same as for conventional hyperparathyroidism. Prior thyroid surgery for C-cell disease can make this procedure as difficult as a typical parathyroid reoperation. In 20% of cases, asymptomatic parathyroid tumor is encountered during thyroid surgery for MEN2a. Standard treatment is surgical removal of enlarged parathyroid glands. Hyperparathyroidism in MEN2a does not have a high rate of postoperative recurrence in the manner of that in MEN1.

OTHER FEATURES

Patients with MEN2a occasionally have cutaneous lichen amyloidosis. These are intrascapular plaques preceded by pruritus. This condition is limited to occasional MEN2a families, and the associated *RET* mutations are not specific. Patients with MEN2b have a characteristic marfanoid habitus plus hypertelorism, bumpy lips, and bumpy tongue. They also have characteristic neural lesions—submucosal neuromas, ganglioneuromas, and thickened corneal nerves. Submucosal neuromas cause the bumpy lips and bumpy tongue. Intestinal ganglioneuromas cause bowel motility problems.

PREVENTION AND MANAGEMENT OF MALIGNANT DISEASE

Unlike the malignant growth in MEN1, that in MEN2 often can be prevented or cured with early intervention. *RET* mutation testing is the most effective way to ensure correct diagnosis and early intervention. Although MEN2 is rare, it is a paradigm for early testing and early therapy for malignant neoplasia. This testing once was conducted with mixed results by means of radioimmunoassay for pentagastrin-evoked calcitonin. With the possibility of finding the *RET* mutation in almost all cases, robust DNA diagnostic testing has replaced calcitonin testing for this purpose. For MEN2b and MEN2a the earliest ages at cancer detection are 1 and 5 years. These are the best ages for *RET* mutation testing and preventive thyroid surgery. For these purposes, FMTC is handled as MEN2a.

DIAGNOSIS OF MEN2 AND FOLLOW-UP CARE

Clinical diagnosis in a sporadic case of MEN2 is based on tumor multiplicity or on characteristic histologic features (C-cell hyperplasia and tumor multifocality). Once the diagnosis is suspected, *RET* mutation testing is the critical index. It is possible to identify a *RET* mutation in virtually every case of MEN2. C-cell follow-up testing depends on whether the tumors have been completely extirpated. Carriers and patients with MEN2 should undergo annual tests for pheochromocytoma and tests for hyperparathyroidism every 5 years.

CHAPTER 416: GENETIC DISORDERS

RICHARD W. ERBE

[Mendelian Inheritance and Disorders](#)
[Chromosomes and Chromosomal Disorders](#)
[Multifactorial Inheritance and Disorders](#)
[Mitochondrial Inheritance and Disorders](#)

Genetic disorders have traditionally been classified into three major groups—chromosomal disorders, mendelian disorders, and multifactorial disorders. The chromosomal disorders consist of numerical or structural abnormalities in one or more chromosomes that are visible with a light microscope or detected by means of molecular techniques. The phenotypic abnormalities associated with these disorders are caused by the gain or loss of often large numbers of genes produced by structural or numeric chromosomal changes or by inactivation of genes at chromosomal breakpoints. More recently recognized are disorders resulting from imbalance of the paternal and maternal genetic contributions at particular loci, designated parent-of-origin defects. Mendelian disorders are caused by mutations at a single genetic locus. These mutations usually consist of substitutions of a single DNA base or a few bases or the addition or deletion of bases in a region too small to be seen with a light microscope.

In mendelian disorders, one mutant gene or a pair of mutant genes at a single locus is sufficient to produce an abnormal phenotype under the usual environmental conditions. Some mendelian disorders in which the severity of the phenotype characteristically increases in successive generations are known to be caused by expansion in the corresponding locus of a special segment of coding or noncoding DNA known as a trinucleotide repeat. Multifactorial disorders are caused by the collective contributions of mutant genes at several loci acting in concert and with usually unidentified environmental factors. These mutations may be similar to those that produce mendelian disorders, but the loci at which the mutations occur are individually less influential in determining the phenotype. Still other disorders are caused by mutations in the circular 16,569 base pair mitochondrial chromosome or by mutations in somatic cells alone acting in concert with meiotically inherited, or germ line, mutations. Somatic mutations, and combined somatic and germ line mutations, underlie the diverse forms of cancer.

Many references in this chapter, especially in the tables, are to OMIM numbers. These represent the on-line version of the numbering system originated many years ago by Dr. Victor A. McKusick in his book *Mendelian Inheritance in Man*. OMIM and another database of genetic disorders, GeneClinics, are especially useful examples of the wealth of readily accessible, current information about genetic disorders available at the World Wide Web addresses at the end of this chapter.

MENDELIAN INHERITANCE AND DISORDERS

Mendelian traits, normal and abnormal, are those that follow the pedigree patterns described in 1865 by Gregor Mendel in research with garden peas and only decades later recognized to apply to humans. Mendelian traits or disorders are determined by genes at a single locus in either the homozygous or heterozygous state. Variant DNA sequences for genes at a given locus are alleles or alternative forms of a gene. A *locus* is a site on a chromosome occupied by a gene or a set of alleles. When the paired genes at a locus on homologous chromosomes are identical, the person is homozygous at that locus and is called a *homozygote*. When the genes differ, the person is heterozygous and called a *heterozygote* or if phenotypically unaffected a *carrier*. The term *compound heterozygote* describes a genotype in which two different mutant, potentially pathogenic alleles are present rather than one mutant allele and one normal allele. The term *hemizygous* applies to the state of men and boys with regard to the X chromosome because the Y chromosome does not provide corresponding paired genes. *Hemizygous* also applies to genes in the region of an autosome for which the corresponding region on the homologous chromosome has been deleted.

The pedigree patterns exhibited by mendelian phenotypes depend on whether the gene responsible is on an autosome or on a sex chromosome and whether the trait is dominant or recessive. They may thus be autosomal dominant, autosomal recessive, or X-linked. Distinctions between dominant and recessive traits apply at the level of the phenotype, the outward expression of the gene, rather than the gene itself. A *dominant trait* is one in which heterozygosity is sufficient to produce a recognizable corresponding phenotype. A *recessive trait* is fully expressed only when the person is homozygous or hemizygous for that allele. According to the formal definition, a recessive gene has no detectable expression in heterozygotes. There are techniques to detect expression at some level of nearly all functional genes. In practice, phenotypes are classified as recessive when they are not evident at clinical examination of a heterozygote. The term *codominant* is used to describe loci at which the products of both alleles are expressed in heterozygotes, generally in regard to serum proteins (e.g., globins), cell-surface markers (e.g., ABO blood groups), and the like.

To illustrate these distinctions, consider the sickling hemoglobin disorders that involve one or more genes for hemoglobin S or its potentially pathogenic alleles, hemoglobin C or b-thalassemia (see [Chapter 241](#) and [Chapter 244](#)). The homozygous disorder is sickle cell anemia, in which the person's genotype at the b-globin locus is SS. The heterozygote or carrier has sickle cell trait and has the b-globin genotype AS. The compound heterozygote is represented by hemoglobin SC disease, a sickling disorder that is usually less severe than sickle cell anemia, or by Sb-thalassemia, a variable sickling disorder. The terms *homozygous*, *heterozygous*, and *compound heterozygote* can be applied either to a person or to a genotype. With regard to whether a trait is considered dominant or recessive, sickle cell anemia is an autosomal recessive disorder, the life-threatening signs and symptoms of which are manifest in the homozygote. In contrast, sickling phenomenon (sickling of erythrocytes in vitro under appropriate test conditions) is dominant, occurring when either one or two genes for hemoglobin S are present.

AUTOSOMAL DOMINANT DISORDERS

Pedigree Patterns

Autosomal dominant disorders typically exhibit generation-to-generation transmission without intervening unaffected offspring, expression among both sexes, a 50% probability that offspring of an affected person will inherit the gene for the disorder, transmission from an affected parent of either sex to offspring of either sex, and absence of the disorder among offspring of persons who have an affected parent but did not themselves inherit the gene. A new mutation often can be inferred to have occurred when a person with clear phenotypic evidence of an autosomal dominant disorder is born to a family in which neither the parents nor other relatives are similarly affected.

Many autosomal dominant disorders, however, exhibit incomplete penetrance and variable expressivity. *Penetrance* is the degree to which a gene is likely to be expressed when it is present. It is an all-or-none phenomenon for any one person but can be expressed as a percentage when large numbers of persons known to have a particular allele are examined. (For example, when one-half of a large number of persons with a mutant allele for a particular disorder express one or more characteristics of that disorder and one-half do not, the penetrance is 50%.) In general, the more thorough the clinical examination, the greater the penetrance proves to be. *Expressivity* is the variability in severity of manifestations of a genetic disorder or trait among different persons with the same genetic disorder as defined with clinical criteria and sometimes additional laboratory, radiographic, and other criteria. In some autosomal disorders the phenotypic severity varies little between affected members of any given family, whereas in others it varies greatly. Factors contributing to greater variability seldom are specifically identified. They may, however, include the effects of other genes, of stochastic factors in one or more steps leading to gene expression, or of environmental factors alone or in combination.

Genetic heterogeneity is the principle that similar phenotypes can be caused by different genotypes. For example, both Charcot–Marie–Tooth disease of hereditary motor and sensory neuropathy and Alport syndrome of hereditary nephritis and sensorineural deafness have both autosomal dominant and X-linked forms. These are examples of locus heterogeneity, because the loci for the two clinically similar forms of these disorders must reside on an autosome and on the X chromosome, respectively. Polycystic kidney disease and osteogenesis imperfecta both have autosomal dominant and recessive forms. *Allelic heterogeneity* is phenotypic differences between affected individuals and families caused by different mutant alleles. For example, 85% of families with cystic fibrosis have pancreatic insufficiency as one of the manifestations; the other 15% do not have pancreatic insufficiency as part of the cystic fibrosis phenotype.

In autosomal dominant disorders, heterozygotes manifest the abnormal features of the disorder. Through various mechanisms, the deficiency or defectiveness of the product of one of two paired alleles produces an abnormal phenotype. In contrast, partial or complete loss of function of one allele in autosomal recessive disorders produces a carrier state and little or no phenotypic change. By definition, a dominant disorder should have its full expression regardless of the presence or absence of a normal allele at the homologous locus. This is rarely the case among humans. When apparent homozygosity for an ordinarily autosomal dominant disorder has been observed, the child is consistently much more severely affected. Examples include familial hypercholesterolemia and achondroplasia. The only known exception

to increased severity of expression of an autosomal dominant phenotype in the homozygous state is Huntington's disease. In this disease, there is no observable phenotypic difference between the homozygote and the heterozygote, as it is a truly autosomal dominant disorder.

Examples of Autosomal Dominant Disorders

[Table 416.1](#) presents examples of disorders that illustrate the principles of autosomal dominant inheritance. Achondroplasia is a fully penetrant, dominantly inherited form of dwarfism characterized by short limbs, a large head, and a characteristic habitus. The proportion of persons with achondroplasia caused by new mutation is high, 85% to 90% being born to parents of normal stature. In general, the more severe the phenotypic effect of a disorder, the higher the proportion of new mutations. Achondroplasia poses several major barriers to reproduction. The result is a reduction in *fitness*, the likelihood of reproducing and transmitting one's genes. Achondroplasia due to new mutation, like new mutations in several other autosomal dominant (neurofibromatosis type 1) and X-linked (hemophilia A) disorders, is more likely with increasing age of the father, the paternal age effect.

Disorder	Major Features	Gene and Gene Product	Additional Information	Availability of Molecular Testing
Achondroplasia	Short stature, short limbs, large head, characteristic habitus, osteoarthritis, spinal stenosis, sleep apnea, and hearing loss	Fibroblast growth factor receptor 3 gene (FGFR3) on 4q12	OMIM 103200	Yes
Neurofibromatosis (NF1)	café-au-lait spots, neurofibromas, Lisch nodules, optic pathway gliomas, and learning disabilities	Neurofibromin 1 gene (NF1) on 17q11.2	OMIM 134930	Yes
Marfan syndrome	Connective tissue disorder, tall stature, long limbs, aortic aneurysm, and lens dislocation	Fibrillin-1 gene (FBN1) on 15q21.1	OMIM 154700	Yes
Polycystic kidney disease (ADPKD)	Progressive renal enlargement and cyst formation, extrarenal manifestations include hepatic and pancreatic cysts and cerebral artery aneurysms	Polycystin-1 gene (PKD1) on 16p11.2 and polycystin-2 gene (PKD2) on 4q13	OMIM 103400 and 103420	Yes

TABLE 416.1. AUTOSOMAL DOMINANT DISORDERS

Charcot–Marie–Tooth disease (CMT) is a group of inherited disorders that together constitute the most common form of hereditary motor and sensory neuropathy. Autosomal dominant, autosomal recessive, and X-linked forms occur. The various forms share clinical features. Diagnostic distinctions are based on findings at physical examination, electromyography, nerve conduction velocity testing, and molecular testing. About one-half of cases of CMT are classified as CMT1, 70% to 80% of which are of the CMT1A type (OMIM 118220), which involve the peripheral myelin protein gene (*PMP22*) on 17p11. These patients exhibit 1.5 million base pair duplications on one copy of chromosome 17. This results in the presence of three, rather than two, copies of this region, which contains *PMP22*. In an unknown manner, the associated gene dosage sensitivity produces the demyelination that underlies this disorder. Within some of these families are persons with a disorder known as *hereditary neuropathy with liability to pressure palsies* (HNPP; OMIM 162500). Affected individuals are predisposed to repeated, reversible, usually mild episodes of pressure neuropathy such as carpal tunnel syndrome and peroneal palsy with foot drop. About 70% to 80% of these persons have a microdeletion of the short arm of chromosome 17p11-p12, which includes the *PMP22* gene. Families segregating both disorders may represent the expected outcomes of misalignment of the paired homologous chromosomes during meiosis with crossing-over in the mispaired region.

Genetic disorders of lipids and lipoproteins are described in [Chapter 12](#) and [Chapter 31](#). Of these, familial hypercholesterolemia (FH; OMIM 143890) illustrates the principle that although heterozygotes manifest an autosomal dominant disorders, homozygotes or compound heterozygotes often have even more severe manifestations. FH is inherited in an autosomal dominant pattern and is especially frequent. FH heterozygotes have only half-normal quantities of the cellular receptor for low-density lipoprotein (LDL) cholesterol, resulting in reduced entrance of LDL cholesterol into the cell and therefore reduced degradation and diminished feedback inhibition of endogenous cholesterol biosynthesis. Receptor deficiency increases the circulating level of cholesterol and causes infiltration of lipid into tissues. With a FH heterozygote frequency of 1/500 in the general population, about 1/25,000 matings are between two FH heterozygotes and about 1 in 1 million persons has two copies of a mutant FH allele. These compound heterozygotes completely lack functional LDL receptors and have extreme elevations in serum cholesterol concentration, extensive tissue deposition, and often fatal coronary artery disease by their teen years. Molecular studies of patients with this disorder have identified more than 350 mutations in the LDL receptor gene, most families having unique mutations that other families do not. Sixty percent of French Canadian patients have a large 5& deletion, suggesting inheritance of this mutation from an early ancestor of the group, called a *founder effect*.

Marfan syndrome, in its fullest manifestation, produces characteristic changes in the skeletal, ocular, and cardiovascular systems with an autosomal dominant pedigree pattern. Variable expression in Marfan syndrome is the rule both within families and between families. Complete nonpenetrance has not been definitively documented. About one-fourth of affected persons have new mutations; a paternal age effect is present, on average, in sporadic cases. Most Marfan syndrome families carry unique mutations scattered throughout the gene. Although molecular studies have identified mutations in the fibrillin gene on 15q in some patients with Marfan syndrome, the proportion of families with identifiable *FBN1* mutations has ranged from 15% to 80% in large series. Many patients with Marfan syndrome thus do not have a demonstrable mutation in the fibrillin gene. Mutations in *FBN1* have been found in several related connective tissue disorders with different but overlapping phenotypes. Although DNA testing can be used for some families in which a *FBN1* mutant allele has been identified, it is very limited in diagnosing new cases because not all Marfan patients have identifiable *FBN1* mutations; because *FBN1* mutations occur in other disorders; and because identification of a mutant allele may still be a poor predictor of phenotypic severity. As described in [Chapter 186](#), studies of Marfan syndrome, the various autosomal dominant forms of osteogenesis imperfecta, and other inherited connective tissue disorders have shed light on the mechanisms by which heterozygosity for mutant alleles can produce a dominantly inherited disorder and on the often complex genetic heterogeneity of these disorders.

The most frequent forms of polycystic kidney disease are inherited in an autosomal dominant pattern with locus heterogeneity. Autosomal dominant polycystic kidney disease (ADPKD) affects about half a million people and is the reason for renal transplantation for about 10% of the patients undergoing transplantation. With an incidence of approximately 1/800 in all populations, mutations in the *PKD1* gene account for about 85% of cases and those in the *PKD2* gene account for the others. A third possible locus, *PKD3*, remains to be identified. The phenotypes associated with mutations in *PKD1* and *PKD2* are clinically very similar and consist mainly of progressive renal enlargement and cyst formation, which usually leads to end-stage renal disease in later life. Extrarenal manifestations include hepatic and pancreatic cyst and cerebral artery aneurysms. Marked variation in clinical presentation of ADPKD exists between and within families. This may be explained in part by evidence of a genetic two-hit mechanism in renal and hepatic cyst formation. Germ line and somatic inactivating mutations of the *PKD1* gene have been identified in cyst-lining epithelial cells.

AUTOSOMAL RECESSIVE DISORDERS

Pedigree Patterns

Homozygotes and compound heterozygotes are affected in autosomal recessive disorders. The health and life expectancy of heterozygous carriers of genes for autosomal recessive disorders are normal, although the carrier state may be apparent under special circumstances. Autosomal recessive inheritance is suggested in pedigrees in which siblings with a known or suspected autosomal recessive phenotype are born to unaffected parents, particularly in the case of a rare disorder in a consanguineous mating. In theory, when all of those with the gene are identified and large numbers of families are studied, the sexes are affected in equal numbers, and 25% of the offspring of carrier–carrier couples are affected. In practice, however, large deviations from expected mendelian proportions are common because of chance and the small size of most families.

Autosomal recessive disorders constitute most of the inborn errors of metabolism. The primary biochemical lesions have been identified in about 800 of these disorders, simplifying their identification and sometimes providing a basis for therapy. Many of these defects are demonstrable in skin fibroblasts, peripheral blood lymphocytes, and amniotic fluid cells cultured from those affected. In a growing number of instances, characterization at the DNA level has made it possible to test for these disorders independently of actual gene expression. In other instances, the identification of a large number of alleles, variable expression, and other factors have made biochemical assays the most accurate means of assessing the presence and severity of a disorder.

Autosomal recessive disorders occur in both the homozygous and genetic compound states. Compound heterozygotes may have clinical or laboratory findings that differ from the classic phenotype. Homozygosity is more likely when an allele occurs at high population frequency and in consanguineous matings. Compound

heterozygosity is more likely with lower allele frequency and nonconsanguineous matings, as is usually the case.

Examples of Autosomal Recessive Disorders

Various combinations of alleles at a complex locus on chromosome 6 near HLA result in four clinical forms of 21-hydroxylase (CYP21) deficiency, the most frequent cause of congenital adrenal hyperplasia (Table 416.2). Severe CYP21 deficiency causes the salt-losing form of congenital adrenal hyperplasia with marked deficiencies of both mineralocorticoids and glucocorticoids. Lesser CYP21 deficiencies cause the simple virilizing and late-onset forms. Impairment of 21-hydroxylation in the adrenal cortex reduces the conversion of 17-hydroxyprogesterone (17-OHP) to 11-deoxycortisol. The lack of cortisol increases corticotropin, resulting in overproduction and accumulation of cortisol precursors (especially 17-OHP) proximal to the block. This leads to excessive production of androgens, resulting in varying degrees of virilization. Women pregnant with a female fetus found to have inherited the alleles for this autosomal recessive disorder can be treated with dexamethasone (because cortisol does not cross the placenta) starting at no later than 5 to 6 weeks of gestation to suppress fetal androgen production and prevent virilization of the external genitalia of affected girls. Reflecting the very high allele frequency, the late-onset form of CYP21 deficiency is a common cause of hirsutism and even infertility among women.

TABLE 416.2. AUTOSOMAL RECESSIVE DISORDERS

Albinism of the oculocutaneous type manifests as generalized hypopigmentation and nystagmus. More than a dozen forms of oculocutaneous albinism (OCA) have been identified that together occur at an overall frequency of approximately 1 case among 20,000 persons. These are grouped according to several clinical and laboratory findings, especially whether hair bulbs from affected persons can produce melanin when incubated in a tyrosine solution, indicating the presence of the enzyme tyrosinase. Some melanin pigment develops in persons with tyrosinase-positive albinism, as a result of which they have less severe visual defects and sun sensitivity than those with tyrosinase-negative albinism, in whom no pigment develops. In addition to these outward manifestations, persons with OCA have a defect in decussation of the optic pathways, an abnormality that must have originated early in development. OCA1 is caused by a variety of mutations in the tyrosinase gene and is further classified into types based on the amount and type of residual tyrosinase activity and corresponding pigmentation. OCA2 is the most prevalent type of albinism worldwide. It is caused by mutations in the gene for P protein, also called *melanocyte-specific transporter protein*. Disturbances of pigmentation occur in many other single-gene disorders.

Persons with α_1 -antitrypsin deficiency lack the major serum protease inhibitor that normally prevents the tissue damage that would otherwise be produced by neutrophil elastase. Many mutant alleles have been characterized, and both homozygotes and compound heterozygotes have been identified. The deficiency is most often associated with the Z allele, the product of which is unable to leave the liver cells in which it is synthesized. Infants and young children with the deficiency may have hepatitis or cirrhosis. For adults, the deficiency is associated with emphysema that develops in the third decade among smokers and the fifth decade among nonsmokers. This disorder is present in about 120,000 persons in the United States.

Ataxia-telangiectasia (Table 416.2) is one of several autosomal recessive disorders that manifest abnormal sensitivity to physical agents, such as light and radiation, or to chemicals, often resulting in somatic chromosomal abnormalities and an increased risk of cancer. Bloom syndrome (OMIM 210900), several forms of xeroderma pigmentosum (OMIM 278700-80), several forms of Fanconi's anemia (OMIM 227650 and others), and hereditary nonpolyposis colon cancer are other examples of severe inherited disorders caused by specific defects in DNA repair.

Cystic fibrosis (CF) affects about 1 in 2,500 white newborns in the United States, and approximately 1 in 25 is a carrier. About 30,000 persons in the United States have CF. Great excitement was generated by the cloning of the CF transmembrane regulator (*CFTR*) gene in 1989 and the observation that a single mutant allele, designated $\Delta F508$, was present on 68% of CF chromosomes (that is, if one were to analyze the mutant CF-related alleles on all of the pairs of number 7 chromosomes in persons affected with CF and the single number 7 chromosome bearing the CF mutation in their carrier parents, the $\Delta F508$ allele would account for 68% of the total). Hopes for the development of a population-based carrier screening and genetic counseling program grew dimmer as an increasing number of low-frequency alleles were found. No other single mutation accounts for more than 5% of CF chromosomes in most populations. At least a dozen alleles must be screened in most situations for the carrier detection rate to approach 90%. Whereas in most autosomal recessive disorders the finding that one parent is not a carrier is enough to reduce the risk of the disorder in that couple's offspring to near zero, a negative result of a CF carrier screen reduces the risk only 90%. In couples in

which one parent is a known carrier, a negative CF screen result for the other parent reduces the risk of CF in the fetus to $1/500$ ($1/2 \times 1/25 \times 1/10$), still five times the a priori risk in the general white population.

Inability to detect all mutant alleles and inability to predict the severity of abnormalities in an affected child have posed obstacles to population screening for CF. Studies of molecular defects resulting from more than 800 mutant *CFTR* alleles have identified a group of mild *CFTR* mutations with residual chloride-channel function in the approximately 15% of patients with a pancreatic-sufficient phenotype rather than pancreatic insufficiency, as is present in the other approximately 85%. The severity of pulmonary involvement is not correlated with the *CFTR* alleles, however, nor is meconium ileus, the severe intestinal obstruction present in approximately 15% of newborns with CF. Studies of the pathogenesis of CF, and of various approaches to conventional and gene therapies are ongoing.

Most men with CF have congenital bilateral absence of the vas deferens (CBAVD) which results in aspermia. CBAVD (OMIM 277180) also occurs, however, among men who are heterozygous for a *CFTR* mutation, especially when associated with a polymorphic sequence of thymidine bases in intron 8, even though they have few if any other evidence of CF. This type of heterozygosity is said to account for about 10% of male infertility in the general population.

Gaucher disease (Table 416.2) is the most common of the lysosomal storage diseases. These are disorders associated with one or more of the approximately 50 lysosomal enzymes needed for catabolism of numerous cellular macromolecules. In Gaucher disease, classified in three types, deficiency of glucocerebrosidase causes lysosomal accumulation of glucosylceramide in mononuclear phagocytes during turnover of cell membranes, resulting in hepatosplenomegaly, skeletal disease, bone-marrow failure, pulmonary infiltration and, in some persons, neurologic disease. Type I (adult, chronic, non-neuronopathic) is characterized by hypersplenism, bone lesions, skin pigmentation, and the absence of neurologic abnormalities. The disorder is particularly frequent among Ashkenazi Jews, among whom the carrier frequency is about 1 in 13. Variable expressivity is prominent, the disease having been diagnosed as early as the first week of life and as late as 86 years. Type II (infantile, acute, neuronopathic) is characterized by infantile onset and severe neurologic involvement. Type III (juvenile, subacute, neuronopathic) is characterized by neuronopathic abnormalities that usually begin later in the first decade and progress more slowly than in the type II disorder. Correlation of genotype with clinical type is imperfect. Affected siblings and even identical twins sometimes manifest different clinical types. Treatment of patients with type I disease by means of enzyme replacement with purified human or recombinant glucocerebrosidase is expensive and widespread despite uncertainties about the variable expression of the various genotypes.

Hereditary hemochromatosis (HH) is among the most common human genetic disorders. The rare classic clinical manifestations of bronzed diabetes caused by widespread iron deposition occur late in life and predominantly among men. The diagnosis of overt HH usually is based on clinical features, elevated serum transferrin saturation, elevated ferritin levels, characteristic findings at liver biopsy, and elevated hepatic iron levels. Measurement of transferrin saturation is the single best screening test. Early molecular studies identified two missense mutations, designated C282Y and H63D, associated with HH in a gene tightly linked to the HLA class I region on chromosome 6. Homozygosity for the C282Y mutation is found among 85% to 90% of persons of northern European origin who have typical HH.

Fifteen to 20 percent of the HH patient population is heterozygous for the H63D mutation, which may contribute to increased hepatic iron levels but does not cause iron overload in the absence of the C282Y mutation.

It is not clear whether heterozygosity for C282Y, H63D, or compound heterozygosity increases risk of HH. In HH family studies of relatives of known genotype, as many as one-fourth of those homozygous for the C282Y mutation did not have iron overload. The prevalence of the C282Y allele in the general population approaches 10% among Europeans. The high frequency of the C282Y allele in the target population, the availability of a simple DNA test, and the effectiveness of phlebotomy in preventing or reversing iron overload have led some authorities to urge that a population-based mass screening program be initiated. Uncertainties about genotype–phenotype correlations, reduced penetrance and cost-to-benefit ratios have led others to recommend delaying any such program until more is known.

Phenylketonuria (PKU) is the prototype of treatable inborn errors of metabolism. Occurring in 1 in 13,000 births in the United States, the classic form of PKU is caused by an inherited deficiency of phenylalanine hydroxylase that limits conversion of phenylalanine to tyrosine, resulting in deficient neurotransmitter and melanin synthesis and increasing the concentration of phenylalanine in blood and tissues. Untreated persons with PKU have mental retardation, often severe. Lifelong treatment, however, beginning in early infancy with a phenylalanine-restricted diet, prevents the mental retardation, although other learning and behavioral abnormalities may persist. Adult women with PKU risk damage to the fetal brain and heart if not treated beginning at conception despite the heterozygosity of the fetus. Prenatal diagnosis of classic PKU was not available before the development of DNA methods, because phenylalanine hydroxylase activity is expressed in diagnostically useful amounts only in the liver.

The differential diagnosis of neonatal hyperphenylalaninemia includes other disorders, such as dihydropteridine reductase deficiency (OMIM 261630) and 6-pteroyltetrahydropterin synthase deficiency (OMIM 261640), that elevate blood phenylalanine concentrations by decreasing the amount of cofactor needed by phenylalanine hydroxylase. Unlike classic PKU these disorders cannot be controlled with restriction of phenylalanine intake. Treatment is attempted by means of supplementation with appropriate forms of the missing cofactors. The latter two disorders can be phenotypically severe, and both can be diagnosed for patients and prenatally by means of direct DNA methods.

Forms of polycystic kidney disease with severe manifestations before or soon after birth are inherited in an autosomal recessive pattern ([Table 416.2](#)), unlike the ADPKD discussed earlier ([Table 416.1](#)), that manifests between 30 and 60 years of age. Designated polycystic kidney and hepatic disease (PKDH1; OMIM 263200), these forms are distinguished by clinical onset before birth, in infancy, or in childhood and by the presence of hepatic fibrosis and involvement of the intrahepatic biliary tree. Prenatal diagnosis by means of ultrasonography is unreliable but often can be achieved with linkage of DNA markers to the PKDH1 locus at 6p21.1-p12. This is an example of the tendency, due to fitness, or likelihood of reproduction, considerations, for phenotypically severe disorders to be inherited in an autosomal recessive pattern. Phenotypically milder disorders with similar types of manifestations are more often inherited in a dominant pattern. Homozygotes or compound heterozygotes for PKDH1, for example, would not reproduce, and thus their mutant genes would be lost to the gene pool. In contrast, the fitness of the much more numerous heterozygous carriers of severe autosomal recessive disorders usually is indistinguishable from that of persons with normal genes. The rarer the autosomal recessive disorder, the greater is the proportion of genes for the disorder that reside in heterozygous carriers rather than homozygous affected persons. Genetic selection against deleterious genes is thus weak in the case of genes for the rarer autosomal recessive disorders.

Sickle cell anemia is present in approximately 1 in 400 to 600 African American newborns and affects about 50,000 persons in the United States. About 1 in 12 African Americans has sickle cell trait. The discovery of hemoglobin S and its mutational basis are landmarks in the history of biochemical genetics. The high gene frequency in an identifiable population, the lack of a cure or fully effective treatment, and the availability of accurate carrier screening and prenatal diagnostic methods have been the bases for the widespread availability of screening and genetic counseling programs for the sickling disorders (hemoglobin disorders SS, SC, and S β -thalassemia). The great variability of clinical severity, hopes for effective conventional or gene therapy, and other issues have contributed to the low level of use of such programs in the United States.

Spinal muscular atrophy (SMA) affects 1 in 10,000 live births. The disorder is characterized by degeneration of anterior horn cells of the spinal cord, symmetrical weakness and wasting of the proximal voluntary muscles, and evidence of denervation with normal conduction times. There are three forms of SMA. The acute form of Werdnig–Hoffman disease (SMA 1; OMIM 253300) is characterized by severe, generalized weakness, hypotonia at birth or within the first 3 months, and death of respiratory failure usually before 2 years of age. The intermediate form (SMA 2; OMIM 253550) and the mild form of Kugelberg–Welander disease (SMA 3; OMIM 253400) are characterized by a chronic course with later onset (6 months to teens) and milder muscle weakness ranging from inability to walk to death in the teen years. SMA is caused by disruption of the telomeric copy of a duplicated gene called *SMN1* at 5q12.2-q13.3. Approximately one-half of patients with severe SMA1 also are missing both homologues of a neighboring gene, neuronal apoptosis inhibitory protein (*NAIP*; OMIM 600355). The possible roles of loss of this and possibly other genes in this complex region in the pathogenesis and severity of these disorders is the focus of ongoing studies.

Tay–Sachs disease is a classic inborn error of metabolism due to deficiency of the lysosomal enzyme hexosaminidase A. The disorder is untreatable, and progressive accumulation of the specific glycosphingolipid GM2 ganglioside destroys neural cells in the brain, resulting in death at about 4 years of age. With a carrier frequency of about 1 in 30 among Ashkenazi Jews and 1 in 300 in other groups, the number of children born with Tay–Sachs disease annually in the United States has decreased from about 50 per year to about 6 through the efforts of an extensive program of carrier detection, genetic counseling, and prenatal diagnosis. Juvenile, chronic, and adult-onset variants of GM2 gangliosidosis also occur.

Wilson's disease ([Table 416.2](#)), or hepatolenticular degeneration, is an inherited disorder of copper transport that can manifest as hepatic abnormalities from childhood to early adulthood or as neurologic abnormalities after 12 years of age. A related but distinct disorder of copper transport, Menkes' disease (OMIM 309400) manifests in infancy. In Wilson's disease, reduced incorporation of copper into ceruloplasmin and reduced biliary excretion leads to progressive accumulation of copper in the liver with eventual overflow to the brain, cornea (Kayser–Fleischer rings), kidney, heart, and other tissues. If the condition is not diagnosed and the person is not treated with copper chelating agents, potentially fatal hepatic, neurologic, or hematologic complications can occur.

X-LINKED INHERITANCE AND DISORDERS

Pedigree Patterns in the X-Linked Disorders

The key feature of X-linked inheritance is the absence of male-to-male transmission. Because a man transmits his single X chromosome to his daughters and gives his sons his Y chromosome, men do not transmit X-linked disorders to their sons. The presence of male-to-male transmission in a pedigree is evidence that the genetic disorder in this family is not X-linked.

The pedigree patterns of X-linked *recessive* disorders show affected boys and men with affected uncles and nephews when the gene is inherited. Female carriers are not affected, but they may show mild signs and symptoms, and the disorder often can be detected when specific tests exist. X-linked *dominant* disorders are rare but can be recognized because when the disorder occurs among both sexes in successive generations, although without male-to-male transmission, males are more severely affected, sometimes fatally, than females but on the average only one-half as often. Ornithine transcarbamoylase (OTC) deficiency is an example of an X-linked dominant disorder.

In the case of a new X-linked mutation, the pedigree shows one of two possible patterns. In one, a single affected son is born to a woman who is not a carrier. Here the new mutation occurred in a gene on one of the two X chromosomes in the mother's gonadal cells. In the other pattern, one or more affected sons are born to a carrier mother who is the first family member to carry that mutant gene. In this case, the mutation occurred in a gene on the X chromosome in her father's gonad. Recognizing new mutation is thus more complicated for X-linked disorders than for new autosomal mutations.

Examples of X-Linked Disorders

Alport's syndrome manifests as hereditary nephritis and sensorineural deafness associated in some families with ocular abnormalities ([Table 416.3](#)). Both renal dysfunction and hearing loss develop earlier and become more severe among affected boys and men than among their affected female relatives. A large number and variety of mutations have been identified in the gene for the α -5 chain of basement membrane collagen. Accordingly, molecular diagnosis entails linkage methods.

Disorder	Major Features	Gene and Gene Product	Additional Information	Availability of Molecular Testing
Androgen resistance	Androgen resistance is a clinical entity with the clinical picture of androgen deficiency. It is caused by mutations in the androgen receptor gene (AR) on the X chromosome. TABLE 416.3. X-LINKED DISORDERS

Androgen resistance is discussed in [Chapter 410](#). Genetic forms of androgen resistance are now known to include a spectrum of clinical defects associated with mutations in the androgen receptor gene (*AR*) at Xq11-q12. These range from complete androgen insensitivity in the disorder known previously as testicular feminization through Reifenstein's syndrome to various other types of partial androgen resistance. A specific trinucleotide repeat amplification in this gene is responsible for the X-linked neurologic disorder known as *spinal and bulbar muscular atrophy*, or *Kennedy's syndrome*.

Duchenne type and Becker type muscular dystrophies are caused by different mutant alleles at a single large locus that encodes the essential muscle protein dystrophin at Xp21.2. They differ in severity. Duchenne's muscular dystrophy becomes apparent in childhood and causes death by the early third decade of life. Becker's muscular dystrophy begins later and is compatible with a normal life span. Duchenne's muscular dystrophy exhibits one of the highest mutation rates observed among humans. Studies have shown that Duchenne's and Becker's muscular dystrophies are associated with mutations within the gene for dystrophin on the short arm of the X chromosome. This locus is the largest identified, occupying more than 2,000 kilobases. The gene was one of the first identified by means of positional cloning, an approach in which the approximate location of a particular gene is signaled by cytogenetic abnormalities. Approximately two-thirds of the new mutations at this locus are deletions of various sizes generated through meiotic mispairing and unequal crossing-over events related to the tandem duplication of DNA sequences in this locus. The Duchenne's muscular dystrophy phenotype usually results from deletions that produce frameshifts, changing the protein sequence distal to the mutation, so that a substantial portion of the normal dystrophin sequence is either changed or lost. In contrast, Becker's muscular dystrophy usually is associated with mutations that do not produce frameshifts.

Glucose-6-phosphate dehydrogenase (G6PD) deficiency is the most common inborn error of metabolism, affecting 400 million persons worldwide. More than 400 allelic variants have been described, making G6PD the most polymorphic human enzyme. Some variants produce no abnormalities, others produce abnormalities under specific conditions, and still others produce abnormalities under all conditions. The A⁻ deficiency is present in about 12% of male African Americans, and 24% of girls and women are carriers. In this variant, hemolysis occurs in response to agents such as antimalarial drugs. Yet the A⁻ variant appears to cause little or no mortality among otherwise healthy persons. Most men and boys with other G6PD variants have no symptoms except for hemolytic episodes that may occur with exposures or infection, and many have a normal life expectancy. In rare instances G6PD deficiency causes chronic hemolytic anemia that can be severe. In contrast, the Mediterranean variant is associated with hemolysis without additional stress, and variants such as Canton G6PD produce severe hemolysis that usually is fatal in infancy.

Hemophilia A, or classic hemophilia, occurs among about 1 in 5,000 liveborn male infants (see [Chapter 237](#)). New mutations in the *F8C* gene that encodes factor VIII are frequent and varied. Of the 475 mutations presently recorded, 300 are missense or nonsense, 24 affect splicing, 49 are small deletions, 17 are small insertions, 76 are gross deletions, 3 are gross insertions and duplications, and 6 are complex rearrangements. Molecular analysis of this gene was among the first to demonstrate the importance of CpG dinucleotides as a major "hotspot" for point mutations, the spontaneous deamination of a methyl-cytosine causing it to be read as thymine during DNA replication. Remarkably, about 40% to 50% of patients with severe factor VIII deficiency proved to have an inversion of the distal X chromosome that disrupts the factor VIII gene. The inversion is the product of homologous recombination between a small gene, called *gene A*, located within intron 22 of the factor VIII gene and one of the two additional copies of gene A located upstream of factor VIII toward the tip of the X chromosome. This recombination event removes exons 23 through 26 and with them the portion of the factor VIII molecule that they encode, resulting in severe deficiency. This recombination event recurs so often that it constitutes the basis of the severe hemophilia A found in 40% to 50% of unrelated families.

OTC deficiency is one of a group of five hyperammonemic disorders caused by urea cycle enzyme defects. OTC is an X-linked, mitochondrial matrix enzyme expressed almost exclusively in the liver. It catalyzes the second reaction of the urea cycle, the condensation of carbamylphosphate and ornithine to form citrulline. Some cases have an X-linked dominant pattern of inheritance with partial deficiency in heterozygous females and complete deficiency in hemizygous males, for whom it usually is lethal. Male infants with OTC deficiency usually have intractable and lethal neonatal hyperammonemia. Blood ammonia levels always exceed 1,000 μmol per liter. This is accompanied by generalized amino aciduria with particular elevations of glutamine, alanine, and glutamate in the plasma. Citrulline concentration is reduced and may be undetectable. A late-onset form occurs and leads to episodes of hyperammonemia, severe metabolic disturbance, and neurologic abnormalities resulting eventually in developmental delay. Treatment is limitation of the protein content of the diet to the tolerance of the patient and leaching the obligatory excess amino groups with sodium phenylacetate and sodium benzoate as originally described by Brusilow.

Mechanisms of X-Linked Recessive Disorders

Like autosomal recessive disorders, the basic defects are known in many X-linked disorders and frequently consist of amino acid substitutions in enzymes and other proteins. The consequences of these mutations are similar in many respects to those of the autosomal recessive disorders but also differ, primarily because of X-chromosome inactivation. One normal allele and one mutant allele are active in each cell of a male or female carrier of an autosomal recessive disorder. In contrast, carriers of X-linked recessive disorders are always women and girls. Some cells of female carriers have an active normal allele; in other cells, only the mutant allele is active. If the normal gene product cannot be obtained from other cells and used, cells in which the mutant gene is active may become abnormal or even die.

The basic tenets of the single-active-X principle are as follows. In each somatic cell of a girl or woman, one of the two X chromosomes is inactivated for most functions except replication. Some loci on the X chromosome, including the Xg blood group and steroid sulfatase loci, escape inactivation. The inactivated X chromosome condenses as the sex chromatin or Barr body, a darkly staining clump at the periphery of the nucleus. Inactivation occurs early in embryologic development, about 16 days after conception, when the number of stem cells is limited. In normal human female embryos, it is a matter of chance whether the X chromosome inherited from the father or that inherited from the mother is inactivated. Once inactivated during development, that X chromosome remains inactive in that somatic cell and all its progeny. Exceptions to the random inactivation of one of the two X chromosomes in female humans occur in some embryonic tissues and with some cytogenetic abnormalities, especially X-autosome translocations. As a consequence of X inactivation, a normal female human is a mosaic with respect to the X chromosome, some of her cells having the X inherited from the mother as the active X and others having the active X from the father. Male humans are hemizygous with respect to the X chromosome and its genes; their cells contain only one X chromosome, which is inherited from the mother and remains active.

Some female humans with the full complement of manifestations of an X-linked recessive disorder are encountered. This may occur among female progeny of an affected man and a female carrier when the gene frequency is high (e.g., G6PD deficiency), with consanguinity (in which random X inactivation has inactivated most of the X chromosomes bearing the normal allele), or in women with 45, X Turner's syndrome or boys who appear to be girls because of an X-linked androgen receptor defect.

SINGLE-GENE CAUSES OF CANCER

Inherited forms of cancer require special comment (see [Chapter 20](#)). The cause of all cancers is fundamentally genetic, but the various forms of cancer differ in regard to whether the genetic contribution is limited to mutations in somatic cells or whether both inherited (germ line) and somatic mutations are involved. Observations regarding retinoblastoma, the most common eye tumor of childhood, led Knudson to postulate the two-hit model, which led to the recognition of tumor suppressor genes. Although initially applied to childhood tumors such as retinoblastoma and Wilms' tumor, far broader relevance has emerged. Many relatively common cancers in some proportion of families follow an autosomal dominant pattern at the level of the pedigree but an autosomal recessive pattern at the level of the cell. A germ line mutation affecting one allele of a tumor suppressor locus is passed from a person in one generation to one or more offspring in an autosomal dominant pattern and is

present in all of the cells of the affected offspring. When mutations inactivate the other allele of the tumor suppressor gene in one or more susceptible cells, a tumor may develop from the progeny of those cells in which both copies of the tumor suppressor gene have been inactivated. Indeed, tumor suppressor genes may be first recognized when loci are found that exhibit a high degree of mutation, known as *loss of heterozygosity*, in somatic cells from common cancers.

The proportion of cases caused by combined inherited plus somatic mutations versus somatic mutations alone differs for different forms of cancer. For example, inherited–somatic causation accounts for about two-thirds of cases of retinoblastoma but only a small percentage of cases of colorectal cancer or breast cancer, as currently understood. The mutations underlying most cancers are complex and involve multiple loci as well as environmental factors. Loci that may undergo mutation to contribute to the initiation and progression of cancer include, in addition to tumor suppressors, protooncogenes, mutator genes, and mismatch repair genes.

Single gene disorders associated with a high risk of cancer include familial adenomatous polyposis (FAP; OMIM 175100), hereditary nonpolyposis colon cancer (HNPCC; OMIM 120435), multiple endocrine neoplasia types 1, 2, and 3 [(MEN1; OMIM 131100) (MEN2; OMIM 171400) (MEN3; OMIM 162300)], neurofibromatosis types 1 (NF1; OMIM 162200) and type 2 (NF2; OMIM 101000), retinoblastoma (RB1; OMIM 180200), tuberous sclerosis type 1 (TS1; OMIM 191100) and type 2 (TS2; OMIM 191092), and von Hippel–Lindau syndrome (VHL; OMIM 193300) (see [Chapter 19](#) and [Chapter 218](#)).

DISORDERS DUE TO TRINUCLEOTIDE REPEAT EXPANSION

The list of disorders associated with trinucleotide repeat expansion has increased in the past few years. Beginning with fragile X syndrome, these disorders now include autosomal dominant, autosomal recessive, and X-linked phenotypes. Some features of the trinucleotide repeat expansion disorders have emerged. A group of autosomal dominantly inherited neurologic disorders appear with the expansion of a CAG trinucleotide located in an exon. In various disorders, the normal allele ranging, for example, from 4 to 16 repeats to 11 to 34 repeats expands to 21 to 27 or 40 to 62 repeats in the fully affected state. Although a normal-sized allele is stable to transmissions through many generations, an intermediate state of partial expansion known as a *premutation* carries with it a substantial risk of full expansion. This liability to further expansion when the premutation is transmitted between generations gives rise to the phenomenon of anticipation, in which the severity of a particular phenotype worsens in successive generations of an affected family. In some manner, the longer sequence of glutamyl residues in the protein product of this gene produces neurologic abnormalities. This group of disorders includes Huntington disease, spinal and bulbar muscular atrophy, dentatorubral–pallidoluysian atrophy, and more than half a dozen distinguishable forms of spinocerebellar ataxia. In these disorders, the risk of expansion with the resulting abnormality is greater with transmission through the father.

Myotonic dystrophy also is inherited in an autosomal dominant pattern but involves a CTG trinucleotide repeat in the 3' untranslated portion of the corresponding locus, which is more likely to expand with maternal transmission. Friedreich's ataxia involves expansion of a GAA trinucleotide located in an intron of the corresponding locus. As the only autosomal recessive trinucleotide repeat disorder recognized to date, transmission must be through both parents. Fragile X syndrome (FRAXA) is associated with a dramatic expansion of a CGG trinucleotide in the 5' untranslated region of the *FMR1* gene from the normal 6 to 52 repeats to 230 to 2,000 repeats, accompanied by methylation and transcriptional silencing of the corresponding region of the X chromosome at Xq27. Although many questions about the pathophysiological mechanisms of these disorders remain unanswered, DNA testing is available for clinical use.

CHROMOSOMES AND CHROMOSOMAL DISORDERS

THE KARYOTYPE

Diploid human cells normally have 46 nuclear chromosomes occurring in 23 pairs. One pair of chromosomes, the sex chromosomes, consists of the X and the Y. Women and girls have a homologous pair of sex chromosomes (XX), whereas men and boys have a heteromorphic sex chromosome pair (XY). The remaining 22 homologous pairs constitute autosomes. They are numbered 1 through 22 and are grouped according to size and shapes into groups A through G. Although the chromosomes are usually dispersed in the cell nucleus during the cell cycle, during the metaphase stage of mitosis, they are condensed and can be visualized with a light microscope directly or after staining. At this stage each chromosome has already replicated in preparation for the next cell division, but the two separate, replicated strands, called *chromatids*, remain joined at the centromere, the point of attachment of the mitotic spindle.

Chromosome material above the centromere is called the *short arm* (p arm). Material below the centromere is the *long arm* (q arm). The photographed, cut out, and systematic arrangement of pairs 1 to 23 constitutes the *karyotype*. The standard karyotype notation consists of the total number of chromosomes followed by the sex chromosomes followed by a description of any abnormalities. Each term is separated by a comma. According to this convention, the normal male chromosome constitution is 46,XY, and the normal female constitution is 46,XX. In Klinefelter's syndrome, the karyotype is 47,XXY. In Turner's syndrome, it usually is 45,X. The karyotype of a boy with Down syndrome due to trisomy 21 is 47,XY+21. Cytogenetic analysis can be performed on any cell type that can be induced to undergo mitosis, such as mitogen-stimulated peripheral blood T lymphocytes, or any cell type that spontaneously undergoes mitosis, such as skin fibroblasts, cells from amniotic fluid or chorionic villi, tumor cells, and bone marrow and leukemic cells.

CHROMOSOMAL DISORDERS

Approximately one-third of human conceptuses are chromosomally abnormal, but most are spontaneously eliminated before implantation in the uterus. Whereas chromosomal disorders are present in about 60% of first-trimester abortuses and 6% of perinatal deaths, only 0.6% of live newborns have major chromosomal disorders.

The most common chromosomal disorders are caused by abnormalities of the total chromosome number, or aneuploidy, in which the person has more or fewer than the normal 46 chromosomes. Most chromosomal abnormalities among live-born infants are detected in childhood because of associated multiple malformations or mental retardation. The features of Down syndrome, the most common autosomal disorder, include microcephaly, small size, hypotonia, flat facial profile, cardiovascular malformations, and an increased incidence of leukemia. In about 95% of cases, Down syndrome is caused by trisomy 21. The other 5% of cases are caused by unbalanced translocation or mosaicism with a trisomy 21 component.

Survival rates from aneuploidy of the sex chromosomes are greater than for autosomal chromosomal aneuploidy. Klinefelter's syndrome (nearly all 47,XXY) is the most prevalent of the sex chromosome anomalies, occurring in 1 in 900 live births of boys but also in about 1 of every 50 stillbirths of boys, and 1 in 10 cases of aspermia. Affected newborns are structurally normal at birth and have normal external genitalia. At the time of expected puberty, however, the testes are functionally deficient in regard to production of androgens and sperm. Fertility is reduced, and affected boys usually have small testes, aspermia, gynecomastia, and elevated levels of plasma and urinary gonadotropins.

Turner's syndrome (most are 45,X) occurs in 1 of 2,500 live births of girls but is many times more frequent in abortions. Girls with Turner's syndrome have primary amenorrhea, short stature, multiple congenital anomalies (small stature, shield-like chest, webbed neck, and coarctation of the aorta), and bilateral streak gonads. About one-half of cases of Turner's syndrome are recognized in childhood because of alterations in morphologic features. The other cases usually come to attention as late as adolescence when a girl is evaluated because of amenorrhea. Other cytogenetic abnormalities, such as isochromosome Xq (two copies of the long arm of an X chromosome joined at the centromere), occur among patients with Turner's syndrome, but all of these have deficiency of a second copy of the X chromosome short arm as a unifying feature. The XYY syndrome is present in 1 in 800 boys. Males with XYY syndrome tend to be tall and to have nodulocystic acne at puberty. XYY males as a group, like XXY males, reportedly are somewhat less intelligent than XY males. This may increase their risk of socialization and academic problems.

Other chromosomal abnormalities relate to abnormalities of chromosomal structure. Translocations are chromosomal abnormalities caused by breakage and rejoining with redistribution of genetic material between chromosomes. Such rearrangements are said to be *unbalanced* translocations when they cause a net gain or loss of genetic material and *balanced* translocations when they produce no net change. About 1 in 500 newborns has a balanced translocation, and about 1 in 1,500 has an unbalanced rearrangement. Even without an apparent gain or loss, translocations occasionally inactivate a critical gene at one of the breakpoints and thereby signal the location of a gene for the resulting mendelian disorder. Balanced chromosome translocations, if detected at all, usually are not recognized until adulthood, when they may cause recurrent abortions or chromosomal imbalances and other abnormalities. Translocation can be detected during pregnancy when, for example, amniocentesis is performed for an indication such as advanced maternal age. A translocation first identified in a fetus usually proves to have been inherited from one of the parents, who is healthy. This unexpected result often causes great anxiety. Specialized knowledge is needed to assess the risk to the fetus in this situation and later to determine which relatives to test for the presence of the translocation.

Mitotic chromosomal abnormalities, which occur after conception, can produce mosaic forms of chromosomal syndromes and somatic chromosomal abnormalities of

the types frequently found in leukemia and lymphoma, in which they often involve oncogenes (see [Chapter 20](#), [Chapter 227](#), and [Chapter 251](#)).

MICRODELETIONS, CONTIGUOUS GENE SYNDROMES, AND IMPRINTING

The identification of barely visible small chromosomal deletions in association with some phenotypes, and their subsequent analysis with fluorescence in situ hybridization and other molecular techniques, has led to the recognition of a growing number of microdeletions. Although many of these are smaller than the 5×10^6 base pairs required to be visible with a microscope, they are large enough to remove part or all of several adjacent genes. The complex phenotype thus produced often includes features of more than one mendelian disorder and is known as a *contiguous gene syndrome*. For example, a patient whose X-chromosomal deletion was important in identifying the locus of the Duchenne's muscular dystrophy gene had chronic granulomatous disease, retinitis pigmentosa, and McLeod syndrome, in addition to the muscular dystrophy.

Deletion of portions of autosomal chromosomes causes hemizygoty. The resulting haploinsufficiency of the affected genes often is sufficient to produce a characteristic abnormal phenotype. Microdeletions have been recognized as causing or contributing to several dozen disorders. Examples of disorders due to microdeletions include Williams syndrome (cognitive impairment, unique personality characteristics, distinctive facial features, and cardiovascular disease with or without hypercalcemia; more than 99% of those affected have a contiguous gene deletion of chromosome 7q11, which includes the *ELN* gene), Langer-Gideon syndrome [del(8q24.1)], Miller-Dieker syndrome [del(17p13.3)], and DiGeorge and velocardiofacial syndromes [both associated with del(22q11.2)]. In other instances, however, the associated phenotypic abnormalities differ depending on whether the deletion affects the member of the chromosome pair that was inherited from the person's mother or from the father. For example, deletion of paternal 15q11-13 results in Prader-Willi syndrome (OMIM 176270), whereas deletion of maternal 15q11-13 results in Angelman syndrome (OMIM 234400). Although both syndromes include severe mental retardation and hypopigmentation, Prader-Willi syndrome is differentiated with the presence of severe neonatal hypotonia, distinctive facies with prominent bitemporal depression and almond-shaped eyes, undescended testes or hypoplastic labia, small hands and feet, and massive hyperphagia and obesity that develop in childhood.

Distinctive features of Angelman syndrome include seizures, ataxic gait, bouts of inappropriate laughter, absent language development, and characteristic facies, including prominent jaw, thin upper lip, wide mouth, and protruding tongue. These and other parent-of-origin differences are thought to be caused by a process known as *imprinting* in which methylation and perhaps other processes differentially modify the expression of genes present in some portions of chromosomes 7, 11, 14, 15, and 16. Imprinting is thought to silence the expression of some genes, but the precise mechanism linking imprinting and phenotype is incompletely understood. Both Prader-Willi and Angelman syndromes can be produced by genetic defects other than chromosomal deletions, but the other defects also act through parent-of-origin differences at 15q11-13.

MULTIFACTORIAL INHERITANCE AND DISORDERS

In common medical usage, the term *multifactorial* generally applies to disorders and processes in which several etiologic factors, rather than a single overriding factor, are thought to be involved. The concept in medical genetics is similar but more explicitly defined and based on a quantitative theoretical framework. Multifactorial inheritance generally is divided into continuously varying traits with associated empirical definitions of disease and threshold traits. Threshold traits may be identifiable at birth or may become apparent later. Environmental influences frequently are especially prominent. Multifactorial disorders are thought to be produced by the action of several genes of smaller effect that act in concert in association with an often prominent environmental complement. Multifactorial disorders include congenital malformations (anencephaly, meningomyelocele, and other neural tube defects and most forms of congenital heart disease), metabolic disorders (most forms of diabetes mellitus), and many familial, late-onset disorders (hypertension, most coronary artery disease, most gout, schizophrenia, bipolar depression). Multifactorial inheritance applies to continuously varying traits, such as height, weight, or blood pressure. Measurements within the general population generate a continuous distribution of values that approximates a normal curve. Theoretical formulations of multifactorial inheritance can account for the degree of resemblance of relatives for these traits, depending on the degree of relatedness. Several genetic loci appear to be involved, and environmental factors also contribute to the phenotype.

MITOCHONDRIAL INHERITANCE AND DISORDERS

Unlike the nuclear chromosomes, inheritance of which forms the basis for mendelian inheritance, mitochondrial genes are inherited only from the mother. The mother transmits her mitochondrial DNA (mtDNA) through the cytoplasm of the ovum to all of her offspring. Her daughters transmit their mtDNA to all of their offspring. In contrast, men never transmit their mtDNA. This maternal inheritance pattern produces a distinctive pedigree pattern for mitochondrial disorders in which, if penetrance were complete, all of the sons and daughters of an affected woman would themselves be affected, whereas none of the offspring of an affected man would be affected. Penetrance is, however, rarely complete, and confusing pedigree patterns can result.

Each human cell contains thousands of molecules of mtDNA. Human mtDNA is a closed circular molecule 16,569 base pairs long that contains no introns and in which some genes overlap. The mitochondrial genome encodes 13 of the 80 essential polypeptides that form the five complexes that make up the respiratory chain. It also encodes two ribosomal RNAs and 22 transfer RNAs.

The mutation rate in mitochondrial DNA is 5 to 10 times greater than the mutation rate in nuclear DNA. Cells that contain a mixture of mutant and wild-type mtDNA are said to be *heteroplasmic*. Cells that contain only a single sequence of mtDNA are called *homoplasmic*. During replication of heteroplasmic cells, the mtDNA genotype can shift as the mitochondria and mtDNAs are partitioned randomly into daughter cells. In this way some lineages drift toward becoming homoplasmic for the mutant mtDNA, whereas others become homoplasmic for wild-type mtDNA, and still others remain heteroplasmic. The cell phenotype reflects the relative proportions of constituent mutant and wild-type mtDNA, and the degree to which that cell depends on oxidative phosphorylation. The central nervous system is most dependent on mitochondrial energy, followed by skeletal muscle, heart, kidney, and liver. The mitochondria of cells that contain mutant mtDNA may show distinctive electron micrographic changes.

Molecular studies have identified more than 60 pathogenic mutations of mtDNA associated with multisystemic, maternally inherited syndromes. A database of mtDNA, called MITOMAP, can be found at <http://www.gen.emory.edu/mitomap.html>. The database contains a wealth of current information about normal and disease-related mtDNA.

CHAPTER 417: TESTING AND EVALUATION OF PITUITARY END-ORGAN FUNCTION

ARIEL L. BARKAN AND JOHN C. MARSHALL

[Investigation of Pituitary Hypofunction](#)
[Investigation of Pituitary Hyperfunction](#)
[Guidelines for the Selection of Pituitary Function Tests in Clinical Situations](#)

In the care of every patient with hypothalamic–pituitary disease, the following four questions should be answered:

1. What is the nature of the process?
2. Are there any mass effects?
3. Which hormone is missing?
4. Which hormone is being hypersecreted?

The first two questions usually are answered through a combination of patient history and findings at clinical examination, such as previous trauma, presence of coexistent disease, results of neuroophthalmologic studies and through appropriate radiologic procedures, such as computed tomography (CT) or magnetic resonance imaging (MRI). The latter two questions require performance of basal hormone measurements and dynamic tests.

Pituitary diseases may manifest as pituitary hypofunction or hyperfunction, or a combination of the two. For most patients, the major abnormalities can be identified through clinical assessment and basal measurement of corresponding pituitary (trophic) and peripheral (target gland) hormones. Clinical assessment is most important for planning and interpretation of pituitary function tests. For example, the presence of regular ovulatory cycles in women is evidence of normal hypothalamic–pituitary–ovarian function, and endocrine testing of this system is not indicated. After menopause, low estradiol and high gonadotropin concentrations are normal, but the same findings for a young woman with amenorrhea indicate premature ovarian failure.

When clinical or laboratory features suggest excessive production of pituitary hormone, suppression tests are needed to diagnose autonomy of pituitary function. If hypofunction of the pituitary gland is suspected, appropriate stimulation tests are performed. Blood samples should be drawn from indwelling venous cannulas to minimize the stress of multiple venipunctures. For urinary measurements, the correct procedure for collecting an accurate 24-hour urine sample should be explained to the patient, and creatinine should be measured to assess the completeness of the collection. Important factors for interpreting results of pituitary function tests include age, sex, exposure to acute stress, drug therapy, nutritional status, and timing of the test. Some hormones, such as corticotropin, cortisol, growth hormone (GH), and luteinizing hormone (LH), are secreted in a pulsatile manner, and a single basal estimate may be misleading. In these cases, serial blood sampling or measurement of two or three pooled samples improves diagnostic accuracy.

INVESTIGATION OF PITUITARY HYPOFUNCTION

The presence of low or low-normal levels of tropic and target hormones—such as thyroid-stimulating hormone (TSH) and thyroxine (T_4), corticotropin and cortisol, LH, follicle-stimulating hormone (FSH), and gonadal steroid, or GH and insulin-like growth factor I (IGF-I)—together with appropriate clinical findings suggests pituitary failure. The failure may be caused by deficiency of hypothalamic stimulatory hormones or anterior pituitary cell failure.

The indications for dynamic pituitary function tests include establishment of the diagnosis if basal measurements are borderline low; assessment of the degree of pituitary failure (complete versus partial); localization of the defect (pituitary versus hypothalamic); and assessment of the feasibility of therapy with hypothalamic hormones, such as gonadotropin-releasing hormone (GnRH) or growth hormone-releasing hormone (GH-RH). A combined pituitary function test is used to assess simultaneously secretory reserves of corticotropin, GH, TSH, LH, and FSH. The results of combined stimuli, however, may be confusing in evaluation of some patients with pituitary dysfunction. Administration of several test substances may provoke release of the same hormone by different mechanisms (eg, GH release to insulin, thyrotropin-releasing hormone [TRH], and GnRH in acromegaly; prolactin release to insulin and TRH). When hypopituitarism or nonfunctioning pituitary tumors are suspected, a combined test can be used to assess pituitary reserve. Individual stimulation tests often are more appropriate for assessment of pituitary secretion in the presence of functioning tumors.

SUSPECTED CORTICOTROPIN DEFICIENCY

Whether corticotropin can be secreted in response to stress is important in two clinical situations: when a patient is believed to have hypothalamic–pituitary disease and when a patient has been treated with exogenous glucocorticoids. Assessment of corticotropin secretory reserve is most important and should precede institution of replacement glucocorticoid therapy. During stressful situations, such as pain, fever, or surgery, plasma cortisol level normally rises to more than 20 μg per deciliter, and this can be regarded as the minimal level needed for adaptation to stress. For patients not receiving exogenous glucocorticoids, the finding of a spontaneous basal plasma cortisol greater than 20 μg per deciliter establishes normal function of the hypothalamic–pituitary–adrenal axis, and further testing is unnecessary. Other factors should be considered in interpreting basal measurements of plasma cortisol. The cortisol levels of patients taking hydrocortisone are normal, of patients taking prednisone may be measurable because of cross-reaction in the cortisol assay, and of patients using estrogen therapy are increased because of elevation of cortisol-binding globulin.

Insulin Hypoglycemia Test

Mechanism

The mechanism is a stress-induced increase in hypothalamic corticotropin-releasing hormone (CRH) secretion.

Protocol

If the patient is being treated with dexamethasone or prednisone, replacement therapy should be changed to hydrocortisone, 25 mg per day for 2 to 4 days before testing, with the last dose of hydrocortisone 12 hours before the test. The patient should fast overnight and be recumbent throughout the test. Crystalline (regular) insulin is injected as an intravenous (IV) bolus. The usual insulin dose is 0.15 U per kilogram, but for patients with obesity, cushingoid symptoms, or diabetes, higher doses (0.2 to 0.6 U per kilogram) may be needed to overcome insulin resistance. Patients with suspected hypopituitarism should be given a lower dose (0.1 U per kilogram). Blood glucose is measured with glucose oxidase strips every 15 minutes and as soon as signs of hypoglycemia appear (sense of hunger, perspiration, tachycardia, tremor, confusion). These symptoms are allowed to continue for 5 minutes, and glucose is administered by mouth or IV to correct hypoglycemia. If hypoglycemia (blood glucose level greater than 40 mg per deciliter) does not develop within 45 minutes of insulin injection, a second insulin injection is given at 50% of the initial dose. Cortisol samples are drawn 30, 60, and 90 minutes after the onset of clinical and biochemical hypoglycemia. When the test has been completed, the patient should be given oral carbohydrates and be warned to eat breakfast.

Contraindications

Contraindications to the insulin hypoglycemia test include seizure disorder, history of angina, recent myocardial infarction, arrhythmia, and known or suspected primary adrenal failure.

Interpretation

A plasma cortisol level greater than 20 µg per deciliter in any sample indicates normal function of the hypothalamic–pituitary–adrenal axis. A blunted response is considered abnormal only if adequate hypoglycemia (less than 40 mg per deciliter) was achieved.

Metyrapone Tests

Mechanism

Metyrapone blocks 11-hydroxylation in adrenocortical cells. This leads to a decrease in cortisol production, an increase in corticotropin secretion, and stimulation of synthesis of precursor steroids up to the level of the enzymatic block. The amount of substrate for the 11-hydroxylase enzyme, 11-deoxycortisol (compound S), increases and can be measured directly in plasma or indirectly as urinary 17-hydroxycorticosteroid (17-OHCS).

Standard Test

Protocol

The protocol for the standard metyrapone test is as follows:

Day 1: 8:00 A.M. Collect sample for plasma cortisol; 24-hour urine collection for 17-OHCS and creatinine.

Day 2: Begin metyrapone, 750 mg by mouth every 4 hours (total of six doses); second 24-hour urine collection for 17-OHCS and creatinine.

Day 3: 8:00 A.M. Collect sample for plasma cortisol and 11-deoxycortisol; third 24-hour urine collection for 17-OHCS and creatinine.

Contraindications

Contraindications to the metyrapone test include known corticotropin deficiency or Addison's disease.

Side Effects

Headaches and dizziness may be alleviated with bed rest. Nausea and gastric discomfort are reduced if the drug is taken with food. Close supervision is needed because patients with partial corticotropin deficiency may have symptoms of cortisol insufficiency. If this occurs, metyrapone should be stopped and hydrocortisone given.

Interpretation

On day 3, the plasma cortisol level should be less than 5 µg per deciliter to confirm suppression of 11-hydroxylation. The level of compound S should increase to more than 7 µg per deciliter, and the urinary level of 17-OHCS should rise at least twofold over baseline on day 2 or 3. Antiepileptic drugs (phenytoin, barbiturates, primidone) increase the metabolism of metyrapone, and responses may be attenuated. Reduced absorption of the drug owing to vomiting or diarrhea also may reduce responses.

Rapid (Overnight) Test

Protocol

Administer a single oral dose of metyrapone (2 g if weight is less than 70 kg; 2.5 g if weight is 70 to 90 kg; 3 g if weight is more than 90 kg) at midnight with a light snack. At 8:00 A.M. the next day, obtain blood for measurement of cortisol and 11-deoxycortisol.

Interpretation

Plasma 11-deoxycortisol level normally increases to more than 7 µg per deciliter. If the increase is blunted, the concomitant plasma cortisol level must be less than 5 µg per deciliter to exclude inadequate suppression of 11-hydroxylation.

Corticotropin Stimulation Tests

Mechanism

Corticotropin stimulates adrenocortical cells.

Short Test

Protocol

Obtain a basal sample for cortisol. Inject synthetic corticotropin 1-24 (cosyntropin [Cortrosyn]), 250 µg IV or intramuscularly. Obtain samples for cortisol measurement 30 and 60 minutes after injection.

Interpretation

A normal response is a plasma cortisol level greater than 20 µg per deciliter in any sample. A blunted response indicates primary or secondary adrenal insufficiency. A normal response excludes primary adrenal failure but does not exclude corticotropin deficiency of recent onset.

Long Test

Mechanism

Repeated stimulation of the adrenal cortex by corticotropin restores cortisol secretion in corticotropin deficiency but not in primary adrenal failure.

Protocol

The protocol for the long test is as follows:

Day 1: 8:00 A.M. Obtain blood specimen for plasma cortisol measurement; obtain a 24-hour urine collection for 17-OHCS and creatinine measurement.

Days 2 through 4: Infuse 250 µg cosyntropin in 500 mL normal saline solution IV over 8 hours. Obtain 24-hour urine collection for measurement of creatinine and 17-OHCS.

Day 4: Measure plasma cortisol at the end of the cosyntropin infusion.

Interpretation

Primary adrenal failure is indicated by an absent or subnormal increase in plasma cortisol and 17-OHCS levels. Corticotropin deficiency is indicated by a plasma cortisol level greater than 20 µg per deciliter and a twofold to threefold increase in urinary 17-OHCS level over baseline on day 4. A normal response to corticotropin infusion does not mean that CRH and corticotropin secretion can respond to stress. This can be assessed only with hypoglycemia or metyrapone tests.

Corticotropin-releasing Hormone Test

CRH stimulates pituitary corticotropic cells. CRH, 1 µg per kilogram, is given IV in the evening, when endogenous cortisol secretion is low. Plasma corticotropin and cortisol levels increase twofold to threefold 30 to 90 minutes after administration of CRH. CRH appears to differentiate endogenous CRH deficiency from pituitary corticotropic failure.

SUSPECTED GROWTH HORMONE DEFICIENCY

Deficiency of GH is a problem in pediatric endocrinologic practice. In the past, GH secretory reserve in adults usually was evaluated to gain information about hypothalamic-pituitary function in general rather than to evaluate GH secretion per se. GH deficiency has come to be associated with increased cardio-vascular mortality, abdominal obesity, osteoporosis, and neuro-psychiatric abnormalities, even among adults. GH has been approved for treatment of adults with hypopituitarism. Testing of the somatotrophic axis became widely used in adult endocrinologic practice.

In children, GH secretion is best assessed with frequent (every 10 to 20 minutes) sampling over 24 hours, especially during sleep. The presence of spontaneous GH pulses (amplitude >10 ng per milliliter) and normal integrated GH concentrations (2 to 4 ng per milliliter) indicates normal GH secretion. This approach is clinically impractical, and stimulation tests of GH secretion are used on an outpatient basis. Screening tests include an exercise test or clonidine hydrochloride 250 µg by mouth. If plasma GH level increases to more than 10 ng per milliliter 15 to 30 minutes after exercise (20 minutes of running or climbing a staircase) or 60 to 90 minutes after clonidine administration, further testing is not needed.

General Considerations

The definition of normalcy of the stimulated GH level is still problematic. It is important to remember that the currently accepted levels of more than 10 ng per milliliter (indicating normalcy) or less than 3 ng per milliliter (indicating severe deficiency) are established by convention rather than from solid physiologic or clinical data.

Ten percent to 20% of healthy persons have impaired responses to any single test, and two different stimuli, preferably including insulin hypoglycemia, should be used to establish the diagnosis of GH deficiency. Obese patients often have blunted responses to all stimuli, and these responses increase after weight loss. Hypothyroidism blunts GH responses, and euthyroidism should be present before GH reserve is tested. GH responses to all stimuli may be blunted by hyperglycemia, high-dose glucocorticoids, and phenoxybenzamine. For boys, GH responses can be augmented by estrogen pretreatment (Premarin 5 mg twice a day for 3 days) or by β-blockers (propranolol 20 to 30 mg per square meter by mouth) given 2 hours before administration of insulin, arginine, or levodopa. Normalization of a blunted GH response is regarded as evidence of normal GH secretory reserve. Some children with short stature and low IGF-I levels may have normal GH responses to provocative stimuli. In this case, the diagnosis of neurosecretory GH dysfunction can be established only with frequent GH sampling (every 10 to 20 minutes) for 24 hours or during sleep.

Levodopa Test

Mechanism

Levodopa probably stimulates hypothalamic secretion of GH-RH.

Protocol

After an overnight fast, the patient is recumbent for 30 minutes. Obtain a basal blood sample for measurement of GH. Administer levodopa (500 mg by mouth for adults, less for children according to body weight). Obtain blood samples for measurement of GH 30, 60, and 90 minutes after administration of levodopa.

Side Effects

Side effects include nausea and vomiting.

Interpretation

A normal response is a GH level of 10 ng per milliliter or more in any sample. Not all healthy subjects respond.

Arginine Tests

Mechanism

The mechanism of the arginine test is unknown, but it requires hypothalamic GH-RH for action.

Protocol

After an overnight fast, the patient remains recumbent for 30 minutes. Obtain a blood sample for basal measurement of GH. Administer arginine hydrochloride, 0.5 g per kilogram (maximum 30 g) in 200 mL normal saline solution by means of IV infusion over 30 minutes. Obtain blood samples for measurement of GH at the end of infusion and 30 and 60 minutes later.

Contraindications

Contraindications to the arginine test are hepatic or renal failure.

Interpretation

A normal response is a GH level of at least 10 ng per milliliter on any sample. Male subjects, particularly boys, may have lower GH responses.

Insulin Hypoglycemia Test

The insulin hypoglycemia test is the standard for GH stimulation tests. It is especially useful because corticotropin and cortisol reserve can be assessed simultaneously.

Mechanism

The mechanism is complex and requires endogenous hypothalamic GH-RH for its action.

Protocol

After an overnight fast, the patient remains recumbent for 30 to 60 minutes. The insulin dose and glucose sampling are the same as described for testing corticotropin secretory reserve. Measure plasma GH before and 30, 60, and 90 minutes after the onset of hypoglycemic symptoms.

Contraindications

Contraindications include seizure disorder, history of angina, recent myocardial infarction, arrhythmia, and known or suspected primary adrenal failure.

Interpretation

A normal response is a GH level of at least 10 ng per milliliter in any sample. A lower GH response is regarded as abnormal only if adequate hypoglycemia (clinical signs and blood glucose level less than 40 mg per deciliter) is achieved.

Growth Hormone-releasing Factor Test

Growth hormone-releasing factor (GHRF) stimulates somatotroph cells. It is given as an IV bolus, 1 µg per kilogram. Blood samples for measurement of GH are obtained before drug administration and 30, 60, and 90 minutes later. GH responses depend on prevailing somatostatin secretion and may be absent among some healthy persons. Among children with GH deficiency, GH responsiveness to GHRF suggests that GHRF may be used for future therapy.

SUSPECTED DEFICIENCY OF GONADOTROPIN (LUTEINIZING AND FOLLICLE-STIMULATING HORMONES)

Gonadotropin deficiency may be caused by gonadotropic failure or GnRH deficiency. Confirmation of gonadotropic responsiveness to GnRH is necessary when long-term GnRH therapy to induce puberty or restore fertility is contemplated. The test is indicated when amenorrhea for a woman or a low plasma testosterone level for a man is accompanied by low levels of LH and FSH.

Gonadotropin-releasing Hormone Test

Mechanism

The mechanism is direct stimulation of pituitary gonadotropins.

Protocol

Obtain a basal blood sample for measurement of LH and FSH. Administer GnRH 100 µg IV bolus. Obtain samples for measurement of LH and FSH 30, 60, and 90 minutes after injection.

Side Effects

Usually there are no side effects, but transient hot flushing or a metallic taste may occur.

Interpretation

A normal response is an increase in LH level of at least twofold 30 minutes after injection of GnRH. Serum FSH may not respond in adults, but it usually increases at 60 to 90 minutes. LH and FSH responses to GnRH depend on the age (prepubertal, pubertal) and sex of the patient. After a single bolus of GnRH, patients with GnRH deficiency may have absent, subnormal, or normal LH responses, depending on the degree of GnRH deficiency. An absent or subnormal LH response to a single bolus of GnRH does not establish the diagnosis of gonadotropic failure. In GnRH deficiency, LH and FSH increase into the normal range after 3 to 5 days of treatment with GnRH, 25 ng per kilogram IV given in a pulsatile manner every 1 to 2 hours. LH and FSH responses to GnRH may be blunted by exogenous estrogens or androgens and by high levels of glucocorticoids.

Clomiphene Test

Clomiphene binds to hypothalamic receptors and interferes with the negative feedback of estradiol and testosterone. As a result, GnRH secretion and plasma LH and FSH increase. After 5 to 7 days of administration of clomiphene, 50 to 100 mg per day by mouth, LH and gonadal steroid levels increase twofold in adults. No response occurs in among patients with hypopituitarism or GnRH deficiency or among prepubertal children. The clomiphene test is rarely used but is occasionally of value in the diagnosis of suspected GnRH deficiency in adults.

SUSPECTED PROLACTIN DEFICIENCY

Except for lactation, prolactin deficiency has no known clinical significance. Therefore, tests of prolactin secretory reserve are performed not to assess prolactin secretion per se but to gain additional information about pituitary function.

TRH directly stimulates pituitary lactotropic cells, and the test is performed by means of IV infusion of 200 to 500 µg of TRH over 2 to 3 minutes. Serum prolactin level normally increases twofold 30 minutes after administration of TRH, and peak values are greater than 12 ng per milliliter. Metoclopramide (Reglan), 5 to 10 mg IV, blocks dopamine receptors, and serum prolactin level increases twofold 30 to 60 minutes later. Prolactin responses to both stimuli are augmented by estrogen and are higher among women. Serum prolactin level is low in pituitary destruction and does not respond to TRH or metoclopramide. In contrast, patients with a hypothalamic lesion or with a stalk section have elevated prolactin levels that may not respond to metoclopramide but increase after administration of TRH.

Combined Pituitary Function Tests

Concomitant administration of insulin, TRH, and GnRH allows simultaneous testing of corticotropin, GH, TSH, prolactin, LH, and FSH reserve function. Details of normal responses are discussed earlier.

Protocol

After an overnight fast and IV cannulation with the patient recumbent, the protocol is as follows:

30 minutes: Obtain blood samples for measurement of free thyroxine (FT₄), IGF-I, and testosterone (for men).

0 minutes: Sample for glucose, TSH, GH, cortisol, LH, FSH, and prolactin. Inject crystalline (regular) insulin 0.15 U per kilogram (use 0.1 U per kilogram if hypopituitarism is suspected), TRH 200 µg; and GnRH 100 µg IV.

15 minutes: Sample for glucose (glucose oxidase strips)

30 minutes: Sample for glucose, TSH, prolactin, LH, and FSH

60 minutes: Sample for glucose, TSH, prolactin, LH, FSH, cortisol, and GH

90 minutes: Sample for glucose, cortisol, and GH

120 minutes: Sample for glucose, cortisol, and GH. Ensure that adequate hypoglycemia (less than 40 mg per deciliter) is present and allow symptoms to persist for 5 minutes before giving glucose by mouth or IV. If hypoglycemia does not occur within 45 minutes, give additional insulin IV (half the initial dose) and perform cortisol and GH sampling 30, 60, and 90 minutes after the onset of hypoglycemia. If symptoms of cortisol deficiency occur, inject hydrocortisone 100 mg IV and give additional glucose at 120 minutes.

Growth hormone secretion in acromegaly should not be assessed with this test because normal GH responses to hypoglycemia cannot be differentiated from paradoxical responses to TRH or GnRH. A variation of this test involving administration of GHRF and CRH instead of insulin has been described. Although this provides more direct information about the function of GH- and corticotropin-producing pituitary cells, insulin hypoglycemia offers the advantage of testing stress-associated corticotropin secretion and thus is more relevant in clinical practice.

INVESTIGATION OF PITUITARY HYPERFUNCTION

SUSPECTED PROLACTIN HYPERSECRETION

A serum level of prolactin in excess of 200 ng per milliliter almost always indicates the presence of prolactinoma. Serum prolactin elevation to less than 200 ng per milliliter may be caused by prolactinoma or another condition. Dopamine agonists (levodopa, bromocriptine) invariably suppress serum prolactin level and thus have little or no value in the differential diagnosis of hyperprolactinemia. Prolactin responses to stimulation by TRH or dopamine antagonists likewise do not help establish the cause of hyperprolactinemia.

SUSPECTED HYPERSECRETION OF GROWTH HORMONE

Pathologic hypersecretion GH manifests as gigantism or acromegaly, and IGF-I levels are elevated. Patients with malnutrition, chronic renal failure, cirrhosis, uncontrolled diabetes mellitus, and Laron-type dwarfism may have elevated serum GH values, but these are accompanied by low or normal IGF-I levels. A normal GH level is low (less than 0.1 ng per milliliter) during most of the day, but spontaneous GH pulses, postprandial GH pulses (2 to 3 hours after meals), or nocturnal GH pulses (1 to 3 hours after falling asleep) may reach levels of more than 20 ng per milliliter. Stress (physical exercise, anxiety, pain) also cause acute increases in GH level. Testing of GH secretion should be performed after an overnight fast, with a 30-minute rest period after insertion of the IV cannula. Random plasma GH values in excess of 2 ng per milliliter in association with elevated IGF-I concentrations and appropriate clinical findings strongly suggest abnormal GH hypersecretion, but dynamic tests may be needed to confirm the diagnosis.

Glucose Suppression Test

Mechanism

The mechanism of glucose suppression is uncertain but probably is the result of stimulation of hypothalamic somatostatin secretion.

Protocol

Obtain blood samples for basal measurement of GH and glucose. Administer glucose 100 g by mouth. Obtain blood samples for measurement of GH and glucose 30, 60, 90, and 120 minutes later.

Contraindication

Moderate or severe glucose intolerance is a contraindication to the glucose suppression test.

Interpretation

The normal response is a decrease in GH to less than 1 ng per milliliter at any time during the test when sensitive immunoradiometric or immunochemiluminescent assays are used. In acromegaly or gigantism, GH is not suppressed to less than 1 ng per milliliter and may even increase. If basal GH level is not clearly elevated (3 to 5 ng per milliliter), a decrease after glucose administration is difficult to document, and a TRH stimulation test may have to be performed.

Thyrotropin-releasing Hormone Stimulation Test

Mechanism

The mechanism by which TRH stimulates release of GH is unknown.

Protocol

Obtain blood samples for basal measurement of GH and TSH. Inject TRH, 200 µg IV over 15 to 30 seconds. Sample for GH and TSH 15, 30, and 60 minutes later.

Side Effects

Urge to urinate, metallic taste, or flushing may persist for 1 to 2 minutes after injection of TRH.

Interpretation

The normal response is no change in GH concentration. Among 60% to 80% of patients with acromegaly or gigantism, GH increases at least 50% 15 to 30 minutes after administration of TRH. This test may be useful in evaluation of patients with low basal GH concentrations (less than 5 ng per milliliter) when an excess of GH is suspected clinically. The presence of TRH also may increase serum GH level in patients with renal failure, cirrhosis, primary hypothyroidism, uncontrolled diabetes, or malnutrition and in some apparently healthy adolescents with tall stature.

Bromocriptine Suppression Test

Mechanism

The mechanism of the bromocriptine suppression test is uncertain but probably is related to direct pituitary inhibition of GH secretion.

Protocol

Obtain blood samples for basal measurement of GH and prolactin. Administer 2.5 or 5.0 mg bromocriptine, and obtain blood samples for measurement of GH and prolactin at hourly intervals for 6 hours.

Contraindications

Hypotension of any cause is a contraindication to the bromocriptine suppression test.

Side Effects

Orthostatic hypotension, nausea, vomiting, and epigastric discomfort may be caused by administration of bromocriptine.

Interpretation

Bromocriptine suppresses plasma GH level in about one-half of patients with acromegaly or gigantism. This suggests that bromocriptine may be effective for long-term treatment of patients with the disease.

SUSPECTED HYPERSECRETION OF CORTICOTROPIN

Hypersecretion of corticotropin in primary adrenal failure is accompanied by low plasma cortisol values, and further testing is not required. Hypersecretion of corticotropin caused by a pituitary tumor leads to bilateral adrenal hyperplasia and elevated cortisol production (Cushing's disease). Cushing's disease is one cause of Cushing's syndrome. *Cushing's syndrome* is the term used to describe the clinical features of glucocorticoid excess. This syndrome may be caused by exogenous glucocorticoid therapy, overproduction of corticotropin (pituitary or ectopic source), or an adrenal tumor. Corticotropin and cortisol levels may be elevated in healthy persons under acute or chronic stress, such as pain, fever, or exercise. Dynamic tests of corticotropin secretion are designed to answer two questions: First, does the patient have endogenous glucocorticoid overproduction? Second, is the glucocorticoid overproduction caused by pituitary or ectopic corticotropin excess or by an autonomous adrenal tumor?

Basal Tests

All basal blood samples should be drawn with minimal stress. Insert an IV cannula and wait 30 minutes before drawing the sample.

Morning and Evening Plasma Corticotropin and Cortisol

Loss of the normal diurnal variation of plasma corticotropin and cortisol levels is the hallmark of endogenous Cushing's syndrome. Obtain samples between 8:00 A.M. and 9:00 A.M. and between 10:00 P.M. and midnight. Normal values for corticotropin and cortisol, respectively, are 20 to 90 pg per milliliter and 10 to 25 µg per deciliter in the morning and less than 20 pg per milliliter and less than 5 µg per deciliter in the evening. When drawn under nonstressful conditions, elevated corticotropin or cortisol levels in the evening suggest Cushing's syndrome.

Plasma corticotropin is undetectable (less than 10 pg per milliliter) in the morning among patients with adrenal tumors or during exogenous glucocorticoid therapy. Evening values are elevated among persons with Cushing's disease. Both morning and evening levels are elevated (100 to 200 pg per milliliter) among persons with the more severe forms of Cushing's disease, but values greater than 200 pg per milliliter suggest an ectopic corticotropin-secreting tumor.

Evening levels of plasma cortisol are greater than 10 to 15 µg per deciliter among 95% of patients with Cushing's syndrome. Both morning and evening cortisol values may be elevated, usually with a preserved diurnal rhythm, in the presence of chronic alcoholism (pseudo-Cushing's syndrome), during estrogen therapy (elevated cortisol-binding globulin levels), and among depressed or malnourished patients. Undetectable levels of cortisol in a patient with Cushing's syndrome indicate exogenous glucocorticoid administration (usually dexamethasone), but cortisol can be measured for patients taking hydrocortisone or prednisone (cross-reaction in cortisol assays).

Urinary Free Cortisol Excretion

The normal range for urinary free cortisol (UFF) excretion in most laboratories is 20 to 100 µg per 24 hours. UFF is elevated (greater than 150 µg per 24 hours) among more than 90% of patients with Cushing's syndrome. Some obese and chronically ill patients may have mildly increased (more than 120 µg per 24 hours) UFF excretion.

Urinary 17-Hydroxycorticosteroid Excretion

The normal range for secretion of 17-OHCS is 5 to 12 mg per 24 hours. In Cushing's syndrome, values exceed 12 mg per 24 hours in 90% of cases, but values also are elevated among 20% of obese patients.

Dynamic Tests

Basal measurements do not always help differentiate patients with true Cushing's syndrome from those with other diseases. Dynamic tests establish the diagnosis and also help differentiate the various forms of the syndrome.

Dexamethasone Suppression Tests

Dexamethasone suppression tests are based on the principle that the negative feedback of glucocorticoids on pituitary corticotropin secretion is intact in healthy persons, defective (high threshold) in Cushing's disease, and already maximally expressed in adrenal tumors or ectopic corticotropin secretion.

Overnight Test

The dexamethasone suppression test can be performed as an outpatient screening procedure by means of administration of 1 mg dexamethasone by mouth at 11:00 P.M. the night before the test. Plasma cortisol is measured at 8:00 A.M. the next morning. For 99% of healthy persons, the plasma cortisol level is less than 5 µg per deciliter. Among persons with Cushing's syndrome, the plasma cortisol value is not suppressed to this level. In addition, 10% to 15% of obese patients and 20% to 25% of sick, hospitalized patients may not have normal suppression in response to dexamethasone. One-half of patients with alcoholism likewise have impaired suppression, but alcohol withdrawal restores normal cortisol suppression within a few days. One-half of the patients with endogenous depression also exhibit impaired suppression, but this condition can be differentiated from Cushing's syndrome with a normal plasma cortisol response to insulin hypoglycemia. This response is absent or blunted in the presence of Cushing's syndrome. Antiepileptic medications (phenytoin, barbiturates, primidone) increase the metabolic degradation of dexamethasone, and cortisol levels may not become normally suppressed among patients taking these drugs.

Low-dose Test

Dexamethasone suppression with a 2-mg dose can confirm the diagnosis of Cushing's syndrome. The protocol for this test is as follows:

Day 1: 8:00 A.M. Measure plasma cortisol. Examine 24-hour urine specimen for 17-OHCS, UFF, and creatinine.

Days 2 and 3: Administer 0.5 mg dexamethasone by mouth every 6 hours (eight doses). Examine 24-hour urine specimen for 17-OHCS, UFF, and creatinine.

Day 4: Measure plasma cortisol at 8:00 A.M. at completion of urine collection.

Normal suppression is present if plasma cortisol is less than 5 µg per deciliter; 17-OHCS less than 4 µg per 24 hours; and UFF less than 20 µg per 24 hours. Fewer than 5% of patients with Cushing's syndrome have normal suppression. Obesity, depression, and use of antiepileptic drugs may cause incomplete suppression

(false-positive results).

High-dose Test

To establish the cause of Cushing's syndrome, an 8-mg dose often is administered as a continuation of the low-dose, 2-mg dexamethasone suppression test. The protocol is as follows:

Days 4 and 5: Administer 2 mg dexamethasone by mouth every 6 hours (eight doses). Examine 24-hour urine for 17-OHCS, UFF, and creatinine.

Days 5 and 6: 1:00 A.M. Measure plasma cortisol.

Among 70% to 80% of patients with Cushing's disease (pituitary corticotropin-secreting tumor), plasma cortisol, 17-OHCS, and UFF are suppressed in at least half. The other patients with Cushing's disease show incomplete suppression. Fewer than 10% of adrenal tumors have normal suppression, but results are variable in ectopic corticotropin secretion, and 20% to 30% exhibit normal suppression. The results of this test may be difficult to interpret, and a metyrapone or CRH test may be needed to establish the cause of Cushing's syndrome.

Metyrapone Tests

Mechanism

Blockade of 11-hydroxylation lowers cortisol production. Removal of cortisol-negative feedback augments pituitary corticotropin secretion and 17-OHCS excretion in Cushing's disease but not in adrenal tumors or ectopic corticotropin secretion.

Protocol

See Suspected Corticotropin Deficiency.

Interpretation

Among 98% of patients with Cushing's disease, 17-OHCS excretion increases by more than 10 mg per day. This response may occur among 20% to 50% of patients with other causes of Cushing's syndrome. A negative response almost excludes the presence of a pituitary corticotropin-producing tumor, but a positive response is inconclusive.

Corticotropin-releasing Hormone Test

Plasma corticotropin and cortisol increase twofold to threefold after administration of an IV bolus of CRH (1 µg per kilogram) to patients with Cushing's disease. No increase occurs among most patients with ectopic corticotropin secretion or adrenal tumors.

Suspected Hypersecretion of Thyroid-stimulating Hormone

An elevated serum TSH level most commonly reflects primary hypothyroidism. The diagnosis is made clinically and confirmed by low levels of FT₄. Further testing is not required. Primary TSH hypersecretion is extremely rare and may be caused by TSH-producing pituitary tumors or by pituitary resistance to thyroid hormone. Serum TSH and thyroxine (T₄) levels are elevated, and responses to TRH often differentiate the two conditions. TSH does not respond to TRH in TSH-producing tumors but usually increases more than 30 µU per milliliter in the presence of pituitary resistance to thyroid hormone.

Suspected Hypersecretion of Gonadotropin (Luteinizing and Follicle-stimulating Hormones)

Hypersecretion of LH and FSH occurs most frequently in primary gonadal failure and is accompanied by low concentrations of gonadal steroids. In this situation, dynamic testing is not indicated. In rare instances, gonadotropin-secreting pituitary tumors producing free α subunit, FSH, or LH are encountered. Elevation of plasma α subunit is a helpful sign, but gonadotropin and α subunit responses to GnRH stimulation or gonadal steroid suppression are variable and may not help establish the diagnosis.

GUIDELINES FOR THE SELECTION OF PITUITARY FUNCTION TESTS IN CLINICAL SITUATIONS

WITHDRAWAL OF GLUCOCORTICOID THERAPY

Among patients treated with supraphysiologic doses of glucocorticoids (more than 7.5 mg prednisone, more than 0.75 mg dexamethasone) for more than 2 to 3 weeks, the hypothalamic–pituitary–adrenal axis is suppressed. The question often arises whether glucocorticoids can be safely discontinued. The following steps allow safe withdrawal of glucocorticoid therapy:

1. Taper steroid dose to 10 mg prednisone (or equivalent) per day.
2. Change to hydrocortisone 20 mg per day given as a single morning dose, and continue for 3 to 4 days.
3. Measure 8:00 A.M. plasma cortisol before the morning hydrocortisone dose is given. If plasma cortisol level is greater than 10 µg per deciliter, discontinue hydrocortisone. If plasma cortisol level is less than 10 µg per deciliter, continue hydrocortisone replacement and measure cortisol once a month until the 8:00 A.M. cortisol level is greater than 10 µg per deciliter; then discontinue replacement.
4. Perform the short corticotropin test. If plasma cortisol level is greater than 20 µg per deciliter, a normal ability to respond to stress is probable, and steroid coverage is not needed. If cortisol is less than 20 µg per deciliter, steroid cover should be given for any stressful illness or surgery. Repeating the short corticotropin test a few months later may show a normal response, which indicates recovery of the hypothalamic–pituitary–adrenal axis.
5. Perform an insulin hypoglycemia (preferably) or metyrapone test to confirm normal CRH responsiveness to stress. This test often can be omitted if hypothalamic–pituitary disease is not present. If hypothalamic–pituitary disease is suspected, however, the results of the short corticotropin test are not predictive of responsiveness to stress, and an insulin hypoglycemia test should be performed.

SUSPECTED HYPOPITUITARISM

1. Conduct a clinical history interview to elicit information about medications, previous pituitary surgery or irradiation, menstrual history of women, reduced libido and potency among men, and symptoms of hypothyroidism, polyuria, and vision changes.
2. Perform a physical examination to find signs of hypothyroidism or hypogonadism, testicular size and consistency, signs of cortisol or GH excess, and galactorrhea. Examine the visual fields.
3. Obtain basal measurements of prolactin, cortisol (8:00 A.M. to 9:00 A.M.), FT₄, TSH, LH, FSH, testosterone, or estradiol. If corticotropin deficiency is strongly suspected on the basis of clinical evidence, administer 10 mg hydrocortisone three times a day by mouth without waiting for the test results.
4. Request CT or MRI of the hypothalamus and pituitary gland.
5. Perform a combined pituitary function test. If a large tumor is present and emergency surgery is needed to reduce pressure symptoms, preoperative dynamic tests are not indicated.
6. If basal measurements suggest deficiency, replace hydrocortisone and T₄ before surgery. T₄ replacement alone may precipitate cortisol insufficiency among patients with partial corticotropin deficiency.
7. If surgery is not needed, replace hydrocortisone, T₄, and gonadal steroids as indicated by the results of the pituitary function tests.
8. Diabetes insipidus may be unmasked by cortisol or T₄ replacement.

SUSPECTED PITUITARY HYPERFUNCTION

Elevated Prolactin

1. Assess menses or sexual potency in the history. A drug history is most important. Physical examination should include signs of hypogonadism, galactorrhea, goiter, and chest wall lesions.
2. Conduct biochemical screening to exclude renal failure and hypercalcemia. Measure FT₄, TSH, and for men, testosterone.
3. If possible, discontinue any drugs that may elevate prolactin level, and treat the patient as if primary hypothyroidism is present. Reassess prolactin in 1 month.
4. If serum prolactin level remains elevated, request CT or MRI. A serum prolactin level greater than 200 ng per milliliter usually indicates the presence of prolactinoma. Non-prolactin-secreting tumors may elevate prolactin level up to 150 ng per milliliter through compression of the pituitary stalk.

Small prolactinomas (less than 1 cm) rarely compromise other pituitary functions, and dynamic testing is not required. Large tumors may be associated with hypopituitarism, and the approach outlined previously should be followed.

Elevated Levels of Growth Hormone

1. At physical examination, look for changes in the size of the hands and feet, the need for new dentures, an unusual growth pattern, increased perspiration, and characteristic features of elevations in the level of growth hormone.
2. Obtain basal measurements of GH, IGF-I, FT₄, 8:00 A.M. cortisol, gonadal steroid (testosterone or estradiol), prolactin, calcium, phosphate, and fasting glucose.
3. Replace cortisol and thyroxine, if required.
4. Request CT or MRI and a visual field examination.
5. If GH and IGF-I are elevated, perform a glucose suppression test (measure GH and glucose). Consider the need for a TRH test (measure GH and TSH), bromocriptine suppression test, and insulin hypoglycemia test to assess corticotropin reserve, if surgery is not planned.
6. If an abdominal or lung tumor is present, suspect ectopic GHRF secretion and measure plasma GHRF.

Cushing's Syndrome

1. Obtain a thorough history and seek characteristic features of Cushing's syndrome at physical examination. Exclude exogenous use of glucocorticoids.
2. Perform a 24-hour urine (10:00 P.M. to 10:00 P.M.) screening test for UFF. At 11:00 P.M., administer 1 mg dexamethasone by mouth. Measure plasma cortisol at 8:00 A.M. the next morning. If UFF is normal (less than 100 µg per 24 hours) and 8:00 A.M. cortisol is less than 5 µg per deciliter, endogenous Cushing's syndrome is excluded.
3. If screening test results are abnormal, schedule the patient for hospitalization and perform the following tests: morning and evening corticotropin and cortisol; formal dexamethasone suppression tests (2 mg and 8 mg); and maybe a metyrapone or CRH test to define the cause (pituitary, adrenal, ectopic corticotropin). Request appropriate CT or other imaging studies.

CHAPTER 418: EVALUATION OF THYROID FUNCTION TESTS

RASA KAZLAUSKAITE, BRUCE D. WEINTRAUB AND KENNETH D. BURMAN

[Screening for Thyroid Dysfunction](#)
[Serum Thyroid-Stimulating Hormone Concentrations](#)
[Serum Thyroid Hormone Concentrations](#)
[Ancillary Tests of Thyroid Function](#)
[Approach to the Patient with Abnormal Thyroid Function Test Results](#)

Secretion of the thyroid hormones thyroxine (T_4) and triiodothyronine (T_3) is regulated by pituitary thyroid-stimulating hormone (thyrotropin; TSH). TSH secretion is controlled through negative feedback by thyroid hormones and both positive and negative hypothalamic factors. This tight interrelation of the hypothalamic–pituitary–thyroid axis allows for convenient and accurate assessment of steady state thyroid function. Laboratory tests of thyroid function have been widely used in clinical practice.

SCREENING FOR THYROID DYSFUNCTION

Screening refers to the testing of thyroid function among persons believed to have thyroid disease but not known to have thyroid disease. The cost-effectiveness of screening of patients without symptoms is a matter of debate. Decision analysis, however, indicates that measurement of serum TSH concentration is as cost-effective as many other preventive medicine measures. The American College of Physicians recommends screening for hypothyroidism among women older than 65 years. Even though in most circumstances a TSH test alone is an appropriate initial screening tool, addition of a free thyroxine (FT_4) test to the screening panel may be indicated (Fig. 418.1). Persons with suspected pituitary or hypothalamic disease cannot be screened with serum TSH measurement alone.

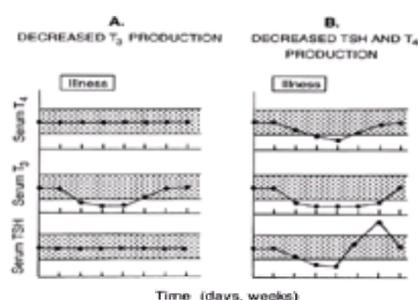

FIGURE 418.1. Thyroid function screening strategies based on results of serum TSH testing. Screening should include a careful history and physical examination. TSH, thyroid-stimulating hormone; T_3 , triiodothyronine; T_4 , thyroxine; anti-TPO, anti-thyroid peroxidase antibody.

SERUM THYROID-STIMULATING HORMONE CONCENTRATIONS

Measurement of serum TSH is the single best test of thyroid function, in steady state conditions and in the absence of pituitary or hypothalamic disease (Table 418.1). The level of free thyroxine is inversely related to the logarithm of the serum TSH concentration. A small change in FT_4 level may produce a large change in TSH level. Therefore if a single screening test is used to detect primary thyroid dysfunction, third-generation TSH assays are more sensitive and specific than FT_4 measurements for outpatients.

TSH	Free T_4	Free T_3	Assessment
Normal	Normal	Normal	Euthyroid
Normal	Low	Normal or low	Central hypothyroidism
Normal	Low	High	T_3 therapy
Normal	High	Normal or high	TSH-mediated hyperthyroidism or RTH
Normal	Low normal	Normal or high	Thyroid extract therapy
High	Low	Normal or low	Primary hypothyroidism
High	Normal	Normal	Subclinical hypothyroidism
High	High	High	TSH-mediated hyperthyroidism or RTH
Low	High	High	Primary hyperthyroidism
Low	Normal	Normal	Subclinical hyperthyroidism
Low or normal	Low	Low	Central hypothyroidism
Low	Low	High	T_3 toxicosis

T_3 , triiodothyronine; T_4 , thyroxine; TSH, thyroid-stimulating hormone; RTH, resistance to thyroid hormone.

TABLE 418.1. PATTERNS OF STEADY-STATE THYROID FUNCTION TESTS

The serum TSH concentration of healthy persons ranges from approximately 0.5 to 5.0 mU per liter. The most common cause of elevated TSH level is primary hypothyroidism caused by thyroid gland hypofunction. Patients with overt primary hypothyroidism have TSH values usually greater than 20 mU per liter. Patients with subclinical hypothyroidism, who by definition have few or no symptoms of hypothyroidism and thyroid hormone serum concentrations within the normal range, usually have serum TSH values between 5.0 and 20 mU per liter. The assessment and treatment of patients with subclinical hypothyroidism are controversial.

Inability to detect TSH with a third-generation assay (sensitivity approximately 0.01 mU per liter) is a reliable indicator of the presence of overt primary hyperthyroidism. Subnormal (less than 0.5 mU per liter) serum TSH concentrations with normal serum thyroid hormone concentrations (FT_4 and T_3) in clinically euthyroid patients define subclinical hyperthyroidism (Table 418.1).

If a defect in TSH secretion is present because of hypothalamic or pituitary disease, measurement of TSH levels alone may not be sufficient to define the functional status of the hypothalamic–pituitary–thyroid axis.

SERUM THYROID HORMONE CONCENTRATIONS

Serum FT_4 concentrations should be measured for all patients for diagnosis and follow-up of evaluation of central hypothyroidism, central hyperthyroidism, and thyroid hormone resistance. Measurements of serum TSH and FT_4 levels are the first line tests to investigate thyroid dysfunction for all inpatients, patients with dementia or psychiatric disease, patients with infertility or amenorrhea, patients taking drugs that interfere with thyroid hormone metabolism or function, and patients who need monitoring of thyroid disease.

SERUM FREE THYROXINE CONCENTRATIONS

The serum total thyroxine (TT₄) concentration of healthy adults typically ranges from 4.6 to 11.2 µg per deciliter (64 to 142 nmol per liter). Almost all (99.96%) T₄ in the circulation is bound to carrier proteins, in particular thyroxine-binding globulin (TBG), and to a lesser extent, to transthyretin and albumin. The bound hormone represents a circulating T₄ storage pool; the hormone is not immediately available for uptake into cells. Because drugs and illness ([Table 418.2](#)) can alter concentrations of binding proteins or interaction of the binding proteins with T₄ or T₃, the free and total hormone levels may not be concordant.

Increased	Decreased

TABLE 418.2. DRUGS AFFECTING THYROXINE BINDING IN SERUM

The FT₄ fraction is responsible for hormonal activity; therefore FT₄ rather than TT₄ concentration is a better estimate of thyroid function in clinical practice. The best laboratory estimate of FT₄ concentration is achieved with an equilibrium dialysis method. In most instances this method is cumbersome and expensive; therefore it is not routinely used in clinical practice. However, some commercial laboratories in the United States (e.g., Nichols) have a good and convenient kit in which FT₄ is measured by means of dialysis.

Because of simplicity of interpretation direct FT₄ measurement by means of radioimmunoassay is used in most clinical laboratories. This method has almost replaced the older methods used to estimate FT₄ concentration. The disadvantage of FT₄ radioimmunoassay is that no currently available kit provides correct FT₄ values for all the binding abnormalities that have been described. However, in most cases this method gives enough information about the hormonal activity of T₄. FT₄ levels are typically 0.7 to 1.9 ng per deciliter, and they vary among the laboratories.

The traditional method was calculation of FT₄ index by use of the thyroid hormone binding ratio or index (THBR or THBI) through measurement of T₃ resin uptake (T₃RU). This method has the advantage that both TT₄ and thyroid hormone binding ratio or index are reported, making it clear when the patient has a potential binding protein abnormality rather than a pathophysiologic condition. It also provides the opportunity to calculate FT₃ index using the thyroid hormone binding ratio or index if total T₃ (TT₃) is measured. Disadvantages of this method are that many clinicians do not understand the calculation and that the FT₄ index, as with direct FT₄ measurement by means of radioimmunoassay, does not give correct values for many described binding protein abnormalities. Most important, a small change in the T₃RU result produces a relatively larger change in calculated FT₄ index. These calculated FT₄ values do not consistently correspond to FT₄ values from equilibrium dialysis measurements in many clinical circumstances. We prefer the use of FT₄ measurements over use of a calculated FT₄ index.

The T₃RU was designed to differentiate TBG excess and deficiency from hyperthyroidism and hypothyroidism ([Table 418.3](#)). However, the index may not fully correct at the extremes of binding protein abnormalities. In these cases FT₄ may be measured by means of the equilibrium dialysis method, or TBG concentration itself can be measured.

Condition	Total T ₄	T ₃ RU or THBI	Free T ₄ index	TSH
Hyperthyroidism	High	High	High	Low
TBG excess	High	Low	Normal	Normal
Hypothyroidism	Low	Low	Low	High
TBG deficiency	Low	High	Normal	Normal

T₃, triiodothyronine; T₄, thyroxine; TSH, thyroid-stimulating hormone; T₃RU, T₃ resin uptake; TBG, thyroxine-binding globulin; THBI, thyroid hormone binding index.

TABLE 418.3. PATTERNS OF FREE T₄ INDEX ESTIMATE

SERUM TRIIODOTHYRONINE CONCENTRATIONS

Total serum T₃ concentration (also called T₃ by radioimmunoassay or stable T₃) in the absence of thyroid binding abnormalities is measured to estimate the severity of hyperthyroidism or to diagnose T₃ toxicosis. T₃ is less tightly bound to TBG but more tightly bound to transthyretin and albumin than is T₄. The normal range typically is 75 to 195 ng per deciliter, and it varies among laboratories.

Serum T₃ concentration changes with alterations in TBG such that, for example, T₃ level increases among euthyroid women taking oral contraceptives. The normal range in this circumstance is different from that among persons not taking estrogen, but the precise normal ranges are not reported on the laboratory slip and must be remembered and recorded by the clinician. It may also be useful to measure T₃ levels for patients who may be having a relapse of Graves' disease after treatment and for patients who are taking exogenous levothyroxine, especially when the dose is sufficiently high to decrease TSH level. A FT₃ index can be calculated with the thyroid hormone binding index. The FT₃ measurements are available commercially and may be used instead of total T₃ if T₃RU is not measured.

ANCILLARY TESTS OF THYROID FUNCTION

The next step after documentation of thyroid function abnormalities is to determine the cause of the abnormality. Valuable information is obtained from the history and physical findings, and any type of thyroid function test must be interpreted in the context of the patient's clinical situation. Ancillary tests may help to isolate the causes of the abnormalities.

ANTI-THYROID ANTIBODY TESTS

The anti-thyroid peroxidase (anti-TPO) antibody test has largely replaced the less sensitive anti-microsomal antibody test. Anti-microsomal antibody was identified as anti-TPO, but the latter is a better test because of the pure recombinant reagents used. Tests for these antibodies, however, do not contribute direct information about thyroid secretion. Nevertheless, when results of thyroid function tests are ambiguous, evidence of autoimmune thyroid disease may influence the decision regarding therapy versus observation. Low titers of anti-TPO can be found in many thyroid and other autoimmune diseases; however, higher titers suggest Hashimoto's thyroiditis or Graves' disease, or an overlap syndrome called *Hashitoxicosis*. The diagnosis of Hashimoto's thyroiditis among patients with ambiguous thyroid function

test results has important clinical implications. The likelihood of the presence or development of hypothyroidism is higher than it is among other patients. The possibility of development of other autoimmune diseases, such as Addison's disease, also increases, as does the possibility of development of thyroid lymphoma.

Thyroid-stimulating immunoglobulin or thyroid binding-inhibiting immunoglobulin assays are an important clinical tool in the care of patients with autoimmune thyroid disease with or without hormone abnormalities. These tests typically are used to determine the likelihood of the presence of transient neonatal thyrotoxicosis or hypothyroidism in the offspring of a mother with autoimmune thyroid disease. Autoimmune thyroid disease may develop in the newborn within the first several weeks of life because of the transplacental passage of IgG antibodies that can stimulate or inhibit the neonatal thyroid gland. Measurement of serum thyroid binding-inhibiting immunoglobulin or thyroid-stimulating immunoglobulin can be used clinically to predict the recurrence of Graves' disease after clinical remission is achieved, to assist in the diagnosis of autoimmune thyroid disease when it is not readily apparent, to help in the diagnosis of Graves' orbitopathy, which can affect any patient with autoimmune thyroid disease, or to differentiate Graves' disease from other causes of orbitopathy.

RADIONUCLIDE TESTS

Many clinicians confuse thyroid scans with uptake tests. These are two different tests that give related but different information. No isotopic test should be performed on a woman who is or may be pregnant.

Thyroid radioiodine uptake among healthy persons in the United States typically ranges from 5% to 15% at 4 hours and 10% to 25% at 24 hours after oral administration of iodine I 131 or iodine I 123. It depends on the iodide intake of a given population. The results usually cannot be interpreted for patients who have substantial exposure to nonradioactive iodide, such as patients who have recently undergone injection of radiographic contrast medium dye for computed tomography scan or angiography. After this kind of exposure, it may take 4 to 6 weeks to clear the iodine load. It seems reasonable to measure 24-hour urine iodine excretion before testing radioiodine uptake. The radioactive iodine test is useful to differentiate hyperthyroidism caused by subacute thyroiditis or exogenous administration of thyroid hormone, in which uptake is low (usually less than 5%), from other causes of hyperthyroidism, such as Graves' disease, multinodular goiter and autonomous nodules, in which it is high ([Table 418.4](#)). It is not useful to differentiate hypothyroidism from normal thyroid function.

Thyrotoxicosis factitia
Subacute thyroiditis
Silent thyroiditis
Iodine
Ectopic thyroid hormone production (e.g., struma ovarii)
Excess iodine exposure

TABLE 418.4. CAUSES OF LOW RADIOIODINE UPTAKE THYROTOXICOSIS

The radioactive iodine uptake test is not a thyroid function test per se, and it is possible for the uptake to increase even among patients with Hashimoto's thyroiditis, who may be clinically euthyroid or even hypothyroid. This probably occurs because of altered iodine uptake and organification in these patients. For breast-feeding women, a rough estimate of thyroid uptake can be obtained with technetium Tc 99m pertechnetate, which is eliminated faster than iodine I 131. Breast-feeding typically may be resumed 24 hours after the test.

Thyroid radionuclide scanning, which can be performed with technetium Tc 99m pertechnetate, iodine I 123, or iodine I 131, provides information about the function, size, and shape of thyroid nodules but not necessarily about overall thyroid function. Most physicians prefer to use iodine I 123 or technetium for scanning because of the lower radiation dose to the patient.

Thionamide drugs (propylthiouracil, methimazole) and recent administration of iodine or iodide (including amiodarone and iodinated radiocontrast agents) may interfere with the interpretation of results of radionuclide tests.

THYROGLOBULIN

Measurement of serum thyroglobulin in the evaluation of thyroid function is used when factitious ingestion of thyroid hormone preparations is suspected. The thyroglobulin levels of those patients are suppressed, whereas those of patients with thyroiditis are not. Clinicians must be aware not only of prescription thyroid hormone preparations such as levothyroxine (Synthroid, Levoxyl) and liothyronine (Cytomel) but also of thyroid hormone extracts in health foods and food supplements. If a patient has taken a compound that contains thyroglobulin, then serum measurement and interpretation of thyroglobulin levels becomes more problematic.

The most common use of serum thyroglobulin levels is follow-up care of patients with known thyroid cancer to look for recurrence or presence of disease. Most of these patients have undergone complete thyroidectomy and therapy with radioactive iodine. They should have no detectable thyroid tissue, normal or abnormal, and serum thyroglobulin level should be less than 1 ng per milliliter. An increase in serum thyroglobulin level in this circumstance suggests the return of disease. Serum thyroglobulin levels are not useful to detect the presence of thyroid cancer in patients with intact thyroid glands because the normal range is quite wide.

THYROID ULTRASONOGRAPHY

Ultrasonography of the thyroid has minimal value in the evaluation of thyroid function. In some instances it can be helpful in the evaluation of multinodular goiter or autonomous nodules, for example, to help isolate the size and location of nodules and to help ascertain whether nonfunctioning nodules are present that may require aspiration or observation.

PITUITARY AND HYPOTHALAMIC IMAGING STUDIES

Imaging of the pituitary gland and hypothalamus usually is needed after the biochemical diagnosis of central hypothyroidism, which is secondary if caused by pituitary disease or tertiary if caused by hypothalamic disease. In rare instances, hyperthyroidism is caused by a TSH-secreting pituitary tumor, and imaging of the pituitary gland is needed. The optimal imaging study in these circumstances is magnetic resonance imaging of the pituitary and hypothalamic area, although individual circumstances may indicate adjunctive studies, such as high-resolution computed tomography or octreotide scintigraphy.

APPROACH TO THE PATIENT WITH ABNORMAL THYROID FUNCTION TEST RESULTS

Abnormal thyroid function test results for a patient without signs or symptoms of thyroid dysfunction or thyroid function test results discordant with the clinical presentation warrant exclusion of laboratory error, usually through analysis of the clinical context and repetition of the laboratory analysis. Artifacts in the measurement of TSH may be caused by the presence of heterophilic antibodies against mouse immunoglobulins that interfere with the TSH assay and cause false elevation in many results. Artifactual elevations in T₃ or T₄ may be caused by anti-T₃ or anti-T₄ antibodies (increased titers of anti-thyroglobulin antibody may have some predictive value).

The approach to evaluation of a patient with abnormal thyroid function test results varies with the clinical situation. We recommend evaluation in consultation with an endocrinologist for patients with hyperthyroidism, suspected central causes of thyroid dysfunction, suspected resistance to thyroid hormone or TSH, or abnormal thyroid function test results in the presence or absence of an anatomic abnormality of the thyroid and for pregnant patients with a history of thyroid disease.

Consultation should be considered when patients have nonthyroidal illness syndrome, drug-induced thyroid dysfunction or thyroid function test results that are difficult to interpret. When to seek endocrinologic consultation depends on many factors, including the clinical context and laboratory results as well as the background and experience of the referring physician.

PATIENTS WITH SUSPECTED HYPERTHYROIDISM

After a thorough history interview and physical examination, the laboratory evaluation of a patient believed to have hyperthyroidism begins with measurement of serum TSH with or followed by estimation of serum FT₄ and TT₃ or FT₃ (Fig. 418.2). Suppressed undetectable TSH levels with increased FT₄ concentrations help to confirm the diagnosis of primary hyperthyroidism, the most common form of thyrotoxicosis. If serum FT₄ values are normal, serum FT₃ may be elevated, indicating T₃ toxicosis. A decreased serum TSH level with normal FT₄ and T₃ in the proper clinical context indicates subclinical hyperthyroidism. If TSH level is decreased or undetectable, measurement is best performed with a third-generation TSH assay. Serum TSH levels can vary during the day, and interassay variation can be a factor. As a result, it is important to document a TSH level less than 0.01 mU per liter (undetectable with a third-generation assay), which strongly suggests the presence of hyperthyroidism. If TSH is detectable and slightly below normal range, hyperthyroidism may or may not be present.

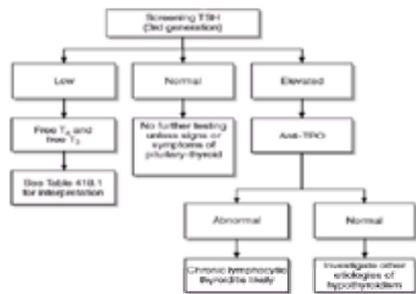

FIGURE 418.2. Strategies for evaluation of thyrotoxicosis. Evaluation should include a careful history and physical examination and should be individualized according to the clinical situation. TSH, thyroid-stimulating hormone; FT₃, free triiodothyronine; FT₄, free thyroxine; RTH, resistance to thyroid hormone; NTIS, nonthyroidal illness syndrome.

EVIDENCE LEVEL: C. Expert Opinion.

A normal serum TSH concentration is strong evidence that hyperthyroidism is not present. The exception is the extremely rare instance of TSH-induced hyperthyroidism. Patients with this disorder usually have elevated FT₄ and T₃ levels. Also in rare instances, serum TSH concentration is normal when a patient has secondary hypothyroidism related to a pituitary tumor. The immunoreactive TSH level may be normal, but the pituitary tumor may be producing a form of TSH that is not biologically active but does react with the in vitro antibodies in the TSH assay. As a result, FT₄ and T₃ must be measured when a patient may have secondary hypothyroidism. The two situations just described represent circumstances in which the use of TSH measurement alone as a screening tool can be misleading.

The thyroid gland may be enlarged in primary hyperthyroidism due to Graves' disease or rare cases of secondary hyperthyroidism due to a TSH-producing tumor. The size of the thyroid may decrease in the presence of secondary hypothyroidism or ingestion of thyroid hormone. Subacute thyroiditis may manifest as a painful thyroid gland and hyperthyroidism due to destruction of the thyroid.

After thyrotoxicosis is confirmed, the most cost-effective step may be a referral to an endocrinologist, who chooses the appropriate tests for the differential diagnosis of thyrotoxicosis (Table 418.5) and the mode of treatment. An alternative is to request an anti-TPO antibody titer to test for autoimmune thyroid disease; a thyroid uptake study to differentiate low- from high-uptake thyrotoxicosis; and a thyroid radionuclide scan to detect autonomous (hot) thyroid nodules.

Toxic diffuse goiter (Graves' disease)
 Toxic adenoma
 Toxic multinodular goiter
 Silent thyroiditis, including lymphocytic and postpartum variations
 Subacute painful thyroiditis
 Excessive exogenous thyroid hormone ingestion
 Drug-induced hyperthyroidism, including iodine-induced
 Miscellaneous (TSH hypersecretion, chorionic gonadotropin-induced hyperthyroidism, including pregnancy and trophoblastic disease, struma ovarii, thyroid carcinoma, nonautoimmune autosomal dominant hyperthyroidism, radiation thyroiditis, infarction of thyroid adenoma, congenital thyrotoxicosis, transient neonatal thyrotoxicosis)

TSH, thyroid-stimulating hormone.

TABLE 418.5. CAUSES OF THYROTOXICOSIS

PATIENTS WITH SUSPECTED HYPOTHYROIDISM

After a complete history interview and physical examination, the evaluation of hypothyroidism (Table 418.6) begins with measurement of TSH concentration with or followed by estimation of FT₄ concentration. In most instances serum T₃ levels are not needed in the evaluation of hypothyroidism.

Chronic autoimmune thyroiditis (atrophic or goitrous)
 Radiation therapy (¹³¹I) therapy-induced, external radiation therapy to the thyroid area, including for head and neck cancer and Hodgkin's lymphoma)
 Surgery
 Iodine deficiency
 Drugs with antithyroid action (including amiodarone and interferon)
 Pituitary or hypothalamic hypothyroidism
 Silent thyroiditis, including postpartum thyroiditis
 Subacute thyroiditis
 Riedel's thyroiditis
 Withdrawal of thyroid hormone treatment from euthyroid patients
 Miscellaneous (congenital, including resistance to TSH, generalized resistance to thyroid hormone, infiltrative disease of the thyroid, including severe granulomatous or cancerous destruction of the thyroid, lymphoma, metastatic disease)

TSH, thyroid-stimulating hormone.

TABLE 418.6. CAUSES OF HYPOTHYROIDISM

A high serum TSH concentration with low serum FT₄ concentration confirms the diagnosis of primary hypothyroidism, which is most commonly caused by chronic autoimmune thyroiditis (Hashimoto's thyroiditis). Primary hypothyroidism with a positive anti-TPO antibody result is sufficient to confirm this diagnosis and initiate thyroid hormone supplementation. In cases of subclinical hypothyroidism, the decision regarding treatment may be influenced by high anti-TPO antibody titers, which

TSH may depend on the risks and benefits of thyroid hormone suppressive therapy in individual clinical circumstances.

After a change in levothyroxine dose, steady state is achieved in 4 to 6 weeks, because of the 5- to 7-day half-life of T_4 in blood circulation. Therefore, measurement of serum TSH concentration should be performed 4 to 6 weeks after the intervention. Measurement of FT_4 alone is insensitive in assessing the appropriateness of the levothyroxine dose in primary hypothyroidism. However, FT_4 concentrations may be helpful to exclude pseudomalabsorption of levothyroxine, which is much more common than true malabsorption, as in severe gastrointestinal disease or with use of some medications ([Table 418.8](#)). Patients who are not compliant with thyroid hormone replacement therapy and take thyroid hormone only a few days before a physician appointment may have an elevated TSH and a normal FT_4 concentration. Therefore measurement of both TSH and FT_4 is reasonable in monitoring levothyroxine therapy. The quoted normal range for T_4 or FT_4 does not strictly apply to patients who have primary hypothyroidism and are taking exogenous levothyroxine, presumably because all of T_3 must be converted from T_4 rather than from direct thyroidal secretion. To achieve T_3 levels similar to those of a person with normal thyroid function, a person with hypothyroidism has to have a T_4 level higher than that of a person with a normal thyroid gland and normal physiologic T_4 and T_3 secretion and kinetics.

The one setting in which the FT_4 is used as the primary test to titrate dosage of thyroid hormone is secondary hypothyroidism. These patients do not respond appropriately to hypothyroidism by increasing TSH secretion. In fact, serum T_3 also is measured and used to ensure appropriate levels for the clinical situation.

CHAPTER 419: HUMAN GENE THERAPY

JAMES M. WILSON

Advances in our understanding of the molecular basis of human diseases have suggested novel approaches to treatment, such as somatic gene therapy. The two general models of gene therapy are based on gene transfer occurring either *ex vivo* or directly *in vivo*. Early models in gene therapy were primarily focused on *ex vivo* manipulations of autologous cells, such as the hematopoietic stem cell, which are transplanted into the individual from which they were derived after genetic modification. The more practical and effective approach to gene therapy is direct administration of the gene *in vivo*, a strategy that resembles more traditional pharmacologic therapy.

Critical to the success of gene therapy is the development of efficient and safe gene delivery vehicles. An important concept in the early development of the field was the use of recombinant forms of viruses as gene delivery vehicles. The initial application of this concept was the development of recombinant forms of murine retroviruses for *ex vivo* gene transfer. Retroviruses can be rendered truly replication defective through deletion of the *gag-pol-env* genes. The resulting vectors are grown in appropriate packaging cell lines that provide these functions *in trans*. An advantage of retroviruses as vectors is that they efficiently integrate their genome into target cells. However, they are difficult to purify and isolate in high yields, and the target cell must be actively dividing at the time of exposure to the virus to achieve gene transfer. A more recently developed virus-based delivery system entails recombinant forms of human adenovirus. Important advantages of this system are that the virus can be grown in extremely high quantities and purified to near homogeneity and is capable of efficiently transferring genes into nondividing target cells. Current limitations of recombinant adenoviruses relate to immunologic responses of the recipient to the virus and virus-infected cells. Consequences of these problematic host responses are immune-mediated clearance of the genetically corrected cells and difficulty in obtaining efficient gene transfer on a second administration of virus because of the development of neutralizing antibody.

Gene delivery vehicles based on synthetic constructs are being developed as an alternative to the virus-based systems. Synthetic complexes of lipid and DNA, called *liposomes*, have undergone extensive analysis in preclinical models with selected experience in clinical trials. Another approach is the development of molecular conjugates constructed through the formation of complexes between DNA and polycationic proteins. The molecular conjugate approach to gene transfer will ultimately prove to be more versatile than liposome technology in that selected components of the gene transfer vehicle can be easily manipulated, as in the development of cell-specific ligands. The nonviral approaches to gene therapy have proved to be extremely inefficient, far outweighing the safety advantages inherent to them.

Several years ago it became clear that the vector systems under development for *in vivo* gene therapy—adenoviruses and synthetic constructs—did not confer stable expression of the recombinant gene. This made it difficult to treat patients with chronic diseases. Progress has been made in overcoming this limitation through the use of vectors based on recombinant forms of adenoassociated virus (AAV) and lentivirus.

AAV vectors are based on disabled forms of a human parvovirus not associated with human disease. These vectors efficiently transfer their genomes into nondividing cells *in vivo* (e.g., fibers of skeletal and cardiac muscle, hepatocytes, neuro and photoreceptors) where they randomly integrate into chromosomal DNA. AAV accomplishes efficient *in vivo* gene transfer without inciting destructive cellular immune responses against the transgene product. Lentiviral vectors are based on certain types of retroviruses, such as HIV, which efficiently infect nondividing cells. The vector is rendered completely defective, and its tropism is expanded by incorporation of a heterologous envelope. Lentivirus performs in much the same way as AAV; there is far less experience with this system.

INHERITED DISEASES

Adenosine Deaminase Deficiency

The best-described model of gene therapy is inherited deficiency of adenosine deaminase (ADA), which leads to severe combined immunodeficiency. The only effective long-term therapy for this disease is allogeneic bone marrow transplantation from a matched donor who expresses normal levels of ADA. The success of allogeneic bone marrow transplantation suggests an alternative therapeutic approach in which the patient is reconstituted with autologous bone marrow that has been genetically modified to express ADA. An attractive aspect of this model is that expression of ADA may confer onto hematopoietic stem cells a selective advantage that facilitates lymphoid reconstitution with ADA-expressing cells. Recombinant retroviruses have been used to transfer the human ADA gene into bone marrow cells from a variety of species. Difficulties working with the human hematopoietic stem cell and lack of an appropriate animal model for ADA deficiency redirected the initial human trials away from bone marrow toward a more accessible and easily characterized cell, the T lymphocyte. The first human trial of gene therapy was performed with ADA-deficient patients. They received autologous T lymphocytes that had been genetically corrected with a recombinant retrovirus *ex vivo*. Subsequent studies were based on stem cell gene therapy.

Familial Hypercholesterolemia

An inherited defect in the low-density lipoprotein (LDL) receptor gene causes the disease familial hypercholesterolemia (FH), which in its homozygous form leads to fulminant coronary artery disease in childhood. The only effective long-term therapy for FH is orthotopic liver transplantation from an allogeneic donor with normal LDL receptor function. These considerations provide a rationale for development of gene therapies for FH that are based on LDL receptor gene transfer into hepatocytes.

The first attempt at gene therapy directed at the liver was based on an *ex vivo* strategy in the treatment of patients homozygous for FH. Extensive work in a variety of animal models suggested the feasibility and safety of this protocol. The initial pilot experiment has been completed with modest reductions in LDL realized by most of the patients. Current efforts are directed at development of *in vivo* approaches to gene therapy to the liver. Recombinant forms of human adenoviruses and AAV have proved to be effective vehicles for accomplishing *in vivo* directed gene transfer to the liver. There have been substantial reductions in LDL in FH animal models treated with LDL receptor—suppressing adenoviruses. Current limitations of this strategy are immune responses to the virus and viral infection of cells.

Cystic Fibrosis

After isolation of the gene responsible for cystic fibrosis (CF) in 1989, research in this field was redirected at development of a cure based on genetic correction of the disease in the lungs. CF is caused by a defect in a gene that encodes an epithelial cell-specific chloride channel. The defect causes obstructive lung disease. The development of gene therapy for CF proceeded quickly after the isolation of the gene. Recombinant forms of retroviruses and vaccinia viruses were used to transfer a normal version of the CF gene into patient-derived cells and demonstrate functional correction of the chloride secretory defect. Efforts then focused on an *in vivo* approach to gene therapy in which the gene delivery vehicle was delivered to airway epithelial cells by means of inhalation techniques. Both recombinant adenovirus and liposome technology have been tested in animal models and human pilot experiments with encouraging results. Problems of immune responses to the vehicle and genetically corrected cells that have been encountered in the *in vivo* therapies to the liver also have surfaced in the early development of *in vivo* applications to the lung.

Hemophilia

Genetic deficiencies of blood clotting factors IX or VIII cause bleeding diatheses that are often severe and life threatening. Current treatment involves infusion of normal clotting factors at the time of uncontrolled hemorrhage. Recombinant proteins have largely replaced blood replacement products, which were associated with a high incidence of hepatitis and HIV transmission. Gene therapy for hemophilia involves transfer of a normal factor IX or VIII gene into a somatic cell capable of expressing functional protein, such as liver or skeletal muscle. Stable engraftment of the gene with a vector such as AAV has shown amelioration of the coagulation defect in murine and canine models of factor IX deficiency. Pivotal clinical trials in hemophilic patients are underway.

ACQUIRED DISEASES

As research in somatic gene therapy has expanded, so has its list of potential clinical applications. Many experts now believe that gene therapy will eventually have its greatest effect on the prevention and control of common acquired diseases. Progress in this area is viewed with specific examples from the general areas of

cardiovascular disease, AIDS, and cancer.

Application of gene therapy to cardiovascular diseases is a fast growing area. A promising strategy under evolution in multiple clinical trials is expression of angiogenic factors in limbs or organs compromised by atherosclerosis-induced vascular insufficiency. Site-specific expression of these factors leads to formation of new blood vessels that improve vascular perfusion in animal models. Important data should emerge from several later stage clinical trials.

Several interesting forms of gene therapy have been considered in the management of AIDS. The most promising genetic approach is intracellular immunization, which is an attempt to render the hematopoietic system resistant to infection with HIV by introducing genes into stem cells that interfere with HIV replication. Specific strategies for blocking viral replication by means of gene transfer have been demonstrated in cultured cells. In the initial clinical trials of this approach to HIV an antiviral gene was transferred into peripheral blood T cells. Somatic gene transfer also is being considered in the development of an effective vaccine for HIV. It is hoped that more effective cellular immunity will be elicited with genetically modified autologous cells that express antigenic HIV proteins.

The most extensive investment in gene therapy has been in the context of cancer. The initial clinical application of gene therapy for cancer was a modification of adoptive immunotherapy, which involves infusion of large quantities of autologous tumor-infiltrating lymphocytes directed against the tumor. Somatic gene therapy could enhance the antitumor function of tumor-infiltrating lymphocytes through genetic modification of the cells *ex vivo*.

Another strategy is to introduce into tumor cells *in vivo* a gene capable of aborting growth or modifying the program of differentiation. A variety of molecular strategies have been entertained that use molecules such as well-characterized oncogenes. The problem with this strategy is difficulty achieving efficient gene transfer *in vivo*, especially in the setting of metastatic disease. One approach to overcoming the inherent limitations of *in vivo* gene transfer is to focus on diseases that cause morbidity and mortality due to local disease. The prototype of this strategy is to transfer a gene, such as thymidine kinase from herpes simplex virus, into the tumor site that renders the cells sensitive to a chemotherapeutic agent, such as ganciclovir in the case of thymidine kinase. This strategy has met with success in animal models. It appears that thymidine kinase-mediated tumor cell ablation is associated with a substantial bystander effect in which adjoining cells also are eliminated. Clinical trials using *in vivo* gene transfer of thymidine kinase have been initiated for the management of malignant tumors of the central nervous system and mesothelioma, with other types of cancer to follow.

The most versatile strategy for managing metastatic malignant tumors is based on the concept of tumor vaccination. A variety of gene transfer approaches have been considered in an attempt to enhance the patient's immune response to the tumor cells. *Ex vivo* and *in vivo* approaches have been developed in which the tumor cell is genetically modified to enhance activation of cellular immunity by one of many strategies, including expressing an allogeneic human leukocyte antigen, secretion of immune regulatory cytokines, and expression of lymphocyte costimulatory molecules.

GENE DELIVERY

The Human Genome Project has revolutionized the way in which new therapeutics are developed in the biopharmaceutical industry. Discovery begins with an analysis of human genes and an assessment of their role in health and disease in a process called *functional genomics*. The traditional pathway for development of therapeutics is to design a small-molecule drug that inhibits or activates the target protein, or the protein itself is manufactured for delivery to the patient. Gene therapy can be used to short-circuit these expensive and time-consuming steps by incorporating the target gene into a vector administered to patients. The therapeutic protein is manufactured in the patient's cells and delivered directly to the site of disease. Use of vectors that confer stable expression eliminates the need for repeated parenteral administration of the protein. Most applications of this strategy, such as erythropoietin for anemia, insulin for diabetes, interferon for cancer, require genes that can be regulated. Development of these so-called molecular rheostats is progressing. Clinical trials are expected in the next 5 years.

FUTURE DIRECTIONS

Somatic gene therapy represents a novel approach to the prevention, management, and cure of diseases of humans. In the past, experiments with animal models completely dominated research in the area of gene therapy. The 1990s have ushered in a new area of expanded basic biology to develop more effective therapy with selective human experimentation. True successes in therapy for multiple diseases are expected in the first decade of the new millennium.

CHAPTER 420: APPROACH TO THE PATIENT WITH NEUROLOGIC COMPLAINTS

VINCENT P. SWEENEY AND DONALD W. PATY

Many physicians approach the problem of neurologic diagnosis and management with trepidation and insecurity. This results in part from the complexity of the nervous system, but it is also related to the wide range of conditions and diseases that affect the central and peripheral nervous systems and muscles. Consequently, the presentation of neurologic complaints and findings is more varied than the clinical features of disorders of other body systems. However, there are certain pathophysiologic considerations and patterns of presentation of neurologic problems that, if understood, can lead to a more confident approach to diagnosis and management. This chapter and the chapter on the patient with sensory loss and weakness ([Chapter 430](#)) present a method of rational analysis of symptoms and findings that facilitates neurologic diagnosis.

In the approach to the patient with neurologic complaints, it is important to know the scope of diseases and conditions presenting as neurologic complaints. Such conditions may be primarily located in the nervous system or muscles, or may be based in other organ systems and secondarily alter nervous system function. The primary pathologic processes affecting the nervous system include those occurring in other organs, such as vascular disease, infections, and neoplasms, as well as those more common to the brain, such as inborn errors of metabolism, demyelinating disease, certain degenerative processes, and abiotrophies (e.g., senility, Alzheimer's disease). The vulnerability of the central and peripheral nervous systems and muscles to secondary involvement is related to both their large extent and their metabolic requirements. The requirements for a constant supply of oxygen and glucose make the brain more susceptible than other organs to hypoxia, ischemia, and hypoglycemia. Similarly, the nervous system is vulnerable to some vitamin deficiencies and to metabolic disturbances, alterations of blood gases, and electrolyte imbalance. Hence, neurologic complaints such as confusion, delirium, stupor, and seizures may be the presenting features of systemic problems that originate outside the nervous system, in the absence of any detectable pathologic process in the brain. Similarly, diffuse weakness may not be caused by a specific lesion of nerves or muscle, but rather by remote effects of such conditions as cancer, thyrotoxicosis, or potassium imbalance.

Other important considerations of neurologic symptoms and findings relate to pathophysiologic processes unique to the nervous system. *Seizures* result from electrophysiologic disturbances affecting cerebral neurons, a process not known to occur elsewhere in the body. Seizures are also unique in producing positive symptoms of cerebral excitation such as convulsions, sensory "march," complex automatic behavior, hallucinations, and other bizarre disturbances. Postseizure cortical dysfunction may present with temporary paralysis or neurologic dysfunction (Todd's palsy). *Syncope* is the brain's reaction to hypoperfusion, designed to compensate for the decrease in blood flow by placing the body flat rather than upright. Again, this is a unique pathophysiologic process determined by specific vulnerability to hypoxia and ischemia. The common phenomenon of *migraine* represents an incompletely understood process primarily affecting the cerebral circulation and metabolism. The central and peripheral nervous systems are vulnerable to *trauma* that may result in irreversible dysfunction.

LOCALIZATION

The traditional teaching in neurologic diagnosis has emphasized the primary consideration of locating the lesion and then determining what the lesion is. Although these considerations are paramount in many situations (focal brain disease, spinal cord compression, nerve root or peripheral nerve root lesions), they do not encompass the full range of neurologic presentation of disease. As discussed earlier, many disturbances of cerebral function and other neurologic dysfunction are not caused by a lesion but are secondary phenomena. With this limitation in mind, the classic tenets of neurologic diagnosis can be applied in a manner that simplifies the process of deductive analysis of complaints and findings. The location of a lesion is determined by relating it to a knowledge of neuroanatomy and neurophysiology. *Such knowledge need not be extensive if certain principles are understood.* Most neurologic symptoms relate to altered nervous system function, which in turn alters the normal activities of daily living. Disorders of thought, memory, speech, and vision reflect dysfunction of cortical neuronal tissues. Essential functions of walking, balance, and coordination result from altered motor, sensory, or cerebellar control. Loss of bladder and bowel control and sexual dysfunctions result from autonomic dysfunction. Thus, if the clinician understands that language disorders are usually related to lesions in the dominant (left) hemisphere of the brain, it follows that an associated weakness of the right side of the body is likely related to the same lesion. A complete right hemiplegia with normal language function is less likely to be cortical in origin, and therefore is probably subcortical, involving white matter pathways rather than neurons. A similar right-sided weakness associated with a symptom or sign pointing to the left side of the brain stem (e.g., left facial weakness or sensory loss, left abducens weakness producing diplopia) accurately locates the site of the lesion to the left brain stem. Lesions in the spinal cord often produce "levels" of involvement. Cervical cord lesions may produce lower motor disturbance in the arms and upper motor neuron weakness in the legs. Bilateral weakness of the legs with sparing of the arms characterizes lesions below the cervical cord. If associated with a sensory level below which pain and temperature sensation are altered, then an accurate diagnosis of the site of the lesion is possible. Conditions affecting spinal roots produce symptoms and findings related to dermatomes and recognized motor disturbances different from those affecting peripheral nerves. Diffuse conditions affecting peripheral nerves preferentially affect long nerve processes, which are more vulnerable. It follows, therefore, that in diffuse polyneuropathy, motor or sensory involvement of the feet first, followed by the fingers and hands, is the usual mode of presentation. Such conditions likely present with clumsy and weak hands and feet and a stocking-and-glove type of sensory loss, usually quickly accompanied by loss of reflexes. On the other hand, large muscles situated proximally are most vulnerable to most conditions presenting as muscle disease. Weakness of the pelvic girdle causing difficulty rising from a chair or weakness of the shoulder girdle causing difficulty with hair grooming are likely presentations. Such muscle weakness is bilateral and symmetric. Sensory loss is not present, and the reflexes are usually preserved in muscle disorders.

ETIOLOGIC CONSIDERATIONS

Determination of *what* the lesion is depends on the nature of the underlying pathologic process and the nervous system's reaction to the lesion. Many pathologic and pathophysiologic processes have a recognized temporal profile in their evolution and clinical presentations ([Table 420.1](#)). The most sudden onset of symptoms results from ischemia, seizure, or trauma. Thus, the term *stroke* is related to the sudden onset of symptoms due to either cerebrovascular occlusive disease or hemorrhage. Although frank convulsive seizures or epileptic loss of consciousness can be preceded by an aura, the aura is the commencement of the seizure and is itself sudden in origin. The effects of trauma are usually immediate but may also be delayed or progressive if associated with delayed to slow intracranial bleeding. Space-occupying processes present in a temporal manner depending on their speed of expansion and the brain's reaction to the underlying disease. Thus, cerebral abscesses due to bacterial agents with associated cerebral edema are likely to present over a matter of days, in contrast to the slower, more gradual clinical expression of slower-growing neoplasms. The process of brain shift and herniation down through the tentorial notch or foramen magnum adds another dimension of rapidity to the clinical features in many expanding pathologic lesions. Most degenerative processes are slow in the development of clearcut symptoms or findings. Examples include the general motor problems associated with Parkinson's disease or the dementia and personality changes of Alzheimer's disease. The occasional rapid onset of symptoms of such diseases is usually explained by some intercurrent environmental change or associated aggravating illness that brings the condition to light. Multiple sclerosis is unique in the scatter "in time and place" of symptoms and findings, which usually manifest over a number of years.

Type of Onset	Most Likely Cause
Abrupt	
Seconds	Seizure, trauma
Seconds to hours	Vascular disorder
Hours to days	Infection
Subacute	
Days to weeks	Metabolic, inflammatory disorder Neoplasia
Chronic	
Weeks to months	Neoplastic; nutritional disorder
Years	Degenerative disorder

TABLE 420.1. TEMPORAL PROFILE IN NEUROLOGIC DIAGNOSIS

Demographic characteristics are also helpful in determining the likelihood of underlying disease processes. To a large extent, age determines the distribution of many conditions (Table 420.2). The hereditary and congenital diseases usually present in infancy and childhood. However, hereditary conditions such as polyneuropathies may be recognized only in middle life. Presumably, the nervous system has compensated in some fashion, and the clinical expression of neurologic dysfunction has been so gradual that it has escaped notice for many years. The likely etiology of seizures is also related to age. Congenital anomalies, infections, and trauma account for most seizures in childhood and young adulthood. Tumors become more prominent in causation in middle and older years, closely followed in chronologic sequence by vascular diseases. Metabolic and toxic causes are distributed throughout all ages. Multiple sclerosis has its onset maximally in the third and fourth decades, although epidemiologic studies suggest that exposure to the causative agent takes place in childhood.

Age	Cause
Childhood	Congenital, infectious, genetic, some neoplastic disorders
Adolescence	Genetic, traumatic disorders
Young adulthood	Traumatic, metabolic, inflammatory disorders
Middle age	Metabolic, inflammatory, neoplastic, vascular disorders
Old age	Vascular, metabolic, neoplastic, degenerative disorders

TABLE 420.2. RELATION BETWEEN AGE AND CAUSE IN NEUROLOGIC DISEASE

A few neurologic conditions are sex specific, such as the X-linked forms of muscular dystrophy. Men are more subject to trauma and have an earlier onset of atherothrombotic cerebrovascular disease than women. Younger women are more prone to development of autoimmune diseases such as myasthenia gravis, systemic lupus erythematosus, and multiple sclerosis and are at risk for the neurologic consequences of pregnancy.

The socioeconomic status of patients may reflect particular vulnerability to the neurologic complications of malnutrition and alcoholism, drug abuse, and sexually transmitted diseases.

Background medical problems are most important in the assessment of patients presenting with neurologic complaints, and no neurologic investigation is complete without a thorough review of a patient's past and current health status and a complete physical examination.

CHAPTER 421: APPROACH TO THE PATIENT WITH HEADACHE

JAMES W. LANCE

[Presentation](#)
[Headache Syndromes of Uncertain Origin](#)
[Pathophysiology](#)
[History and Physical Examination](#)
[Laboratory Studies and Diagnostic Tests](#)
[Headache Syndromes with Identifiable Cause](#)
[Strategies for Optimal Care Management](#)

Headache is one of the most common symptoms encountered in medical practice, and its differential diagnosis depends mainly on the clinical history. Special investigations are required only if the pattern of headache suggests an underlying organic disorder. The successful management of headache depends on the physician's motivation and knowledge. The process may be exasperating at times, but the outcome is often rewarding.

PRESENTATION

The temporal pattern of headache gives some indication of its cause and whether further investigation is advisable.

ACUTE

The sudden onset of headache, instantaneously or developing over minutes or hours, raises the possibility of some life-threatening condition such as subarachnoid hemorrhage or meningitis that requires prompt investigation and treatment. Acute headache may be accompanied by neck rigidity when there is meningeal irritation and by elevated temperature when there is systemic infection or meningitis.

PROGRESSIVE SUBACUTE

Headache increasing in severity over a period of days, weeks, or months also arouses suspicion of serious organic disturbance. When the headache is aggravated by jarring, coughing, sneezing, or bending forward, it suggests an intracranial origin with dilatation or displacement of intracranial vessels, or obstruction of the ventricular system. If such a headache is associated with drowsiness, mental changes, epileptic seizures, or any form of neurologic deficit, the probability of a progressive intracranial lesion becomes greater. In older patients, temporal arteritis must always be considered.

RECURRENT EPISODIC

Possible causes include the following:

- Migraine, occurring from less than once per year to two or more times each week
- Cluster headache, occurring in bouts lasting from weeks to months in 80% of cases
- Ice cream headache
- Ice pick pains (sudden stabs of pain in the head, more common in migrainous and tension headache patients)
- Paroxysmal hypertension (e.g., pheochromocytoma)
- Transient ischemic attacks (headache is usually a minor component compared with neurologic deficit)
- Tolosa–Hunt syndrome
- Recurrent sinusitis
- Postalcoholic hangover
- Benign recurrent syndromes (benign only if an intracranial lesion has been excluded): headaches associated with coughing, exertion, or orgasm.

CHRONIC CONTINUOUS

Possible causes include the following:

- Tension headache
- Posttraumatic headache
- Postherpetic neuralgia
- Atypical facial pain
- Psychogenic headache

HEADACHE SYNDROMES OF UNCERTAIN ORIGIN

Most headaches encountered in practice are of uncertain origin. A clinical diagnosis can usually be made from the history, but the precise mechanism remains elusive.

MIGRAINE

Migraine is an episodic cerebral disturbance (aura), headache, or both, with intervening periods of relative freedom from headache and no evidence of primary structural abnormality. The headache, usually severe, unilateral, and associated with nausea, vomiting, and photophobia, may recur without any aura (common migraine). About one third of patients experience some attacks in which an aura (blurring, scintillations, or zigzag hallucinations of vision), paresthesias, or speech disturbance precedes the characteristic headache by 5 to 60 minutes (classic migraine). When some neurologic symptoms persist for 24 hours or more after the cessation of headache, ischemia (migrainous infarction) has probably damaged the cortex. Recurrence of the aura phase without ensuing headache (migraine equivalents) can be encountered at any age, even in the elderly, and may be distinguished from transient ischemic attacks by typically gradual onset and resolution. Variations on the migrainous theme have been designated as follows: vertebrobasilar migraine (brain stem and cerebellar symptoms and signs, blurred vision, and impaired consciousness, attributed to ischemia of the hindbrain); retinal migraine (visual disturbance limited to one eye); ophthalmoplegic migraine (paresis of extraocular muscles at the height of headache); facial migraine (episodic pain involving the face more than the head); and hemiplegic migraine (unilateral paresis, not solely paresthesias that are a common feature of classic migraine). Periodic syndromes of childhood, such as recurrent abdominal pain or vomiting, are more common in children who subsequently develop migraine.

Migraine is a common disorder. A U.S. survey showed marked differences in the prevalence of migraine in patients from various ethnic backgrounds. The prevalence in those of Caucasian, African and Asian origin was, respectively, 20.4%, 16.2%, and 9.2% for women and 8.6%, 7.2%, and 4.2% for men. Prevalence is roughly equal between the sexes until puberty, after which it more than doubles in females.

There is a strong hereditary factor in migraine. Twin studies have shown that about half the susceptibility to migraine is of genetic origin with environmental influences determining the other half. Russell and Olesen found that the first degree relatives of patients subject to migraine with aura had nearly four times the risk of this disorder. Relatives of patients without aura had 1.9 times the risk of migraine without aura and 1.4 times the risk of migraine with aura.

The gene responsible for familial hemiplegic migraine, an autosomal dominant, has been localized to chromosome 19 in 55% and chromosome 1 in 15% of families, with the remainder being undetermined at present.

Many patients are subject to attacks at regular intervals of days, weeks, or months as though regulated by some internal clock, whereas others can identify specific

trigger factors such as excessive afferent stimuli (flickering light, loud noise, strong perfumes), a sharp blow to the head (footballer's migraine), stress or relaxation after stress, certain foods, the ingestion of alcohol or other vasodilator agents, physical exertion, or menstrual periods (menstrual migraine). About one fourth of all patients recognize certain symptoms, such as a feeling of elation, hunger, or a craving for sweet foods, that anticipate headache by up to 24 hours and may help to plan preemptive treatment.

CLUSTER HEADACHE (MIGRAINOUS NEURALGIA)

Cluster headache has a prevalence of about 3% that of migraine and derives its name from its tendency to recur in bouts or clusters lasting weeks or months, separated by months or years of freedom. It is uncommon to find a family history of cluster headache but cases have been reported in twins, and segregation analysis suggests that cluster headache is transmitted by an autosomal dominant gene with a penetrance of 0.30–0.34 in males and 0.17–0.21 in females. During a bout, patients (85% of whom are male) suffer each day or night from one or more attacks of severe pain in and around the eye or adjacent areas of the head or face, lasting for 10 minutes to hours at a time. The eye on the affected side usually becomes red and waters; the ipsilateral nostril blocks or runs. An ocular Horner's syndrome can be observed during attacks in about one third of cases and may become permanent after repeated episodes.

This typical pattern is known as episodic cluster headache. Some 20% of patients have attacks regularly without remission, called chronic cluster headache. A rare variant, affecting women more than men, is characterized by many brief cluster attacks in one day that are controlled promptly by indomethacin. This entity has been named episodic or chronic paroxysmal hemicrania.

A rare variation of cluster headache is the SUNCT syndrome (Shortlasting Unilateral Neuralgiform headaches attacks with Conjunctival injection and Tearing) with pains lasting less than a minute and recurring 5–30 times each hour.

TENSION HEADACHE

The term *tension headache* is applied to the sensation of tightness around or pressure on top of the head that may recur daily in its chronic form. It affects women more commonly than men and may start at any age.

PATHOPHYSIOLOGY

Peripheral receptors responsible for the registration of pain are present in the proximal parts of the cerebral and dural arteries, the large veins and venous sinuses, and the extracranial arteries. Distention or displacement of these vessels by inflammation, aneurysms, hematomas, tumors, or ventricular dilatation from obstruction of the cerebrospinal fluid (CSF) pathways gives rise to headache. Pain from the internal carotid and middle cerebral arteries is felt behind or around the ipsilateral eye. Pain may also result from irritation of the meninges, cranial nerves, or occipital nerves. Pain originating in the anterior or middle fossa is referred to the distribution of the first division of the trigeminal nerve, in front of a line drawn vertically above the ear. Pain from the posterior fossa is felt behind that line.

Referral of pain from occipital to frontal region and vice versa is common because fibers from the second and third cervical roots, serving pain from the posterior fossa, occiput, ear lobe, and upper neck, converge on second-order neurons of the spinal trigeminal nucleus in the upper cervical spinal cord (Fig. 421.1). The activity of these neurons is modulated by the endogenous pain-control system, which arises in the periaqueductal gray matter (PAG) and locus ceruleus (see Figure 421.1) and influences transmission at the first-order synapse by inhibitory neurons, using enkephalins and GABA as neurotransmitters as well as projecting upwards to modulate thalamic function. Activity of the pain-control system is thought to play a part in "idiopathic" headaches such as migraine, cluster, and tension headaches.

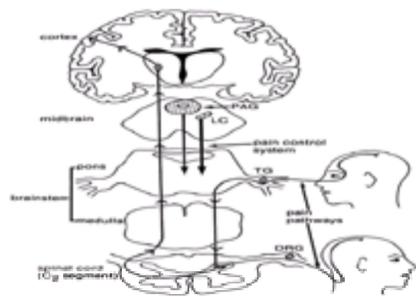

FIGURE 421.1. Pain pathways in the brain. Pain impulses from the front of the head are conveyed to the trigeminal ganglion (TG) and then to the brain stem, where they descend to the upper spinal cord. Here they synapse on the same cells as fibers coming from the back of the head via the dorsal root ganglion (DRG). After this convergence, the combined pathway crosses to the opposite side and travels up to the cerebral cortex. The pain-control system projects down to the brain stem and spinal cord from the periaqueductal gray matter (PAG) and locus ceruleus (LC) to regulate the transmission of pain impulses. (Lance JW. *Migraine and other headaches*. 2d ed. New York: Scribner, 1986:17.)

MIGRAINE AND CLUSTER HEADACHE

PET scanning has shown that the contralateral midbrain surrounding the PAG becomes metabolically active during and after migraine headache, possibly as a "central generator" for migraine, disinhibiting the trigeminothalamic pathway.

Migraine and cluster headaches are accompanied by vascular dilatation that contributes to the headache, which is usually eased by vasoconstrictors such as sumatriptan, related triptans and ergotamine tartrate. Vasodilator substances may induce migraine headache, but more often vasodilatation is secondary to changes in the central nervous system and is thought to be mediated by activation of the parasympathetic pathway via the greater superficial petrosal nerves and sphenopalatine ganglia. The level of the vasodilator agent calcitonin gene-related peptide (CGRP) increases in external jugular venous blood in migraine and cluster headaches with vasoactive intestinal polypeptide (VIP) also being released during cluster pains. Migraine and cluster headache thus appear to involve interaction between the brain and the cerebral, dural and extracranial arteries.

Serotonin (5-hydroxytryptamine, 5-HT) is discharged from blood platelets at the onset of migraine. Free 5-HT could play some part in sensitizing blood vessels to pain, but it is more likely that changes in the peripheral blood mirror changes in central neurotransmission that permit the sustained discharge of central trigeminal pathways to produce headache. The intravenous infusion of 5-HT relieves migraine headache, primarily by inducing vasoconstriction. Serotonin analogs, the triptans, are agonists at the 5-HT_{1B} receptor on vessels and the 5-HT_{1D} receptor on neurons as well as 1_A and 1_F receptors. Knowledge of the role of these and 5-HT₂ receptors in the central nervous system and the part that they may play in migraine is incomplete but 5-HT₂ antagonists such as cyproheptadine and methysergide are useful as prophylactic agents.

In the aura phase of classic migraine, regional cerebral blood flow diminishes, a process that starts in the occipital lobe and spreads anteriorly at 2 to 3 mm/min. This is the same speed as the phenomenon described by Leão as spreading cortical depression in experimental animals as the result of dehydration or other insult to the brain, and could account for the slow march of migrainous symptoms such as fortification spectra and paresthesias that some patients experience.

A similar phenomenon has been found by PET scanning in a patient whose migraine headache was accompanied by blurring of vision but not a classical aura, suggesting that cortical hypoperfusion may underly the impairment of vision and concentration common in migraine attacks. The reason why migraine auras are often followed by headache is unclear since each may occur independently.

Hyperacuity of the special senses (smell, vision and hearing) and hyperesthesia often accompany migraine headache, possibly caused by diminished inhibition of thalamic processing simultaneously with the reduction in efficacy of the endogenous pain control pathway. Nausea and vomiting are probably mediated by

dopaminergic receptors in the area postrema.

The nature of the internal clock that begins and ends each bout of cluster headache, and that determines the frequency and timing of episodes in each 24-hour period, remains unknown. The presumption that the hypothalamus is implicated has been strengthened by the demonstration on PET scanning of increased metabolic activity in the ipsilateral hypothalamus during cluster headache but not during migraine. The pain of cluster headache is thought to be caused by a sterile inflammatory response in the wall of the carotid siphon, induced by discharge of vasodilator peptides from fibers of the greater superficial petrosal nerve that end on ganglion cells adjacent to the internal carotid artery. The ocular Horner's syndrome, a common feature of cluster headache, is attributed to edema of the arterial wall that compromises sympathetic fibers in the pericarotid plexus. The autonomic accompaniments (ipsilateral conjunctival injection, lacrimation, and nasal congestion) are abolished by ablation of the greater superficial petrosal nerve or sphenopalatine ganglion.

Tension-type Headache

Some forms of tension headache are associated with overcontraction of frontal and temporal muscles, particularly as a reaction to stress, but some patients may clench their jaws or grind their teeth even during sleep. Certain physical abnormalities, such as temporomandibular joint strain (Costen's syndrome), cervical spondylosis, or eyestrain from ocular muscle imbalance or refractive errors, may aggravate tension headache and warrant specific treatment. Some forms of tension headache are clearly related to stressful situations, and others are associated with anxiety or depression, but some patients suffer from chronic daily headache following viral infections or without apparent physical or psychological cause. This may represent malfunction of the endogenous pain-control pathway.

HISTORY AND PHYSICAL EXAMINATION

The diagnosis of most headache problems depends on taking a careful history. A suggested sequence is displayed in [Table 421.1](#).

Section	Questions
History	1. What is the nature of the headache? (Location, quality, severity, duration, frequency, timing, associated symptoms)
Associated features	2. Are there any associated symptoms? (Nausea, vomiting, photophobia, phonophobia, visual aura, focal neurologic signs, systemic illness)
Precipitating factors	3. What factors precipitate the headache? (Stress, fatigue, changes in diet, sleep, posture, weather, menstrual cycle, sexual activity)
Relieving factors	4. What factors relieve the headache? (Rest, sleep, analgesics, relaxation, environmental changes)
Previous therapy	5. What therapy has been tried? (Medications, non-pharmacological measures, response)
Physical findings	6. What physical findings are present? (Vital signs, general appearance, focal neurologic signs, meningeal signs, systemic illness)

TABLE 421.1. HEADACHE: TAKING THE CASE HISTORY

The case history may alert the clinician to look for signs of meningeal irritation, raised intracranial pressure, or other signs of organic disease. In such patients, a careful examination of the nervous and other systems is mandatory, looking for localizing neurologic signs and indications of systemic illness. Even when the history is typical of migraine, cluster, or tension headache, a general examination should always be undertaken. It is often completely normal, which is reassuring for patient and clinician.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

Only a few headache patients require investigation other than a careful history and physical examination. Consideration of the differential diagnosis determines which, if any, of these investigations is necessary.

A blood cell count and erythrocyte sedimentation rate is advisable when systemic infection is suggested or when headache is of recent onset in a patient over age 50 years. The erythrocyte sedimentation rate is usually above 40 mm/h in temporal arteritis.

The sudden onset of headache or a progressive course warrants investigation. If a patient with acute headache is febrile and meningitis is suspected, immediate lumbar puncture may be justified, provided there are no signs of raised intracranial pressure. Except for such an emergency, computed tomography (CT) scanning of the brain is usually the first step because it demonstrates blood in the CSF in most cases of subarachnoid hemorrhage and displays or excludes space-occupying lesions, hydrocephalus, and other structural causes of headache. Lumbar puncture is required only rarely; for example, in the investigation of headache for the diagnosis of meningitis or other infections, for confirmation of subarachnoid hemorrhage if the story is typical but the CT scan is negative, or for the measurement of CSF pressure in benign intracranial hypertension. A chest x-ray is always advisable to exclude a carcinoma of the lung or other relevant lesion. Cerebral angiography is reserved for patients with cerebral aneurysm or other cerebrovascular problems. Magnetic resonance imaging (MRI) may help determine the site of obstruction of CSF pathways in patients with hydrocephalus. MR angiography is a noninvasive alternative to contrast-medium angiography in the search for a cerebral aneurysm.

HEADACHE SYNDROMES WITH IDENTIFIABLE CAUSE

PAIN ARISING FROM EXTRACRANIAL STRUCTURES

Temporal Arteritis

See [Chapter 182](#) for a full discussion of vasculitis.

Temporal arteritis occurs in women more than men in the ratio of 3:1. It mostly affects persons over age 50. It is probably an immune disorder of the arterial wall, which becomes thickened with cellular infiltration of the media, giant cell formation, deposition of immune complexes, and thrombus formation in the lumen. The scalp arteries are most commonly involved to cause headache and tenderness, but the condition may be more diffuse, with generalized muscle and joint pains (polymyalgia rheumatica). The condition may spread to the ophthalmic arteries, producing sudden blindness, or less commonly to branches of the aorta. Temporal arteritis should be suspected when a constant headache develops in an older patient; the diagnosis is supported by the finding of an erythrocyte sedimentation rate above 40 mm/h. Temporal artery biopsy is advisable to confirm the diagnosis because corticosteroid therapy is specific for the condition and may have to be continued for years. If the index of suspicion is high, corticosteroids should be started immediately while awaiting biopsy results to minimize the risk of blindness, which has been reported in 20% to 50% of cases in different series; this rate is halved by corticosteroid therapy.

OCULAR CAUSES

Acute angle-closure glaucoma may cause severe orbital pain with circumcorneal injection, but it is rare for other ocular conditions to cause headache, although refractive errors and imbalance of the eye muscles may contribute to the muscle-contraction variety of tension headache. Optic (retrobulbar) neuritis is usually associated with a dull ache in the orbit accentuated by eye movement.

SINUSITIS

Frontal and maxillary sinusitis are responsible for pain and tenderness over the appropriate areas, but both sphenoid and ethmoid sinusitis cause midfrontal headache, sometimes in the absence of nasal congestion. Radiography of the sinuses is recommended in any patient with midfrontal pain of recent onset. Recurrent frontal headache of migrainous origin is often misdiagnosed as sinusitis (see [Chapter 311](#) and [Chapter 368](#)).

DENTAL CAUSES

Apical root infection can cause a constant or jabbing pain in the upper or lower gums. Pain can be referred to the head if the bite is unbalanced so that undue strain is placed on one temporomandibular joint (Costen's syndrome). In this case, pain may radiate from the joint to the temple, face, or neck. A tendency to clench the jaw (bruxism) aggravates the condition, which should be treated as for tension headache as well as by dental management to restore a normal bite.

CERVICAL CAUSES

Any disorder of the upper cervical spine may cause occipital headache in the distribution of the second and third cervical roots and can refer pain to the frontal region and eye by convergence on second-order trigeminal pain neurons. Constant or jabbing pain in one occipital region may be associated with numbness in this area and tenderness over the greater occipital nerve (occipital neuralgia). Provided serious structural changes in the cervical spine, such as fracture, neoplasm, or rheumatoid arthritis, can be excluded, the condition may be managed by the injection of a local anesthetic agent and long-acting corticosteroid preparation around the greater occipital nerve, followed by traction and gentle mobilization of the cervical spine. A light surgical collar may be helpful in some cases. Some patients, usually adolescents, with a tendency to subluxation of the atlantoaxial joints may experience numbness of the tongue on the same side as occipital pain and numbness on sudden head turning (neck-tongue syndrome). The reason is that proprioceptive fibers from the tongue travel with the hypoglossal nerve and transfer to the second cervical root, which is stretched during unilateral subluxation.

PAIN ARISING FROM THE CRANIAL NERVES

Headaches may be caused by excessive stimulation of peripheral branches of the first division of the trigeminal nerve, by exposure to cold, by swallowing cold food or drinks (ice cream headache), or by the pressure of a tight hat or band around the head (swim-goggle headache).

A granuloma in the region of the superior orbital fissure may produce ocular pain and palsies of the third, fourth, or sixth cranial nerves that are responsive to corticosteroids (Tolosa–Hunt syndrome). Any lesion compromising both the trigeminal ganglion and the sympathetic plexus surrounding the internal carotid artery produces pain in one eye and forehead associated with an ipsilateral ocular Horner's syndrome (Raeder's paratrigeminal neuralgia). Involvement of the apex of the petrous temporal bone by inflammation or neoplasm may cause pain in half of the forehead, with an ipsilateral sixth cranial nerve palsy (Gradenigo's syndrome).

Herpes zoster may cause a painful eruption in the distribution of the trigeminal nerve, commonly the first division, and may leave a distressing pain (postherpetic neuralgia) in its wake. Treatment by acyclovir or corticosteroids in the acute phase minimizes the pain. Once established, postherpetic neuralgia can be eased by the administration of amitriptyline as for tension headaches.

TRIGEMINAL AND GLOSSOPHARYNGEAL NEURALGIA

See [Chapter 424](#).

PAIN OF INTRACRANIAL ORIGIN

Headache is a symptom of many intracranial and systemic disorders and may be caused by meningeal irritation or by displacement or dilatation of pain-sensitive blood vessels. Investigation determines whether the patient requires neurosurgical or medical management.

BENIGN INTRACRANIAL HYPERTENSION

Symptoms and signs of raised intracranial pressure (headache, vomiting, transient obscuration of vision, and papilledema) sometimes occur with no obvious systemic or local cause. CT scanning of the brain demonstrates normal or small ventricles and obliteration of the cerebral sulci, and subsequent lumbar puncture confirms the clinical impression of elevated intracranial pressure. This condition is called benign intracranial hypertension (pseudotumor cerebri)—although it is not always benign, as optic atrophy may follow chronic papilledema. It commonly develops in overweight young women with menstrual irregularities for some obscure hormonal reason, but may also be caused by tetracycline and vitamin A (used in the treatment of acne), other drugs such as nalidixic acid, and the withdrawal of corticosteroid therapy.

The probable sequence of events is that a partial thrombosis of the superior sagittal sinus or malfunction of the arachnoid villi leads to reduced CSF absorption, thus increasing intracranial pressure, obstructing venous outflow from the brain, and producing chronic cerebral edema. Management involves repeated lumbar punctures to reduce CSF pressure, diuretics (particularly acetazolamide, which helps reduce CSF formation), and sometimes the administration of corticosteroids. Decompression of the optic nerves or shunting procedures to reduce CSF pressure may be necessary in cases not responding to conservative therapy.

STRATEGIES FOR OPTIMAL CARE MANAGEMENT

The treatment of headache produced by an identifiable organic cause is management of the underlying condition as indicated above, with the use of analgesics or other measures to control pain. Handling migraine, cluster, and tension headaches presents difficulties in the absence of a clearly defined pathophysiology. Despite this, most patients can be helped and many headaches can be relieved completely by using the following measures.

MIGRAINE

The management of migraine relies on psychological counseling, avoidance of trigger factors, relaxation therapy, and pharmacologic agents to treat each attack as it comes (acute therapy) or given daily to reduce the frequency and severity of attacks (interval therapy), as outlined in [Figure 421.2](#).

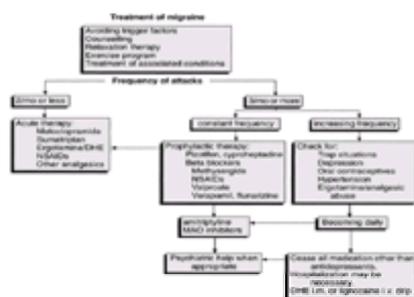

FIGURE 421.2. A logical sequence of therapy in the management of migraine headaches. DHE, dihydroergotamine; NSAIDs, nonsteroidal antiinflammatory drugs; MAO, monoamine oxidase. (Updated from a diagram first published in *Current Therapeutics*, April 1980. Reproduced by permission of Adis International 1994.)
EVIDENCE LEVEL: B. Reference: Lance JW, Goadsby PJ. *Mechanisms and management of headache*, sixth edition. Butterworth-Heinemann, 1998.

Mild attacks of migraine may respond to metoclopramide (10 mg intramuscularly (IM) or intravenously (IV), or even orally if given early enough) to promote gastric absorption, followed by effervescent aspirin (600 to 900 mg orally).

The treatment of migraine headache has been transformed by the advent of the triptans, 5-HT_{1B/D} agonists, of which sumatriptan (Imitrex) was the first. Sumatriptan relieves 50–60% of migraine headaches within 2 hours if given as 50–100mg orally or 20mg intranasally and about 75% in one hour by subcutaneous injection of 6mg. Zolmitriptan (Zomig) 2.5–5.0mg has much the same efficacy as sumatriptan and may be effective in some patients who have not responded to sumatriptan.

Rizatriptan (Maxalt) 10mg is marginally more effective than both whereas naratriptan (Naramig) 2.5mg is less so although it has a longer action and fewer side-effects. Other triptans such as eletriptan are undergoing clinical trials. Because of their vasoconstriction action, they should not be prescribed for patients with suspected coronary disease, Prinzmetal's angina, or uncontrolled hypertension; for the same reason they should not be administered for 24 hours after ergotamine tartrate.

Ergotamine tartrate (1 to 2 mg) may be given orally at the onset of symptoms, alone or in combination with caffeine (Cafergot) or with antiemetic agents. Ergotamine is more effective if the gastric route of absorption is bypassed by rectal administration (Cafergot suppository) or inhalation. The related drug dihydroergotamine may be given as 1 mg IM or 0.5 mg IV or by inhalation of the powder from a pressure pack at the onset of headache. Patients who do not respond to ergotamine preparations, or become nauseated by them, may find relief from one of the triptans or nonsteroidal antiinflammatory drugs (NSAIDs) such as naproxen (550 mg, repeated in 30 minutes if necessary). Narcotics should be avoided except in the most severe cases because of the risk of habituation.

Patients who are subject to two or more migraine headaches each month that are incompletely relieved by acute therapy may be placed on regular interval therapy (see Fig. 421.2). Provided there is no contraindication, such as asthma, propranolol may be prescribed, increasing from 20 mg twice daily to full β -blocking doses if necessary and if there are no side effects. Nadolol, timolol, atenolol, and metoprolol are also effective in prophylaxis, but not the β -blockers that have partial agonist action (intrinsic sympathomimetic activity). Antiserotonin agents (5-HT₂ antagonists) such as pizotifen (pizotyline; Sandomigran) or cyproheptadine, are also useful in prophylaxis and are best given as a single dose at night to avoid daytime drowsiness. The same applies to the administration of amitriptyline (Elavil), which is particularly useful in the prevention of frequent, almost daily, migraine attacks as well as for tension headache. The dosage of amitriptyline should be increased slowly from 10 to 75 mg at night, depending on the patient's tolerance, because blood levels vary 10-fold in subjects given the same dose per kilogram of body weight.

If headaches continue despite a conscientious trial of these medications, methysergide (Sansert), 1 to 2 mg, may be given three times daily, starting with a test dose of one half to one tablet to ensure that there are no vasoconstrictive or other side effects. Methysergide therapy should be interrupted for 1 month every 4 to 6 months to minimize the possibility of the rare complication of retroperitoneal fibrosis. Physical examination and blood urea estimation is advisable at 3-month intervals. NSAIDs, the anticonvulsant valproate, and the calcium channel blockers verapamil and flunarizine have also proven useful for the prevention of migraine.

Patients whose headaches prove refractory to all these medications may get relief from the monoamine oxidase inhibitor phenelzine (15 mg two or three times daily), with the usual restriction of the intake of red wine, certain foods, and drugs containing sympathomimetic agents.

Nifedipine is useful in the treatment of migraine equivalents: a few drops from a 10-mg capsule are usually sufficient to abort or shorten the episode.

CLUSTER HEADACHE

As in migraine, there is no cure, but most episodes can be suppressed with ergotamine preparations, timed to anticipate the cluster pains (e.g., ergotamine 2 mg at night to prevent attacks recurring regularly during sleep) or with methysergide (2 mg three times daily). Verapamil 80mg four times daily will often control a bout. The inhalation of 100% oxygen at 7 L/min delivered through a humidifier and a resuscitation mask (without side vents) relieves cluster pains within 10 minutes in two thirds of patients. The subcutaneous injection of sumatriptan (6 mg) stops cluster headache rapidly in about 75% of patients.

Prednisolone (40 to 50 mg/d) interrupts the cluster pattern in most cases. The dose may then be lowered progressively to the minimum necessary to control attacks for the rest of the bout, after which it is slowly tapered off. The slight risk of delayed aseptic hip necrosis after courses of corticosteroid therapy must be weighed against the relief obtained by the suppression of the bout in about 75% of cases.

Chronic cluster headache that does not respond to these measures may be suppressed by lithium carbonate in a dose sufficient to maintain a blood level of 0.7 to 1 mEq/L.

TENSION HEADACHE

The management of tension headache requires psychological counseling, readjustment of physical or emotional stress situations, and muscle relaxation therapy, with or without biofeedback. Amitriptyline or other tricyclics given as a single dose at night as described for frequent migraine headache, is useful in patients who can tolerate an adequate dosage without side effects. Monoamine oxidase inhibitors can be used in patients refractory to other treatment.

COMPLICATIONS AND PITFALLS

Misinterpretation of the acute or progressive subacute onset of headache may have serious consequences. The abrupt onset of pain ("thunderclap headache") may be migrainous in origin, but it is important to exclude subarachnoid hemorrhage, "sentinel headache" (enlargement of a cerebral aneurysm without rupture), meningitis, acute obstruction of the CSF pathways, or a precipitous rise in blood pressure as causes. Intravenous antibiotics should be given immediately if meningitis is suspected because pyogenic meningitis can kill within 24 hours. A CT brain scan detects most cases of subarachnoid hemorrhage; reassurance that there is no shift of midline structures or other contraindications to lumbar puncture enables the CSF to be obtained safely. If the CT scan and CSF are both normal but the suspicion of a sentinel headache remains, MR angiography is a noninvasive way of checking the cerebral circulation.

Temporal arteritis may be overlooked as a cause of headache in the older patient. The erythrocyte sedimentation rate is not always elevated, and a temporal artery biopsy may be warranted if there is localized scalp tenderness. Early diagnosis and the institution of corticosteroid therapy minimizes the possibility of blindness.

There is a tendency to consider headaches or recurrent vomiting attacks in children as psychosomatic because they may develop during excitement or stress. Attention to the symptoms will make it clear that most of these episodes are migrainous and deserve to be treated as such. In adults, migraine headache beginning in the upper neck or occipital region is often misdiagnosed as "cervicogenic," whereas migraine or cluster headache affecting the frontal region or cheek is considered to be caused by sinusitis. Careful consideration of the case history usually leads to the correct diagnosis and appropriate therapy.

Patients found to have a structural abnormality requiring surgical treatment or suspected of having meningitis need hospitalization. Most headaches do not have a sinister cause and can be treated in the office or outpatient department. Patients who suffer chronic daily headaches as the result of excessive consumption of analgesics or ergotamine tartrate may require admission during withdrawal of medication.

Various regimens have been recommended for patients who present to the emergency department with severe continuing migraine headache. These include metoclopramide (10 mg IM or IV), dihydroergotamine (1 mg IM or 0.5 mg IV), the NSAID ketorolac (10 to 30 mg IM; not to be given if renal function is impaired), and chlorpromazine (12.5 mg IV, repeated every 2 hours to a total of 37.5 mg). The use of narcotics is to be avoided whenever possible. Lignocaine (1 mg/kg IV followed by an IV lignocaine drip at 2 mg/min) may be given if the patient is under surveillance in the hospital.

Subarachnoid hemorrhage and meningitis are neurologic emergencies requiring immediate referral for specialist treatment. It is advisable to refer any patient with headaches that are unexplained or not responding to treatment to a neurologist or a physician with a particular interest in headache management.

COST EFFECTIVENESS

The estimates of workdays lost per person each year due to headaches vary from 0.5 to 6.7 in different countries. Effectiveness was reduced for another 10 days each year in the United States. The cost of lost productivity in the United States due to headaches is an estimated \$1.4 billion annually. The cost effectiveness of treatment must be assessed by each individual, depending on the rapidity and completeness of response to medication, the cost of medication, and the benefit obtained in working capacity and in enjoyment of life.

CHAPTER 422: APPROACH TO THE PATIENT WITH DIZZINESS AND VERTIGO

MARK F. WALKER AND DAVID S. ZEE

[Clinical Signs and Symptoms](#)
[History and Physical Examination](#)
[Diagnostic Tests](#)
[Disorders](#)
[Treatment](#)

CLINICAL SIGNS AND SYMPTOMS

The complaint of “dizziness” encompasses a variety of symptoms. A feeling of lightheadedness or impending fainting may suggest a cardiovascular cause. *Vertigo* is an illusion of motion of self or of the environment. Patients may describe sensations of spinning or tumbling; perceptions of tilt or linear motion may also occur. Vertigo results from an imbalance in the vestibular inputs from the two labyrinths or in their central connections. Patients with symmetric vestibular lesions (e.g., gentamicin ototoxicity) and those with a slowly developing vestibular imbalance (e.g., vestibular schwannoma), in which adaptation has time to take place, may not have vertigo. *Disequilibrium* is a feeling of imbalance while standing or walking, for example, in the case of bilateral vestibular loss or as the result of cerebellar disease. Patients with nystagmus may have *oscillopsia*, an illusion of back-and-forth movement of the environment produced by movement of visual images across the retina. Symptoms of anxiety, phobias, and panic attacks may be labeled as dizziness. Some patients with otherwise normal vestibular function describe an enhanced sensitivity to visual motion. This perception has been included in the syndrome of psychophysiologic dizziness, often triggered in patients who have or have had recurrent attacks of vertigo. Thus, the first, and sometimes challenging, step in the evaluation of dizziness is to determine which of these symptoms the patient has.

HISTORY AND PHYSICAL EXAMINATION

A careful history is important in the evaluation of vertigo and imbalance. The first questions are whether symptoms are acute or chronic and whether they occurred once or are recurrent. If vertigo is episodic, the duration of each episode is important. Brief (less than 1 minute) episodes of vertigo, precipitated by a change in the attitude of the head with respect to gravity, are typical of benign paroxysmal positional vertigo (BPPV). Vertigo lasting for several minutes up to an hour suggests transient ischemic attacks (TIAs). Longer episodes may be caused by migraine, Ménière's disease, labyrinthitis, or infarcts. The presence of associated hearing loss and other auditory symptoms (tinnitus, fullness) indicates a peripheral vestibular origin, whereas symptoms of brain stem or cerebellar dysfunction implicate a central cause.

What is the effect of head movement? In general, symptoms provoked by head movements or changes in head position with respect to gravity are the hallmark of a disturbance in the vestibular system. Other factors provoking vertigo, such as loud noises and valsalva maneuvers (coughing, sneezing, straining) should be determined. If oscillopsia is present, does it occur at rest, such as from nystagmus, or only with head movement (e.g., while walking), such as with bilateral vestibular loss? Of course, it is important to be aware of any other medical conditions or medications that may play a contributing role.

A complete neurologic examination must be carried out, with particular attention to eye movements, hearing, other cranial nerves, coordination, gait, and balance. Vestibular function may be tested using rapid, but small-amplitude horizontal head thrusts; a catch-up saccade—a rapid eye movement to “catch up” with the head—indicates an insufficient vestibulo-ocular reflex. Visual acuity during head shaking (dynamic visual acuity) is diminished in patients with an abnormal vestibulo-ocular reflex. The eyes must be observed in the absence of visual fixation, which may suppress spontaneous nystagmus. This may be done either with Frenzel lenses or by looking for movement of the optic disc during direct ophthalmoscopy with the opposite eye occluded. Positioning maneuvers can identify BPPV. Hyperventilation may elicit nystagmus in some patients, such as those with vestibular schwannoma.

DIAGNOSTIC TESTS

Vestibular tests include electronystagmography with caloric or rotatory chair testing and posturography. Every patient with vestibular complaints should have an audiogram. A low-frequency hearing loss is characteristic of Ménière's disease. Unilateral hearing loss raises the possibility of a tumor involving the vestibulocochlear nerve, such as a vestibular schwannoma. Magnetic resonance imaging (always including contrast) of the posterior fossa should be ordered whenever a structural lesion is suspected or if there are symptoms or signs suggesting a brain stem or cerebellar lesion. Patients suspected of having TIAs should undergo magnetic resonance angiography of the head and neck and additional evaluation for stroke, as indicated.

DISORDERS

A summary of the more common and important vestibular disorders follows. For a more comprehensive discussion, the reader is referred to the references listed at the end of the chapter.

BENIGN PAROXYSMAL POSITIONAL VERTIGO

BPPV is the most common cause of recurrent vertigo. It results when calcium carbonate crystals (otoconia) are released from the otolithic membranes and aggregate in a semicircular canal, usually the posterior canal. Many patients can identify a preceding event, such as an episode of labyrinthitis or trauma or a prolonged period of having the head back, such as being at the hairdresser or dentist. Symptoms are produced when a change in position of the head, such as looking up or rolling over in bed, causes the debris to move, creating a shift of endolymph that excites the canal and produces vertigo. Symptoms are usually worse in the morning, perhaps owing to aggregation of debris while the head is relatively still during sleep.

BPPV is diagnosed with the Dix–Hallpike maneuver: with the head turned 45 degrees to one side, the patient is moved rapidly from a seated to a supine position with the head hanging down. This may cause debris to shift within the posterior canal such that a mixed vertical–torsional type of nystagmus is produced: the eyes beat up, and the upper poles of the eyes beat toward the affected (down) ear. There is typically a latency of several seconds to the onset of nystagmus, which then lasts for less than a minute. Fatiguing of nystagmus occurs with repeated maneuvers, presumably owing to dispersion of debris. BPPV occasionally involves the horizontal canals; anterior canal BPPV is rare. BPPV is treated with a particle-repositioning maneuver (e.g., Epley or Semont), which moves the debris out of the canal into the vestibule, where it can be reabsorbed. BPPV must be distinguished from central causes of positional nystagmus, such as craniocervical junction abnormalities, which usually produce a sustained, purely vertical (downbeat) nystagmus.

MIGRAINE

Vestibular migraine is a common cause of recurrent vertigo. Attacks usually last minutes to hours and may or may not be associated with headache. Sometimes there are other associated posterior circulation symptoms or signs (basilar migraine). Other vestibular symptoms of migraine include motion sensitivity and disequilibrium, which may last for hours to days or longer. Benign paroxysmal vertigo of childhood also is probably a form of migraine. Treatment of vestibular migraine consists of the usual migraine prophylactic agents. Antiemetics may be needed for acute treatment of attacks in severe cases.

MÉNIÈRE'S DISEASE

Ménière's disease is attributed to endolymphatic hydrops, which causes increased pressure in the inner ear. Attacks may be difficult to distinguish from vestibular migraine, but characteristic features in addition to vertigo include aural fullness, fluctuating hearing loss in the affected ear, and a low-pitched tinnitus. Occasionally, patients have a sudden loss of balance provoking a fall (otolithic crisis of Tumarkin). Evaluation should include screening for syphilis and autoimmune disorders. Transtympanic electrocochleography may assist in the diagnosis. Treatment is aimed at minimizing hydrops and includes a low sodium diet and diuretics, such as acetazolamide or hydrochlorothiazide. Vestibular suppressant medications (see later discussion) may be helpful during an attack. Refractory cases may be treated with ablative procedures, such as transtympanic gentamicin or surgical labyrinthectomy. It is important to remember, however, that many patients will go on to

experience symptoms in the other ear.

LABYRINTHITIS/VESTIBULAR NEURITIS

Vestibular neuritis often is attributed to a viral infection of the vestibular nerve or labyrinth. Severe vertigo, nausea, and vomiting appear suddenly and improve over several days. Central compensatory mechanisms prompt further improvement over several weeks to months. Important differential diagnoses are labyrinthine and cerebellar infarctions or hemorrhage; patients with risk factors for stroke should have a cerebrovascular evaluation. Cerebellar infarction or hemorrhage is of particular concern, because the resulting mass effect may lead to brain stem compression. Treatment with vestibular suppressants and antiemetics (see later discussion) may be necessary in the initial stages of labyrinthitis, when symptoms are most severe.

TRANSIENT ISCHEMIC ATTACKS

When recurrent vertigo is caused by ischemia, it usually occurs in the context of other posterior circulation symptoms. Rarely, episodes of vertigo may develop in isolation. Recognition of vertebrobasilar TIAs as the source of vertigo is important, because TIAs may herald an impending brain stem or cerebellar infarct. Vertigo caused by TIAs typically lasts minutes but now and then may last longer. Vertigo in older patients and anyone with risk factors should prompt an evaluation for a vascular cause; if vertigo is acute, a computed tomography scan should be undertaken to exclude a hemorrhage or swollen infarct in the cerebellum.

BILATERAL VESTIBULAR LOSS

Patients with bilateral vestibular loss typically have initial symptoms of gait imbalance and oscillopsia during head movement. The most commonly identified cause of bilateral loss is exposure to ototoxic agents, such as aminoglycoside antibiotics and certain chemotherapeutic agents (e.g., cisplatin). Vertigo is uncommon, because vestibular loss is symmetrical. In addition, susceptibilities of the labyrinth and cochlea may differ, such that patients may lose considerable vestibular function with little effect on hearing. Gentamicin ototoxicity has been reported in patients with serum levels and cumulative doses within the accepted ranges. Therefore, patients receiving potentially ototoxic medications should be monitored closely for signs of vestibular toxicity, such as inability to read with the head moving, abnormal head-thrust responses, or a positive Romberg sign. Other causes of bilateral vestibular loss include meningitis, vestibular involvement in hereditary forms of cerebellar degeneration, autoimmune disorders (sarcoid, Cogan's syndrome), hereditary and acquired (vitamin B₁₂ deficiency) neuropathies, tumors (bilateral vestibular schwannomas or metastatic disease), bilateral vestibular neuritis, and bilateral Ménière's disease.

TREATMENT

In general, treatment is directed toward the specific diagnosis. Vestibular suppressant and antiemetic medications (diazepam, lorazepam, promethazine, meclizine) may be useful in the initial phase of an acute vestibular syndrome (labyrinthitis) and in the treatment of recurrent attacks of vertigo that last at least several hours, such as in Ménière's disease. Brief episodes of vertigo (BPPV) are not amenable to symptomatic treatment with vestibular suppressants. Long-term prophylactic vestibular suppression may be appropriate when attacks are frequent, but prolonged use following an acute vestibular lesion may impede central adaptation processes and should be avoided.

Vestibular rehabilitation may be beneficial in both acute and chronic vestibular disorders. After an acute vestibular injury, a prompt resumption of normal activity may promote recovery by facilitating central compensation. Specific vestibular exercises may assist in this process. Vestibular therapy also may help patients who have lost vestibular function bilaterally to learn to substitute visual and somatosensory information to maintain balance. When psychiatric factors play a role in patients with complaints of dizziness, either primary (as part of an anxiety disorder or depression) or secondary (as in the case of patients with chronic neurologic diseases) psychiatric intervention, with counseling and medications, is important.

CHAPTER 423: APPROACH TO THE PATIENT WITH TUMORS OF THE CENTRAL NERVOUS SYSTEM

LISA M. DEANGELIS AND J. GREGORY CAIRNCROSS

[Classification](#)
[Epidemiology](#)
[Etiology](#)
[Symptoms and Signs](#)
[Diagnosis](#)
[Treatment—General Considerations](#)
[Treatment—Specific Tumor Types](#)

The diagnosis and treatment of intracranial and spinal tumors form a major part of neurologic and oncologic practice. Early diagnosis, facilitated by noninvasive imaging techniques, is essential, to minimize neurologic disability. Many central nervous system (CNS) tumors can be controlled or cured with modern treatment.

CLASSIFICATION
